It has been pointed out by M. Jackson Marr that the reason that Dews felt so comfortable with operant technology was its similarity to the methodology he was using in his physiological investigations. This methodology had been developed many years earlier by Claude Bernard, the French physiologist of the nineteenth century who is considered to be the founder of modern physiology and the field of experiential medicine. Bernard studied the function of individual organs by continuously recording their response to the exposure and then the

removal of various environmental and chemical changes such as temperature and drugs.

Dews was soon to demonstrate how useful operant methodology could be when he published a series of papers that are now considered to be the seminal works of the field that was to become Behavioral Pharmacology. Figure 1 is from Dews' 1955 paper, which shows the effect of different doses of pentobarbital on the rate of key pecking of pigeons responding for food on two different schedules of reinforcement. Pentobarbital had a distinctly different effect depending on the schedule in effect when the drug was administered. At doses of 1.0–2.0 mg, the drug increased response rates if the pigeon was responding on a fixed ratio 50 schedule (FR 50 – every 50th response was followed by an exposure to food), but decreased responding if a 15-min fixed interval was in effect (FI 15 min – the first response after 15 min had elapsed was followed by an exposure to food).

Dews showed that pentobarbital altered the behavior of the pigeon in a different manner depending on the schedule of reinforcement in effect at the time the drug was given. This showed convincingly that drug effects depend on the type of behavior that is occurring rather than simply 'depressing' or 'stimulating' all behavior. This paper and several more like it were published in pharmacology journals. Operant techniques finally captured the attention of pharmacologists and became the method of choice for studying the effects of drugs on behavior. Roy Pickens has pointed out that prior to 1955, 83% of published studies involving animal testing of drugs involved instrumental techniques and only 10% involved operant techniques, but between 1955 and 1963, 42% of all drug studies used instrumental procedures and the number studies using operant methodology had increased fivefold to 52%. The use of respondent behavior remained at 6–7%.

In addition to the work of Dews, in the mid- and late-1950s, Joseph V. Brady established the first university-related

laboratory using operant technology for the study of drug-behavior interactions at Walter Reed Army Medical Center and later at the University of Maryland. Brady stimulated the development of behavioral pharmacology by training many young researchers and urging the pharmaceutical industry and the federal government of the United States to support this new field.

In 1956, a conference was held on 'The Techniques for the Study of the Behavioral Effects on Drugs' sponsored by the New York Academy of Science. It was chaired by Dews and Skinner and the participants included D. S. Blough, Richard Herrnstein, H. F. Hunt, Neil Miller, William Morse, Murray Sidman, and many others who had made significant contributions to the field at that time. Also in 1956, Skinner made a formal call for the development of a new science of behavioral pharmacology. The new science got its formal start when the Behavioral Pharmacology Society was founded. In about 1955, a group interested in pharmacology started having informal evening dinner meetings during the annual meeting of the Eastern Psychological Association. The Society evolved a year or two later.

Behavioral Pharmacology in Europe

Early interest in the behavioral analysis of drug effects was not confined to North America. In Britain, interest in the field was stimulated by a pioneering symposium held in London sponsored by the Ciba Foundation in 1963. It was attended by many prominent European researchers of the time as well as those from North America, including Len Cook and Peter Dews. The proceedings were edited by Hannah Steinberg and published in 1964. Since that time, researchers such as D. E. Blackman, David Sanger, Susan Iverson, Trevor Robbins, and Ian Stolerman and their students have had an extensive impact on the field.

The operant tradition of behavioral analysis of drug effects also spread to the continent. Marc Richelle, after spending a year at Harvard with B. F. Skinner returned to Belgium in 1959 where he set up a behavioral pharmacology laboratory and began publishing in European journals. Other prominent Belgian behavioral pharmacologists include C. Niemegeers and F. Colpaert. Other European pioneers in the field include R. Dantzer in France, J. Slangen in Holland, and Daniel Bovet, G. L. Gatti, and Georgio Bignami in Italy. The continued expansion of behavioral pharmacology in Europe was marked by the founding of The European Behavioural Pharmacology Society in 1986. In 1989, the journal *Behavioural Pharmacology* was started and the official journal of the European Behavioural Pharmacology Society.

Figure 1 The log dose-effect curves for pentobarbital on the relative response rate of pigeons responding on FI 15-min (open circles) and FR 50 schedules (closed circles). The dotted lines indicate response levels after a control injection of saline. Reproduced from Dews PB (1955) Studies on behavior: 1. Differential sensitivity to pentobarbital of pecking performance in a pigeon depending on the schedule of reward. *Journal of Pharmacology and Experimental Therapeutics* 113(4): 393–401, with permission from Aspet.

Graduate Training in Behavioral Pharmacology

Until the 1990s, most researchers in behavioral pharmacology came from one of two backgrounds; either they had been trained as psychologists and acquired an understanding of pharmacology, or they had been trained as pharmacologists and taught themselves the techniques of behavioral analysis. For several decades now, a number of graduate programs have been developed which combine training in both traditions.

Environmental Influences on Drug Effects

As James Barrett has put it "... a drug is not simply a molecule with static unitary behavioral effects. The same dose of a drug can exert an array of effects on behavior depending on the immediate consequences of responding, the prior experience of the organism, and the total environmental context in which the behavior takes place."

In the years since Dews's early studies, many behavioral pharmacologists have explored the complex interaction between environmental factors and the effect of various drugs. In addition to schedule of reinforcement, these factors include rate of responding, extent of stimulus control, the nature of the reinforcer, and the behavioral and pharmacological history of the organism.

Schedule of Reinforcement

Dews's 1955 study showed that the effects of a barbiturate depend on the schedule of reinforcement. It has been demonstrated that each class of drugs has a unique pattern of effects on various schedules. Drugs such as cocaine and amphetamine, for example, have effects quite different from barbiturates. When various doses of amphetamine are administered to animals responding on an FI and FR schedule similar to those used in the Dews experiment, a dose range is encountered where FI responding is increased considerably above control levels and FR responding is nearly eliminated – exactly the opposite of the barbiturates.

Rate of Responding

The rate at which an operant response is emitted has traditionally been the primary dependent variable analyzed by operant psychologists, and early in the development of the field it was discovered that response rate had a pervasive influence on the effect of many drugs. In one of his early experiments with amphetamine, Dews noticed that the drug seemed to be interacting specifically with the rate of responding. He noticed that the drug increased low rates of responding, while at the same time it decreased responding in situations that normally engendered high rates. This phenomenon has become known as the rate dependency effect. It appears to be responsible for the observation described earlier that responding on FI (which normally engenders comparatively low rates of responding) is increased, and responding on FR (which normally engenders high rates) is slowed by amphetamine. In fact, it is likely that drugs often affect different schedules differently because different schedules produce different base rates of responding.

Rate-dependent effects are caused by many different drugs in many different species responding on a wide variety of tasks. At one point, in fact, rate-dependent effects were thought to be so universal that many researchers were more interested in exceptions to rate-dependent effects than in rate effects themselves.

Other Factors

Many other environmental influences have been shown to interact dynamically with drug effects, but the pervasiveness of rate has made it necessary to eliminate the influence of

rate before the role of these other factors can be demonstrated. For example, different reinforcing events must be presented in such a manner that they engender identical rates and patterns of behavior before it is possible to show that in some cases a drug will differentially alter behavior controlled by different reinforcers. James Barrett trained monkeys to respond on an FI 5-min schedule. The reinforcing event was either food or a brief electric shock. (Shock can serve as a reinforcer if the organism has a suitable history of responding.) Responding on both schedules was identical in terms of rate and pattern, but the effect of several drugs was different depending on whether the reinforcing event was food or shock. Pentobarbital, for example, slowed the food reinforced performance, but created a considerable increase in the shock reinforced behavior.

Drugs as Discriminative Stimuli

A large and productive branch of contemporary behavioral pharmacology deals with drugs as discriminative stimuli. Investigations into the discriminative properties of drugs originated with research in the instrumental learning tradition and the early neurophysiological theories of Donald Hebb at McGill University.

For years there had been anecdotal accounts that suggested that events experienced in a drugged state might not have the ability to control behavior when the organism was undrugged and vice versa. This phenomenon is called dissociation or state-dependent learning.

While investigating dissociation, Donald Overton, then a graduate student at McGill University's Psychology Department, did a series of experiments with rats using an instrumental learning task; shock avoidance in a T-maze. Overton was easily able to demonstrate that rats that learned to avoid the shock in the maze when drugged with pentobarbital were unable to avoid the shock later when given a placebo and vice versa.

To explore the extent of dissociation, Overton wanted to determine whether information learned on drug days (turn right) would interfere with information acquired on saline days (turn left) and vice versa. On alternate days, the rats were administered pentobarbital and one arm led directly to safety. On other days, they were given a saline placebo and the other arm was safe. Overton discovered that the rats very quickly learned to make the appropriate response depending on whether they were drugged or not. In other words, he showed that the drug administration was acting as a discriminative stimulus which controlled the direction the rat would turn at the choice point of the maze on the first trial each day. He also found that rats would learn to make the appropriate response at doses much lower than those required to cause complete dissociation.

Since Overton's early experiments, research on the discriminative stimulus properties of drugs has rapidly expanded, and the electrified T-maze has been replaced with the Skinner box. Herbert Barry III, then at Yale, is generally credited with applying operant techniques to the field. Barry trained experimental animals to press a lever for food in a two-lever Skinner box. On days when a drug is administered, presses on one lever are reinforced, and on saline days, the other lever is reinforced. Animals rapidly learn to respond to the appropriate lever depending on whether they had been injected with a drug or saline.

Using these techniques, it has been demonstrated that most centrally acting drugs have discriminative stimulus properties, although some classes of drugs such as the barbiturates appear to be more easily discriminable than other classes. Such drugs can acquire discriminative control at least as rapidly and, in some cases, more rapidly than more conventional stimuli like noises and lights. It has also been shown that as well as discriminating between a drug and saline, laboratory animals can discriminate between different doses of the same drug and between different drugs.

In addition to determining whether a drug can act as a discriminative stimulus, behavioral pharmacologists have also been able to test for generalization between drugs. In this situation, an animal is trained to discriminate between saline and a drug and then is tested with a different drug, a technique similar to generalization. Animals will usually generalize responses between drugs of the same pharmacological class, thus making it a valuable in drug screening and drug development.

The drug discrimination paradigm has been successfully used to investigate many aspects of drug action including the temporal and kinetic features of drug action, reversibility of receptor binding, stereo-specificity and other structure-activity relationships, agonist-antagonist interactions, and receptor sensitivity changes, to mention a few. It continues to be applied to new and interesting problems including investigations of genetic manipulations on responses to drugs.

In 1978, The Society for the Stimulus Properties of Drugs (SPDD) was founded by Donald Overton, Herbert Barry III, and John Roseceans. In 2008, a special edition of the journal *Psychopharmacology* was issued to mark its 30th anniversary.

Ian Stolerman and others have maintained a drug discrimination database online for many years. It contains a searchable record of all drug discrimination studies. The project is now supported by NIDA in the United States and in 2009 was combined with a similar database for drug self-administration studies.

Drugs as Reinforcing Stimuli

Research with Nonhumans

Early research was generally not able to demonstrate that laboratory animals would administer drugs to themselves in the same manner humans do. Most of these studies involved the oral administration of drugs, usually alcohol, and even though some studies showed that animals could demonstrate a preference for some drugs, they were seldom ever able to show that animals would make themselves physically dependent on a drug, that is, voluntarily consume enough drug that withdrawal symptoms would develop if the drug were discontinued. Physical dependence was believed to be the defining characteristic of addiction at the time. Also, these studies were not able to demonstrate the compulsiveness usually associated with human drug-seeking behavior. Because of these failures and other widespread beliefs about the nature of drug addiction, it was generally believed that drug addiction was restricted to humans.

In 1962, three groups of researchers announced at a meeting of The Committee on Problems of Drug Dependence in Ann Arbor, Michigan, that they had developed the now

classic technique which permits laboratory animals to administer drugs to themselves intravenously. The technique involves implanting a cannula into a vein of a laboratory animal and attaching the cannula to a motor-driven pump. The pump is connected to programming apparatus so that it can be operated by the animal when it depresses a lever. Thus, the animal can administer an intravenous injection to itself. Using this method, Travis Thompson and Charles Schuster of the University of Maryland, and Gerald Deneau, Tomoji Yanagita, and M. H. Seevers at the University of Michigan showed that monkeys would self-administer morphine, and James Weeks and James Collins demonstrated that rats would self-administer morphine.

The importance of these experiments was that they demonstrate quite clearly that the administration of a drug can be a reinforcing event in the same manner as food to a hungry animal or water to a thirsty one. They showed that there is nothing special or different about drug taking and that the general principles that have been learned about operant behavior are applicable to drug self-administration. Furthermore, they showed that drug use is not a result of a pathology or a disease and is not independent of normal psychological processes.

One of the earliest important findings using this technique was that physical dependence is not necessary for drug self-administration. Travis Thompson and Roy Pickens demonstrated that drugs such as cocaine would be self-administered even though they do not normally induce physical dependence. This made it clear that drugs are self-administered because they are positive reinforcers, not negative reinforcers, that is, they are not self-administered to delay or relieve unpleasant withdrawal symptoms.

Research with Humans

A number of very successful attempts have been made to apply operant learning techniques to the study of human drug taking. Pioneers in this field are Jack Mendelson and Nancy Mello. At The Massachusetts General Hospital and later at McLean Hospital in Belmont, Massachusetts, they studied drug self-administration of human volunteers living on a research ward. Volunteers, all with previous drug experience, could earn drugs by performing some activity such as riding an exercise bicycle or pushing a button. Using these techniques, it is possible to meet the scientific standards achieved previously with laboratory animal subjects and also satisfy ethical and safety standards required by governments and institutions.

Drugs studied in such situations include heroin, methadone, cocaine, diazepam, barbiturates, THC, nicotine, and caffeine. These studies have also made it possible to concurrently observe the effects of self-administered drugs on variables such as health, mood, and human social behavior, and provide a model to evaluate drug abuse treatment strategies.

Similarities Between Human and Nonhuman Self-Administration

It has been shown that most drugs consumed by humans are also self-administered by nonhumans. These include alcohol, nicotine, caffeine, barbiturates, opiates, anxiolytic or benzodiazepine, amphetamines, and THC. It is also clear that the

patterns of behavior generated by different schedules of drug reinforcement are similar in both humans and nonhumans to those generated when more traditional reinforcers are used, and that other phenomena such as extinction, discriminative stimulus control, chaining, second-order schedules, etc., are also observed.

Drug administration patterns over time appear to be very similar for humans and nonhumans. For example, a human volunteer drinking alcohol in a research ward in a hospital and a rhesus monkey self-administering ethanol through a cannula both show an erratic pattern of intake and abstinence with occasional self-inflicted withdrawal symptoms: a pattern very similar to that shown by alcoholics in the natural environment. Moreover, both humans and nonhumans administering opiate drugs show a smooth gradual increase in intake from day to day without severe daily fluctuations, and the cocaine pattern in both humans and animals involves cycles of intake and abstinence when the drug is freely available.

Factors that Affect Reinforcing Properties of Drugs

The drug self-administration studies have provided much useful information into the nature of drug use and abuse. For example, it provides a method for assessing which drugs are the most reinforcing and consequently, the most likely to be abused. Several methods have been used to answer this question. In one, known as the progressive ratio schedule, the schedule demand increases as the session progresses. For example, a drug may be available on an FR 25 schedule, meaning that the animal must make 25 responses for an infusion. After the first infusion, however, the schedule changes to an FR 50 and then to an FR 100 and so on. Eventually, the schedule value will reach a point where responding will not continue. This is known as the breaking point. Drugs that are highly reinforcing would be expected to have high breaking points. Experiments such as these generally show that cocaine and amphetamine have higher breaking points than other drugs. Analogous results have been found in choice experiments where the animal must make a choice between two levers, each of which delivers an infusion of a different drug or a different dose of the same drug.

Apart from assessing the inherent abuse liability of a drug, techniques such as the progressive ratio and choice have been used to assess the effect of situational and pharmacological and even genetic variables on reinforcing strength of drugs. For example, the influence of such variables as the extent of previous exposure to the same or a different drug, the relief of unpleasant symptoms such as withdrawal sickness, drug dose, task demand, stress and the extent of other motivations such as hunger have all been investigated.

Behavioral Economics

The use of operant procedures has facilitated the application of the principles of behavioral economics to drug and abuse. For example, the choice procedure has also been used to present animals with a choice between a drug and some other reinforcer such as food. Generally, it has been shown that acquisition of drug self-administration and total consumption of a drug will be reduced when other attractive reinforcers such as

sweetened water and social interaction are made simultaneously available. This observation may well explain why drug abuse appears to thrive in environments where there is unemployment, poverty, and boredom, that is, environments where there are few other sources of reinforcement to compete with drugs as reinforcers of behavior.

Experiments such as these have shown that many of the rules of microeconomics apply to drug use both by humans and nonhumans. For example, if the cost of a drug infusion increases (the animal is required to make more responses to earn the infusion), fewer and fewer infusions will be earned. This is similar to the demand function described by economists where consumption of a commodity decreases as the price increases.

In the early 1970s, people doing research on drug self-administration started the International Study Group Investigating Drugs as Reinforcers (ISGIDAR), which meets once a year in conjunction with the College on Problems of Drug Dependence (CPDD) in the United States and publishes a newsletter. ISGIDAR also maintains a database of research of self-administration studies which is now available online in conjunction with the Drug Discrimination Database.

Conditioned Drug Effects

One area of research of modern behavioral pharmacology has its origin in classical or respondent conditioning rather than operant analysis of behavior. This involves the study of the conditioning of drug effects. Many years ago, a student of Pavlov's laboratory in Leningrad gave a dog an injection of apomorphine and then sounded a tone when the drug began to have its effect of causing the dog to salivate. After a few pairings of the tone and the drug, the tone by itself caused the dog to exhibit this effect of the drug, that is, it caused the dog to salivate. In Pavlov's terminology, the drug was the UCS (unconditioned stimulus), the salivation was the UCR (unconditioned response), the tone was the CS (conditioned stimulus), and the salivation produced by the tone was the CR (conditioned response).

Since that time, there have been many demonstrations of conditioned drug effects. Shepard Siegel of McMaster University in Hamilton has shown that in many cases, the CR is in fact, opposite to the UCR. In other words, if the effect of the drug is in one direction, an increase in body temperature, for example, then the conditioned effect of the drug will be in the opposite direction, a decrease in body temperature.

Siegel and other researchers have shown that this conditioned effect in the opposite direction, called a conditioned compensatory effect, follows the principles of classical conditioning. Siegel also demonstrated that in many cases this compensatory response is responsible for the development of tolerance for drugs. If a stimulus reliably precedes the delivery of a drug, the conditioned compensatory response will occur in response to the stimulus. Because this response is physiologically opposite to the effect of the drug, the normal drug effect is diminished. This lessening of the drug effect after repeated administrations is a type of tolerance. Siegel has shown that tolerance to many effects of drugs will disappear if the stimulus condition normally present when the drug is taken is no longer present, that is, there is no stimulus to evoke the conditioned

compensatory effect. This is an example of a type of tolerance called behavioral tolerance to distinguish it from other types of tolerance that arise from metabolic and physiological mechanisms.

The reinforcing effects of a drug can also be conditioned to environmental stimuli. Sights, sounds, and even places that have reliably been associated with drug administration can acquire reinforcing properties which can also control behavior in the same manner as the drug. Animals will bar press for lights that have been paired with a reinforcing drug, and will actively seek out and return to places where they have experienced the effect of the drug in the past, an effect called place conditioning. Place conditioning techniques have been used to investigate the reinforcing effects of many drugs.

The Behavior-Genetics of Intelligence

M A Runco, University of Georgia, Athens, GA, USA

© 2012 Elsevier Inc. All rights reserved.

Glossary

Adoption studies Comparisons of (a) biological mothers and their children with (b) adoptive parents and their foster children.

Dizygotic twins Also known as fraternal twins; they share approximately 50% of their genetic makeup.

Heritability A statistical index of genetic contributions.

Monozygotic twins Also known as identical twins; they share approximately 100% of their genetic makeup.

Nature A label for genetic, biological, nonenvironmental contributions to development and behavior.

Nurture A label for environmental, experiential, nongenetic contributions to development and behavior.

Range of reaction It indicates an interaction of nature (which determines a range of potentials) and nurture (which determines how much genetic potential is fulfilled).

The nature and nurture of intelligence has been debated for centuries. One of the more significant breakthroughs on this topic resulted from the development and refinement of methods in behavioral genetics. This ensured that objective data would be brought to bear and that theories could go beyond a simple either/or theory of 'nature *or* nurture' to the more reasonable view that biology and environment both play a role. This article briefly reviews the behavioral genetic approach to intelligence and summarizes the key findings, as well as the limitations and remaining issues. It has a historical flavor which reflects the fact that methods in behavioral genetics were developed before more sophisticated and accurate chemical analyses of genes were available. Still, there is much to learn from the behavioral genetics research on intelligence, especially when findings agree with those obtained with the other more recently developed methodologies.

The starting point must be the definition of 'intelligence.' As is implied by the claim that behavioral genetics research would allow objective data to be brought to bear on the topic, some sort of operational definition and reliable assessment of intelligence is required. Unfortunately, the assessment of cognitive abilities is itself a hotly debated topic. Paradoxically, the 'intelligence quotient,' or IQ, is both the most employed and the most infamous of the standardized measures of intelligence. The debate concerning its reliability, validity, and utility has now extended through several decades. Arthur Jensen, one of the most vocal and prolific advocates, holds that the evidence in favor of reliable IQ testing is more than convincing. Stephen Jay Gould, in one of the most informative and least political of critiques, suggested that reliable testing is not possible because the IQ assumes the existence of one general intelligence, known as 'g.' Gould insisted that there is no mathematical, psychological, or even theoretical justification for 'g.' He concluded that 'g' is a statistical artifact, and in particular, an artifact of subjective factor analyses. Many other critics of IQ testing concur that IQ is only a 'hypothetical construct' which has no inherent, objective validity.

There is little doubt that many of the tasks contained in IQ tests can be biased by experience. Some tasks seem to draw mostly on factual information, and thus individuals who

receive a good education or have intellectual resources readily at hand are likely to have an advantage. Yet psychometricians deny this is a bias. They argue that individuals who score high on an IQ test have above average information processing capabilities. These in turn allow the individual to perceive, evaluate, and remember more and more accurate information from their experiences, compared to other individuals in the same population. In other words, the psychometric view is that having experience is by itself not enough for intelligence. The person needs the intellectual ability to benefit from experience as well. As a historical aside, this view parallels what Donald Hebb said long ago about bright canines making better use of the stimuli in their environments.

In another corner there are those who feel that IQ tests are too strongly tied to the personality factors that can facilitate or inhibit intellectual performance. Examples of this perspective are numerous, but two stand out. John Loehlin, Arthur Lindsey, and J. Spuhler pointed to an inflation of ability resulting from an individual's tendency to actively seek cognitive challenges. The second example is that of Sandra Scarr, who gave a detailed description of how personality factors determine whether an individual (a) maximizes intellectual opportunities or (b) passively accepts whatever is available. To what degree the relevant personality factors are genetically or environmentally based is, once again, an ongoing debate, but it does appear that IQ performance may be a function of both personality and cognitive abilities.

Those in favor of IQ hold that, even if not a perfect measure of cognitive capacity, IQ is still useful. Phillip Vernon wrote, "Psychometry is quite entitled to use its own brand of operationalism, regardless of philosophical theories of scientific method, provided it works." Certainly IQ tests offer a standardized assessment. As a matter of fact, they have demonstrated a high level of utility specifically in the area of behavioral genetics.

Behavioral Genetics Methods

The idea of calculating an accurate 'heritability' of intelligence was advanced over 60 years ago. At that point the size of the

human genome was being estimated and enormous variation was acknowledged. One early estimate was that there are 2^{23} alternative genomes based on the human chromosomal supply. Variety is insured by mutation, recombination, and meiosis of the genes; and since these can occur at different loci at different times with different frequencies, a probabilistic index of heritability was the goal. Two methods were used to that end.

In the first, identical or monozygotic (MZ) twins are examined. MZ twins have a virtually identical genetic makeup, and if they happen to be separated shortly after birth, any eventual differences between them can be attributed to environmental discrepancies. The second behavioral genetic method compares an adopted child and her or his biological parents and the same child with his or her foster parents. Presumably, any correlations between the former can be attributed to genetic similarity – an implication of the Mendelian principle that the closer the biological kinship, the higher the genetic similarity – while any correlations between the latter can be attributed to the environment. Typically, a regression coefficient is used in both the within-family and the between-family studies.

In one study, using these methods Alice Mary Leahy compared 194 adopted children to a large control group. The two groups were matched in terms of age, sex, education, and parental SES. The experimental group had been placed in their foster homes before they were 6 months of age, and they had lived there for at least 5 years. The controls were, of course, raised by their own parents. Leahy found an average correlation of 0.56 between the control's IQ scores and their parents' educational level, parents' vocabulary, parents' IQ, and a general index about the home atmosphere. The correlation for the adopted children and their adoptive parents was 0.20. As a check for *selective placement*, Leahy correlated the biological mothers' education with the foster parents' occupation and education. The results were high enough to show that the placement agencies did in fact select the foster parents so as to match the child's background. Consequently, the differences between the two groups are on the conservative side, and the correlational discrepancies between them are even more impressive. Leahy concluded that the 'measurable environment' could only alter the IQ from three to five points in either direction. She reported that the genetic component in IQ is far more influential than the environmental impact.

Longitudinal research with adoptive children and their biological and foster parents often allows collection of more data about the samples. In one such investigation 180 children born to unwed mothers were tested five times between 1949 and 1966. Notably, they were not typical, even for adopted children. For example, their biological mothers had subnormal IQ scores (an average between 83 and 86). Also, selective placement was again evidenced by moderate correlations between the biological mothers' average educational level and the foster parents' ('midparent') average educational level. For this research the children were first tested with the Kuhlmann test and then with the Stanford-Binet. The correlation coefficient calculated between the children and their biological mothers increased at each testing, peaking at 0.44. Correlations with nonbiological mothers never exceeded 0.10. One caveat: the average IQ of the children at 13.5 years was 107–120 points above the mothers' average. With such low scores for the

mothers, 'regressions effects' are likely, with the children tending to score closer to the mean.

Sandra Scarr and Robert Weinberg reported similar findings with adoptive families, but they too had atypical samples. In particular, SES and IQ averages were one standard deviation above the norm. This implies a restricted range, though Scarr and Weinberg argued that the patterns of variables were 'sufficiently similar' to more representative samples. They therefore endorsed the generalization of the empirical findings. More specifically, they felt that the 'relative magnitude' of the coefficients was accurate and valid. Using 150 adopted children and 122 matched controls they compared Wechsler adult intelligence scale (WAIS) scores. The children were adopted quite young, averaging only 2.6 months at the time of placement. Analyses indicated that the parental educational level, family income, and parental IQ were each highly correlated in the biological parent-child analyses. The adoptive parent-child correlations were very low. Family size was unrelated to the child's IQ in the adoptive families, and negatively related in the biological families. Birth rank was significantly related to IQ in both families, with later born children having a marked disadvantage. The correlation between the adoptive fathers' IQ and the child's IQ averaged 0.15, and the correlation between the mothers' and the child's IQ's averaged 0.04. The correlations between the biological mothers' educational level and the adoptive mothers' IQ averaged 0.20 and 0.10 with the adoptive fathers' IQ. Here again there is evidence for selective placement.

Similar patterns and heritabilities are apparent in twin studies. Alan Gottesman, for instance, described one study in which MZ twins, reared apart, were found to have an average Stanford-Binet difference of 24 points. A second study used another measure of mental age, but still found an average difference of 14 points on verbal tasks and an average difference of 10 points on nonverbal tasks.

Another analytic method uses additive variances. Here within-groups variability on IQ tests is delineated. In particular, the variance attributed to genetic differences is added to the variance due to environmental differences, and this is added to the variance due to errors in measurement. When this method was used variability attributable to genetic factors was very close to 60%! A similar analytic method involves subtracting MZ correlations from dizygotic (DZ) twin correlations, with the difference attributed to the environment. As expected, given the heritabilities already cited, the results show genetic influence to be greater than the environmental ones.

L. Erlenmeyer-Kimling and Lissy Jarvik summarized all of the research available when the behavioral genetic approach was the most sophisticated methodology available. Their summary, which was according to Robert Plomin and Stephen Petrill one of the most influential publications on the behavioral genetics of intelligence, clearly supported the genetic view. In particular:

In 14 studies with MZ twins reared together, when the genetic expectation was 1.00 (MZ twins sharing virtually all genes), the median correlation was 0.87. In the four studies when MZ twins were reared apart, that coefficient dropped only to 0.75.

In 11 studies with DZ like-sex twins reared together, the genetic expectation being 0.50, the coefficient was 0.56. When unlike DZ twins were reared together it was 0.49.

In 36 studies with siblings (not twins) reared together, the genetic expectation again being 0.50, the median coefficient was 0.55. In three studies with siblings (nontwins) reared apart, this dropped to 0.47.

In 12 studies with biological parents and their children, the genetic expectation again being 0.50, the median coefficient was in fact 0.50. This is in direct contrast to the three studies with foster parents and their children, the genetic expectation being 0.00, the median correlation being 0.20. In five studies with unrelated children raised together, and thus a 0.00 genetic expectation, the median correlation was 0.24. Finally, in four studies with unrelated children reared apart, the median correlation was -0.01 .

The median correlations were remarkably close to the expected values in almost every case. Note especially the MZ twins reared apart in contrast to other siblings reared apart and unrelated children reared apart. These medians are even more impressive considering that the data came from a diverse set of investigations. Certainly experimenter effects can be disregarded. Importantly, much more recently Plomin and Petrill reviewed the available research and again concluded that the highest correlations of IQ are for MZ twins reared together, and then MZ twins reared apart. All other twins, siblings, and intrafamily correlations are lower, even when individuals were reared together or shared the home.

Cross-cultural studies tended to result in the same correlational patterns. That is, the environmental impact was detectable, but small in comparison to the genetic influence. Findings such as these led to conclusions about a high heritability of IQ. Yet methodological weaknesses in all behavioral genetic studies – not just the cross-cultural investigations – bring this into question. Clearly the measurement concerns outlined earlier, especially those focused on the IQ, are relevant to any correlation calculated from parent–child or intratwin IQs.

The behavioral genetic approach itself has notable limitations. Adoption studies, for example, tend to be restricted. When there is a restricted range of scores, there is not as much variability and correlations are attenuated. Additionally, as noted above, restricted samples severely limit generalizations. If the sample is restricted, generalizations about heritability to other samples or a population are not warranted. Certainly the children in adoption studies were not typical: by definition adopted children will have unusual emotional and physical personal histories, histories that are different from those of nonadopted children. Their backgrounds are simply atypical, even if entirely healthy. Also, the placement of the children is far from random. Adoption agencies use screening techniques, checking the prospective foster homes for income, family size, and the like. All of these are pertinent and very possibly could exaggerate intrafamilial correlations. A last concern along these lines is that the biological parents are often unknown, or their mental ages only estimated from educational level or from equally noncomparable indices.

A major concern in the twin studies is that the home atmosphere always holds some similarities. There are constants

across all homes and all families. Such similarity will probably contribute to correlations. Finally, assortative mating is common. Surely no one chooses a mate at random! The parents probably share some of the same child-rearing ideals and attitudes, and thus intrafamilial correlations would be increased relative to interfamilial correlations.

Conclusions

Behavioral genetics research often leads to high heritability estimates for IQ, but the validity of that conclusion is often questioned because of methodological concerns, including the meaning of the term 'IQ'. Additionally, the heritability reported in behavioral genetics research probably has low generalizability. Urie Bronfenbrenner was correct when he described heritability as contextual: it is applicable to one trait, for one population, at one point in time. And very importantly, high heritability does not exclude environmental effects. On the contrary, both genetic givens and environmental inputs are required for human growth of any kind, but either or both may cause differences between individuals. Intelligence grows, but it grows only particular potentials.

Plomin and Petrill offered a careful and precise view in their 1997 overview of behavioral genetics:

The word genetics is used very narrowly to refer to DNA differences among individuals that are inherited from generation to generation. It does not refer to the vast majority of DNA that is the same for all of us or to the many DNA events that are not inherited, such as mutations in DNA in cells other than the sex cells. Furthermore, genetic research describes what the genetic and environmental origins of differences among individuals in a particular population at a particular time are. It does not predict what could be, nor does it prescribe what should be. Evidence for genetic influence (what is) does not imply that differences among individuals are immutable or irremediable—novel environmental factors could make a difference (what could be).

The most important term in behavior-genetics is the *range of reaction*. Everyone has a different responsiveness to similar conditions, and that is hardwired. Technically put, different genotypes may have the same phenotype, and different phenotypes may be expressed by the same genotype. Some researchers have accepted the heritability statistic as an index of genetic influence, but with questionable methodologies and the reliance on IQ as a dependent measure, any generalizations must be strongly qualified. Still, it is possible to conclude that every individual has a range of alternative developmental outcomes. IQ and the entire phenotype are products of a bipartite system (environment and genes) and reactions within ranges. Behavioral genetic research suggested that the genetic contribution to intelligence was larger than the environmental, and as Plomin and Petrill pointed out in 1997, that conclusion was consistent with research on the heritability of psychopathology. It is fortunate that large strides are being made with more accurate molecular genetic methodologies.

Big Five Model and Personality Disorders

T A Widiger, University of Kentucky, Lexington, KY, USA

Glossary

Big Five Dimensional model of personality structure, consisting of five broad domains of neuroticism, extraversion, openness, agreeableness, and conscientiousness. Each broad domain is differentiated into six more specific facets.

Categorical Describing personality disorders in terms of distinct types, each having distinct etiology, pathology, and treatment implications. Differential diagnosis is focused on identifying which specific disorder best describes the person's condition.

Dimensional Describing personality disorder multifactorially, which each person characterized by a

relatively unique profile or constellation of maladaptive and adaptive personality traits, with each component having specific implications for etiology, pathology, and treatment.

DSM-IV-TR The official manual of the American Psychiatric Association for the diagnosis of mental disorders (i.e., *Diagnostic and Statistical Manual of Mental Disorders*, 4th edn., text revision).

Personality One's characteristic manner of thinking, feeling, behaving, and relating to others.

Personality disorder The presence of personality traits that result in clinically significant impairment to social or occupational functioning or personal distress.

An alternative to DSM-IV-TR is to consider personality disorders to be maladaptive variants of general personality structure. The predominant model for general personality structure within psychology is the Big Five, otherwise known as the five-factor model (FFM). The FFM consists of five broad domains: neuroticism (or emotional instability), extraversion versus introversion, openness versus closedness, agreeableness versus antagonism, and conscientiousness. The FFM was derived originally through empirical studies of the trait terms within the English language. Language can be understood as a sedimentary deposit of the observations of persons over the thousands of years of the language's development and transformation. The most important domains of personality functioning are those with the most number of trait terms to describe and differentiate the various manifestations and nuances of a respective domain, and the structure of personality is suggested by the empirical relationships among these trait terms. The initial lexical studies of the English language converged well onto the five-factor structure. Subsequent lexical studies have been conducted on many additional languages (e.g., German, Dutch, Czech, Polish, Russian, Italian, Spanish, Hebrew, Hungarian, Turkish, Korean, and Filipino) and these have confirmed well the existence of the five broad domains. The five domains have been differentiated into 30 more specific facets on the basis of their development of and research with the NEO Personality Inventory-Revised (NEO PI-R), by far the most commonly used and heavily researched measure of the FFM. Table 1 provides a brief characterization of both the normal and abnormal variants of each of the 60 poles of the 30 facets of the FFM in terms of the five-factor form (FFF), a more elaborated version of the FFM rating form (FFMRF).

Advantages of Integrating DSM-IV-TR with the Big Five

Integrating the diagnosis of personality disorders with the Big Five has a number of distinct advantages, including

the resolution of the many failures of the existing diagnostic system, such as the heterogeneity among persons sharing the same categorical diagnosis, the excessive diagnostic comorbidity, inadequate coverage, the inadequate scientific base, and the arbitrary and unstable boundary with normal psychological functioning. Each of these will be discussed in turn.

Heterogeneity of Persons Sharing the Same Diagnosis

The DSM-IV-TR personality disorders describe prototypic cases, yet very few actual cases are prototypic. As a result, a personality disorder diagnosis provides a misleading description of any particular patient's unique personality profile. Persons can in fact be provided the same diagnosis of antisocial personality disorder yet not share one feature in common, as any three of seven diagnostic criteria can be used to make the diagnosis.

Heterogeneity among persons is addressed by the Big Five through the provision of multifactorial descriptions of an individual's psychopathology (personality disorder) profile that matches well his or her actual constellation of maladaptive personality traits. In addition, the Big Five or FFM allows for the inclusion of normal and adaptive personality traits within the profile description, thereby providing a more complete and comprehensive description. Personality disorder diagnoses can be quite stigmatizing, suggesting that the person's characteristic manner of thinking, feeling, and relating to others (i.e., the person's sense of self) is itself a mental disorder. The FFM's inclusion of normal and adaptive personality traits provides a means to recognize and appreciate that a person is more than just the personality disorder and that there are aspects to the self that can be adaptive, even commendable, despite the presence of the personality disorder. Some of these strengths may also be quite relevant to treatment, such as openness to experience indicating an interest in exploratory psychotherapy, agreeableness indicating an engagement in group therapy, and conscientiousness indicating a willingness and ability to adhere to the demands and rigors of dialectical behavior therapy.

Table 1 Adaptive and maladaptive variants of the five-factor model as presented in five-factor form

	<i>Maladaptively high</i>	<i>Normal high</i>	<i>Normal low</i>	<i>Maladaptively low</i>
<i>Neuroticism</i>				
Anxiousness	Fearful, anxious	Vigilant, worrisome, wary	Relaxed, calm	Fearless
Angry hostility	Rageful	Brooding, resentful, defiant	Even-tempered	Won't even protest exploitation
Depressiveness	Depressed, suicidal	Pessimistic, discouraged	Not easily discouraged	Unrealistic, overly optimistic
Self-consciousness	Uncertain of self or identity	Self-conscious, embarrassed	Self-assured, charming	Glib, shameless
Impulsivity	Unable to resist impulses	Self-indulgent	Restrained	Overly restrained
Vulnerability	Helpless, emotionally unstable	Vulnerable	Resilient	Feels invincible, oblivious
<i>Extraversion</i>				
Warmth	Intense attachments	Affectionate, warm	Formal, reserved	Cold, distant
Gregariousness	Attention-seeking	Sociable, outgoing, personable	Independent	Isolated
Assertiveness	Dominant, pushy	Assertive, forceful	Passive	Resigned, uninfluential
Activity	Frantic	Energetic	Slow-paced	Lethargic, sedentary
Excitement-seeking	Reckless, foolhardy	Adventurous	Cautious	Dull, listless
Positive emotions	Melodramatic, manic	High-spirited, cheerful, joyful	Placid, sober, serious	Grim, anhedonic
<i>Openness</i>				
Fantasy	Unrealistic, lives in fantasy	Imaginative	Practical, realistic	Concrete
Esthetics	Bizarre interests	Esthetic interests	Minimal esthetic interests	Disinterested
Feelings	Intense, in turmoil	Self-aware, expressive	Constricted, blunted	Alexithymic
Actions	Eccentric	Unconventional	Predictable	Mechanized, stuck in routine
Ideas	Peculiar, weird	Creative, curious	Pragmatic	Closed-minded
Values	Radical	Open, flexible	Traditional	Dogmatic, moralistically intolerant
<i>Agreeableness</i>				
Trust	Gullible	Trusting	Cautious, skeptical	Cynical, suspicious
Straightforwardness	Guileless	Honest, forthright	Savvy, cunning, shrewd	Deceptive, dishonest, manipulative
Altruism	Self-sacrificial, selfless	Giving, generous	Frugal, withholding	Greedy, exploitative
Compliance	Yielding, docile, meek	Cooperative, obedient, deferential	Critical, contrary	Combative, aggressive
Modesty	Self-effacing, self-denigrating	Humble, modest, unassuming	Confident, self-assured	Boastful, pretentious, arrogant
Tender-Mindedness	Overly soft-hearted	Empathic, sympathetic, gentle	Strong, tough	Callous, merciless, ruthless
<i>Conscientiousness</i>				
Competence	Perfectionistic	Efficient, resourceful	Casual	Disinclined, lax
Order	Preoccupied w/organization	Organized, methodical	Disorganized	Careless, sloppy, haphazard
Dutifulness	Rigidly principled	Dependable, reliable, responsible	Easy-going, capricious	Irresponsible, undependable, immoral
Achievement	Workaholic	Purposeful, diligent, ambitious	Carefree, content	Aimless, shiftless, desultory
Self-discipline	Single-minded doggedness	Self-disciplined, willpower	Leisurely	Negligent, hedonistic
Deliberation	Ruminative, indecisive	Thoughtful, reflective, circumspect	Quick to make decisions	Hasty, rash

Excessive Diagnostic Co-occurrence

DSM-IV-TR provides diagnostic criterion sets to help guide a clinician toward a correct diagnosis and an additional section devoted to differential diagnosis when persons meet diagnostic criteria for more than one disorder. The intention of this information is to help the clinician determine which particular mental disorder is present, the identification of which would hopefully indicate the presence of a specific pathology and suggest a specific treatment. It is evident, however, that DSM-IV-TR routinely fails in this goal, despite the best efforts of the leading clinicians and researchers who have authored the manual.

The authors of the diagnostic manual construct personality syndromes and then hope that persons will share the same

precise profile and not have any traits of any other profile. This assumption of distinct types is not supported empirically, contributing not only to the heterogeneity of persons sharing the same diagnosis but also the need to provide multiple diagnoses to the same patient in order to fully describe all of his or her maladaptive personality traits. The problem is further compounded by the considerable overlap among the personality syndromes included within DSM-IV-TR, a comorbidity that is well explained by overlap in FFM personality traits (e.g., most of the personality disorders are heavily saturated with neuroticism; schizoid, avoidant, and schizotypal share traits of introversion; antisocial, narcissistic, and paranoid share traits of antagonism).

Inadequate Coverage

Clinicians provide a diagnosis of not otherwise specified (NOS) when they determine that a person has that particular class of mental disorder but the symptoms are not adequately represented by any one of the individual diagnostic categories. Personality disorder NOS (PDNOS) is often the single most frequently used diagnosis in clinical practice, as indicated in studies of clinical records and in a meta-analysis of NOS usage across structured and unstructured assessments.

The FFM is considered to be a reasonably comprehensive dimensional model of general personality structure. One of its strengths is its ability to accommodate the personality traits included within alternative models of personality. The FFM also accommodates well the maladaptive personality traits included within the DSM-IV-TR diagnostic categories, as well as additional maladaptive personality traits not included within the existing nomenclature. Table 2 provides a description of each of the DSM-IV-TR personality disorders in terms of the FFM. For example, the FFM includes the traits of

DSM-IV-TR antisocial personality disorder (deception, exploitation, aggression, irresponsibility, negligence, rashness, angry hostility, impulsivity, excitement-seeking, and assertiveness), and goes beyond DSM-IV-TR to include additional traits within the widely popular Psychopathy Checklist-Revised (PCL-R), such as glib charm (low self-consciousness), arrogance, and lack of empathy (tough-minded callousness) and goes even further to include traits of psychopathy emphasized originally by Cleckely but not included within either the DSM-IV-TR or the PCL-R, such as low anxiousness and low vulnerability or fearlessness.

It is evident from Table 2 that there is considerable overlap among the DSM-IV-TR personality disorders with respect to their FFM profile. For example, many of the personality disorders are characterized by facets of high neuroticism and low agreeableness, contributing to their considerable diagnostic co-occurrence. However, the FFM also identifies traits that are relatively unique to a respective diagnosis. For example, the FFM has the social withdrawal evident not only in the

Table 2 DSM-IV-TR personality disorders from the perspective of the five-factor model of general personality structure

	PRN	SZD	SZT	ATS	BDL	HST	NCS	AVD	DPD	OCP

PRN, paranoid; SZD, schizoid; SZT, schizotypal; ATS, antisocial; BDL, borderline; HST, histrionic; NCS, narcissistic; AVD, avoidant; DPD, dependent; OCP, obsessive-compulsive; H, high; L, low.

avoidant, schizoid, and schizotypal personality disorders, but also the anxiousness and self-consciousness of the avoidant, the anhedonia that is considered to be specific to the schizoid, and the cognitive-perceptual aberrations of the schizotypal. The FFM has the intense attachment needs, the deference, and the self-conscious anxiousness of the dependent, the perfectionism and workaholism of the obsessive-compulsive, and the fragile vulnerability and emotional dysregulation of the borderline. The FFM also goes beyond the DSM-IV-TR nomenclature to include (for instance) closed-mindedness (evident in racist, prejudicial persons) and alexithymia.

Most individual persons will have personality profiles that fail to match perfectly any one of the 10 DSM-IV-TR prototypes provided in Table 2. The need for the frequently used wastebasket NOS diagnosis would decrease substantially if the DSM-V shifted to a profile description in terms of the domains and facets of the FFM as subthreshold, atypical, and idiosyncratic profiles of individual cases would be readily described in terms of the 60 poles of the 30 facets of the FFM.

Scientific Foundation

One fundamental benefit of integrating the DSM-IV-TR with the FFM is the presence of a considerable body of basic scientific research to support the validity of the FFM in contrast to the inadequate scientific foundation for at least half of the DSM-IV-TR personality disorders. Briefly discussed here will be genetics, childhood antecedents, temporal stability, and universality.

Genetics

There is behavior genetic research to support the validity of the DSM-IV-TR personality disorders but the extent of support does pale in comparison to the FFM. In addition, research concerning the FFM has gone beyond univariate behavior genetics that simply indicate extent of heritability to multivariate behavior genetics to provide validity for the specific FFM personality structure. There is also quite a bit of molecular genetic research on FFM neuroticism. In contrast, it might be difficult to find even one molecular genetic study of a DSM-IV-TR personality disorder as the heterogeneous constellations of maladaptive personality traits that describe each of them are antithetical to discovering a specific genetic contribution.

Childhood Antecedents

Very little is said in DSM-IV-TR on the childhood antecedents for most of the personality disorders because little is in fact known. Much has been written on childhood antecedents but this literature is based largely on clinical experience, theoretical expectations, and retrospective studies. There has been only one longitudinal prospective study providing information concerning the histrionic, dependent, avoidant, obsessive-compulsive, paranoid, schizoid, schizotypal, and narcissistic personality disorders, and this project was sorely limited by the absence of adequate assessments in childhood and adolescence.

In contrast, there is a considerable body of research on childhood personality traits and temperaments all of which has been well integrated within the FFM. Rather than seek an understanding of the childhood antecedents of personality disorder from studies of personality disorder symptomatology in children and adolescents, it might be more fruitful to seek an understanding from the study of childhood temperaments. If childhood temperaments do not provide an initial foundation or disposition toward the development of an adult personality disorder, what would be the genetic foundation for an adult personality disorder?

However, the adult outcome of childhood temperaments is well understood to be a general personality structure. It would be rather incongruous to suggest that the temperaments of childhood and adolescence provide a disposition or vulnerability to adult personality disorder, yet they also suggest that these personality disorders cannot themselves be understood as maladaptive variants of these temperaments and traits within adulthood. Researchers have even developed a model and instrument for the assessment of FFM personality disorder in childhood and adolescence.

Temporal Stability

Temporal stability is central to the validity of personality traits. Fundamental to the distinction between a personality disorder and most other mental disorders is the temporal stability of personality. However, there is increasing concern regarding the temporal stability of the DSM-IV-TR personality disorder diagnoses and DSM-IV-TR personality disorder researchers are now even suggesting that it should no longer be a defining feature of a personality disorder.

In contrast, there is considerable support for the temporal stability of FFM personality traits across the lifespan. A meta-analysis of the findings of 152 longitudinal studies was conducted, involving 3217 test-retest correlations that covered various spans of time from childhood to old age. The conclusion was that the FFM traits are quite consistent over the life course. One prominent study compared directly the temporal stability of the DSM-IV-TR diagnoses and FFM personality traits over a 2-year span of time, and reported weak stability for the DSM-IV-TR diagnoses but strong stability for the FFM traits.

Universality

A common distinction in cross-cultural research is between etic and emic studies. Etic studies use constructs and measures from one culture imported into another, determining (in part) whether the importation reproduces the nomological net of predictions previously obtained in other cultures. Emic studies use constructs and measures that are indigenous to a particular culture, determining whether a particular model of personality structure is evident from the perspective or experiences of that culture.

There is only limited etic support for the universality of the DSM-IV-TR nomenclature and virtually no emic support. It is perhaps noteworthy that DSM-IV-TR narcissistic personality disorder was not included within the World Health Organization's (WHO) International Classification of Diseases (ICD-10) despite its presence since 1980 within DSM-III. Of course,

it now appears that ICD-11 may simply accept whatever nomenclature is developed by the APA so there will no longer be any inconsistency.

The universality of the FFM is supported by extensive etic and emic research. Emic support for the FFM is provided by the many lexical studies of the trait terms within the indigenous languages of other cultures (e.g., German, Dutch, Czech, Polish, Russian, Italian, Spanish, Hebrew, Hungarian, Turkish, Korean, and Filipino). Etic support is provided by a replication of the FFM personality structure using observer ratings of 11 985 individuals obtained in 51 different cultures. The largest cross-cultural study of the FFM to date included 100 researchers and 17 837 participants from 56 countries. Results indicated that the five-dimensional structure was highly robust across major regions of the world, including North America, South America, Western Europe, Eastern Europe, Southern Europe, the Middle East, Africa, Oceania, South-Southeast Asia, and East Asia.

FFM Personality Disorder Diagnosis

The FFM or Big Five personality disorder diagnosis consists of four steps. The first step is to obtain an FFM description of the patient. This can be accomplished most easily through the scoring of a one-page rating form that covers all of the domains and facets of the FFM, as assessed (for instance) by the FFF (see [Table 1](#)), or through a self-report inventory (e.g., NEO PI-R) or through a semistructured interview (e.g., Structured Interview for the FFM, SIFFM). There are also many other available measures of the FFM.

The second step is to identify impairments associated with any elevations on a respective facet of the FFM. [Table 1](#) provides typical impairments associated with each of the 60 poles of the 30 facets of the FFM. More detailed descriptions are available elsewhere (see Further Reading). This assessment is included explicitly within the administration of the SIFFM. For example, if persons endorse going out of their way to help others (high altruism) they are asked if they do this at the sacrifice of their own needs; if persons endorse confiding in others (high trust) they are asked in the SIFFM if they have ever been mistreated or used by others as a result.

The third step of the FFM four-step procedure is to determine whether the impairments are at a clinically significant level warranting the diagnosis of a personality disorder. This step is in contrast to the thresholds for the diagnosis of individual personality disorders provided within the DSM-IV-TR (e.g., five of nine diagnostic criteria for borderline, three of seven for antisocial). There has never been an effort to set a consistent diagnostic threshold for the personality disorders within any edition of the APA diagnostic manual. In each instance, the thresholds have been set independently of one another. The diagnostic thresholds in DSM-IV-TR (with the exception of antisocial) were determined by an individual assigned to that diagnosis who selected a threshold which seemed on the basis of a visual inspection of the criterion set to be an optimal point of demarcation.

The DSM-III and DSM-III-R personality disorder diagnostic thresholds (with two exceptions) were never based on any explicit or published rationale. The two exceptions are the

diagnostic thresholds for the DSM-III versions of the borderline and schizotypal personality disorders. Their DSM-III cutoff points were selected on the basis of maximizing agreement with diagnoses provided by a large sample of clinicians. However, it evident there have since been so many revisions, deletions, and additions to their criterion sets that the current diagnostic thresholds no longer relate well to the original thresholds. There was never an effort to provide any rationale for the diagnostic thresholds for the DSM-III paranoid, schizoid, narcissistic, histrionic, antisocial, avoidant, dependent, or obsessive-compulsive personality disorders. With the exception of the DSM-IV-TR antisocial personality disorder, no effort has been taken to maintain a consistent threshold across revisions to the diagnostic manual. Hence, with each revision, remarkable, unanticipated, and unintended changes to prevalence rates have occurred.

The FFM of personality disorder, in contrast, proposes using a uniform and consistent basis for determining when a personality disorder is present. The cutoff point is modeled after the Global Assessment of Functioning (GAF) scale provided on Axis V of DSM-IV-TR that has itself been used in quite a number of studies within clinical populations. A score of 71 or above on the GAF indicates a normal range of functioning (e.g., problems are transient and expectable reactions to stressors); a score of 60 or below represents a clinically significant level of impairment (moderate difficulty in social or occupational functioning, such as having few friends or significant conflicts with coworkers) that would warrant a diagnosis of personality disorder. Further explication of this scale is provided by the Global Assessment of Relational Functioning and the Social and Occupational Functioning scales. This approach to setting the diagnostic threshold would bring to the diagnosis research that has been conducted with the GAF and would provide a threshold that would be consistent across all personality disorders as well as facilitate consistency across all future revisions to the nomenclature.

The fourth step, prototypal matching, is an optional step for those who still wish to provide single diagnostic terms to describe a particular patient's personality profile. In this step, one correlates the patient's actual FFM profile with the FFM description of a prototypic case (see [Table 2](#)). Research has demonstrated that these personality disorder indices are just as valid for the assessment of the borderline, the psychopathic and other personality disorders as any two explicit measures of these personality disorders. In other words, one can readily translate an FFM description back into a DSM-IV-TR personality disorder construct. In most cases, however, the quantitative matching will serve primarily to indicate the extent to which any single construct (e.g., antisocial) is inadequately descriptive of the individual person. In the vast majority of cases, the optimal description will be provided by the actual FFM profile of the person rather than the extent to which the person's FFM profile resembles a hypothetical prototype.

Feasibility

Most clinicians may understandably respond with a deep breath of concern upon first inspection of [Table 1](#), finding it daunting to conceive of having to become familiar with

both the adaptive and maladaptive variants of all 60 poles of all 30 facets of the FFM. However, there are a few points to keep in mind. First, the language of the FFM is the language with which one is already familiar. FFM constructs are already known to anyone who understands his or her own language. This is not to say that the FFM fails to accommodate sophisticated clinical constructs. Research has indicated that constructs within the California Q-set, the Shedler–Westen Assessment Procedure-200, and the DSM-IV-TR personality disorder criterion sets are well understood and articulated in terms of the FFM.

The FFM structure is also not difficult to learn as it is the structure within which one already conceptualizes and thinks about these traits. The FFM structure reproduces the naturally occurring structure within one's language. It is no accident that persons reviewing disparate trait research concerning (for instance) gender differences, childhood temperament, health psychology, consequential outcomes of personality, and even animal behavior have all used the FFM as the structure with which to organize these vast trait literatures.

The administration of the SIFFM, a structured interview assessment of the FFM, takes approximately half the time it takes to administer a DSM-IV-TR personality disorder semistructured interview, despite the fact that it is assessing normal as well as abnormal personality traits. The reason is in part that the SIFFM assessment of maladaptive personality traits is appreciably less redundant than an assessment of the markedly overlapping DSM-IV-TR personality disorder criterion sets. In addition, much of the time spent in the administration of a DSM-IV-TR personality disorder semistructured interview is spent in the assessment of diagnostic criteria that are not present. The DSM-IV-TR requires that all of the diagnostic criteria for each personality disorder be assessed in every patient. A substantial proportion of this time is eliminated in the FFM of personality disorder as abnormal variants are not assessed if the respective normal variant is not present.

Nevertheless, clinicians may still find it daunting to have to consider (potentially) 60 maladaptive traits for each patient, in contrast to just the ten personality disorders of DSM-IV-TR.

Figure 1 provides an abbreviated version of the FFM of personality disorder. Figure 1 reduces the 60 maladaptive variants to just 26. This reduction was achieved in part by eliminating poles of facets that were considered to be relatively less frequent or even obscure (e.g., maladaptively high openness to esthetics) for most clinical use.

Figure 2 provides further detail on how the domain and maladaptive variants could be assessed. Provided within Figure 2 are draft diagnostic criteria for neuroticism and for the eight respective maladaptive facets for that domain included within the abbreviated version (additional domains are covered in papers listed in the section for Further Reading). A patient is first assessed with respect to the six facets of FFM neuroticism. Each facet is rated on a 1–5 Likert scale, consistent with the FFMRF and FFF. If the person receives an elevated score for the domain of neuroticism, then the clinician would assess for the presence of the six maladaptive variants of high neuroticism (i.e., anxiousness, depressiveness, angry hostility, emotional instability, self pathology, and helplessness) and would not need to assess for the maladaptive variants of low neuroticism. If the person receives a low score for neuroticism, then the clinician would not need to assess for any of the maladaptive variants of high neuroticism and would assess instead the two maladaptive variants of low neuroticism (i.e., glib, shameless charm, and fearlessness). If the person receives a score within the middle range, then no further assessment would typically be necessary.

The abbreviated version does naturally fail to include all of the maladaptive traits present within the FFM, as illustrated within Table 1. Missing from the abbreviated version, for instance, are such maladaptive variants as attention-seeking (high gregariousness), gullibility (high trust), guilelessness (high straightforwardness), exploitativeness and greed (low altruism), callousness (high tough-mindedness), ruminative indecisiveness (high deliberation), hedonism (low self-discipline), and aimlessness (low achievement-striving). Any one of these could, in some instances, be very clinically important. One cannot have an abbreviated model without losing

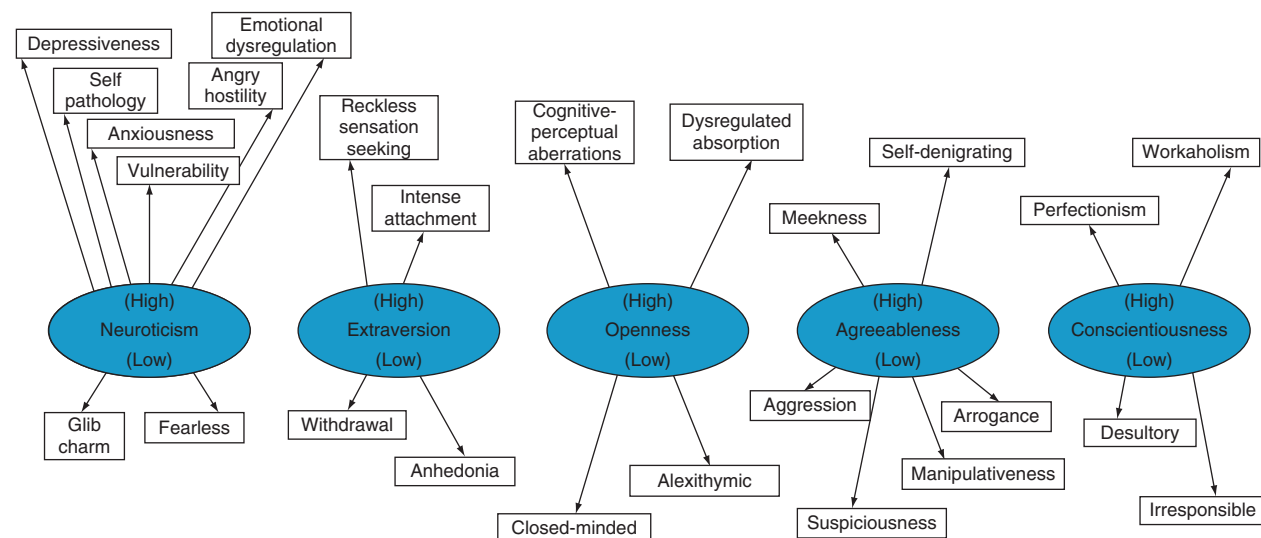

Figure 1 Abbreviated version of FFM proposal for DSM-V.

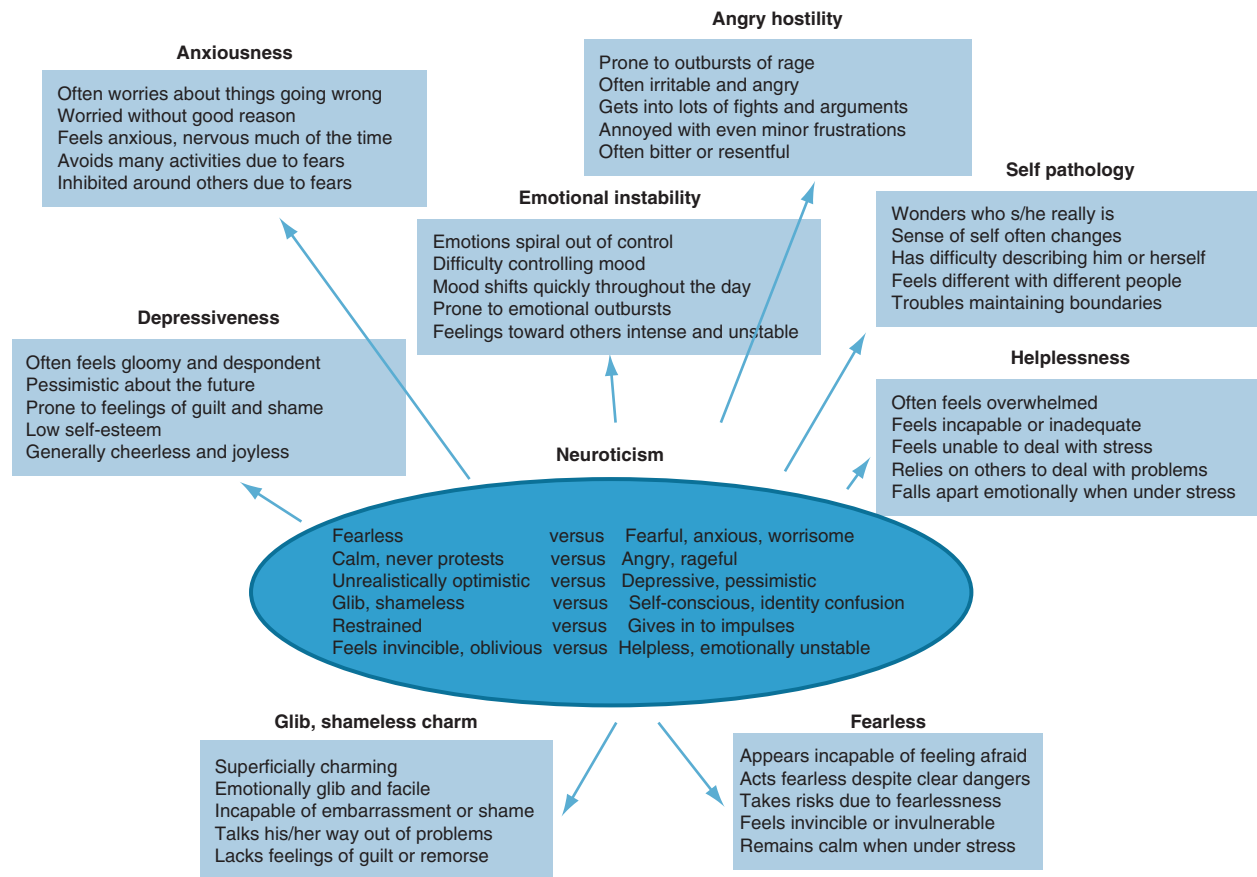

Figure 2 FFM diagnosis of maladaptive neuroticism.

information and some of this information will at times have important clinical significance. In addition, in the abbreviated model it will be relatively more difficult to identify complex profiles (e.g., elevations in opposite directions on facets within the same domain). Many clinicians will then likely prefer the complete model, once they become familiar with the simpler, abbreviated model.

However, even in the abbreviated version clinicians would be alerted to the potential presence of the additional maladaptivity through elevations on specifically relevant facet scales within each of the five domains. If a person receives a high (or low) score on a respective facet for which no maladaptive variant is provided within the abbreviated version (e.g., a score of 5 for the facet of impulsivity for neuroticism, suggesting a potential difficulty in control affectively driven impulses and urges, or a score of 1 for angry hostility, suggesting the potential for never standing up for oneself in protest or justifiable anger; see [Table 1](#)) the maladaptive personality functioning could still be assessed, if wished, through an implementation of the more complete, full version of the FFM of personality disorder.

Conclusions

There are many advantages of shifting the classification of personality disorder to the FFM. One straightforward advantage is the provision of a description of abnormal personality

functioning with the same model and language used to describe general personality structure. It would address the many fundamental limitations of the categorical model (e.g., heterogeneity within diagnoses, inadequate coverage, lack of consistent diagnostic thresholds, excessive diagnostic co-occurrence, and inadequate scientific base). It would contain the means of providing more comprehensive and individually specific descriptions of each patient's normal and abnormal personality structure and, it would transfer to the psychiatric nomenclature a wealth of knowledge concerning the origins, childhood antecedents, stability, and universality of the dispositions that underlie personality disorder.

Glossary

Affective filter hypothesis Emotions function as a filter that reduces the amount of language input the learner is able to comprehend. Negative emotions such as anxiety, self-doubt, and mere boredom interfere with the process of acquiring a second language. Positive emotions such as interest and self-esteem can facilitate the process.

BAMFLA Bilingual and multilingual first language acquisition, that is, acquiring more than one language simultaneously as first language from birth.

Code-switching Alternation between languages in the same conversational interaction or across different modalities such as sign and speech.

Compound bilingual A bilingual who has learned two languages at the same time and often in the same context.

Coordinative bilingual A bilingual who has learned two languages in different contexts and kept the two languages fairly separately.

Critical period hypothesis A hypothesis that claims that there is an ideal 'window' of time to acquire language, after which this is no longer possible, that is, language acquisition is biologically linked to age.

Input hypothesis Also known as the comprehensible input hypothesis, it claims that learners acquire a language only when they receive comprehensible input.

Interaction hypothesis A hypothesis that proposes that language acquisition is strongly facilitated by the use of the target language in interaction.

Language contact Situations where groups of speakers of different languages are in contact with each other. Language contact is the main cause of bilingualism and multilingualism.

Language ideology or linguistic ideology The explicit and implicit attitudes regarding language that define what is perceived as proper speech or good language behavior. It also encompasses what people believe a particular language can do for its users and the user community.

Language socialization A process whereby children and other novices in society acquire tacit knowledge of principles of social order and systems of belief through exposure to and participation in language-mediated interaction. It involves both socialization through language and socialization to use language.

Negative motivation A response that involves the undertaking of tasks for fear that there should be undesirable outcomes.

Negotiation of identity A process through which people reach agreements regarding 'who is who' in their relationships. It helps to establish what people can expect of one another.

Output hypothesis A hypothesis that claims that meaningful output is as necessary to language learning as meaningful input.

Positive motivation A response which includes enjoyment and optimism about the tasks that the learner is involved in.

Sign bilingualism Dual modality bilingualism of sign language and other human languages.

Subordinative bilingual A bilingual whose two languages are not of equal status or proficiency level, with one being subordinate to the other in structure, cognitive processing, and usage.

Introduction

One of the major discoveries of modern linguistic science is that human beings have the capacity to learn as many languages as they are willing to and as they are allowed to by the social conditions. In principle then, anybody can be bilingual and multilingual. Indeed, the vast majority of the world's population is bilingual and multilingual. Nevertheless, there are different pathways to bilingualism and multilingualism, and there are plenty of examples of people who have failed to acquire a language sufficiently to communicate with others in it, or those who, despite knowing other languages, function as monolinguals. The questions then are the following:

- What are the conditions that facilitate the learning and use of multiple languages?
- As far as individuals are concerned, what does it mean to be bilingual or multilingual?

Pathways to Bilingualism and Multilingualism

People often assume that bilingualism and multilingualism are for the privileged few – those who have had a good schooling where they learned new languages and those who have traveled a lot or lived in different countries. Education and migration, either temporary or long-term, are clearly opportunities for learning languages, but most people become bilingual and multilingual within their immediate families and communities. **Table 1** illustrates six different processes whereby children can become bilingual or multilingual at home.

There are many other factors that can lead individuals on to a path to bilingualism and multilingualism. Most of them are external to the individual's cognitive capacities but have something to do with the broader social environment. For example, political or military acts such as colonization, annexation, resettlement, and federation of a country or region can have critical linguistic effects. People may become refugees, either in

Table 1 Processes of bilingual acquisition

	<i>Parent</i>	<i>Community</i>	<i>Strategy</i>
1. One person one language	The parents have different native languages with each having some degree of competence in the other's language	The language of one of the parents is the dominant language of the community	The parents each speak their own language to the child from birth
2. Nondominant home language/one language one environment	The parents have different native languages	The language of one of the parents is the dominant language of the community	Both parents speak the nondominant language to the child, who is fully exposed to the dominant language only when outside the home, and in particular in nursery school
3. Nondominant home language without community support	The parents share the same native language	The dominant language is not that of the parents	The parents speak their own language to the child
4. Double nondominant home language without community support	The parents have different native languages	The dominant language is different from either of the parents' languages	The parents each speak their own language to the child from birth
5. Nonnative parents	The parents share the same native language	The dominant language is the same as that of the parents	One of the parents always addresses the child in a language which is not his/her native language
6. Mixed languages	The parents are bilingual	Sectors of community may also be bilingual	Parents code-switch and mix languages

a new place or in their homeland, and be required to learn the language of their new environment. After a successful military invasion, the indigenous population may have to learn the invader's language in order to prosper. Colonization is exemplified by the former British, French, Spanish, Portuguese, and Dutch colonies in Africa, Asia, and South America, most of which achieved independence in the nineteenth century. A modern example of annexation can be found in the absorption of the Baltic republics – Lithuania, Latvia, and Estonia – into the Soviet Union after the Second World War. In the latter part of the twentieth century, military conflicts in Central Africa and the former Yugoslavia have seen the resettlement of people of different ethnic backgrounds. Examples of federations where diverse ethnic groups or nationalities are united under the political control of one state include Switzerland, Belgium, and Cameroon. Individuals in these countries and regions may have the opportunity to become bilingual or multilingual. Similarly, natural disasters such as famine, floods, and volcanic eruptions can be the cause of major movements of population. New language contact situations emerge as people begin to resettle. Some of the Irish and Chinese resettlements in North America have been the result of natural disasters. People are exposed to new languages as a result of the resettlements. In today's world, the availability of information and communication technologies (ICT), such as the Internet, has led to a further expansion of the use of certain languages across the world. People who wish to use modern technologies need to learn and use the languages of the media.

Some of the pathways to bilingualism and multilingualism may be more personal than environmental. For instance, people may wish to live in a country because of its religious significance, or to leave a country because of its religious oppression. In either case, a new language may have to be learned. The Russian speakers in Israel are a case in point. Similarly, very large numbers of people across the world have migrated to find work and to improve their standard of living. The economic

factor accounts for most of the linguistic diversity of the United States and for the increasing proportion of multilingualism in present-day Europe.

Factors Contributing to the Success or Failure of Becoming Bilingual and Multilingual

From the above list, one can easily conclude that becoming bilingual or multilingual is a consequence of what the environment provides the individual with and has little to do with individuals' mental capacity. Yes, it is true that in theory anyone could learn as many languages as he or she wishes to. But the reality is that not everyone becomes bilingual or multilingual even if the environmental conditions are favorable for language learning. It is certainly a fact that not everyone becomes equally proficient in the languages he or she learns even if he or she is exposed to the same learning conditions. Linguists have spent a great deal of time investigating the various factors that lead to success or failure in becoming bilingual and multilingual. Some of the factors appear to be learner-internal, that is, they are conditioned by the learner's biological and cognitive capacities, while others are more social.

Research evidence suggests that human beings' ability to learn languages is closely related to age and memory capacity. Infants seem to be able to acquire new languages with great ease, whereas adults often have difficulty in achieving the same level of fluency or accuracy in the later-learned languages. Such facts gave rise to the 'critical period hypothesis,' which claims that there is an ideal age to acquire a language in a linguistically rich environment, after which the individual will never achieve a full command of the language. However, there is little agreement as to what that critical period is. Research results are varied: some demonstrate that prepubescent children acquire language easily, and some that older learners have a certain advantage and can achieve native-level

proficiency. Brain plasticity has often been cited as the factor underlying the critical period. More recently, it has been suggested that the delayed development of the prefrontal cortex in children and a concomitant delay in the development of cognitive control may facilitate convention learning, allowing young children to learn language far more easily than cognitively mature adults and older children. Nevertheless, this is a highly controversial and vital topic for research. Advances in brain imaging technologies are generating new findings all the time.

Many researchers do not believe in the existence of the critical period for language learning at all. Instead, they point to social and environmental factors, attitude, motivation, input and interaction, as well as pedagogical effect, and language policy. Individuals learn languages for very different reasons and with very different motivations: some learn new languages because they are married to speakers of other languages, while others seek employments that require the use of certain languages. Community attitudes toward the language being learned can also have a profound impact on the individual learners. Where the community has a broadly negative view of the target language and its speakers, or a negative view of its relation to them, learning is typically much more difficult. At the same time, the learner's direct contact with the target language, that is, input, has a crucial impact on the learning process and learning outcome.

Generally speaking, the amount of input a learner receives is one of the most important factors affecting his or her learning. However, it must be at a level that is comprehensible to the learner. In his study of second language learning, Stephen Krashen advanced the idea that language input should be at the 'i + 1' level, that is, just beyond what the learner can fully understand. In other words, the input is comprehensible, but contains structures that are not yet fully understood. While there has been criticism of Krashen's theory that factors other than structural difficulty (such as interest or presentation) can affect the actual conversion of input into intake, the i + 1 idea has been found useful in language teaching.

In contrast, Merrill Swain proposed an Output Hypothesis that meaningful output is as necessary to language learning as meaningful input. However, most studies have shown little if any correlation between learning and quantity of output. It is likely that meaningful output is important to language learning because the experience of producing language leads to more effective processing of input.

A rather different perspective on success or failure of language learning is the so-called Interaction Hypothesis, which proposes that language acquisition is strongly facilitated by the use of the target language in interaction. In particular, the negotiation of meaning has been shown to contribute greatly to the acquisition of vocabulary.

In addition to the Input Hypothesis, Krashen also proposed an Affective Filter Hypothesis, which claims that the relative success or failure of language learning is often filtered through motivation, attitude, and other affective factors. Many researchers have suggested that more motivated learners tend to be more successful. Motivation involves four key aspects:

1. A Goal
2. An Effort

3. A Desire to attain the goal
4. Favorable attitude toward the activity in question.

It has been suggested that good L2 learners have the following characteristics. They

- are willing and accurate guessers;
- have a strong drive to communicate;
- are often uninhibited, and if they are, they combat inhibition by using positive self-talk, by extensive use of practicing in private, and by putting themselves in situations where they have to participate communicatively;
- are willing to make mistakes;
- focus on form by looking for patterns and analyzing;
- take advantage of all practice opportunities;
- monitor their speech as well as that of others; and
- pay attention to meaning.

In short, they are more motivated and have a more positive attitude toward learning the language.

Motivation is a desire to achieve a goal, combined with the energy to work toward that goal. It determines the extent of active, personal involvement in L2 learning.

Sometimes, a distinction is made between positive and negative motivation. Positive motivation is a response which includes enjoyment and optimism about the tasks that you are involved in, whereas negative motivation involves undertaking tasks for fear that there should be undesirable outcomes. Questions then arise as to where positive and negative motivations came from, the answer to which lies largely in individuals' personal experience. A person growing up in a multilingual environment where the majority of people he or she interacts with on a routine basis speak a variety of different languages freely and where there is no societal control over which language should be used in what manner would, at least in principle, have a more positive attitude toward learning new languages and using different languages. In contrast, a person who has been forced to learn or to drop a particular language or experienced drama in a particular language may develop a negative motivation. The links between personal experience and motivation and other affective and emotional aspects of language learning are an area worthy of further investigation.

Other factors that researchers have examined in terms of success or failure of becoming bilingual and multilingual include gender and personality. These factors are at the interface between learners' internal and external dimensions. Evidence from neuroscience suggests that boys and girls use different parts of their brains to process some basic aspects of grammar. Sociolinguists have shown that men and women use languages in different ways for communicative purposes. However, there is very little research into the gender differences in bilingual or second language acquisition. Some researchers have suggested that there are gender differences in motivations for language learning. It certainly seems to be the case that more girls than boys prefer to learn modern languages in schools and have somewhat better attainment in school-based language examinations. Yet none of the apparent difference can be solely attributed to biological differences between the two genders. It is more likely to be a sociocultural effect in that language learning and use is closely related to the different

roles of girls and boys and women and men in society. Similarly, some personality traits have been linked to the relative success or failure in second or additional language learning. Extraverts or unreserved and outgoing people tend to acquire a second language better than introverts or shy people. But extraversion and introversion are sociocultural constructs, rather than biologically determined.

What Does it Mean to Be Bilingual or Multilingual?

In theory, these different routes to bilingualism would result in different language behaviors and cognitive organizations of the bilingual brain. But at the moment, there is very little systematic research linking the process of bilingual acquisition with the outcome of bilinguality at the individual level. What we do know, however, is that the different languages being acquired by the child do not always develop at the same speed or to the same level, resulting in different configurations of language dominance in individual children and different proficiencies in the languages.

In an early study, Uriel Weinreich proposed three types of bilinguals representing three types of relationship between the linguistic sign (or signifier) and the semantic content (signified). In Type A, the individual combines a signifier from each language with a separate unit of signified. Weinreich called them 'coordinative' (later often called 'coordinate') bilinguals. In Type B, the individual identifies two signifiers but regards them as a single compound, or composite, unit of signified; hence they are called 'compound' bilinguals. Type C relates to people who learn a new language with the help of a previously acquired one. They are called 'subordinative' (or 'subordinate') bilinguals. His examples were from English and Russian:

Weinreich's typology is often misinterpreted in the literature as referring to differences in the degree of proficiency in the languages. But it is a fact that the relationship between the language proficiency and cognitive organization of the bilingual individual, as conceptualized in Weinreich's model, is far from clear. Some 'subordinate' bilinguals demonstrate a very high level of proficiency in processing both languages,

as evidenced in grammaticality and fluency of speech, while some 'coordinative' bilinguals show difficulties in processing two languages simultaneously (i.e., in code-switching or in 'foreign' words identification tasks). It must also be stressed that, using Weinreich's distinctions, bilingual individuals are distributed along a continuum from a subordinate or compound end to a coordinate end, and can at the same time be more subordinate or compound for certain concepts and more coordinate for others, depending on, among other things, the age and context of acquisition. There are now a number of psycholinguistic models of the bilingual lexicon, including the Concept Mediation Model, the Word Association model, and the Revised Hierarchical Model. These models take into consideration factors such as proficiency level, age, and context of acquisition and have much more explanatory power than the earlier models for bilingual language use.

In terms of bilingual and multilingual first language acquisition (BAMFLA), that is, acquiring multiple languages from birth, both linguists and psychologists have spent a considerable amount of time investigating the developmental patterns of bilingual and multilingual children. Earlier studies suggested that bilingual acquisition went through three key stages:

- Stage I: The child has one lexical system comprising words from both languages.
- Stage II: The child distinguishes two different lexicons, but applies the same syntactic rules to both languages.
- Stage III: The child speaks two languages that are different both in lexicon and syntax, but each language is associated with the person who uses that language.

Although some studies have produced evidence supporting the model, there has been much criticism, particularly of the claims made regarding the first two stages. This is generally known as the 'one-system-or-two' debate, that is, whether bilingual children begin with a fused linguistic system and gradually differentiate the two languages, or whether they start with a differentiated system. Part of this debate centers around the question: What counts as evidence for differentiation or fusion? Some researchers based their decision on whether the child made appropriate sociolinguistic choices, that is, whether the child spoke the 'right' language to the 'right' person. It was argued that awareness of the two languages as distinct plays a crucial role in deciding the issue of differentiation, and a child's ability to make appropriate language choices reflects that awareness. However, the argument that bilingual children separate the languages when they are aware that there are two systems is circular, unless some criterion is provided for assessing whether awareness means anything other than children separating the languages. In any case, we need to bear in mind that a child's apparent (in)ability to choose the right language for the right addressee is a rather different issue from whether the child has one or two linguistic systems. Part of the problem is the familiar one of what we can infer about competence from performance. There now exists a large body of literature rebutting the 'fused' system hypothesis, arguing instead that bilinguals have two distinct but interdependent systems from the very start.

Is bilingual acquisition the same as monolingual acquisition? Theoretically, separate development is possible without

there being any similarity with monolingual acquisition. Most researchers argue that bilingual children's language development is by and large the same as that of monolingual children. In very general terms, both bilingual and monolingual children go through an initial babbling stage, followed by the one-word stage, the two-word stage, the multiword stage, and the multiclausal stage. At the morphosyntactic level, a number of studies have reported similarities rather than differences between bilingual and monolingual acquisition. Nevertheless, one needs to be careful in the kinds of conclusions one draws from such evidence. Similarities between bilingual and monolingual acquisition do not mean that (1) the two languages a bilingual child is acquiring develop in the same way or at the same speed; (2) the two languages a bilingual child is acquiring do not influence and interact with each other. For example, studies have found that while 2–3-year-old French–English bilingual children displayed patterns that characterize the performance of monolingual children acquiring these languages separately and they acquired these patterns within the same age range as monolingual children, they (1) used finite verb forms earlier in French than in English; (2) used subject pronouns in French exclusively with finite verbs but subject pronouns in English with both finite and nonfinite verbs, in accordance with the status of French clitic subject pronouns (or agreement markers) as against full NPs in English; and (3) placed verbal negatives after lexical verbs in French (e.g., *n'aime pas*) but before lexical verbs in English (*do not like*).

There is one area in which bilingual children clearly differ from monolingual children, namely, code-mixing. Studies show that bilingual children mix elements from both languages in the same utterance as soon as they can produce two-word utterances. As with adult code switching, bilingual children's language mixing is highly structured. The operation of constraints based on surface features of grammar, such as word order, is evident from the two-word/-morpheme stage onward, and the operation of constraints based on abstract notions of grammatical knowledge is most evident in bilingual children once they demonstrate such knowledge overtly (e.g., verb tense and agreement markings), usually around 2.6 years of age and older. These findings suggest that, in addition to the linguistic competence to formulate correct monolingual strings, bilingual children have the added capacity to coordinate their two languages online in accordance with the grammatical constraints of both languages during mixing. While these studies provide further evidence for the separate development, or two-systems, argument, they also suggest that there are both quantitative and qualitative differences between bilingual acquisition and monolingual acquisition.

The ability to switch from one language to another turns out to be a crucial aspect of being bilingual and multilingual. Indeed, one cannot tell who is or who isn't a bilingual until the person uses two or more languages in the same conversation. There is a widespread impression that bilingual speakers code-switch because they cannot express themselves adequately in one language. This may be true to some extent when a bilingual is momentarily lost for words in one of his or her languages. However, code-switching is an extremely common practice among bilinguals and takes many forms. A long narrative may be divided into different parts which are expressed in different languages; sentences may begin in one language

and finish in another; words and phrases from different languages may succeed each other. Linguists have devoted much attention to the study of code-switching. It has been demonstrated that code-switching involves skilled manipulation of overlapping sections of two (or more) grammars, and that there is virtually no instance of ungrammatical combination of two languages in code-switching, regardless of the bilingual ability of the speaker. Some suggest that code-switching is itself a discrete mode of speaking.

One important aspect of code-switching is that the two languages involved do not play the same role in sentence making. Typically, one language sets the grammatical framework, with the other providing certain items to fit into the framework. Code-switching therefore is not a simple combination of two sets of grammatical rules but grammatical integration of one language in another. Bilingual speakers of different proficiency levels in their two languages or speaking two typologically different languages can engage in code-switching and indeed vary it according to their needs.

There is a group of bilinguals who engage themselves in cross-modality language production. This is the case with speech–sign bilinguals who, in addition to the oral modality, use the manual–visual modality in everyday communication. They are special in one aspect: that is, the two different modalities allow for the simultaneous production of the two languages. In other words, one can speak and sign at the same time. Research has shown that such simultaneous bimodal production is typically exemplified by the use of lexical items from both languages but only one set of grammatical rules, which is usually from the spoken language. Right now, we know relatively little about how the two linguistic systems interact in the language production and processing of speech–sign bilinguals. Indeed, much more work needs to be undertaken before we can fully appreciate the complexity of the language behavior of bilinguals in general.

It should be emphasized that code-switching is not only an effective means of communication but also an act of identity. Every time bilingual speakers say something in one language when they might just as easily have said it in another, they are reconnecting with people, situations, and power configurations from their history of past interactions and imprinting on that history their attitudes toward the people and languages concerned. Through language choice, they maintain and change ethnic group boundaries and personal relationships, and construct and define 'self' and 'other' within a broader political economy and historical context. So, the issue of language use of bilinguals and multilinguals becomes an issue of identity and identification.

The notion of identity has gone through considerable change in sociolinguistics. In the earlier variationist sociolinguistic work, identity was taken to mean the speaker's socioeconomic class, gender, age, or place of origin. It is assumed that speakers express, rather than negotiate, identities through their language use. Several scholars later criticized such assumptions and argued instead that identities are negotiated through social interaction. Linguistic forms and strategies have multiple functions and cannot be directly linked to particular identities outside of interactional contexts. More recent studies by sociolinguists have emphasized the negotiation of identities and demonstrated that identities are local constructions.

Parallel to the work on multilingualism and negotiation of identities, sociolinguists critically examine some of the concepts and notions commonly used by other researchers in the field of bilingualism and multilingualism. For example, the very idea of code-switching raises questions as to what a language is. Instead of thinking of languages as discrete systems, sociolinguists tend to see multilingual speakers as actors of social life who draw on complex sets of communicative resources which are unevenly distributed and unevenly valued. The linguistic systematicity therefore appears to be at least as much a function of historically rooted ideologies (of nation and ethnicity) and of the ordering practices of social life as of language per se. This perspective goes beyond a focus on mental representation of linguistic knowledge and opens up the possibility of looking at bilingualism and multilingualism as a matter of ideology, communicative practice, and social process.

This particular sociolinguistic perspective has important implications for the way researchers collect, analyze, and interpret data. Informed by developments in anthropology, sociology, and cultural studies, sociolinguists have examined communicative practices within and across sites that can be ethnographically demonstrated to be linked. Working with the ideas of *trajectories* (of speakers, linguistic resources, discourses, institutions) across time and space and of *discursive spaces* which allow for, and also constrain, the production and circulation of discourses, sociolinguists have examined multilingual practices in a number of communities and argued that multilingual practices contribute to the construction of social boundaries and of the resources those boundaries regulate. They therefore also raise the question of the social and historical conditions that allow for the development of particular regimes of language, for their reproduction, their contestation, and, eventually, their modification or transformation.

A further, closely related, area in which sociolinguists have extended the work by linguists and psycholinguists on bilingualism is that of the acquisition of linguistic knowledge. Building on earlier research on language socialization, which focused on young children acquiring their first language in culturally specific ways, they have examined bilingual and multilingual children's developing competence in various speech and literacy events. Particular attention is given to the range of linguistic resources available, or not, in bilingual and multilingual communities and the ways in which children, as well as adolescents and adults, learn to choose among these resources for their symbolic value. The researchers emphasized language socialization as an interactive process, in which those being socialized also act as agents rather than as mere passive initiates. This line of inquiry also demonstrates how domains of knowledge are constructed through language and cultural practices, and how the individual's positioning affects the process of knowledge acquisition and construction.

Conclusion

Increased contacts with peoples speaking different languages as a result of globalization mean that bilingualism and multilingualism are becoming more commonplace a phenomenon for

today's world. People are more aware of the linguistic diversity around them. As the article shows, there is a considerable amount of knowledge related to bilingual and multilingual individuals, the manner in which they acquire languages, and the way they use them in daily life. Paradoxically, however, much of the research still uses the monolingual as the yardstick and often sees bilingualism as a deviation from the norm. Many issues also require further empirical research: for example, the organization of the bilingual brain; the structure and organization of the bilingual's different languages; the various processing operations involved in the perception, production, and memorization of language when the speaker is using one or all his or her languages; and the linguistic and psycholinguistic differences and similarities between code-switching, borrowing, and interference. Advances in research technologies will clearly help the field to develop more sophisticated methods. Research findings will have impacts on policy and practice regarding the bilingual and multilingual individuals as well as the communities they form and live in.

Biofeedback Therapy

K W Jung, D-H Yang, and S-J Myung, Asan Medical Center, Seoul, South Korea

Glossary

Classical conditioning The formation of a conditioned reflex through the temporal pairing of an unconditioned stimulus, which reflexively elicits a response, and a neutral conditioned stimulus. After the pairing, the formerly neutral conditioned stimulus acquires the ability to elicit a response similar to the one elicited by the unconditioned stimulus.

Operant conditioning The presentation of a stimulus dependent on the occurrence of a response for the purpose of modifying the strength or the frequency of the response.
Reinforcer In operant conditioning, any stimulus when presented or removed depending on the occurrence of a response results in the modification of the response. In a classical conditioning, the presentation of a conditioned stimulus and an unconditioned stimulus is in a close temporal proximity.

Underlying Learning Theory and Biologic Mechanism

Learning Theory

Learning theories have traditionally distinguished between two types of learning. One type, called classical conditioning, involves the pairing of two stimuli in a close temporal proximity. One of the two stimuli, known as the unconditioned stimulus, normally elicits some reflex behavior such as salivation, eye blink, or a change in skin conductance. The other stimulus, known as the conditioned stimulus, is neutral prior to the pairing but acquires the ability to elicit a response similar to the unconditioned response after the pairing process. The second type of learning recognized by learning theorists is known as operant conditioning. In operant conditioning, the response is generally thought of as emitted on a more or less voluntary basis, rather than being reflexively elicited by any particular stimulus. Also, the operant conditioning process involves the pairing of the stimulus dependent on the occurrence of a response. The paired stimulus leads to an increase in the frequency or the magnitude of the response and it is known as a negative reinforce if its removal leads to an increase in the frequency or the magnitude of the response.

Between 1928, when the two types of learning were formally distinguished, and the early 1960s, it was generally assumed that operant and classical conditioning were mutually exclusive processes. All voluntary skeletal motor behaviors were assumed to be subject to operant conditioning, while visceral and glandular responses mediated by the autonomic nervous system were assumed to be involuntary and modifiable only through classical conditioning. It was thought impossible that salivation to a light stimulus could be operantly reinforced by food. This view was retained until the early 1960s when groups of researchers in the Soviet Union, Canada, and the United States began a series of experiments designed to show that responses mediated by the autonomic nervous system can, in fact, be brought under a voluntary control through techniques that closely resemble operant conditioning.

Since the first suggestion regarding instrumental learning and operant conditioning, it demonstrated the medical potential of biofeedback by showing that the normally involuntary

autonomic nervous system can be operantly conditioned with the use of an appropriate feedback. By means of instruments, patients acquire information about the status of involuntary biological functions such as skin temperature and electrical conductivity, muscle tension, blood pressure, heart rate, and brain wave activity. Patients, then, learn to regulate one or more of these biological states that affect symptoms.

Biological Mechanisms

Biofeedback makes physiologic change possible by means of operant conditioning or trial-and-error learning, in which a response is learned and performed depending on whether that response is followed by reinforcement. For biofeedback to be useful, four conditions must be satisfied. First, there must be a readily detectable and measurable response such as the bladder pressure or the pelvic floor muscle activity. Second, there must be variability in that response with a detectable change as opposed to total paralysis. Third, there must be a perceptible cue such as the sensation of urgency that indicates to the patient when control should be performed. Fourth, because biofeedback is based on learning, it requires the active involvement of a motivated patient.

Taking basketball as an example, the information about where the ball went with each shot is called feedback. If both the coach and the novice were blindfolded, there would be no feedback, and the novice would not learn to improve. Some tense patients may not be aware of the fact that certain muscles are tense, and patients with neuromuscular disorders, or even their therapists, may not be able to discriminate small increases in the activity of paralyzed muscles or decreases in the contractions of spastic ones. They are like a blindfolded basketball novice and coach. However, a display of the electrical activity of the muscles (the EMG) can remove the blindfold and give them a better feedback about what the muscles are doing. This feedback might be in the form of a series of auditory clicks that get faster when the muscle contracts more or a tracing of the activity of one or more muscles as a dot draws the curve of a graph on a TV screen. Feedback from a measuring instrument that yields moment-to-moment information about a biological function is called biofeedback.

One of the advantages of biofeedback is that it allows small changes in the correct direction to be noticed and rewarded as success so that they gradually can be built up into larger changes. Eventually, patients learn to perceive these changes without the measuring instrument so that they can practice by themselves. Biofeedback should be especially effective in those cases where the patients cannot perceive their initial small correct responses or even may have the wrong perception of what they are doing.

Other advantages of biofeedback are that by making the early signs of slight progress conspicuous, it can encourage and motivate the patients, relieve their sense of helplessness, and serve as a coping response to reduce symptoms of stress. Instead of having something done to the patients, it teaches them to do something for themselves, increasing their confidence, or what has been called self-efficacy. This factor is particularly important when biofeedback is being used to treat symptoms that are elicited or aggravated by stress.

Early Development

Experiments on Humans

It was first shown that human subjects could learn to voluntarily dilate blood vessels of the finger in order to avoid or escape an electric shock if they were provided with visual information about their vasomotor activity. Subjects provided with an amplified auditory representation of their heart beat also were trained to accelerate their heart rate to avoid an electric shock to the ankle. Other responses generally considered involuntary were brought under voluntary control by providing subjects with feedback information about the targeted response and some form of operant reinforcement. Studies conducted in the 1960s also demonstrated operant conditioning of the skin conductance response and brain wave activity. Voluntary control over the firing of single motor units was demonstrated by providing subjects with auditory and visual displays of individual myoelectric potentials recorded from fine wire intramuscular electrodes.

Experiments on Animals

At about the same time that voluntary control of autonomically mediated behavior was being demonstrated in humans, parallel lines of research were in progress using various animal species. For example, thirsty dogs were trained to increase and decrease the flow of saliva using water as a reinforcer. Bidirectional changes in heart rate and blood pressure were also shown to be subject to operant conditioning in monkeys and rats.

Methods

The feedback instrument used depends on the patient and the specific problem. The most effective instruments are the electromyogram (EMG), which measures the electrical potentials of muscle fibers; the electroencephalogram (EEG), which measures alpha waves that occur in a relaxed state and the thermistor, which measures skin temperature (which drops during tension because of peripheral vasoconstriction). Recently,

fMRI (functional magnetic resonance imaging) has been used to identify both positive and negative emotional stimuli for stress management (neurofeedback).

Patients are attached to one of the instruments that measure a physiological function and translate the measurement into an audible or visual signal that the patients use to gauge their responses. For example, in the treatment of bruxism, an EMG is attached to the masseter muscle. The EMG emits a high tone when the muscle is contracted and a low tone when at rest. Patients can learn to alter the tone to indicate relaxation. Patients receive feedback about the masseter muscle, the tone reinforces the learning, and the condition ameliorates, with all of these events interacting synergistically.

Many less specific clinical applications (e.g., treating insomnia, dysmenorrhea, and speech problems; improving athletic performance; treating volitional disorders; achieving altered states of consciousness; managing stress; and supplementing psychotherapy for anxiety associated with somatoform disorders) use a model, in which frontalis muscle EMG biofeedback is combined with thermal biofeedback and verbal instructions in progressive relaxation.

Relaxation Therapy

Learning relaxation, therefore, involves cultivating a muscle sense. To develop the muscle sense further, patients are taught to isolate and contract specific muscles or muscle groups, one at a time. For example, patients flex the forearm while the therapist holds it back to observe tenseness in the biceps muscle. Patients are repeatedly reminded that relaxation involves no effort. In fact 'making an effort is being tense and therefore is not to relax.' As the session progresses, patients are instructed to let go further and further, even past the point when the body part seemed perfectly relaxed.

Patients would work in this fashion with different muscle groups, often over more than 50 sessions. Patients were also frequently left alone while the therapist attended to other patients.

Neurofeedback

Neurofeedback allowed, for the first time, voluntary self-regulation of brain activity through feedback and reward. Expectancies ran high and many premature announcements of clinical success based on single case studies or uncontrolled observations discredited the field early on. In the 1970s, Miller's demonstrations of operant control of autonomic (and central nervous system (CNS)) functions in curarized rats, supposedly proving 'voluntary' operant regulation of many bodily functions excluding mediation of the motor system through curarization, turned out to be difficult to replicate. Together with the clinical overstatements in the field of biofeedback, this historic incident virtually halted funding from the public sources and blocked large controlled clinical studies despite some indications of its efficiency. However, more recent studies suggested that some patients with drug-resistant epilepsy (mostly with secondarily generalized seizures) experienced a reduction in the number of ictal events during and after training consisting of self-regulation of slow cortical potentials (SCPs), an effect also reported using biofeedback of skin conductance

responses (GSR). Nagai et al. showed that learned increase in autonomic arousal through reduction of skin conductance decreased negative SCPs at the cortical level and thus increased seizures thresholds confirming earlier reports.

The clinical target populations for brain-machine interface (BMI) treatment consist primarily of patients with amyotrophic lateral sclerosis (ALS) and severe CNS damage including spinal cord injuries and stroke, resulting in substantial deficits in communication and motor function. However, an extensive body of literature started in the 1970s using neurofeedback training. Such training implemented to control various EEG-measures provided solid evidence of positive effects in patients with otherwise pharmacologically intractable epilepsy, attention deficit disorder, and hyperactivity ADHD. More recently, the successful introduction and testing of real-time fMRI and a near-infrared spectroscopy (NIRS)-BMI has opened an exciting field of interest in patients with psychopathological conditions.

Clinical Applications

Gastrointestinal Diseases

In the field of gastroenterology, an initial study focused on biofeedback applications in patients with fecal incontinence. Later, biofeedback applications for the treatment of chronic constipation due to pelvic floor dyssynergia (anismus, spastic pelvic floor syndrome, and puborectalis paradox), had been widely performed by pediatric and adult doctors. The goal of biofeedback training in gastroenterology is to restore a normal pattern of defecation. In patients with dyssynergic defecation, the goal of neuromuscular training is twofold: to correct the dyssynergia in coordination of the abdominal, rectal, and anal sphincter muscles to achieve a normal and complete evacuation; and to enhance rectal sensory perception in patients with impaired rectal sensation. This training consisted of improving the abdominal push efforts (diaphragmatic muscle training) together with manometric-guided pelvic floor relaxation followed by simulated defecation training.

The symptomatic improvement rate has varied between 44% and 100% in recent randomized controlled trials of adults with dyssynergic defecation. All of these studies have concluded, however, that biofeedback therapy is superior to controlled treatment approaches, such as diet, exercise, and laxatives, or use of polyethylene glycol, diazepam, or placebo, balloon defecation therapy, or sham feedback therapy.

Recently published meta-analysis showed that biofeedback in fecal incontinence was equally effective as nonbiofeedback therapy. For constipation, more than threefold superiority of biofeedback to nonbiofeedback, but equal efficacy of EMG biofeedback to other applications was shown. Other indications, including chronic proctalgia, irritable bowel syndrome, and functional dyspepsia, still need more data with prospectively designed randomized controlled studies.

Urinary Diseases

Biofeedback is a very specific treatment that can restore bladder control by teaching patients to modulate the mechanisms of continence using a pelvic perineal reeducation technique,

which uses a signal that is usually visual, but may be auditory, which allows the patient with an anorectal or perineal functional anomaly to understand and correct the trouble. Biofeedback has now gained several potential applications for urologic conditions, having been successfully used for patients with urologic disorders such as detrusor instability, detrusor sphincter dyssynergia, and enuresis. In a randomized trial involving older women with urgent urinary incontinence, the percent reduction in incontinence episodes was similar after 8 weeks of behavioral therapy with biofeedback therapy, after 8 weeks of behavioral therapy without biofeedback therapy, and after self-administered behavioral treatment according to a self-help booklet.

Enuresis describes intermittent incontinence at night and refers to any discrete leakage of urine at night. Therefore, dysfunctional voiding has been used as a broad term. The reason of dysfunctional voiding in children could include hyperactive pelvic floor, overactive bladder, incontinence, or lazy bladder syndrome. For children with hyperactive pelvic floor, biofeedback therapy focuses on the relaxation and a return of normal flow. For children with overactive bladder and incontinence, use of the guarding reflex of the pelvic floor musculature can maintain continence during uninhibited contractions. In addition, biofeedback can be used for these children to void optimally and ensure that there is no decompensation of the detrusor muscle that occurs with the lazy bladder syndrome.

Cardiovascular Diseases

Since the beginning of biofeedback in the 1970s, biofeedback was used to control heart rate and blood pressure in patients diagnosed with cardiovascular diseases. It remains unclear whether the biofeedback regarding heart rate variability has more or less potential than other types of biofeedback in patients with cardiovascular disease, but these preliminary observations suggest that it may be useful in improving symptoms and the quality of life. Regarding hypertension, blood pressure can be lowered by 6–10 mmHg when biofeedback is effective, which is less of an effect than what is observed with most antihypertensive medications. Thus, although biofeedback has a potential in hypertension, its efficacy is not well proven and the systemic trials are lacking.

Neurologic Diseases

Biofeedback methods in the treatment of migraine are based on the concept that various relaxation skills, including diaphragmatic breathing or visualization, were helpful to induce the relaxation response, which includes relaxation of the sympathetic nervous system and activation of the parasympathetic nervous system. Recently published meta-analysis showed that biofeedback can be supported as an efficacious treatment option for migraine and tension-type headache according to the Association for Applied Psychophysiology and Biofeedback and the International Society for Neurofeedback and Research criteria.

Epileptic patients who were refractory to anticonvulsant medications have been treated with biofeedback therapy based on EEG. Several positive outcomes were reported

especially regarding complex-partial seizures, an extremely difficult-to-treat seizure type. However, it still needs a randomized, controlled study to prove its efficacy.

Others

Early studies in patients with Raynaud's syndrome demonstrated that biofeedback alone or in combination with various procedures reduced the occurrence of vasospastic episodes, based on the concept that cold hands and cold feet are frequent concomitants of anxiety and also occur in Raynaud's syndrome. Exposure to cold during temperature biofeedback may enhance the effects of biofeedback alone.

Fibromyalgia syndrome and other myofascial pain had been treated with biofeedback therapy. Recently randomized controlled study regarding fibromyalgia based on EEG showed the significant efficacy by a significantly decreased theta/sensory motor rhythm ratio by EEG waves compared to baseline.

Biofeedback therapy based on EMG was also tried in treating bronchial asthma. Children who were instructed to reduce frontalis muscle tension via biofeedback and continue their strategies in the home setting showed improvement in pulmonary function testing compared with children who were instructed to maintain frontalis tension.

Bipolar Disorder

J D Pettigrew, University of Queensland, St Lucia, QLD, Australia

Glossary

Depression Depression is complementary to mania, with an extended period of depressed mood and increased sleep time accompanied by reduced speech, lack of motivation, and excessive caution. The very high risk of suicide in bipolar disorder is most apparent at the time when there is a switch between mania and depression. While there are many different accounts of the mechanism of the cyclicity and the opposite polarity of the two phases, the only compelling theory involves an interhemispheric switch that alternates between the complementary cognitive styles of the two hemispheres and becomes stuck on one side during an episode.

Fractal time A function (after Mandelbrot) of time that shows self-similarity, such that a change at one temporal scale affects all temporal scales. One of the first examples suggesting fractal time in the nervous system came from work on the neural clocks of *Drosophila*. A mutant fly with an altered *per* gene had a longer circadian period than normal (25–30 h), but was also found unexpectedly to have a longer period of the courtship rhythm, which is measured in seconds. The underlying mechanism of this finding is still not clear, despite much progress on the understanding of neural clocks, but there are now many more examples of fractal time in the nervous system. For example, humans with a prolonged perceptual rivalry cycle also have prolongation of other cycles, such as the nasal cycle, which may be many hours long instead of the normal 1.5 h. The concept of fractal time could explain why the prolonged perceptual rivalry cycle of bipolar disorder (8–10s instead of 1–2s) is also associated with much longer lasting alterations (>days) in mood.

Interhemispheric switch A neural mechanism that switches activation from one cerebral hemisphere to the opposite hemisphere. Because of the speed of the switch, it is difficult to visualize it in scanning studies such as fMRI that have time constants around 8–10s. The switch is present in all vertebrate brains, so its location and physiology can be determined by comparative studies. Neuropharmacological studies have further defined the properties of the switch. Activation of the cerebral hemispheres is achieved by dopamine, which produces an 'up' physiological state of activation and readiness for plastic change via the NMDA channels that are turned on. The rhythmicity of the switch is determined by serotonin input using serotonin 1A receptors, whose activation slows the rate of the switch. The most likely physical correlate of the switch in the human brain is the dopaminergic ventral tegmental area (VTA) in the ventral midbrain, with the rhythmic serotonin input coming from the raphe nucleus.

Mania An extended period of elevated mood and sleeplessness. Lack of sleep is not accompanied by tiredness, and perceptual rivalry studies of mania suggest that there is a

primary sleep–wakefulness alteration, rather than one secondary to the mania, mediated by increased time spent by the interhemispheric switch in the left hemisphere at the expense of the right. Manics have increased verbal fluency and may show great facility at fitting rhyme, alliteration, and rhythm to words. They lack caution and may spend unwisely, indulge readily in sexual adventures, and put themselves in harm's way. In an effort to reverse mania speedily, psychiatrists rarely pay any attention to the introspective aspects of mania. These involve striking alterations in the perception of space–time with a dramatic alteration in the feeling of causation that the manic attributes to his/her will for events happening around them. Manics are also attracted by light, bodies of water, and the horizon. In keeping with the interhemispheric switch formulation, there are a number of pieces of evidence that activation is 'stuck' in the left hemisphere during mania. These include a large, almost complete preference for the left hemisphere percept in perceptual rivalry and continuous blockage of the left nostril (left hemisphere activation), instead of the usual alternation between right and left nostril over hours as part of the interhemispheric nasal cycle.

Mood stabilizer These drugs are the key agents for the prevention and treatment of the manic and depressive episodes of bipolar disorder. Mode of action is hard to define in the absence of an accepted model for the episodes of bipolar disorder and given the diverse pharmacology of these agents. One element of their action may be anticonvulsant, since many mood stabilizers (but not all) also act to prevent convulsions, such as valproate, carbamazepine, and topiramate. The 'kindling' process, by which cortical neurons progressively increase their sensitivity to the same input, is moderated by anticonvulsants and could explain a role in bipolar disorder where 'kindling' has been implicated in the triggering of later episodes and the 'falling in love with one's mania' phenomenon. Lithium ions are not particularly anticonvulsant, but do have an effect in development that might be relevant to the likely role of interhemispheric switching in bipolar disorder: right–left asymmetrical structures are eliminated during development by lithium. Since the ventral midbrain of the adult has many aspects shared with embryonic brain, such as high concentrations of retinoic acid not seen in other parts of the adult brain, lithium may be acting by reducing the right–left asymmetry (and thereby the magnitude of the interhemispheric swing from right to left) in this part of the brain. The complexity of the circuit from midbrain nuclei to cortex and back again leaves open many possible sites of action for mood stabilizers.

Nasal cycle This is caused by a slow interhemispheric switch in the hypothalamus. The modal period of the cycle

is 90 min, but in some individuals, the cycle can end even as fast as 20 min, and such individuals are considered to be rare. Many more individuals are found in the long tail of the distribution which stretches to many hours, where those who suffer from bipolar disorders are also found. The link between a slow nasal cycle and a slow rivalry cycle illustrates the principle of 'fractal time' where a slow switcher in perceptual rivalry (seconds) is also a slow switcher on other interhemispheric rhythms such as the nasal cycle (many hours). The alternating, side-to-side patency of the nasal passages can be readily visualized using MRI, but a satisfactory, economical method involves subjective estimation of patency by breathing out through each nostril alternately while the opposite nostril is occluded. Occlusion of one nasal passage is brought about by increased blood supply to that side, which is accompanied by increased blood supply to the brain on that side. In other words, increased activity in the Right hemisphere (as in depression) is accompanied by occlusion of the R nostril and patency of

the L nostril, which can be a diagnostic sign of depression if it is unrelieved by a switch.

Perceptual rivalry A constant, unvarying stimulus may nevertheless be accompanied by an oscillatory perception. By definition, the perceptual oscillation must arise in the brain rather than the stimulus and has been used repeatedly as a tool for the study of consciousness. The oscillation is usually binary, between two alternative interpretations, in keeping with experimental work showing that the perceptual alternation corresponds to a switch between activation of the two hemispheres. In some cases (e.g., plaid motion rivalry where the coherent, 'diamonds' alternative is associated with the left hemisphere and the incoherent, 'sliding' percept with the right) it is possible to gauge which hemisphere is active from the choice of the two alternatives, but in many cases the 'hemispheric assignment' is arbitrary. A variety of perceptual rivalries can be seen at www.uq.edu.au/nuq/jack/rivalry.html

Bipolar disorder, formerly manic depression, is a cyclical disturbance of mood in which episodes of mania and depression alternate.

Mechanism

Basic biological principles clearly underpin bipolar disorder because it is the most heritable of all mental health disorders. The probability is better than 60% that an identical twin will develop bipolar disorder if the other twin is affected. An acute episode of mania certainly has a 'biochemical feel' because of the sleeplessness, elevated mood, and accelerated verbal behavior, so it is easy to understand the emphasis on a biochemical basis for the disorder. But it needs to be realized that biochemical theories provide only a unidimensional gradation of symptoms and do not deal with the bipolar aspect of the disorder, in which there is a switch between complementary aspects, mania, and depression. In contrast to wholly biochemical accounts, there is an interhemispheric mechanism of bipolar disorder that adequately accounts for the complementary aspects.

The dynamics of the interhemispheric switch are determined genetically, as shown by studies of monozygotic twins, and show significant slowing in bipolar disorder. The disorder has the highest heritability of all mental disorders, a fact that may be connected to the high heritability of the interhemispheric switch rate.

Prevention

Post and Weiss have shown that the first episode is always triggered by an environmental stressor, but that later episodes may become spontaneous. This finding has the important implication that bipolar disorder is preventable. One needs to only identify a vulnerable individual before the first episode and then intervene with lifestyle modification

or mood-stabilizer medication. Since the dynamics of the interhemispheric switch are highly heritable and relatively stable throughout life, they can be measured noninvasively using perceptual rivalry. Interindividual variation in rivalry switch rate is more than an order of magnitude, making those susceptible individuals with the slowest switch rates prominent.

Medications

The key medications for bipolar disorder are 'mood stabilizers.' These drugs have an obscure mode of action and have commonly been used to search for the etiology of bipolar disorder.

Mood Stabilizers

1. *Lithium ions*: Have longest history of any mood stabilizers, since Cade showed almost miraculous elimination of mania using lithium. The long history probably explains the longer list of side effects compared with more recent, popular, drugs such as sodium valproate, which have not had time to accumulate such a list. The dose of lithium and its blood level are based on its antimanic effect and may be higher than that required for a maintenance mood-stabilizing effect, whose longer time course is difficult to titrate.

Lithium has nearly a dozen documented biochemical effects. Two effects of lithium are relevant to the interhemispheric hypothesis, a reduction in the degree of asymmetry in brain development and a phase reduction of circadian rhythm.

2. *Sodium valproate*: Its anticonvulsant action may relate to 'kindling' in the very plastic hemispheres.
3. *Omega-3 fatty acids, DHA, and EPA*: These naturally occurring molecules from seafood have a mild, mood-stabilizing effect that is best supplemented with more powerful drugs such as lithium. They may play an important role in prevention.

4. *Carbamazepine*: Powerful mood stabilizer and anticonvulsant that is complicated by a high incidence of serious side effects.
5. *Lamotrigine*: Has the opposite phase reduction to lithium and is more effective, in consequence, on the depressive phase of bipolar disorder. Now often combined with lithium to control both manic and depressive phases.
6. *Topiramate*: Has a powerful effect on the interhemispheric switch and is used as a mood stabilizer of last resort, in addition to its role as an anticonvulsant.
7. *Dopamine antagonists*: Haloperidol and olanzapine (dopamine antagonists) are sometimes used as mood stabilizers in a maintenance role in addition to their well-accepted role in acute treatment of mania. They have major side effects, such as massive weight gain, which limit their long-term use.

Age of Onset

The disorder can appear first at any age, but peaks in late adolescence/early adulthood when sexual relations provide the greatest source of environmental stressors.

Medication and Mood Stabilization

There are two broad classes of medications used in bipolar disorder: (1) mood stabilizers and (2) antidepressants (neuro-transmitter (usually 5HT) re-uptake inhibitors).

The first class does not have any obvious subjective effects. For example, putting aside initial side effects such as nausea, there is no subjective effect of lithium ions, which could be placed in a person's breakfast cereal without him or her noticing. Instead of expecting subjective effects, one needs to keep an extended record of mood changes, which are moderated by lithium ions even though there may not be a detectable introspective mood shift that is attributable to lithium.

Mood Stabilizers: Mode of Action

Understanding the mode of action of mood stabilizers is limited by the lack of an underlying model of bipolar disorder. In fact, many researchers have tried to 'reverse engineer' the basis of bipolar disorder by starting with the actions of the mood stabilizer and then working backwards to try to understand how it might moderate the fundamental cause of bipolar disorder. This approach has not been successful. However, if the evidence that bipolar disorder is based upon a dysrhythmia of interhemispheric switches is accepted, there is plenty of evidence that illuminates the mode of action of the mood stabilizers. For example, it is known that the hypothalamic, suprachiasmatic nuclei can act as a daily interhemispheric switch, whose circadian rhythm is differentially affected by lithium and lamotrigine. Lithium acts to reduce the action of the phase advance mechanism, while lamotrigine acts on the phase retardation mechanism in the circadian cycle. This would explain the action of these two mood stabilizers, with lithium being most effective on mania and lamotrigine most effective on the depressive part of the manic—depressive cycle, since

mania is triggered by a phase advance and depression by a phase retardation. Related to these effects is lithium's action to reduce hemispheric asymmetry. Episodes are characterized by an extreme asymmetry in the interhemispheric switch ('Stuck switch'), with a Left (L) bias in mania and a Right (R) bias in depression. Lithium has a strong action in eliminating R—L asymmetry during development and this is likely to apply also to the interhemispheric switch because it retains many embryonic features not found elsewhere in the adult brain, such as a high concentration of retinoic acid.

Antidepressants (Reuptake Inhibitors)

Billions of dollars in profits flow from this class of drugs. The first of the antidepressants was Prozac, but there are now dozens with a similar action. In view of the large profits, one might expect a detailed mode of action to have appeared that would help one to understand how these drugs bring about mood change. There is detailed biochemical information about how they inhibit the reuptake mechanism in 5HT nerve terminals, but one has to go to animal studies to get a more global understanding of these drugs. One key fact is that the hemispheric asymmetry that is no obvious in the motor and speech system is also present at the level of transmitters like 5HT, with the 5HT system much more well developed in the Right (R) hemisphere. So increasing the overall level of 5HT by blocking reuptake will desensitize the R hemisphere, which has more 5HT transmitter and receptors. In other words, these drugs will enhance the relative activity of the Left (L) hemisphere, thus improving mood because of its cognitive style to choose an alternative and to ignore the rest. The enhancement of L hemisphere action by these drugs have been observed in a number of different animal models.

The danger of this mechanism of action is that it can precipitate mania, also an L hemisphere paroxysm. Mania is a frequent outcome when a depressed person, treated with one of these antidepressants, is actually suffering from unrecognized 'bipolar depression'.

Perceptual Rivalry and Interhemispheric Switching

The cerebral hemispheres have complementary cognitive styles, according to the work of Ramachandran and Pascual-Leone. It makes logical sense to alternate between the denying, choosing, hypothesis-forming abilities of the left hemisphere and the all-accepting, discrepancy-detecting abilities of the right hemisphere. An oscillatory interhemispheric switch has been identified using psychophysics, comparative studies, and neuropharmacology. Caloric vestibular stimulation can be used to activate one hemisphere for around 30 min and can be used to induce a manic-like state (left hemisphere activation), a depressive state (right hemisphere activation), or to reverse mania by activating the right hemisphere. The temporal precision of transcranial magnetic stimulation's disruptive effects can be used to manipulate the switch so that left hemisphere phenomena are interrupted when the left hemisphere, but not the right hemisphere, is manipulated. And vice versa for the right hemisphere. The switch is difficult to demonstrate with functional magnetic resonance imaging (fMRI) because of

the sluggish response of this brain scanning method, but Mao used a very slow version of perceptual rivalry to show an associated interhemispheric switch using fMRI.

Perceptual rivalry is an oscillation of perception that switches between different alternatives in the face of an unchanging, if ambiguous, stimulus. The source of the oscillation must be endogenous to the brain, because the sensory input is unchanging. Extensive work has shown that the source of perceptual rivalry is interhemispheric switching. Caloric stimulation activates one hemisphere and simultaneously increases the proportion of time spent seeing the percept linked to that hemisphere. Likewise, transcranial magnetic stimulation applied to one hemisphere interferes in a highly specific and time-locked fashion with one percept but not the other.

The interhemispheric model predicts that perceptual rivalry will be linked specifically to mania or depression, and this is what occurs. The onset of mania is accompanied by increasing predominance of the left hemisphere percept (e.g., horizontal in H/V rivalry, or coherent 'diamonds' in plaid motion rivalry and approaching motion in form from motion sprees, etc.). Depression is accompanied by increasing predominance of the right hemisphere percept. The bias for one percept disappears and returns to the balanced state where the two percepts are seen for roughly equal amounts of time during recovery.

It is commonly assumed that the interhemispheric switch mechanism is the corpus callosum, the large bundle of fibers that interconnects the hemispheres, but this is not true. Interhemispheric switching is universally phylogenetical in vertebrates and both fish and birds switch without a corpus callosum. Moreover, a back-and-forth mechanism between the hemispheres would be slow and clumsy compared with bilateral projections from the brainstem that have balanced conduction velocities.

The switch has been dissected pharmacologically by examining the effects upon perceptual rivalry of catecholamine and serotonin analogues. The oscillatory mechanism, responsible for the individual's stable and highly heritable switch rate, involves 5HT-1A receptors, whose location in the brainstem help provide confidence about the location of the switch. The switch itself is probably a collection of cortically projecting dopaminergic neurons in the ventral midbrain.

Jet Lag

The circadian shifts of jet lag provide one of the most powerful triggers of an episode. For example, a manic tendency can be triggered to full mania by flying eastward 7–10 h. Similarly depression can be triggered by westward flight.

Fractal Time

There is strong support from a number of independent studies for a prolongation of the perceptual rivalry cycle in bipolar disorder. In turn, this cycle measured in seconds, has been shown to be an interhemispheric cycle. Interhemispheric switches can explain all the features of bipolar disorder, but there is a problem linking the seconds time course of the interhemispheric switch of perceptual rivalry and the days/weeks time course of the switches between mania and depression. This problem is solved by the realization that there are many interhemispheric switches of different time course, such

as the nasal cycle, whose time course is measured in hours and the information from the genetics of circadian cycles that a mutant cycle with a prolonged circadian cycle will have prolonged cycles at all scales from seconds to days ('fractal time').

Bipolar I Versus Bipolar II

A diagnosis of Bipolar I requires at least one hospital admission for mania and has an incidence in the general population around 1%. Those with this diagnosis have a bias of the interhemispheric switch for the left hemisphere, so that if the switch gets stuck it is more likely on the left, that is, mania. Bipolar II is more common, around 3%, and involves recurrent episodes of depression without frank mania. Normal members of the population as a whole show a bias toward the right hemisphere (the 'realistic' side) in the interhemispheric switch. This bias is reflected in a similar rightward bias in the slower switch of Bipolar II, which is therefore more likely to get stuck on the right, depressive side.

Famous Bipolars

The genes for bipolar disorder are widespread in all cultures. The incidence of Bipolar I is around 1% and for Bipolar II much higher; so it can be inferred that there is a selective advantage for these genes that prevents them from being eliminated from the population. The 'Bipolar trait' of a prolonged interhemispheric switch time has consequences that are independent of possible episodes. These include a prolonged attention span that is useful in creative problem solving and composition. Since time is a proxy for sensitivity when receptor activation can be prolonged but receptor numbers not increased, a prolonged switch rate means increased sensitivity. Virginia Woolf illustrates this extraordinary sensitivity in her ability to detect fine nuances and injustices in the interactions of others and to place them in her writings. Woolf was also acutely aware of the rise of Hitler, whose presence was felt nearby despite an actual distance of hundreds of miles, and this sensitivity to the dictator ultimately contributed to her suicide. In a family of children with one bipolar, its sensitivity is commonly recognized as the first to detect the onset of an approaching storm, presumably via barometric pressure changes, and to recognize subtle nuances in interpersonal relations that escape other family members.

Winston Churchill (Bipolar II) was voted the man of the twentieth century, along with Albert Einstein, because of Churchill's leadership in the Battle of Britain. His success may be attributable to a number of features of his bipolar brain, such as the ability to hold the same problem in his mind for much longer than the usual time, extreme sensitivity to small cues about the enemy's intentions provided by their movements, and the lack of normal sleep patterns that enabled a problem to be faced at any time.

Kay Jamison has shown that the chances of finding a bipolar among a group of poets or artists is 20× normal and has further shown the cyclic musical output of Schumann that was linked to the oscillations of bipolar disorder and eventually resulted in his suicide.

fMRI

fMRI relies on the magnetic signal that can be induced by a powerful magnet in hemoglobin molecules that have the Fe^{2+} molecule exposed to water by the loss of an oxygen molecule. In other words, the system detects deoxyhemoglobin in venous blood that is draining from an area of intense activity. It takes about 8s for the deoxygenated venous blood to flow after neural activity begins; so this technique is relatively sluggish and does not pick up the rapid changes when the hemispheres switch back and forth. Some studies have seen switching using fMRI by choosing a form of perceptual rivalry that has a very slow switch rate.

Conclusion

Advances in neuroscience are beginning to clarify the underlying cause of bipolar disorder. Recognition of the predisposing

conditions of this highly heritable disorder may soon be possible and lead to its prevention, by intervention before the first episode.

Birth Order, Effect on Personality, and Behavior

Glossary

Big five Personality trait model that proposes five basic dimensions of personality, conscientiousness, agreeableness, extraversion, openness to experience, and neuroticism.

Birth order An individual's rank by age within their family of birth. For example, in a family of three children, there is a firstborn, secondborn (or middleborn), and a lastborn.

In a family of four children, there is a firstborn, secondborn, thirdborn, and lastborn. In this case, both the second- and thirdborn could also be considered middleborn.

Fitness Fitness can be thought of as the relative probability of survival and reproduction of an individual.

Niche theory Frank Sulloway's theory suggesting that birth order influences the strategies siblings use to gain resources and minimize sibling conflict.

Parental investment Any parental expenditure (time, energy, etc.) that benefits one offspring (through increased

chance of survival and reproduction) at the expense of investing elsewhere (in other offspring, mating opportunities, etc.).

Parent-offspring conflict The conflict resulting from differences in optimal parental investment to an offspring from the perspectives of parent and offspring. Typically, an offspring will desire greater levels of investment for a longer period of time than is optimal from the parental perspective. Well-studied examples include weaning conflict and maternal-fetal conflict.

Personality A set of characteristics possessed by an individual that influence their thoughts, attitudes, and behaviors.

Reproductive value An individual's expected future reproduction.

Sibling competition Conflict between siblings, often over parental investment or other resources. It is also referred to as sibling rivalry.

Introduction

Psychologists have long been fascinated with birth order and its possible role in shaping personality. Over 75 years ago, Adler suggested that personality traits are related to an individual's ordinal position within the family. He believed that firstborns would be resentful when they were displaced by the arrival of a new child and that this would lead to neuroticism and substance abuse; that lastborns would be spoiled and emotionally immature; and that middle children would be the most stable as they were never dethroned or spoiled. Adler's work led to a plethora of studies examining the relationships between birth order and just about everything from personality to psychiatric disorders, intelligence, and creativity. Today, there is reasonable agreement that genetic influences account for a substantial portion (around 40%) of the variance in personality but that an almost equal amount of variance (about 35%) is due to nonshared environment with the remainder due to shared environment and measurement error. Birth order is one part of that nonshared environment, for while siblings usually grow up in the same family, they do not experience that environment in the same way. Recently, researchers such as Frank Sulloway have suggested that birth order shapes strategies for dealing with the family environment that are part and parcel of our personalities. This article will highlight the current thinking on birth order as a strategy shaped by differential parental investment and sibling competition (as originally proposed by Sulloway) and its effects on personality and behavior.

Parental Investment

Many nonhuman species do not engage in parental care. The fact that people do invest significantly in their own offspring is

testament to the substantial reproductive benefits that result from such costly care. Not only do parents provide the basic physical means for survival (food, shelter, and protection), they invest greatly in fostering the development of skills that are required for offspring success across the life span. Theoretical models of the evolution of parental solicitude suggest that parents will often treat their offspring differently in relation to a number of variables including offspring age, sex, birth order, parental age, and cues of phenotypic quality.

Parental investment in an offspring (as first elucidated by Robert Trivers) is any investment that a parent makes that increases the likelihood of that offspring's survival and reproduction at the cost of that parent's ability to invest in other offspring (either current siblings or future ones). In birds, we conceive of this in terms of feeding and nest protection. In people, it covers a wide range of activities from food and shelter to education, piano lessons, or figure skating. Generally, an offspring's fitness increases with the amount of parental care received. Extremely low levels of parental investment can result in the loss of an offspring; a minimum amount is required for survival. But there is also a point of diminishing returns at very high levels of investment beyond which offspring are unable to capitalize on any further investment.

The relevance of birth order to parental investment is related to several factors, including age of the offspring and age of the mother. An offspring's expected contribution to parental fitness rests mainly in their reproductive value. This value increases with age until puberty, making older immature offspring more valuable from a parental fitness perspective than younger ones. It is this assurance of parental favoritism, as well as an early absence of sibling contenders for a share of parental attention, that makes firstborn children defenders of parental values and the status quo while laterborns are more likely to be rebellious.

However, offspring age is not the whole story. As parents themselves grow older, the fitness value of any one offspring increases relative to the parent's residual reproductive value. As parents grow older, their own chance of reproducing again drops, thus older parents have been observed to invest more in offspring, all else being equal, than younger parents. This can be clearly seen in the dramatic decreases in maternally perpetrated infanticide as a function of maternal age. As a result, while firstborns may have an inherent advantage in terms of parental investment, there is a growing willingness of older parents to invest highly in their lastborn, their last chance to invest so to speak. In fact, lastborns are the only birth order to receive their parental investment without the competing demands of a younger sibling. This would seem to imply that middleborns may lose out in terms of parental investment and attention and there are a number of recent studies that support this. However, relatively few researchers have focused on middleborns; the majority have focused on the contrast between firstborns and laterborns.

Sibling Competition

But parental investment on its own does not tell the whole story. Sibling competition has a role in how the battle for parental resources plays out among a group of siblings. Natural selection shaped mechanisms for sibling competition just as it shaped mechanisms for discriminative parental solicitude. Strategies for sibling competition can manifest in several ways including dominance hierarchies, niche picking, and deidentification.

Dominance Hierarchies

In dominance hierarchies, the type of strategy siblings adopt in order to deal with resource competition is influenced by differences in size and strength (usually related to age). Older siblings are able to physically intimidate their younger and smaller brothers and sisters. Several aspects of personality, including dominance and assertiveness on the part of firstborns, can result from this dynamic. Typically, the younger sibling is best served by low-power strategies. Rather than physical force or the threat of it, the baby of the family often appeals directly to the parent in any sibling dispute. The middleborn is typically forced to negotiate on their own, with the parental support given to the youngest.

Niche Picking

Sulloway has argued that children adopt different roles or niches within the family. Some of this are the result of genetic differences, some are connected to sex differences, and some are due to birth order. Specialization of roles within the family, like specialization of species in the wild (the most famous example being Darwin's finches), reduces levels of competition. Specialization also makes children more unique. If your older brother is an awesome football player, a younger brother may be better served by a different niche, attempting to excel in a different sport or a totally different area such as academics or arts. Eldest siblings also often occupy the role of surrogate parent with its sense of responsibility and adherence to rules.

For later born children, there is no advantage to trying to duplicate that role; they have to find their own niche and their openness to experience with less adherence to rules and authority facilitates this.

Deidentification

Deidentification is the process by which siblings try to differentiate themselves from one another. In particular, when there is a very short birth interval and siblings are close in age, their needs are very similar and so competition for parental resources is more acute. Diversifying in terms of strategies leads each sibling to their own niche in the family, reducing direct sibling competition. This type of process is likely to lead to greater differences between siblings who are next to each other in birth order (such as first- and secondborn as opposed to first- and thirdborn).

Personality: The Big Five

Thousands of articles have been published focusing on birth order and its effects on personality, behavior, and intelligence. Recently, attention has been called to methodological issues, in particular the need to control for differences in such variables as socioeconomic status (SES) and family size. While relatively little attention has been paid to the possible interaction of gender and birth order, some evidence suggests that there is a special role, with costs and benefits, for the firstborn boy, whether or not he has an older sister. There have been some researchers who have suggested that birth order differences are nonexistent, while others have documented through individual studies and meta-analysis that there are a number of consistent patterns to be found. One useful way to think about personality in this setting is as a strategy. Birth order differences in personality reflect the different strategies siblings adopt in their attempts to acquire the resources they need, whether they are acquired from family or friends. Here, I will concentrate on the Big five classification of personality dimensions which focuses on the dimensions of conscientiousness, agreeableness, extraversion, openness to experience, and neuroticism. This is not the only model of personality, but it is the one most often focused on (in whole or in part) in studies of birth order and personality. While not all studies of birth order and these factors are consistent, they are quite frequently in accordance with evolutionarily informed predictions.

Conscientiousness

Characteristics associated with conscientiousness include: organized, neat, perfectionist, responsible, practical, and dependable. People who score high on conscientiousness are those that tend to get ahead in life, the industrious go-getters. The result is success in a variety of domains including elementary/high school and college as well as high job performance and satisfaction. High conscientious translates into playing by the rules which usually results not only in job success but also success at maintaining relationships, those that are sexual or romantic as well as family ties.

As one would predict from niche theory, firstborns generally score higher on conscientiousness than their later born

siblings. Family and peers rate them as more disciplined and thorough than their younger siblings. This should not be surprising for several reasons. One is that firstborns often adopt a surrogate parent role within the family, looking after and perhaps also bossing around their younger brothers and sisters. Responsibilities and organizational skills develop along with this role. Two, because of their privileged status as the first child, it is in their best interests to be the supporters of the status quo which generally means being parent-like, reinforcing the parental view of them as not only dependable but obedient. They identify with parents and typically take the resulting traditional approach. This family role is not typically available to laterborns. They must find another parental investment route, exploring and developing their abilities in other areas. The lastborn rarely gets, given the responsibilities that foster the development of conscientiousness, though middleborns sometimes do.

Agreeableness

Those traits most highly associated with the factor of agreeableness are: kind, understanding, helpful, cooperative, trusting, and softhearted. People who score high in agreeableness are highly invested in getting along well with others. They favor strategies of negotiation rather than those of power and are likely to withdraw from confrontation, finding such discord distressing. Harmony and cooperation are important to them in all their relationships, especially with family and friends. As a result, they tend to be well liked by others and are often best served by finding careers where this trait can pay off for them, in particular, those where establishing a friendly relationship with the customer or client is essential.

Generally, laterborns score higher than firstborns here. While firstborns have the physical size advantage with which to dominate their younger siblings, laterborns need to find other strategies to get their way. Rather than power strategies, laterborns use such tactics as negotiation, appealing to their sibling's sense of fairness (not usually the most effective), and puppy-like appeals to parents for help. Middle children, stuck between the dominant firstborns and babies of the family, are often rated most highly on agreeableness. These traits allow them to get what they need, whether at home or from friends. Their negotiating and mediating skills are forged by their position in the middle. They are neither the favored first nor the indulged last. Overall, laterborns tend to score high in social popularity, a reflection of how easy others find their company.

Extraversion

Extraversion includes traits such as talkative, energetic, assertive, and outgoing. Social interaction is the key here. Extraverts often take on positions of leadership; first to offer their opinion and suggestions. They are often quick to approach others, especially on the dating scene. They often report greater levels of happiness. Many people consider extraversion a very positive trait but it can be problematic as they are often easily distracted from a task by their social interactions which can be hazardous under some circumstances (such as driving down the LA freeways!).

Birth order effects on extraversion have often been confusing because some of the specific components, like assertiveness and dominance, are ones that firstborns score highest on.

On the other hand, components such as sociability are ones on which laterborns score higher than firstborns. As a result, many studies do not show clear birth order effects on extraversion unless they break it down into those aspects associated with dominance and those associated with sociability. It should not be surprising that firstborns score high in dominance-related aspects of extraversion considering their often pseudo parental (and sometimes physical) authority in the family and the expectations parents typically have for them and their future success. Laterborns follow a different strategy, one of being outgoing, willing to try new things, meet new people; they are extraverted in a highly sociable way, finding pleasure and excitement in the company of others.

Openness to Experience

Traits associated with openness to experience include being imaginative and creative, inventive, open to unusual ideas, adventure, and nonconformity. Those scoring high in this dimension are independent-minded and willing to tolerate more ambiguity (or less certainty). As a result, they are often the first to entertain new concepts and beliefs (which are sometimes later confirmed and other times refuted). Some studies have indicated a relationship between openness and IQ.

Birth order effects on this factor are also somewhat mixed with firstborns scoring higher on aspects that focus more on intellect and intelligence, while laterborns score higher on measures that center on the desire for novelty, experimentation, and a taste for the unconventional. This interest in being unconventional is perhaps behind the tendency for laterborns to identify themselves (as well as for others to identify them) as rebellious, or the rebel of the family. Some studies have indicated that middleborns may be the most rebellious birth order as they are the ones most disadvantaged in the distribution of parental investment. This personality trait facilitates their ability to find their own unique niche by making them more willing than others to embrace the new and untried.

Neuroticism

The factor represented by neuroticism is also sometimes referred to as emotional instability. Individuals who score high on neuroticism are emotionally reactive and tend to experience persistent negative emotional states such as anger and anxiety. Life is full of challenges and emotional instability reflects the way people deal with such stressful events. Those that are emotionally stable weather the storms of life; they react but not disproportionately. Those that score high on neuroticism are rocked by challenges; they disrupt their lives and emotional balance so that they are often perceived as moody or unpredictable. They are more likely to have high levels of anxiety and are more likely to develop posttraumatic stress disorder in response to highly emotional negative events. As you might imagine, this can put a strain on their personal and professional relationships.

The relationship between birth order and this factor seems quite small. However, one related birth order effect that shows up relatively consistently is that middleborns score lower in self-esteem than their siblings. This may be a result of the lower levels of parental investment they receive in combination with their unclear role in terms of family structure and parental

expectations. They do not know quite where they fit in and this anxiety may be contributing to their issues of self-esteem. There are also a few studies that suggest higher levels of neuroticism in firstborns but the results are typically trends rather than significant relationships. If the connection is there, it is more likely related to the higher levels of anxiety and concern over success (and meeting parental expectations) that sometimes play a role in firstborns' drive to succeed.

Birth Order and Behavior

The impact of birth order on behavior has been demonstrated in a number of domains including interactions with family, friends, sexual partners, the workplace, religion and politics, consumer behavior, risk-taking, and trust and cooperation. While a majority of people recognize that birth order plays a role in the family setting, the magnitude of birth order effects outside the family is still open to debate. This section will illustrate some of the better-documented connections between birth order and behavior, emphasizing that birth order effects are often strongest when the context or situation activates those strategies that were effective in the family setting. We will return to this issue of context in the section on methodology.

Family Interactions

While a significant proportion of personality can be attributed to genetics, birth order differences in personality are forged by the family environment. Birth order is not a genetic trait; it is a proxy for the differences that exist between siblings such as size, power, experience/skills, etc. As such, we would expect birth order to have a greater impact on family relationships and family-related behavior than in any other domain. This has been demonstrated in a wide range of studies looking at everything from emotional closeness and gift-giving to frequency of contact with family members. Firstborns tend to have more contact with siblings and parents than laterborns. First- and lastborns report family identity to be more important to their sense of self as well as feeling closer to parents than middleborns. Middleborns are also less likely to be family genealogists. While firstborns spend more money on gifts for family, middleborns spend more on friends. Middleborns generally have less contact (once they are no longer living at home) with parents than first or lastborns. However, middle-born children do tend to have solid sibling ties, reporting being more satisfied with sibling support than other birth orders. In the absence of strong relationships with parents, they tend to be more sibling- and peer-oriented, seeking advice and support from peers as opposed to parents. Such birth order differences, particularly those of middleborns, are a reflection of the degree of perceived parental investment as well as their sense of their natal family as a source of support. They are more likely to report friends as their greatest social support and they appear to invest more in them, as discussed in the next section.

Friends and Lovers

People often remark on how friends can be like family and many individuals share intensely close friendships. Does birth

order influence the quality or quantity of friendship? What about romantic relationships? Studies in the past several decades have suggested that laterborns, in some cases particularly middleborns, are more popular with their peers. They certainly score highly on the prosocial aspects of extraversion as well as agreeableness, something you would expect from those who seek out friends and get a good response. Middleborns also hold more positive views on friends and friendship generally, seeing them as confidants, reliable sources of help, support. In turn, they are perceived as being good friends, empathetic, reliable, and trustworthy. And middleborns do seem to care about being seen this way, wanting to be perceived as good friends.

When it comes to sexual relations, there are some interesting birth order differences. Firstborns tend to wait until a later age for their first sexual experience. They tend to be slightly younger, however, when they first have a child and seem to have slightly more children overall. Waiting a bit in terms of having sex fits with their more conscientious and cautious nature, as opposed to the move of adventurous lastborns who have often also heard about the sexual exploits of their older siblings. When it comes to marriage, reports from research and marriage counselors seem to suggest that the most happy marriages are those between a first- and a lastborn or anyone with a middleborn. This is another place where the ability to negotiate and mediate conflict that middleborns learn from being sandwiched between siblings comes in handy. Two firstborns seem to produce the most unstable marriages. And some data suggests that there are differences in the likelihood of cheating when in a monogamous relationship with middleborns being the least likely to cheat, followed by firstborns, while lastborns were the most likely to stray.

Workplace

Workplaces are highly variable in nature. People may interact with the same small group of people all the time, or with many different people most of the time. There may be a clear chain of command or a more horizontal structure. But for most people, coworkers are not family. And yet, work can be one place where birth order can have a significant impact not only in terms of such things as occupational choice but also personal dynamics. There are indications that career choice can be influenced by birth order. Firstborns tend to be drawn to the business field as well as accounting and finance. Middle children are often found in greater numbers in service fields, or ones focusing on justice or interpersonal ties between clients or coworkers. Lastborns tend to often gravitate to creative environments, teachers, and performers.

Business leaders and CEOs may also conduct their business differently as a result of their own birth order and resulting personality. They are often assumed to be firstborns, and many are, as many firstborn-associated traits are likely to lead to success at the top of the business world, such as dominance, tough-mindedness, and competitiveness. All part of the perception of the traits required for the drive to the top. But there are also leaders who are laterborns and they have a very different business style producing working environments more characterized by a personable style of interaction with employees and a willingness to take risks with strategies and products,

shaped by the inclination of laterborns to believe in the new and untested. It is not so much that one birth order is more successful here than another but that the style of their success is different. Firstborns tend to find their success in traditional established environments. Laterborns often find a more creative nontraditional style, characterized by flexible and original approaches.

Religion and Politics

Religion and politics are two topics often to be avoided in social situations. Both can be influenced by birth order. As Frank Sulloway thoroughly documented in his 1996 book, *Born to Rebel*, birth order has had a significant impact on who supports radical political and scientific change with laterborns leading the charge. Laterborns, like middleborn Darwin himself, provided much of the initial support for his theory of evolution by natural selection, a concept incredibly revolutionary for the time. A majority of those most resistant to radical change have been firstborns and when firstborns are leaders of revolutions, they typically have less ideological implications (Einstein and relativity, for example). Laterborns' openness to experience makes them more willing to adopt new and radical ideas perhaps especially when there are strong ideological implications (such as Copernicus' theory that the earth revolved around the sun as opposed to the traditional sun rotating around the earth viewpoint).

When it comes to being a politician, firstborns are overrepresented among holders of political office. Perhaps that is one reason that they are predisposed to use political rhetoric in their political speeches. My own study on the use of kin terminology in political speech indicated that both firstborns and lastborns were somewhat susceptible to the use of such language. Appeals to 'my brothers and sisters' were more influential with these birth orders. Interestingly, middleborns were least responsive to such overtures. From an evolutionary perspective, this is not surprising. If middleborns receive less attention and investment from parents, they are less likely to see family as a valuable resource with shared best interests. Instead, friends may be a better source of resources and shared interests and, in fact, middleborns were more responsive to the use of terms indicating friendship in political speech than they were to those of kinship.

There have been relatively few examinations of birth order and religion. Some indicate middleborns score lowest on the importance of religion in their lives, perhaps a reflection of their tendency to score highest on rebelliousness. An individual's sense of religiosity is highly influenced by parental religiosity and the nature of the parent-offspring relationship. Adhering to parental religious views reflects a willingness to conform to parental desires and expectations (i.e., more commonly seen in firstborns). Middleborns, in the unconventional and rebellious way, are less likely to accept the family religious tradition. They do, however, often score high in terms of spirituality.

Consumer Behavior

This is an area you might not immediately assume is influenced by birth order. But there have been a number of

intriguing findings that suggest birth order can shape aspects of consumer behavior. Consider, for example, the middleborn son. In the face of firstborn parental favoritism, he has striven to be the best he can be, not always the top dog but in the top echelon. What kind of marketing campaign might get him to buy your product? Perhaps one that signals that he is not second best, that he is a winner. A study by Reid Claxton suggested that indeed, in an ad campaign that focused on exactly that train of thought, a secondborn son who was second in his class etc. and finally purchased a first-class pen, middleborns were more likely to identify with the character in the ad copy (with the assumption that this would be likely to lead to a future product purchase of this brand of pen). One might also predict that laterborns would be more open to innovative or new products and perhaps less attached to brand names. And indeed it does appear that laterborns are more open to product innovation while firstborns seem to be more susceptible to the influence of others (normative influences and status markers) when it comes to product choices.

Risk-Taking

Considering the impact of birth order on openness to experience, it should not be surprising that studies have noted birth order effects on risk-taking. They are a variety of ways to look at risk-taking, from survey instruments to actual behaviors. Greater participation in high-risk sports such as skydiving, automobile, and motorcycle racing, which are highly correlated with sensation seeking and related to aspects of openness to experience, has been widely noted on the part of laterborns in comparison to firstborns. In fact, a recent study by Sulloway and Zweigenhaft on the risk-taking behaviors of brothers in major league baseball demonstrated that younger brothers were more likely to attempt the high-risk strategy of base stealing and were also more likely to succeed at it than their older siblings. Older siblings were more successful in terms of batting success. While both birth orders were successful, they went after their success in different ways, excelling at different aspects of the game. Other work has indicated that laterborns are at greater risk of indulging in binge drinking, smoking, pot, and more likely to engage in acts of civil disobedience. Sulloway in his 1996 book also documented that laterborns were more likely than firstborns to travel to remote parts of the world, risking death due to accident or disease.

Trust and Cooperation

There are a number of reasons to expect birth order to have an impact on trust and cooperative behaviors. For one thing, birth order influences scores on such personality aspects as altruism and tendermindedness (components of agreeableness) with laterborns scoring higher than firstborns. Being altruistic, agreeable, and tender minded would tend to increase the willingness to give others the benefit of the doubt and engage in activities that would be to everybody's benefit. Some studies have indicated that laterborns are perceived by others as more trusting and straightforward than firstborns. Firstborns even describe themselves as more self-centered and less empathetic than others. Firstborns are also less trustful. There is also some evidence that middleborns may be the most trustful of the

three birth orders toward nonkin and the most concerned with maintaining the balance of reciprocity from their side (in other words, they want to be seen as good reciprocators or cooperators).

Some Methodological Issues

There are several methodological issues relevant to any discussion of the impact of birth order on personality or behavior. The first concerns surveys and personality inventories. Much personality research relies on self-report personality inventories, such as the Revised Neo Personality Inventory (NEO PI-R) which measures the five-factor model. Are people being honest in their responses and are they the best judge of their own traits? Research has compared self-report with peer or parental reports (even sibling pair reports), with a number describing similar findings, some only finding effects for one of the report types. For those who argue that birth order only has an impact within the family domain, if peer reports agree with self or parental, they have a problem to explain as this provides support for the claim that the influence of birth order extends outside the family domain. Another approach is to look at actual behavior, rather than self-report or inventories. Measures of actual behavior rather than surveys may provide more clear and consistent results. An additional problem is the number of participants needed to get reliable birth order effects. Some of the clearest evidence is in the largest sample size studies which make some study designs a challenge for many psychologists.

A related issue also has to do with study design. Most of the early work, and much current research still, involves studies that compare birth orders across, as opposed to within, families. Obviously, there are significant benefits to a within-family design as it controls for between family differences in SES, ethnicity, and family size. Siblings are in direct conflict with their own brothers and sisters, not siblings from other families (for parental investment anyway) so that comparisons between first- and lastborns, for example, are best done with siblings from the same family, such as in Paulhus, Trapnell, and Chen's study of personality and achievement and Sullo-way and Zweigenhaft's recent study of birth order and baseball performance of brothers in the major league.

The question of the relevance of birth order outside the family setting is a good one that needs to be further addressed. Some behaviors are very much situation-specific. Perhaps some of the best approaches to the impact of birth order on behavior are ones that attend to this and look for birth order effects in relevant domains (ones where the context is similar to that of the family or contains family-type cues) in the real world (like major league baseball) or by recreating appropriate situations in the laboratory. For example, I conducted a study, mentioned previously, that examined the impact of kin terms in political speech. This is a context where we might expect susceptibility to kin cues. The speaker is usually trying to convince his audience of their shared agenda and best interests, reinforcing the sense of the people and the orator as a group with common goals. It is a situation ripe for the manipulation of kin cues and there are many documented examples of the use of such terminology in speeches on public record. I expected such techniques with kin language would be less

effective for middleborns who are perhaps less inclined to see their family as always having their best interests at heart (as opposed to their siblings). Similarly, my work with Martin Daly on genealogists and those people who chronicle their family histories was a real world behavioral test of birth order's influence on such a behavior. Again we found that middleborns were underrepresented among family historians. More work needs to be done with attention to the behavioral context and how it may or may not trigger family sentiments and psychology.

One final methodological consideration is that of the specific birth orders. Historically, the majority of birth order research has lumped middleborns and lastborns together and compared them to firstborns or simply compared first and last. Based on a Darwinian or niche model, this is simply not the best approach. We would expect substantial differences between middleborns and both firstborns and lastborns not only on personality dimensions but also in terms of behavior. A number of those who have separated the middleborns out have indeed found such differences. Hopefully more researchers will continue to attend to the relevance of all three birth positions and not merely consider firstborn versus all others. Middleborns are in fact unique in their particular parental investment situation (eldest and youngest do tend to have periods of parental monopolization that the middleborn never has). This has consequences for middleborn traits and behaviors beyond simply not being the first.

Summary

Birth order is one of many environmental factors that play a role in the development of personality and a variety of behaviors. A Darwinian family niche perspective makes clear predictions about the ways in which birth order effects will play out and many of them have been tested in numerous research programs over the past 10 years. In general, higher scores on conscientiousness are found in firstborns while laterborns score higher on agreeableness, and openness to experience. The dominance aspects of extraversion are high-scoring for firstborns while the sociability ones are high-scoring for lastborns. Neuroticism has much smaller and less clear-cut results. These distributions of personality traits serve individuals of different birth orders in their attempts to secure the best resource acquisition outcome possible. In turn, they also shape their behavioral tendencies as children and adults.

Body Dysmorphic Disorder: A Review

J E Grant and B L Odlaug, University of Minnesota Medical Center, Minneapolis, MN, USA

© 2012 Elsevier Inc. All rights reserved.

Glossary

Cognitive behavior therapy A type of therapy used in either individual or group settings in which the therapist attempts to change distorted thoughts and problem behaviors through the identification and modification of these thoughts and changing the rewards for behaviors.

Compulsion Repetitive behaviors (e.g., mirror-checking, camouflaging with makeup or hats, etc.) or mental acts (e.g., comparing with others) undertaken to prevent or reduce anxiety or stress and not to provide pleasure or gratification.

Double-blind A research method in which the identity of the treatment and control groups is concealed (or 'blinded')

from the researchers administering the treatment condition and research subjects involved in the study to eliminate biased results.

Impulsivity A predisposition toward rapid, unplanned reactions to either internal or external stimuli with diminished regard for negative consequences.

Obsession Persistent ideas, thoughts, impulses, or images which are experienced as intrusive and inappropriate and which cause marked anxiety and/or distress.

Serotonin-reuptake inhibitor A class of drug that acts as a neurotransmitter uptake inhibitor on serotonin receptors within the brain.

Introduction

Most people are dissatisfied with some aspect of their appearance. In fact, more than half of all women and nearly half of all men in the United States are dissatisfied with the way they look. For some people, however, the preoccupation with perceived defects in physical appearance is excessive. These patients suffer from body dysmorphic disorder (BDD), a disorder characterized by significant distress, impaired functioning, social withdrawal, and repeated attempts to hide or correct a perceived defect in appearance.

Despite having been described around the world for more than a century, BDD was not included in diagnostic systems until DSM-III and ICD-10. DSM-III included BDD as an example of an atypical somatoform disorder and DSM-III-R provided the diagnostic criteria. Although DSM-IV allows people with delusional BDD to receive a diagnosis of both delusional disorder and BDD, ICD-10 classifies delusional BDD as a variant of delusional syndrome.

BDD is a relatively common disorder. Although studies within the general population have found prevalence rates ranging from 0.7% to 2.4%, studies of clinical samples suggest higher rates: 7% among cosmetic surgery patients; 8.0% in patients with major depression; 8.8% among dermatology patients; 11% in patients with social phobia; 8–12% in patients with obsessive–compulsive disorder (OCD); 13.1% among psychiatric inpatients; and 39% in patients with anorexia nervosa.

BDD affects both children and adults. BDD usually starts in adolescence and appears to be about equally common in men and women or slightly more common in women.

Clinical Characteristics

Individuals with BDD are preoccupied with the idea that some aspect, or aspects, of their appearance look abnormal. They may describe these body areas as being unattractive, deformed, disfigured, ugly, hideous, or 'not right.' Although any body part

can be the focus of concern, and most individuals with BDD are preoccupied with numerous body areas, the face or head is commonly the body area that troubles BDD patients, with a focus on skin flaws, defects, blemishes, wrinkles, scars, or supposed acne. Typical patients are preoccupied with their appearance for several hours each day. The majority also have ideas of reference, thinking that others notice their imagined defect and react to it with dislike or disgust. As a result, many BDD patients limit their social interactions and may become quite isolated. In response to their obsessive thoughts, patients may spend hours checking their skin in the mirror and camouflaging their skin with excessive and unneeded makeup.

Nearly all persons with BDD perform repetitive, time-consuming behaviors. These behaviors focus on examining, improving, being reassured about, or hiding the perceived defect. These behaviors are often described as 'compulsive' in the sense that the urge to perform them is strong and difficult to resist. They are also sometimes referred to as 'safety behaviors,' meaning that they are performed to prevent a feared catastrophe (e.g., camouflaging 'ghost-like' skin with bronzer to prevent feared scrutiny by other people).

The most common behaviors are camouflaging (e.g., with hair, a wig, makeup, body position, sunglasses, a hat, or other clothing), comparing one's appearance with that of other people, excessively checking the perceived flaw in mirrors or other reflecting surfaces (e.g., windows), excessively grooming (e.g., applying makeup or tweezing, styling, or cutting hair), and seeking reassurance that the body area looks normal or acceptable to others. The behaviors are unlimited and varied, however, and may consist of dieting, excessive exercising or weightlifting, touching or measuring the body part, tanning, buying excessive amounts of beauty products and compulsive shopping, (which can lead to financial indebtedness), repeated clothes changing, seeking surgery or medical treatment, and using potentially dangerous anabolic steroids to bulk up.

Nearly all patients with BDD experience impairment in social and occupational/academic functioning as a result of their appearance concerns. People with BDD also have

markedly poor quality of life, and approximately one quarter of patients with BDD are so distressed that they attempt suicide. However, the severity of BDD varies, with some people appearing to lead relatively normal lives despite the suffering and interference they experience.

Gender Differences

The prevalence of BDD appears to have a fairly equal gender distribution. A study examining gender disparities in 200 individuals with BDD reported more similarities than differences. While men were more likely to be older and single, women were significantly more likely to have a lifetime diagnosis of an eating disorder (42.3%), pick at their skin (52.6%), and use camouflaging techniques such as wearing concealing clothing or using makeup. Women were also more likely to be concerned with their buttocks (28.5%) and thighs (28.5%) while men were more concerned with body building (36.5% vs. 9.5%). Men are also more likely to report an alcohol use disorder (55.6% vs. 36.5%) and engage in weight-lifting behavior (25.4%), however, both men and women equally engage in behaviors such as dieting (37.5%) and excessive exercise (21.5%).

Diagnosing BDD

Numerous studies have found that BDD usually goes unrecognized in clinical settings, probably because clinicians fail to screen for the disorder and patients are too ashamed of their symptoms to spontaneously reveal them. Diagnosing BDD, however, is usually straightforward and can be accomplished by asking patients if they are unhappy with how they look or if they worry excessively about their appearance. An affirmative answer can be followed up with questions determining the degree of distress that these concerns cause and whether they cause functional impairment. DSM-IV criteria are met when the patient reports being preoccupied with a nonexistent or minimal appearance flaw that causes clinically significant distress or impairs functioning. It must also be ascertained that the appearance concerns are not better accounted for by an eating disorder. Simple self-report and clinician-administered screening and diagnostic measures are available. It is especially important to screen for BDD in patients who present with some of the disorder's clues – for example, the behaviors described above, histories of seeking cosmetic surgeries, ideas or delusions of reference, or being housebound.

Comorbidity

Most individuals with BDD have other co-occurring psychiatric disorders. Lifetime major depression (84%), substance use (49%), social phobia (40%), and OCD (33%) are the most common. Personality disorders, particularly avoidant (38%), paranoid (38%), and obsessive-compulsive (28%), are also common.

In a recent study of 176 BDD subjects, 49% had a lifetime substance use disorder and a majority of subjects (68%)

reported that BDD symptoms contributed to their substance use. The lifetime substance use disorder rate in subjects with BDD in this study is notably higher than reported rates in the general population (26.6–29.0%). In addition, those with a lifetime substance use disorder had a significantly higher rate of suicide attempts. The high lifetime rate of substance use disorders and the very high rate of suicide attempts in subjects with a substance use disorder suggest that clinicians should carefully screen BDD patients for a substance use disorder, as the presence of a lifetime substance use disorder may have treatment implications.

Relationship to Other Mental Illnesses

Obsessive-Compulsive Disorder

Although BDD is classified as a somatoform disorder in DSM-IV, it has many similarities to OCD – most notably, the presence of prominent obsessions and repetitive compulsive behaviors. There also appear to be differences between these disorders; for example, BDD patients are less likely to be married, possibly because of their avoidance of dating due to an intense fear of evaluation by others. BDD subjects also have poorer insight into their illness and are more likely to think about suicide or make a suicide attempt because of their disorder. They also have higher lifetime rates of major depression and social phobia than individuals with OCD. In addition, BDD appears more often characterized by shame, embarrassment, low self-esteem, and rejection sensitivity – features that it shares with social phobia.

Major Depressive Disorder

BDD and depression often co-occur and both disorders are characterized by low self-esteem, rejection sensitivity, and feelings of unworthiness. Unlike depression, however, a core feature of BDD is prominent obsessional preoccupations and repetitive compulsive behaviors. Many depressed patients focus less on their appearance, even neglecting it, rather than overfocusing on it. In addition, onset of BDD usually precedes that of major depression, suggesting that BDD is not simply a symptom of depression. Perhaps most important, BDD appears to respond to serotonin-reuptake inhibitors (SRIs) but not non-SRI antidepressants, which is an important difference between BDD and depression that has clinical implications. Another apparent difference is that BDD does not appear to respond to ECT, although data on this topic are very limited.

Anorexia Nervosa

BDD and anorexia nervosa share disturbed body image and a preoccupation with perceived appearance flaws. Many patients with anorexia are preoccupied with nonweight aspects of appearance, such as the size of the stomach or thighs, or even body areas such as the skin or nose. Conversely, some BDD patients are preoccupied with body weight and body shape. Both disorders involve intrusive thoughts about appearance, dissatisfaction with appearance, and an overemphasis on the importance of appearance to the evaluation of self-worth.

Both BDD and anorexia may also involve appearance-related ritualistic or repetitive behaviors (e.g., mirror checking

and body measuring), and some BDD patients diet or excessively exercise. Furthermore, people with anorexia or BDD may avoid places, activities, and ways of dressing that provoke self-consciousness about how they look. In addition, in both disorders a quest to improve appearance drives attempts to change the body's appearance – for example, through weight control in anorexia and excessive grooming or cosmetic surgery in BDD.

While anorexia and BDD have similarities (as noted above), as well as a hazy area of overlap, they also appear to have some important differences. For example, while 90% of patients with anorexia are women, this appears to be the case for only 50–60% of patients with BDD. The two disorders also have somewhat different comorbidity patterns. In a controlled family study of OCD, BDD was more common in first-degree relatives of OCD probands than control probands, whereas the eating disorders were not; this finding suggests that BDD and not eating disorders be considered part of a familial OCD spectrum. In addition, a study examining 45 patients with anorexia or bulimia nervosa, 51 patients with BDD, and 50 nonclinical controls, found that the eating disorder and BDD groups had equally severe body image disturbance and negative self-esteem. However, the eating disorder subjects had more widespread psychopathology, whereas the BDD subjects reported more negative self-evaluation due to appearance and more avoidance of activities due to self-consciousness about appearance. Importantly, BDD and anorexia seem to respond differently to treatment. Unlike patients with anorexia, a majority of patients with BDD improve with SRIs, some very robustly. And while preliminary data indicate that BDD often responds well to cognitive behavioral therapy (CBT), CBT has generally been less effective for anorexia nervosa.

Although BDD and anorexia nervosa have various similarities and differences, it is also important to recognize that the disorders may also co-occur. Recognizing BDD in patients with anorexia nervosa is important because the co-occurrence of the two disorders may have clinical implications. In the only study of this issue, 16 patients with both disorders were compared to 25 women with anorexia nervosa alone. Those who had anorexia nervosa plus BDD had significantly poorer functioning, had been psychiatrically hospitalized more often (6.3 times vs. 3.8), and had three times the rate of suicide attempts (63% vs. 20%).

Social Phobia

Previous research has indicated high rates of lifetime co-occurring social phobia in patients with BDD (31.1–37%). The fear of negative evaluation by others and social reclusiveness are hallmarks of both disorders and, in some cultures, BDD is actually regarded as a form of social phobia. Treatment regimens for both disorders have indicated the efficaciousness of certain serotonergic medications, including fluoxetine and clomipramine, indicating at least some shared neurobiological processes between BDD and social phobia. Research specifically examining those with social phobia alone or those with BDD alone, however, has yet to be obtained. Given the significant overlap between the two disorders, screening patients with either social phobia or BDD for the co-occurrence of the other disorder is imperative.

Pathologic Skin Picking

Some research suggests that BDD and pathologic skin picking may share common phenomenological links. In fact, a previous study of patients with BDD found that 81.8% picked at their skin to improve appearance. Therefore picking behaviour may be viewed as a symptom of BDD in many individuals. A recent study of 53 individuals diagnosed with pathological skin picking (excluding those individuals who picked primarily because of appearance), however, found that no individual had co-occurring BDD. This study highlights the heterogeneity of picking. Picking may be a symptom of a disorder such as BDD as well as an independent compulsive behavior. Clinicians should therefore be aware of the possible heterogeneity of picking as treatment options may differ. If seen as an independent disorder, picking may respond to glutamate agents but may respond preferentially to serotonergic medications when it is a symptom of BDD.

Neurobiology

Although the etiology of BDD is most likely multifactorial (biological, psychological, sociocultural), serotonin dysregulation has been associated with BDD. BDD symptoms have been exacerbated after tryptophan depletion and have had their onset after abuse of ciproheptadine, a serotonin antagonist.

Neuropsychological and brain imaging studies have also suggested that there may be impairment of the frontal–striatal and temporo–parietal–occipital circuits which process facial images and emotional information. In previous neuroimaging studies, subjects with BDD demonstrated greater total white matter compared with controls and a leftward shift in caudate asymmetry, which might be suggestive of a striatal pathophysiology similar to that of OCD.

A small functional imaging study of six BDD patients, using single photon emission computed tomography (SPECT), showed variable, discrepant findings including relative perfusion deficits in bilateral anterior–medial temporal and occipital regions and asymmetric perfusion in parietal lobes.

Clinical observation and neuropsychological testing indicate that BDD patients hone in on details of certain appearance features, usually their face, at the expense of global or configural aspects. BDD patients may process faces in a piecemeal manner, whereas healthy controls' perception of faces may be more configural and holistic. The left inferior frontal gyrus and right amygdala in individuals with BDD demonstrate functional hyperactivity for processing faces and their size correlates with symptom severity. These regions may be involved in pathological face processing that underlies the core symptoms of BDD.

Two recent functional magnetic resonance imaging studies in BDD that examined visual processing of faces found that individuals with BDD demonstrated abnormal activation patterns that included greater left hemisphere activity in regions including the inferior frontal gyrus, as well as abnormal amygdala activation compared to controls. Using voxel-based morphometry, a second study found significant positive correlations between severity of BDD and volumes of the left inferior frontal gyrus and the right amygdala.

The structural and functional studies to date suggest a visual and emotional processing deficit involving the inferior frontal

gyrus and amygdala. Caution, however, is required when attempting to interpret data from preliminary studies conducted in small samples of BDD patients in whom comorbidity is common. Although important early insights have been gleaned from research to date, our understanding of the neurobiology of BDD remains lacking.

Treatment

Many people suffering from BDD seek and receive surgical and nonpsychiatric medical treatments (e.g., dermatologic) for their perceived appearance flaws. Available data suggest that such treatments are usually ineffective and that appearance concerns usually persist unchanged. Many patients do not report their symptoms to their physician. A study of 50 patients with BDD reported that only 38% had told their general practitioner of their body concerns. For patients who do report their symptoms, 92% report feeling dissatisfied with their treatment. This makes sense, since BDD involves an obsessional body image disturbance that is not based on reality; changing a physical feature would not be expected to diminish the disorder's core pathology.

Nonpsychiatric Treatments

Individuals with BDD often seek and receive treatment from nonpsychiatric sources. Approximately 63% of BDD patients have sought treatment from dermatologists and almost 75% of those requesting dermatological treatment received it. Antibiotics were most commonly prescribed, as well as isotretinoin or dermabrasion for perceived acne. Only 9.8% of all dermatological treatments led to an improvement in BDD. In a study of 11 patients with BDD, 7 (63.6%) sought treatment from a dermatologist and four of those patients actually received treatment. In the cases in which treatment was received, no improvements in BDD were observed.

Surgical treatments are also common. A study assessing cosmetic surgery patients found that 7% met BDD criteria. Studies on BDD patients have illustrated that 23.2–26% have undergone one or more surgical interventions on their perceived defect. However, unlike most cosmetic surgeries which result in fairly high levels of satisfaction (78–90%), patients with BDD report dissatisfaction with surgical inventions more often than not. In fact, a survey of 178 cosmetic surgeons who had operated on patients with BDD found that in 43% of cases the patient was more preoccupied with the perceived defect after the surgery than before it. Furthermore, despite the high number of surgeries performed, only 1% reported satisfaction and free of BDD symptoms following surgery.

Pharmacotherapy

Case series and open-label studies suggest that selective serotonin reuptake inhibitors (SSRIs), such as citalopram, escitalopram, and fluvoxamine have shown benefit in treating BDD. In addition, the antiepileptic medication levetiracetam has recently demonstrated promise in reducing BDD symptoms in an open-label study of 17 subjects treated for 12 weeks (mean dose of 2044.1 ± 1065.2 mg day⁻¹).

Two placebo-controlled trials of serotonergic medications have been conducted. In the first, 29 subjects with BDD were

randomized to a 16-week cross-over study of clomipramine (mean dose of 138 mg day⁻¹) and desipramine (mean dose 147 mg day⁻¹). Clomipramine was superior to desipramine in the acute treatment of BDD symptoms.

In the second placebo-controlled study, 67 subjects with BDD were randomized to either 12 weeks of fluoxetine (mean dose of 78 mg day⁻¹) or placebo. Fluoxetine was significantly more effective than placebo for BDD beginning at week 8. Eighteen (53%) of 34 assigned to fluoxetine and 6 (18%) of 33 assigned to placebo were responders.

Although some treatments, including serotonergic medications such as fluoxetine and clomipramine, are encouraging treatments for BDD, there is insufficient evidence at this time to definitively recommend these as first-line treatments. Consequently, larger controlled studies are necessary to properly identify efficacious treatments (Table 1).

Psychotherapy

CBT is another promising approach for BDD. Studies have found that BDD often significantly improves when the following approaches are used: cognitive restructuring (e.g., developing more accurate and helpful beliefs about appearance), exposure (e.g., exposing the perceived defect in social situations and preventing avoidance behaviors), response prevention (stopping compulsive behaviors, such as mirror checking), and behavioral experiments (empirically testing hypotheses – i.e., dysfunctional thoughts and beliefs). Additional components, such as mirror retraining and mindfulness, may also be used. CBT has demonstrated effectiveness in treating BDD in both individual and group formats.

There have been three controlled psychotherapy studies in BDD. In the first two, 12 weeks of CBT was compared to wait list. In one study, 22 of 27 subjects with BDD no longer met diagnostic criteria for BDD after treatment with eight 2-h sessions of CBT. In the second study, those subjects receiving CBT reported significant changes on specific measures of BDD and depressed mood compared to those assigned to wait list.

In the only other controlled study, ten subjects with BDD participated in a 6-week course of behavioral therapy followed by 6 months of maintenance treatment. Subjects received a standard behavior therapy protocol which consisted of exposure in vivo and in imagery, with response prevention. Following treatment, a 6-month maintenance program was instituted for five subjects, with the other five serving as controls. Subjects improved when using exposure with response prevention. Although all subjects remained symptom free at follow-up, those in the maintenance program continued to improve. Longer follow-up demonstrated that at 12-, 18-, and 24-month follow-up assessments, subjects participating in the maintenance program were more efficient in managing limited symptom return and had significantly lower anxiety and depression. It is unclear, however, whether participants in the maintenance program were more efficient in managing limited symptom return etc., relative to their pretreatment assessment or relative to the control group.

Similar to conclusions reached for pharmacotherapeutic interventions for BDD, a dearth of information currently exists on psychotherapeutic treatment efficacy. CBT appears very promising, however, larger studies are needed to decipher

Table 1 Medication trials in body dysmorphic disorder

Medication	Mean dose (mg day ⁻¹)	Study design	Subjects	Duration	Results ^a
Clomipramine; Desipramine	138.0 ± 87.0	Double-blind cross-over design	29 randomized; 18 completed	16 weeks	Clomipramine significantly more effective than desipramine; 65% of clomipramine and 35% of desipramine subjects were responders
Fluoxetine	77.7 ± 8.0	Double-blind	67 randomized (fluoxetine = 34; placebo = 33); 59 completed (fluoxetine = 31; placebo = 28)	1 week placebo lead-in; 12 weeks of treatment	Fluoxetine significantly more effective at weeks 8–12; 53% of active and 18% of placebo group were responders
Pimozide augmentation of fluoxetine	1.7 ± 1.0	Double-blind	28 randomized (pimozide = 11; placebo = 17); 19 completed (pimozide = 6; placebo = 13)	8 weeks	Pimozide augmentation of fluoxetine was not more effective than placebo; 18.2% of active and 17.6% of placebo group were responders
Fluvoxamine	238.3 ± 85.8	Open-label	30 enrolled; 18 completed	16 weeks	63.3% responders
Fluvoxamine	208.3 ± 63.4	Open-label	15 enrolled; 12 completed	10 weeks	66.6% responders
Citalopram	51.3 ± 16.9	Open-label	15 enrolled; 11 completed	12 weeks	73.3% responders
Levetiracetam	2044.1 ± 1065.2	Open-label	17 enrolled; 11 completed	12 weeks	60% responders

^aResults are presented for intent-to-treat analyses, except for the clomipramine study, which used a minimum treatment analysis.

whether CBT or another form of therapeutic intervention should be utilized for BDD.

Conclusion

BDD causes significant distress and impairment in functioning, and it is associated with an unusually poor quality of life. Because this disorder appears relatively common, it is important to screen for BDD in clinical settings. Research on the treatment of BDD is in an early stage, so our understanding of the most effective treatments is still incomplete. SRIs, however, appear efficacious, particularly when used at relatively high doses. In addition, CBT, using a combination of cognitive and behavioral techniques, may also be beneficial.

Future research needs to address clinical strategies to minimize the underrecognition of BDD and to improve proper treatment. Because of the high rates of comorbidity in patients with BDD, treatment studies need to include subjects with co-occurring disorders and thereby attempt to understand how these other disorders affect treatment response. Finally, more research is needed to address the pathophysiology of BDD (e.g., by incorporating imaging and genetics). As with any disorder, understanding etiology should allow for more effective treatments.

Glossary

Body image A generic term used to describe a variety of specific phenomena that relate to an individual's perception of his or her body.

Body image disturbance Any form of affective, cognitive, behavioral, or perceptual disturbance that is directly concerned with an aspect of physical appearance.

Body mass index (BMI) This is the most widely used index of weight status. It is a ratio of weight (kg) per height

squared (m). Cutoffs for weight status in adults are: underweight (19.99 or less), average weight (20–24.99), overweight (25–29.99), obese (30 and above).

Incidence The number of new cases of a disease or disorder in a defined population during a specific period of time.

Meta-analysis A method of combining effect sizes across studies with similar independent variables and outcomes.

Prevalence The number of cases of a disease or disorder that exists in a defined population at a specified time.

Introduction

Body image is a subjective, self-evaluation of appearance. It can have a profound effect on how one perceives his or her world and, among other things, can affect an individual's self-esteem, mood, eating behaviors, and social interactions. Negative body image is often described as body image dissatisfaction or body image disturbance. The two terms are often used interchangeably; however, some experts highlight a very important distinction. Body image dissatisfaction is just one component of body image disturbance. The latter is a combination of body-related dissatisfaction, significant emotional distress as a result of the dissatisfaction, and impairment in psychosocial functioning. An extreme form of body image disturbance is body dysmorphic disorder.

Body image disturbance used to be considered a phenomenon that occurred in primarily Western societies, but this trend has shifted in recent decades with the export of Westernized culture and fashion trends via television, magazines, and the Internet. Unfortunately, this has likely contributed to the increased prevalence of body image dissatisfaction and body image disturbance throughout the world. A recent global study reconfirmed these results. The study consisted of females aged 15–64 from 10 countries: Brazil, Canada, China, Germany, Italy, Japan, Mexico, Saudi Arabia, the United Kingdom, and the United States. This investigation found that appearance-related body image disturbance is indeed a global phenomenon: 67% of females avoid doing basic activities (e.g., going to work/school, voicing their opinion, engaging in physical activity, etc.) because they feel badly about the way they look and 90% of females want to change the way they look with the greatest dissatisfaction stemming from body weight and shape followed by height.

Weight, shape, and height are the primary areas of body image dissatisfaction for females worldwide, but there is variation among what aspects of appearance they most want to change after that. The variation is partially dependent on traditional, culturally accepted ideals of beauty and partially dependent on more contemporary, cross-cultural comparisons of beauty. Depending on country, females have varying levels of desire to change their hair, skin complexion, eye shape, eye color, and the overall appearance of their face.

Although much of the research in this area has focused on adult women, recent investigations of younger women, boys, and men indicate that there is also a high level of disturbance in these groups. For men and boys, the particular dimension of dissatisfaction appears to primarily focus on muscularity concerns, rather than level of body fat or overall size. In particular, over the past 10 years, a relatively new subtype of body dysmorphic disorder, muscle dysmorphia, has been described in males who have extreme concerns regarding their level of muscularity.

History

Body image has a rich history in the fields of philosophy, medicine, and psychology. The term body image originated during the late 1800s. Neurologists, with the help of Gestalt psychologists, were trying to understand phenomena that alter body perception as a result of traumatic brain insult or injury. They concluded that there may be an internal mental representation of body information, which they called body image. The concept of body schema is credited to Head, one of the foremost researchers at that time. The concept arose from the discovery that sensory changes accompanied brain lesions.

Although Gestalt psychologists were part of the early discoveries in body image, neuropathology dominated the investigation of body experience. Psychology and psychological variables were rarely considered until Schilder, a neurologist, reconceptualized body image as a multidisciplinary field of study. Schilder argued that body image should be studied from neurological, sociocultural, and psychological viewpoints. Since that time, psychology has embraced the study of body image, and it has been studied from the social, developmental, and clinical perspectives.

Within clinical psychology, body image has been studied from several schools of thought. For decades, psychodynamic theory was the predominant lens through which body image was conceptualized and researched. One of the leading psychodynamic researchers, Fisher, pioneered the theory of body image boundaries. According to the theory, the body is a boundary between the self and the external world. Projective

techniques were used to test the concepts of barriers and penetration, which were considered measures of the strength and permeability of the body image boundary. Shontz was a key figure in shifting the focus of body image from a psychodynamic viewpoint to one that focused more on the physical aspects of the body. He suggested body image be studied from the viewpoints of cognitive theory, field theory, and Gestalt psychology. Since Shontz's time, the study of body image has almost exclusively remained in the realm of physical aspects of the body. The majority of current research focuses on physical appearance, body weight, and body shape concerns. There are several theories that seek to explain body image and body image disturbance within these contexts. The following section offers a brief review of contemporary theories of body image disturbance, as well as emerging evidence in support of each theory.

Theories of Body Image Disturbance

Sociocultural Approach

The sociocultural perspective is an approach to understanding human behavior that focuses on how the values of society affect the values and behaviors of individuals. A sociocultural theoretical model of body image and body image disturbance posits that current societal standards of beauty emphasize the importance of thinness for women and muscularity for men. While this ideal is omnipresent and regularly reinforced through media, parents, and peers, it is often very difficult to achieve, if not completely unattainable.

Social comparison theory is a subcomponent of a sociocultural approach that proposes that humans engage in continuous comparisons of themselves with others in their social environment as a process of collecting information about one's standing on some dimension. Within the context of body image, comparison of one's weight, shape, and overall appearance to that of others provides information about that individual's relative appearance. Research has shown that while women frequently make body-focused comparisons, individuals vary in the degree to which they engage in social comparisons of appearance and in their tendency toward upward or downward comparisons. As would be anticipated, research has suggested that individuals with greater body dissatisfaction tend to engage in more appearance-focused comparisons. When upward comparisons are made, they are associated with an increase in negative affect, body dissatisfaction, and thoughts of exercise, especially among women who report high preexisting levels of body dissatisfaction. A recent meta-analysis of 170 studies revealed a significant relationship between social comparisons and increased body dissatisfaction ($d = 0.77$), which was strongest among young women, compared to men and older women. This indicates a strong and reliable link between appearance-based comparisons and feelings of dissatisfaction with one's body.

Media exposure studies, in which participants view depictions of the thin or muscular ideal, have also provided support to the sociocultural perspective of body dissatisfaction. A meta-analysis on the role of media in body image concerns among women brought together the findings of experimental and correlational research to examine the effect of media exposure on internalization of the thin ideal and body dissatisfaction.

Figure 1 Tripartite influence model of body dissatisfaction. Reproduced from Thompson JK, Heinberg LJ, Altabe M, and Tantleff-Dunn S (1999) *Exacting Beauty*. Washington, DC: American Psychological Association, with permission from American Psychological Association.

Using a sample of 77 studies (141 effect sizes), the authors found strong support for the negative impact of exposure to media depictions of the thin ideal on each of these domains.

The tripartite model of body image is one well-supported socioculturally based approach for understanding how particular formative influences operate to produce body image problems. In this model, three primary influences (peers, parents, and media) are thought to directly and indirectly contribute to body image problems (see [Figure 1](#)). The indirect, or mediated pathways, include an influence through appearance comparison and internalization of societal values regarding appearance norms.

Interpersonal Approach

An interpersonal approach to understanding body image disturbance focuses on the influence of relationships and person-to-person interactions on the development of body dissatisfaction. While sociocultural theory tends to look at macro-level influences (e.g., society, the media), an interpersonal perspective takes a more micro-level approach to examine more proximal subcultural influences on body dissatisfaction. Research has investigated the impact of numerous sources of interpersonal influence, including parents, peers, romantic partners, and personal acquaintances or strangers.

A wealth of research has focused on the influence of appearance-related commentary and has consistently demonstrated the detrimental effect of receiving negative comments about one's appearance. Moreover, actual verbalization of the negative appearance evaluation is not necessary to produce a negative impact. Research has demonstrated that subtle gestures or negative looks (i.e., nonverbal communication) can convey this negative appearance evaluation as well and may have a negative effect on the recipient of the evaluation.

Finally, strong evidence is mounting in support of the role of appearance and weight-related teasing during childhood and adolescence in the development of body dissatisfaction. Numerous studies have investigated both the frequency and effect of such teasing, as well as the differential impact of various sources of teasing (e.g., family, peers). A new meta-analysis compiled the findings of 58 studies, revealing a reliable moderate association between weight-based teasing

($d = 0.39$) or appearance-based teasing ($d = 0.32$) and current levels of body dissatisfaction.

Cognitive–Behavioral Approach

As the name implies, the cognitive–behavioral perspective on body image draws from both cognitive and behavioral paradigms to create a more integrated and comprehensive understanding of body image and its related processes. The cognitive–behavioral model first distinguishes between historical or developmental influences on body image and more proximal events and process. Historical influences refer to personal attributes or past experiences that lay the foundation for the way a person thinks, feels, or acts in relation to his or her body. These historical influences include cultural socialization, interpersonal experiences (e.g., being teased about weight), physical characteristics, and personality attributes (e.g., perfectionism). Each of these factors contributes to one's body image schema (i.e., the cognitive organization of the information about one's physical self), which includes both body image investment (the perceived importance of the physical self to overall self-evaluations) and body image evaluations (satisfaction or dissatisfaction with one's body). Proximal events and process refer to current life events and cognitive processes that activate or maintain appearance schemas. This may include precipitating events such as standing in front of a mirror, receiving an appearance-related comment, or feeling that one's body is being exposed or evaluated. Such events then activate internal dialogues regarding one's appearance, which may include emotion-laden thoughts, inferences, or interpretations about one's appearance. Regarding individuals with body image disturbance, these dialogues are often automatic, inaccurate, and upsetting. Notably, the cognitive–behavioral perspective is the most widely accepted explanation for the formation of individuals' body image. Moreover, there is strong empirical support for the efficacy of cognitive–behavioral therapy (CBT) in the treatment of body image disturbance among community and clinical samples.

Feminist Approach

The feminist perspective of body image disturbance has, in part, grown out of the historical gender disparities in the rates of body dissatisfaction and eating disorders. Feminist theory notes that body image disturbance is significantly more prevalent among women than among men and suggests that these differential rates are born out of differences in the way that society views women and their bodies. While significant diversity in feminist approaches to understanding body image disturbances exists, at its core feminist theory contends that Western culture places an inordinate amount of value and emphasis on women's bodies and their appearance. Moreover, this culture teaches women to equate physical attractiveness with self-worth. Within this appearance-focused environment, women over-identify with their bodies, and their self-esteem becomes contingent upon conforming to the prevailing standards for thinness and attractiveness.

One notable and increasingly studied contribution to the understanding of the etiology of body dissatisfaction is objectification theory. This theory asserts that women are

consistently sexually objectified through multiple modalities including sexual harassment, leering glances, and exposure to both insidious and explicit sexualized media portrayals of women. As a result of this constant sexual objectification from the social environment, girls learn to view themselves from a third-person perspective and subsequently internalize that outsider's perspective as their own primary view of themselves (self-objectification). This leads to habitual body monitoring, which in turn, leads to increased body shame, body anxiety, lowered bodily awareness, and finally, to body dissatisfaction. Indeed, the role of self-objectification in body image disturbance and women's disordered eating has recently received empirical support, although further research in this area is warranted.

Risk Factors for Negative Body Image

There are several risk factors that influence the development of body image dissatisfaction and body image disturbance. This section will focus on four of those factors: biology, family, peers, and media.

Biology

Biological factors may affect body image dissatisfaction in three general ways. First, certain neurological disorders can lead to misperceptions of body image. One of the most intriguing examples of this is the phantom limb phenomenon. With phantom limb phenomenon, a person who has lost a body part (e.g., by way of accident or surgical removal) still feels – mentally and physically – that the body part is still there. Second, certain naturally occurring body parts or features may contribute to disturbances with body image. Examples of this are disproportionately large breasts, a pregnant body, or certain physical disabilities. Third, biological characteristics that are outside of social norms may affect body image, for example, physical deformity.

Family

In general, parents are thought to influence their child's body image in two ways. The first way is that parents' dissatisfaction with their own bodies may indirectly affect the child. For instance, parents model certain weight and body behaviors (e.g., negative comments on their own appearance, dieting behaviors) that the child then internalizes. The second way that parents may influence their child's behavior is by making direct comments to the child about his or her weight or appearance. When parents make critical or derogatory comments about the child's body or encourage the child to lose weight, he or she is more likely to have a poorer body image.

Most of the work regarding family and body image has focused on the parent–child relationship. Far less research has been conducted on sibling relationships. This is unfortunate as it stands to reason that siblings would play an important role in the development of body image in similar ways as parents, that is, indirectly by modeling or directly by targeted critical (or positive) comments. The few studies that include

siblings focus on the frequency and effect of weight- and appearance-based teasing by family members. (The majority of those studies include only female participants.) Researchers have found that the greatest amount of teasing within families is perpetrated by siblings. Approximately 20–30% of siblings engage in weight- or appearance-based teasing.

Peers

Peers can play a significant role in body image development and maintenance. Childhood and adolescence are particularly vulnerable times for influence by peer groups. One of the reasons is the amount of peer-related teasing. Estimates of weight- and appearance-based teasing by peers are as high as 60%. This is problematic as some researchers have established a causal link between weight and shape-related teasing and body image dissatisfaction.

Although it is not clear if people seek groups with similar views on body image or converge on similar body image views over time, it is known that peer groups tend to share ideas on body image and similar levels of body dissatisfaction. In addition, peers are frequently the targets of body comparison. Individuals often compare themselves to the weights and shapes of their peers and use these comparisons to rate their place in the subjective appearance hierarchy.

Media

Media plays a significant role in the development of body image disturbance for certain individuals. In advertisements and fashion magazines, women are extremely thin and tall; men are increasingly overly muscular. The images of both are often further enhanced by graphic alteration of images (i.e., digitally enhanced or reshaped). Even young children are exposed to images of exaggerated, unobtainable body shapes from some of their toys, dolls, and action figures. These idealized images are portrayed as beautiful and successful, but the actual body shapes and sizes are not attainable for the majority of individuals. Studies show that women exposed to thin media images report significantly more negative body image compared to women not exposed to these images in a laboratory setting. The duration of the effect is not known, but some theorize a dose-response effect; more prolonged exposure may result in greater body image disturbance. While some have found support for this, others have found it only holds true with certain types of media. Still other researchers propose that the association between the media and body image is complex and may be moderated by several variables including age, engagement in social comparison, and initial body image dissatisfaction. Specifically, effects of the media are higher for those who are younger, tend to engage in social comparisons, and have higher levels of initial body image dissatisfaction.

Gender Differences

Both males and females become aware of body image at a very young age, typically between the ages of 4 and 6. During this time, there do not appear to be any gender differences in

appraisals of body image. Differences emerge in preadolescence with a larger percentage of girls reporting body image dissatisfaction than boys. Notably, recent studies have concluded that this differential may be changing on at least one aspect of appearance – the desire for thinness. There are now similar proportions of preadolescent boys and girls desiring to be thinner, which may be an artifact of the growing problem of childhood overweight and obesity.

Puberty is considered a pivotal time period for the development of body image disturbance. During this time, females have marked body changes like weight gain and widening hips. These changes are in contrast to societal pressures to obtain the thin ideal and result in a discrepancy between real and ideal images of self. This discrepancy is considered to be one of the greatest precursors to body image disturbance in females. For both sexes, being overweight or obese is associated with higher body dissatisfaction, but as adolescent males reach puberty, being underweight and lacking muscularity are often catalysts for body image dissatisfaction. In this way, in contrast to females, weight gain in adolescent males is not necessarily as taboo. Males are as equally likely to want to be thinner as they are to be larger and more muscular. Overall, body image dissatisfaction is significantly greater in females than males during this time.

In adulthood, body image dissatisfaction and body image disturbance remain considerably higher for females compared to males. Of note, however, the prevalence of negative body image has increased for both genders over the past few decades. Nevertheless, perhaps one of the single greatest differences between the genders in the field lies within research methodology. The overwhelming amount of research in the field of body image has been conducted with females. The amount of research conducted with males is increasing, but is still regrettably far behind that of their female counterparts.

A relatively new area of research on gender differences is on body image and sexual orientation. According to the earliest research in the area, there seems to be an interaction between gender and sexual orientation. As a group, lesbians are less dissatisfied with their bodies than heterosexual females. Conversely, gay males are more dissatisfied with their bodies than heterosexual males. More recent research in the area supports the difference between gay males and heterosexual males, but has not supported a difference in body image dissatisfaction between lesbians and heterosexual females. Clearly, more research is needed to clarify the relationships between sexual orientation, gender, and body image dissatisfaction.

Assessment of Body Image and Body Image Disturbance

In recent years, the field of body image has undergone remarkable growth, which has been partially manifested in the expansion of assessment techniques and measures aimed at evaluating various dimensions of body image. While perceptual measures of body image were once widely used, there is currently considerable debate regarding whether these measures represent a distinct aspect of body image and, over time, newer techniques have largely eclipsed the use of perceptual measures. Current measures generally focus on the

attitudinal component of body image (as opposed to the perceptual component) and can be classified into three dimensions: subjective and affective, cognitive, and behavioral. While it is impossible to cover the full breadth of available measures of body image, the following offers a description of each of these categories as well as a brief review of relevant measures.

Subjective and Affective Measures

Subjective and affective measures essentially assess satisfaction with one's body. Such measures may range from a global rating of overall body satisfaction, to slightly more specific assessment of weight or shape satisfaction, and on to measures of very site-specific satisfaction (e.g., satisfaction with one's thighs, hips, chest). Subjective and affective measures can be further subdivided into figural rating methods and questionnaire measures. The former involves presenting an individual with line drawings of human silhouettes ranging in size and shape (e.g., very thin to very overweight). The individual is instructed to indicate the figure that represents their ideal body as well as the figure that represents their current size. Discrepancy scores (i.e., the difference between these two figures) provide an index of body dissatisfaction. The Contour Drawing Rating Scale is a commonly used figural rating scale with both male and female figures that range from underweight to overweight. The somatomorphic matrix is a computerized measure that presents a more lifelike two-dimensional figure and allows for assessment of dissatisfaction regarding overall body fat and muscularity for both men and women.

Questionnaire measures vary widely in their level of specificity regarding body image concerns. Some provide an estimate of global body dissatisfaction, while others measure satisfaction with specific areas of the body. The Appearance Subscale of the Multidimensional Body Self-Relations Questionnaire is a widely used 7-item measure of overall body dissatisfaction that has been used with both men and women of various ethnicities. An example statement from this scale is 'I like my looks just the way they are.' The Body Shape Questionnaire is a 34-item global assessment measure, which taps overall concerns with one's shape and weight. Finally, the Body Esteem Scale for Adolescents and Adults and the Body Image subscale of the Self-Image Questionnaire for Young Adolescents offer a global measure of body satisfaction for adolescents.

As discussed, other measures provide a more site-specific assessment of body dissatisfaction. The Body Areas Satisfaction Scale (BASS), a subscale of the Multidimensional Body Self-Relations Questionnaire, asks individuals to rate their degree of satisfaction with their overall appearance and with eight specific areas/attributes (e.g., face, hair, lower torso, mid-torso, upper torso, muscle tone, height, and weight). Additionally, the Body Uneasiness Scale, which has been used for adolescent and adult men and women, contains 34 items that assess overall body dissatisfaction, as well as 37 items that assess more specific concerns about individual body parts. Finally, the Physical Appearance State and Trait Anxiety Scale addresses the affective component of body image and assesses both trait and state anxiety regarding 16 body sites. A sample item from the state version of this scale is 'Right now I feel anxious, tense, or nervous about my thighs.'

Cognitive Measures

Cognitive measures of body image attempt to address the thoughts, beliefs, attributions, and attitudes related to an individual's appearance. For example, the Appearance Schemas Inventory-Revised is a 20-item scale that assesses beliefs and assumptions about both the importance (Self-Evaluative subscale) and influence (Motivational Salience subscale) of appearance in one's life. The Beliefs About Appearance Scale (BAAS) contains 20-items that assess an individual's beliefs regarding consequences of their appearance on relationships, achievement, self-perception, and emotions. Sample items from the BAAS include: 'How I feel about myself is largely based on my appearance,' 'My relationships would improve if I looked the way I wished,' and 'The opportunities that are available to me depend upon how I look.' The Drive for Muscularity Scale measures men's desire for a muscular appearance and strategies to obtain this physique. Finally, the Internalization subscale of the Sociocultural Attitudes Toward Appearance Scale-3 assesses the degree to which an individual has internalized or accepted the thin ideal. A sample item from this subscale of the SATAQ-3 is 'I would like my body to look like the models who appear in magazines.'

Behavioral Measures

Behavioral measures of body image have received less attention than subjective, affective, and cognitive measures primarily because of the largely intrapsychic nature of the disturbance. In other words, while body image disturbance can lead to behaviors aimed at avoiding, changing, or constantly monitoring one's appearance, aspects of the disturbance are more readily tapped using self-report assessments of the individual's attitudes and experiences. True objective behavioral measures would ideally require an outside observer to rate the person's body image-related behaviors such as avoidance of mirrors or body-monitoring behaviors. Given the often difficult and time-intensive nature of such assessments, current behavioral assessments of body image rely almost exclusively on subjective self-reports from individuals regarding their frequency of various behavioral manifestations of body disturbance. For example, the Body Image Avoidance Questionnaire assesses the frequency of body image avoidance behaviors including avoiding being weighed or wearing very loose-fitting clothing to avoid body exposure. Example items include: "I don't wear 'revealing' clothes (e.g., bathing suits, tank tops, or shorts)," "I do not go out socially if it involves eating" and "I avoid physical intimacy." The Body Checking Questionnaire is a more recent 23-item measure that assesses frequency of body-checking behaviors related to overall appearance and specific body parts in adult women, while the newly developed Male Body Checking Questionnaire (MBCQ) assesses these behaviors in men. An example item from the MBCQ asks the individual to rate how often he 'checks muscles in most reflective surfaces.'

Recent Advances in Assessment

Assessment measures have received wide utilization in a variety of contexts, including basic and applied research in the field of

eating disorders and body image disturbance. More recently, there has been an application to relatively new topics, such as the inclusion of body image assessment in the evaluation of the effectiveness of pharmacological agents as a treatment for eating disorders and body image problems. Additionally, there has been a tremendous increase in the last decade in the use of cosmetic and plastic surgery options for the modification of the body, and researchers have begun to use selected measures of body image to evaluate the role of these approaches as strategies to modify body satisfaction.

Treatment and Prevention

Body image disturbance has often been treated using CBT. CBT has been found to be effective in improving perceptual distortions, body image evaluations, and body image dysphoria. It improves other areas of psychosocial functioning such as self-esteem, social anxiety, depression, and eating behaviors. An empirically validated, manualized CBT treatment for body image was developed by Cash and colleagues. The treatment adheres to the general tenets of CBT, but is specifically tailored to the challenges of those with body image disturbance.

Research on body image interventions with obese populations is relatively recent but extremely relevant given both the scope of the obesity problem and the research that indicates obese people report higher body image dissatisfaction and distress than those of average weight. Treatment for body image within obese populations occurs mostly within weight loss interventions. Improvements in body image occur for many, but not all, who lose weight. Weight loss is often not sustained, however, and improvements in body image may be lost. However, there is some evidence that body image may be improved, even in the absence of weight loss. Some researchers propose adding a body image treatment post weight loss to aid in long-term weight maintenance. There is also growing empirical support for CBT in the treatment of body dysmorphic disorder. Evidence from randomized controlled trials reveals significant reductions in body dysmorphic disorder symptoms.

Although treatment of body image disturbance is important, prevention is the way to decrease overall prevalence by decreasing rates of incidence. Considering the early onset of body image disturbance, most prevention programs have been developed for and targeted to children and adolescents. As with treatment, outcomes on the prevention of body image disturbance are often part of larger studies on eating disorders. These prevention programs are universal, selective, or targeted. The goal of both universal and selective prevention programs is to reduce the incidence of the disorder. Selective prevention is aimed at asymptomatic, but at-risk individuals, whereas universal prevention programs are aimed at the population at large including those not considered at risk for the disorder. Targeted prevention programs are for subclinical populations that have been identified as high risk because of clear precursors or warning signs. Targeted programs are important for the reduction of symptoms, but do not reduce incidence.

Researchers have found that universal and selective programs show small, but significant effects in the reduction of body image dissatisfaction and internalization of the thin

beauty ideal, but targeted prevention programs are the most effective at reducing body image dissatisfaction and thin-ideal internalization. Targeted prevention programs for children younger than high school age have yet to be developed even though those are critical years in the development of body image disturbance.

Stice and colleagues developed a targeted prevention program for adolescent girls 14 years and older with elevated levels of body image dissatisfaction. The cognitive dissonance program consists of verbal, written, and behavioral activities where the thin ideal is critiqued and challenged. The program has been empirically validated and has been shown to reduce internalization of the thin ideal, body image dissatisfaction, negative affect, and psychosocial impairment. Comparative outcome studies and follow-up studies confirm the superiority of the cognitive dissonance program over other active treatments, active controls, and no-treatment controls. Stice and colleagues also developed another viable treatment alternative called the healthy weight program which focuses on making gradual and healthy diet, exercise, and lifestyle changes. The program leads to reductions in body image dissatisfaction and eating disorder symptomatology as well.

Conclusion

The field of body image has expanded greatly since its humble beginnings in neurology, but there is still much to learn. In the future, researchers should further investigate understudied populations including elderly persons, young children, and males. There should be a push not only to understand the intricacies of various risk factors of negative body image, but to understand protective factors and what leads to the development of a healthy body image across the life span. Researchers should also continue to explore the role of culture and country to appreciate the subtle or stark differences that will aid in prevention and treatment efforts.

Borderline Personality Disorder

J Paris, McGill University, Montreal, QC, Canada; Institute of Community and Family Psychiatry, Montreal, QC, Canada

© 2012 Elsevier Inc. All rights reserved.

Glossary

Affective instability (emotion dysregulation) A tendency for mood to change rapidly in relation to environmental cues.

Borderline personality disorder A disorder that affects mood, impulse control, and interpersonal relationships over many years.

Impulsivity A tendency to act on feelings rather than taking the time to consider them.

Personality disorder Maladaptive personality traits beginning early in life that have consistent and serious effects on long-term functioning.

Clinical Features and Diagnosis of Borderline Personality Disorder

Personality disorder (PD) describes one of the major forms of psychopathology. In the DSM-IV-TR system (American Psychiatric Association, 2000), one first makes an overall PD diagnosis, and then determines whether a patient can fit into any of the ten listed categories. PDs as a group are defined by maladaptive personality traits, beginning early in life, that have consistent and serious effects on long-term functioning. To make a diagnosis, one must establish that personality problems affecting cognition, mood, interpersonal functioning, and impulse control account for dysfunction.

Borderline PD (BPD) differs somewhat from other PDs in that it is associated with serious and distressing symptoms. And since BPD is frequently seen in practice and is problematic for management, it has been the subject of a very large body of research.

The use of the term 'borderline' has led to some confusion. It was originally based on a theory that psychopathology can lie on a border between psychosis and neurosis. While that idea is out of date, nobody has found a better label; so the term has been retained.

BPD is a complex syndrome with dysfunction in mood, impulse control, and interpersonal relationships. The common pattern for all BPD symptoms is *instability*. Mood is characterized by intense and painful affective states that shift rapidly – often within hours – leading to emotional turmoil and enraged outbursts, with a loss of control. These affective symptoms are associated with chronic suicidality, in which patients can think about killing themselves on a daily basis for years on end. BPD patients are also impulsive, and most make repetitive suicide attempts, primarily by overdose. About half of all patients seen in emergency rooms with repeat suicide attempts can be diagnosed with BPD. These incidents often follow disappointments in interpersonal relationships.

BPD patients can show a wide range of other impulsive behaviors, such as substance abuse, bulimia nervosa, sexual promiscuity, and shoplifting. One of the most common features is self-cutting – usually on the wrists or arms. But that is *not* suicidal behavior. BPD patients rarely slash deeply; rather, they cut themselves to relieve tension.

Interpersonal relations in BPD are typically stormy and unstable. These patients have trouble being alone, and all too quickly get involved with people, many of whom take advantage of their neediness. Intimate relations are marked by serious quarrels, as patients require constant reassurance that they will not be abandoned. It is, therefore, not surprising that many of their relationships end in sorrow.

One of the least understood aspects of BPD is that about half of patients show micropsychotic symptoms (transient hallucinations, paranoid trends, or depersonalization). That is the most 'borderline' aspect of the disorder. However, full-blown psychotic episodes are uncommon.

To make a formal diagnosis of BPD, DSM-IV-TR lists nine criteria but requires only five of them to be present. This 'polythetic' structure makes for a heterogeneous diagnostic group. Research definitions have been developed to narrow down the scope of BPD, requiring that patients score high in all pathological domains (affective instability (AI), impulsivity, cognitive symptoms, and interpersonal relationships). DSM-5, scheduled for 2013, will define BPD somewhat differently, based on a rating as to whether cases have prototypical symptoms, supplemented by a trait profile.

PD can, in general, be understood as pathological amplifications of normal personality trait dimensions. One of the most important traits underlying BPD is AI, also known as emotion dysregulation (ED). AI is a construct that describes ultra-rapid mood shifts, in which emotional states are highly responsive to changes in the interpersonal environment. These phenomena must be distinguished from bipolar disorder, in which mood changes remain stable for days at a time and are much less responsive to environmental triggers. When AI is monitored with standardized instruments, emotions are found to be intense, but reactive to circumstances, with more of a tendency to anger than to grandiosity.

AI is a basic aspect of BPD that appears early in development and which can still be found in patients who have recovered from all other symptoms of the disorder. It appears to have a heritable basis in temperament. However, the neurobiological nature of AI remains largely unknown. Understanding may benefit from the large body of recent research on the psychology of emotions, as well as from experience sampling methods that can measure emotional shifts in the course of daily life.

The second fundamental trait behind BPD is impulsivity. This personality dimension has also been the subject of a large body of research. The impulsivity seen in BPD has been sometimes been thought to be secondary to AI. However, patients who are only emotionally dysregulated (and have other mental disorders) do not necessarily overdose, cut, or feel chronically suicidal. Evidence from imaging and from neuropsychological methods suggests that impulsivity is associated with defective executive functioning (a failure of the prefrontal cortex to modulate input from the limbic system), while neurochemical studies have suggested that trait impulsivity is associated with dysfunction of the central serotonergic system.

What is most characteristic of BPD is the combination of AI with impulsivity. These trait dimensions account for most aspects of its clinical presentation, including suicidality and instability of interpersonal relations.

There is a very wide range of symptoms seen in BPD, many of which overlap other diagnoses (mood and anxiety disorders, substance abuse, and eating disorders). This has led to a tendency among clinicians to focus on 'comorbid' diagnoses, and to withhold a diagnosis of PD. However, there are important differences in how any of these symptoms develop when BPD is also present.

The most common comorbidity in BPD patients is with depression or dysthymia. However in BPD patients, depressive symptoms are not episodic but continuous, that is, not necessarily associated with extended and continuous periods of low mood. Unlike classical melancholia, emotions can shift rapidly with changes in environmental circumstances.

In the same way, mood swings in BPD differ greatly from those in bipolar disorder, since patients do not show continuously elevated mood (hypomania), but a pattern of rapid shifts in affect related to life events, with 'high' periods that last only for hours (rather than for days or weeks). Unfortunately, recent enthusiasm for extension of the bipolar diagnosis has led some clinicians to diagnose many BPD patients with mood swings as falling within a bipolar spectrum.

BPD need not be mistaken for schizophrenia. Instead of long-term psychotic symptoms, one sees 'micropsychotic' phenomena of short duration, in which patients hear voices or experience paranoid thoughts under stress, followed by long periods in which these symptoms completely disappear.

BPD is a diagnosis with important implications for clinical management. But it must be recognized that this construct, like almost all other mental disorders, depends entirely on observable signs and symptoms. Unlike general medicine, psychiatry lacks specific markers associated with specific genes, neurochemical changes, or brain imaging. It is possible that BPD is not a single disorder but reflects multiple endophenotypes leading to a common final pathway marked by a cluster of psychological symptoms.

Epidemiology and Cross-Cultural Prevalence

Systematic epidemiological studies of mental disorders have been carried out for several decades. However, data on the community prevalence of PDs has only emerged in the last 10 years.

Most of these community surveys indicate that the prevalence of BPD is close to 1%, a rate similar to that of

schizophrenia. While about 80% of patients receiving treatment are women, gender differences have not been found in most community samples. The explanation is that men with BPD are less likely to seek treatment. This supposition is supported by psychological autopsy studies that have found BPD to be common in young males who commit suicide; most of these patients were never seen in the mental health system. The other notable demographic is that, as is the case for PDs in general, BPD is more common in patients with a lower socioeconomic level and lower levels of education.

There have been no systematic studies of BPD across cultures. The disorder has been described by psychiatrists in large urban centers in countries such as India and China, but its community prevalence in these locations is not known. However, indirect evidence suggests that BPD is more common in modern societies undergoing rapid social change. There has been an increase over the last few decades in developed countries in many of its associated symptoms (youth suicide, self-harm, suicide attempts).

Even if the vulnerability to BPD is rooted in universal trait dimensions, prevalence could vary across cultures. The explanation is that mental disorders present different symptoms in different societies. Similar illness processes need not lead to identical clinical presentations, since specific pictures can be determined by mechanisms of social contagion. Many psychological problems express themselves as physical symptoms, and patients may not report abnormal mental states. Moreover, impulsive ('externalizing') symptoms are less common in traditional societies than are 'internalizing' symptoms. Thus, it is not really surprising that behaviors such as cutting and repetitive overdosing do not seem to have been common historically, but have become more frequent in modern urban societies.

Etiology: Biological, Psychological, and Social

We are only beginning to understand the causes of BPD. As is the case for most mental disorders, no single factor can explain its development. Instead, multiple risk factors (biological, psychological, and social), in interaction with each other, seem to play a role.

The biological vulnerability for PDs depends on temperamental (inborn and/or heritable) characteristics that can be assessed in adulthood as personality traits, that is, stable patterns of thought, affect, and behavior that characterize individuals, and that persist over time. Behavioral genetic research shows that nearly half the variability in personality traits can be accounted for by heritable influences.

Both AI and impulsivity have a similar genetic component. Moreover, most twin studies have found that BPD itself shows a level of heritable influence of about 50%. While it is unusual for BPD itself to be found in first-degree relatives of probands, genetic influences are confirmed by family history studies showing that impulsive disorders such as antisocial personality and substance abuse, as well as mood disorders such as depression, are common.

A heritable vulnerability to BPD would be expected, in principle, to be associated with biological markers. But neuroscience is at an early stage of development, and most

pathological behavioral patterns are not consistently associated with any measurable changes in brain function. No markers specific to the diagnosis of BPD as a whole have been identified. The most robust findings thus far have come from studies of central neurotransmitter activity, which have shown that impulsive traits in these patients tend to be associated with deficits in central serotonergic functioning. While some initial research on AI has been conducted, its biological correlates are largely unknown.

Age of onset can provide clues about the development of the disorder. BPD usually begins around puberty, but first presents clinically at a mean age of 18. (Most patients experience symptoms for a number of years without seeking help.) An adolescent onset suggests that biological changes during puberty (hormonal shifts and synaptic pruning) might convert a temperamental vulnerability into an overt disorder. But it might also suggest that when a diathesis exists, the developmental stressors associated with adolescence can lead to the emergence of overt psychopathology.

There has been a great deal of research on the psychological factors leading to BPD. The results have been striking but not really consistent. Many patients describe experiences reflecting family dysfunction and psychological trauma during childhood. However, other patients state that they felt normal before puberty.

Statistically, one finds a high frequency of reported traumatic events (sexual or physical abuse, parental neglect, family violence) during childhood in patients who develop BPD. There is also support for this relationship from prospective community studies that have examined the precursors of PD symptoms. Even so, one should not conclude that all patients with BPD have had a traumatic childhood, since many do not report such experiences.

Nor should one conclude that children who undergo trauma are necessarily at risk for BPD. Longitudinal studies of the outcome of adversities during childhood show that such early traumatic experiences are risk factors, but not predictable causes, of mental disorders. Moreover, community studies document extensive resilience following trauma, particularly following less severe adversities.

The relationship between childhood abuse and BPD has aroused great interest. However, the most careful studies show that only about a quarter of patients describe sexual abuse over time from a caretaker (community studies show this to be the most damaging type of trauma). In contrast, most incidents of sexual abuse reported by BPD patients have occurred on one occasion, and involve strangers, and about a third of patients do not report any abuse at all. The data on physical abuse are less consistent, although one prospective study of child abuse cases that ended up in court found BPD to be more likely as an outcome.

One crucial issue is that child abuse is a risk factor for mental disorder in general rather than being specific to BPD. But since trauma is a marker for a wide variety of other adversities, and is strongly associated with family dysfunction, the effects may be due more to overall upbringing than to specific events.

Another crucial point concerns interactions between genetic vulnerability and adverse life experiences. By and large, childhood trauma is most likely to produce pathological sequelae in those who are temperamentally vulnerable.

These gene–environment interactions are crucial, and support a stress–diathesis model of BPD.

Finally, social factors play a role in the development of BPD. It is possible that modern societies, which require young people to find their own social roles, may lower the threshold for a disorder in which mood becomes unstable, impulsive actions common, and identity uncertain. It is also possible that the propensity to BPD takes other forms in other societies, and that the specific picture seen in developed countries is a cultural product.

In summary, none of the risk factors for BPD are necessary conditions for the development of the disorder. The sufficient conditions require a combination of biological, psychological, and social vulnerability.

Course and Prognosis

Most patients with BPD improve with time. Follow-up studies show that by age 35–40, about 75% function at close to normal levels. By the age of 50, 90% have recovered from the disorder. Prospective studies have shown that many patients stop meeting diagnostic criteria after a few years, when they stop overdosing and cutting. Social functioning does not improve that rapidly, and full remission usually takes many years. Even so, the fact that most patients improve – and never commit suicide in spite of having threatened to end their lives on multiple occasions – suggests that BPD has a more positive prognosis than previously thought. It is not necessarily a lifelong illness, but most often a disorder of youth.

Nonetheless, about one out of ten BPD patients will eventually commit suicide. The problem is that this outcome is notoriously difficult to predict. But by and large, the patients who die by suicide are those who fail to recover. The peak for completion takes place after age 35, usually after a series of unsuccessful treatments. On the other hand, younger BPD patients are not at so high a risk, so that clinicians who feel alarmed by their dramatic suicidal threats and actions should feel reassured.

The mechanism of improvement in BPD over time is not fully understood. Impulsivity generally decreases with age in everyone. Moreover, many BPD patients learn over time how to avoid the situations that give them the most trouble (intense intimate relationships). Most eventually find stable social and occupational niches that provide them with the structure they need. Once they stop acting impulsively, they no longer meet diagnostic criteria. The minority of patients who fail to find stable employment may remain in the mental health system. Finally, even in those who function well, some traces of AI can be observed.

Nonetheless, earlier perceptions that BPD is an incurable condition have been disproven, and patients should be informed that they are likely to improve. They can also be told that treatment may make recovery proceed more rapidly.

Treatment

BPD is a therapeutic challenge. However, recent research has shown that treatment specifically designed for the disorder

can be successful. While this is a disorder that can remit with time, treatment effects that can be documented over shorter periods, and which are superior to control conditions, are likely to be truly therapeutic.

In modern psychiatry, most patients tend to be managed with drugs. However, no pharmacological agents specific for the symptoms of BPD have been developed. Thus, patients are generally prescribed agents that were originally developed for other purposes, such as antidepressants, mood stabilizers, and antipsychotics.

Quite a few randomized controlled trials of pharmacotherapy for BPD have been published. But this research suffers from a number of defects: small sample size, attrition, as well as durations too short to assess treatment of a chronic disorder. Thus most of these studies have been conducted on less than 20 subjects observed for only a few months. Finally, outcomes in these studies are generally based on self-report, and one cannot tell whether the clinical picture has shown full remission.

In general, clinical trials document only a mild degree of symptomatic improvement with drug therapy. There have not been enough studies to merit a meta-analysis, and neither the British National Institute of Clinical Excellence (NICE) guidelines nor the Cochrane report has found enough data to recommend any specific agent. However, while drugs are over-prescribed for BPD patients, they are sometimes useful to control symptoms. A number of agents, including low-dose atypical neuroleptics, specific serotonin reuptake inhibitors, and mood stabilizers, can reduce impulsive behaviors. However, antidepressants are much less effective for mood symptoms than in patients who have no PD. Again, pharmacological agents only 'take the edge off' symptoms, and do not produce remission of BPD.

The most evidence-based method of treatment for BPD is psychotherapy. However, ordinary methods (sometimes called 'treatment as usual') are unsuitable for these patients. In general, the best results are associated with treatments specifically designed for this group, rather than general methods that can be useful for other clients.

The evidence-based psychotherapies for BPD are highly structured and have specific elements designed to manage symptoms. 'Dialectical behavior therapy' (DBT) is a form of cognitive-behavioral therapy targeting AI and impulsivity, using group and individual sessions to teach patients how to regulate their emotions. In eight clinical trials comparing the method to various types of standard treatment, DBT was more effective in bringing suicidal behaviors under control within a year. However, it is not clear whether effects are entirely specific to the method, or whether they reflect the advantage of using a highly structured treatment. One study that compared DBT with a manualized form of psychiatric management found no difference in outcome.

While DBT has the most evidence supporting it, two clinical trials point to the efficacy of 'mentalization-based treatment' (MBT), a therapy that combines cognitive and psychoanalytic techniques. MBT, like DBT, teaches patients how to self-observe interpersonal situations so as to reduce levels of conflict. These studies showed an advantage for MBT over treatment as usual, both in a day hospital setting, and in an outpatient clinic.

While there have been a few successful trials of other psychotherapy methods for BPD, again suggesting that structured therapies work better than treatment as usual, the main contenders are DBT and MBT. Although there are insufficient data for meta-analysis, the evidence was sufficient for a recommendation for some form of cognitive therapy in both the NICE and Cochrane guidelines.

Unfortunately specialized forms of psychotherapy for BPD are expensive, since they require highly trained personnel and a dedicated team. In most settings, these specific therapies are not readily available.

Nonetheless, psychotherapists conducting a more general practice can learn from evidence-based approaches. It is not enough to sympathize with distress or 'put out fires' every time a crisis arises. It is also not helpful to focus too much on past events. BPD requires a practical and structured approach that teaches patients how to manage emotional dysregulation and impulsivity.

Chronic Suicidality in BPD

One of the main qualifications for therapists treating BPD patients is a thick skin. Chronic suicidality is a troubling problem. But many of the methods that have been used to handle suicidal threats and actions were developed for acute suicidality associated with episodes of depression. In BPD, these approaches are not effective, and they can even make matters worse.

Clinicians are sometimes advised to hospitalize patients who threaten to commit suicide. In BPD, this often leads to unproductive and regressive admissions. These patients need to learn life skills, which is not possible under a suicide watch in a hospital ward. There has been little research on the effectiveness of hospitalization, no evidence that admission prevents completion of suicide, and no evidence that it is an effective treatment modality that can change the course of the disorder.

Suicidity in BPD peaks when patients are in their early 20s. But as we have seen, completions are most common after age 30, in patients who fail to recover. Thus, impulsive overdoses, most often seen in younger patients, do not carry a high short-term risk. These behaviors need to be understood as communicating distress. Self-harming behaviors such as chronic cutting are not even truly 'suicidal.' Given that these behaviors are an attempt to regulate dysphoric emotional states, it is the task of therapists to teach patients better ways of doing so.

In summary, therapists should not be paralyzed by fear of chronic suicidality. Instead, they should respect the need that BPD patients have to contemplate an 'exit' when their life is going badly, and focus on modifying the emotions and behaviors that feed hopelessness.

Conclusions

We need more research to understand the causes and treatment of BPD. If we understood the etiology and pathogenesis of this disorder better, we would be in a position to develop

more evidence-based approaches to therapy. However, an important start has been made, and we can feel hopeful about most cases seen in practice. Management of these patients has improved much over the last few decades. While not all will recover completely, we can help most of them.

The Brain

R G Mair, University of New Hampshire, Durham, NH, USA

© 2012 Elsevier Inc. All rights reserved.

Glossary

Amygdala It is a complex of nuclei in anterior midline areas of the temporal lobe implicated in the perception and expression of emotions and in emotional memory.

Association cortex It includes areas that lack direct sensory or motor connections important for higher aspects of sensory perception, sensorimotor integration, and cognitive processes including language, memory, and executive functions.

Basal ganglia These are a group of nuclei at the base of the forebrain that are strongly connected to cerebral cortex. They play a critical role in selection and initiation of motor responses, procedural learning, and executive functions of prefrontal cortex.

Hypothalamus It consists of a number of nuclei located below thalamus and just in front of the midbrain that

regulate behavior state and functions related to homeostasis: feeding, drinking, thermoregulation, and reproduction.

Motor cortex This includes areas that play a critical role in voluntary control of movements, particularly involving the hands. These include primary motor cortex, which executes voluntary movements, and premotor and supplementary motor areas, which plan and program sequential movements.

Sensory cortex It includes areas of cortex that receive and process information from the senses. These include primary sensory areas that receive direct input from sensory nuclei in thalamus (or olfactory bulb for primary olfactory cortex) and sensory association areas that process sensory input into coherent sensory perceptions.

In many ways, the brain is the ultimate product of evolution. Vertebrate and invertebrate brains share many features that allow organisms to survive and reproduce in ever-changing and sometimes unpredictable environments. The human brain consists of 100–150 billion neurons, organized into systems that allow individuals to sense important information and to perceive the external world, to act adaptively, to maintain internal homeostasis, to think and plan, to learn and remember, and to communicate with other individuals. The human brain evolved from common ancestors and thus shares important cellular and molecular properties with simpler nervous systems found in invertebrate and vertebrate species. The anatomical organization of the human brain bears a striking resemblance to the anatomical organization of the brains of other vertebrates, particularly mammals.

Anatomical Organization of the Brain

Cells

The brain contains two main types of cells: *neurons*, electrically active cells that are specialized to process and transmit information, and *glial cells*, cells that serve a number of functions that support the activity of neurons. Neurons typically have four main divisions (**Figure 1**). *Dendrites* are appendages that serve as input zones, conducting electrical activity toward the cell body. Inputs to neurons are transmitted across *synapses* (points of contact with other neurons). Neurons often have multiple dendrites that tend to branch extensively in the area of the cell body allowing neurons to summate inputs from many other neurons. The *cell body* (or *soma*) contains the nucleus and can act as both an input zone and an integrative zone, summing inputs from multiple dendrites. *Axons* transmit activity away from the cell body, often in the form of brief electrical

impulses called action potentials. Neurons tend to have one axon that can extend up to a meter or more in the peripheral nervous system. Axons are of constant diameter throughout their length. Thicker axons conduct signals more rapidly but are more expensive to maintain metabolically. *Axon terminals* are the output zones. In most neurons, these contain synaptic vesicles that hold molecules of neurotransmitters that are released from specialized areas of presynaptic membranes in response to action potentials transmitted along the axon.

Neurons come in many sizes and shapes. The structure of a neuron can provide important clues about its function. Interneurons (or local circuit neurons) connect between afferent and efferent neurons in neural pathways and tend to be involved in local processing of information. Projection neurons have long axons that communicate between areas of the brain. The organization of dendrites determines what inputs drive a neuron and how they are integrated. Large neurons with thick axons tend to conduct high priority information rapidly (such as visual signals from rapidly moving objects or signals to fast acting muscles). The speed of axonal conduction is also increased by *myelin* sheaths. These are processes of glial cells (oligodendrocytes in the central nervous system, Schwann cells in the peripheral nervous system) that wrap around axons. Myelin increases the speed of conduction by increasing electrical resistance of axonal membranes and causing action potentials to jump between small gaps in the myelin (nodes of Ranvier).

Gross Anatomy

Nervous systems in simple invertebrates, like the sea anemone, consist of nets of interconnected neurons. More complex invertebrates like the fly have nervous systems that include peripheral masses of neurons (ganglia) that are connected to central

Figure 1 Typical organization of the neuron. Dendrites and cell bodies receive inputs from thousands of synapses with other neurons. Dendrites conduct electrical activity toward the cell body, while axons conduct activity away from cell bodies. Axon terminals transmit activity through synapses with postsynaptic neurons. In most mammalian neurons, this involves the release of neurotransmitter molecules that act on receptors on the postsynaptic membrane. This figure is reproduced from Breedlove SM, Watson NV, and Rosenzweig MR (2010) *Biological Psychology*. Sunderland, MA: Sinauer with permission from Sinauer Associates, Inc.

lobes that function as a primitive brain. Many invertebrates have populations of neurons that mediate basic drives, sleep and wakefulness, and species-specific reproductive behaviors. Invertebrates can also demonstrate simple forms of learning and memory. *Vertebrate brains* share the distinction between central and peripheral nervous systems and the evolutionary trend toward central control of peripheral ganglia. Vertebrates tend to have larger numbers of neurons, increased reliance on myelin as a means to speed neural conduction, and central nervous systems encased in a bony skull and spinal column. The vertebrate *peripheral nervous system* consists of *cranial nerves* (12 in humans) that connect directly to the brain, *spinal nerves* (31 in humans) that connect at segments of the spinal cord, and the *autonomic nervous system*, which regulates internal organs. Spinal nerves consist of a dorsal (toward the back) root that consists of sensory projections from the body and a ventral (toward the front) root that consists of motor projections to the muscles. The autonomic nervous system has two divisions (sympathetic and parasympathetic) that have opposite effects on the organs they innervate. The *sympathetic system* mobilizes the body's resources in response to stress, producing the 'flight or fight' response. The *parasympathetic system* promotes vegetative and restorative functions, producing the 'rest and digest' response.

The *vertebrate central nervous system* has four main divisions: spinal cord, hindbrain, midbrain, and forebrain (Figure 2). The *spinal cord* extends caudal (toward the tail) from the

medulla connecting the brain to segments of the body through paired spinal nerves. Spinal nerves provide sensory input to the brain from the body, innervate skeletal muscles to produce movement, and control visceral functions through the autonomic nervous system.

The *hindbrain* is immediately in front of the spinal cord and consists of the medulla, pons, and cerebellum. The *medulla* relays signals between the brain and the spinal cord and contains nuclei that control vital functions related to respiration, cardiac and vasomotor function, and reflex control of swallowing, vomiting, coughing, and sneezing. The *pons* (Latin for 'bridge') is the point at which many fiber tracks connecting the brain to the spinal cord cross (decussate) so that the right side of the brain controls the left side of the body and the left side of the brain the right side of the body. The ascending reticular formation runs through deep areas of the pons extending caudally into medulla and rostrally into the midbrain. This is a poorly differentiated area that plays an important role in arousal and the regulation of sleep-waking cycles. The medulla and pons contain nuclei of cranial nerves that mediate sensory input from the head, taste, auditory (hearing), and vestibular (body orientation) sensations, sensory input from and motor output to bodily organs, and control of chewing, facial expression, salivary and tear glands, and movements of the neck and tongue. The pons is also the point at which the cerebellum connects to the brain. The *cerebellum* is a specialized enlargement at the back of the brain that regulates movement. It receives input from sensory and association areas of cortex, peripheral proprioception (relative position of limbs and other body parts), and the vestibular system (bodily orientation and acceleration) and provides outputs to higher and lower motor control systems. Cerebellum does not directly activate movement, but plays a critical role in the planning and sensory guidance of movements. Ataxia (gross incoordination of muscle movements) is the cardinal sign of cerebellar damage.

The *midbrain* contains the tectum along its ceiling and tegmentum along its floor. The *tectum* consists of two paired structures: the inferior and superior colliculi. The superior colliculi receive input from visual and other sensory systems and play a critical role directing behavioral responses in ego-centric (body centered) space. The inferior colliculi are an important auditory center that receives inputs from brainstem auditory nuclei. The *tegmentum* contains the periaqueductal gray, a site of action of opiates that plays an important role regulating the response to pain. It is also the main source of dopamine in the brain (substantia nigra pars compacta, ventral tegmental area). Dopamine is a neurotransmitter that plays an important regulatory role in voluntary movement, motivation, reward, and executive functions of prefrontal cortex.

The *forebrain* has two main divisions: the diencephalon, which forms an inner segment attached to the midbrain, and the cerebral hemispheres, outer segments extending from the diencephalon. The diencephalon consists of two main areas: hypothalamus and thalamus. *Hypothalamus* is located below thalamus and just in front of the midbrain. It consists of a number of nuclei (clusters of neurons) that regulate behavior state and functions related to homeostasis: feeding, drinking, thermoregulation, and reproduction. The *pituitary* is attached to the base of hypothalamus by a thin stalk (the infundibulum). The pituitary acts as the master gland releasing hormones that

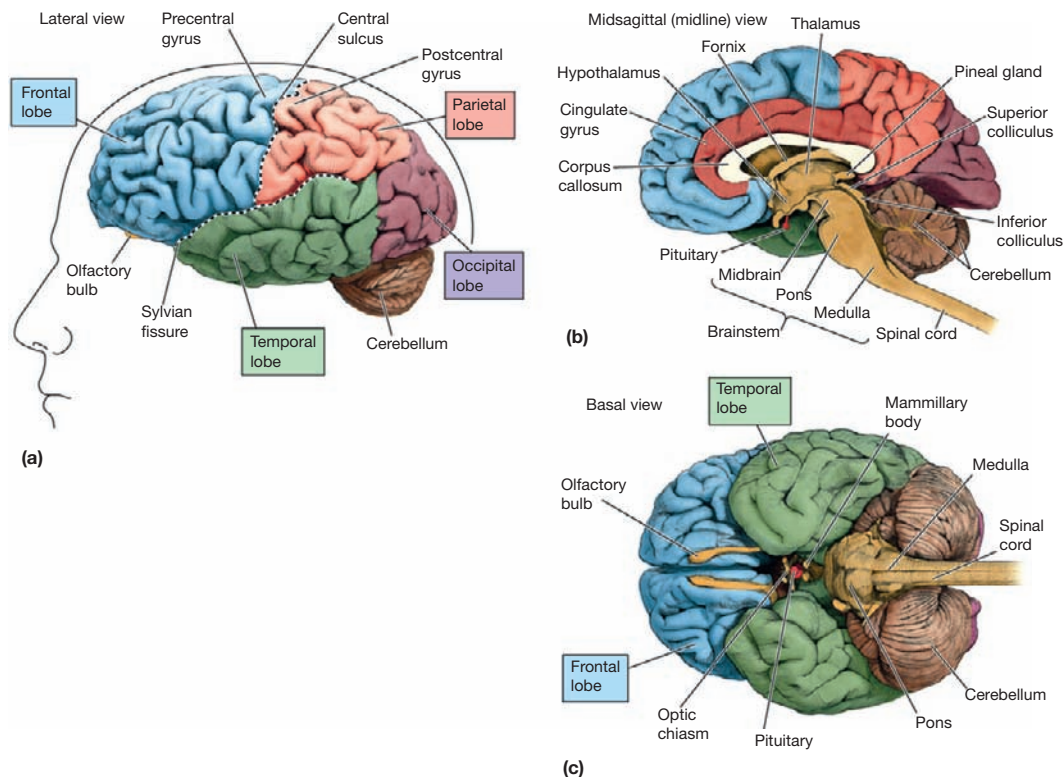

Figure 2 The organization of the human brain as viewed from (a) lateral, (b) midsagittal (midline), and (c) inferior (beneath) perspectives. The major lobes and important divisions are color coded and labeled. This figure is reproduced from Breedlove SM, Watson NV, and Rosenzweig MR (2010) *Biological Psychology*. Sunderland, MA: Sinauer with permission from Sinauer Associates, Inc.

regulate responses related to stress, metabolism, sexual differentiation, reproduction, growth, fluid balance, and blood pressure. The anterior lobe of the pituitary is under humoral control, secreting tropic hormones in response to releasing hormones that originate in hypothalamus and reach the pituitary gland through the portal vein. The posterior lobe is directly controlled by neurons with cell bodies in hypothalamus and axons terminating on secretory cells in the pituitary. The *thalamus* is the gateway to cerebral cortex. Thalamus provides the main source of sensory input to cortex leading to conscious perception of visual, auditory, somatosensory, and taste sensations as well as inputs from the basal ganglia and cerebellum that give rise to intentional responses. Thalamus is also a major target of descending projections from cortex that reciprocate thalamocortical projections and provide information to other areas of cortex. Beyond pathways carrying specific information to distinct areas of cortex, thalamus contains 'nonspecific' midline and intralaminar nuclei. These nuclei have common inputs from arousal- and visceral-related systems in the brainstem and influence the activity of extended neural networks that involve widespread areas of cerebral cortex, the basal ganglia, and the limbic system.

The *cerebral hemispheres* consist of an outer rind, cerebral cortex, and subcortical structures that include amygdala and the basal ganglia. Cerebral cortex includes olfactory cortex, hippocampus, and neocortex. The *amygdala* is a complex of nuclei in anterior midline areas of the temporal lobe that have been implicated in the formation of emotional memories and the perception and production of emotions, particularly fear.

Amygdala is a prominent component of the *limbic system*, a series of interconnected structures that also includes hippocampus and portions of neocortex that are important for learning, memory, and emotions. *Hippocampus* is a primitive cortical area located behind amygdala in medial temporal lobe. Hippocampus has been implicated with adjacent areas of entorhinal and perirhinal cortex as a site of pathology causing profound amnesia. The *basal ganglia* constitute a subcortical system intimately connected with frontal cortex that plays a critical role in cognitive and motor function. *Striatum*, the input side of the basal ganglia, is divided into two main areas in humans: caudate and putamen. The caudate receives input from prefrontal cortex and related cortical areas and is primarily concerned with cognitive functions. The putamen receives inputs from premotor and motor cortex and related cortical areas and is primarily concerned with the selection and initiation of motor responses. *Pallidum*, the output side of the basal ganglia consists of several interconnected structures: globus pallidus, substantia nigra pars reticulata, and the subthalamic nucleus. Globus pallidus and substantia nigra project through thalamus to prefrontal and premotor areas of cortex. The basal ganglia are organized in a series of parallel loop pathways that originate in cortex and project through discrete areas of striatum, pallidum, and then thalamus, that project back to the cortical area of their origin. Each of these parallel cortico-striato-pallido-thalamo-cortical pathways is thought to mediate a distinct aspect of cognitive or motor function. Diseases of the basal ganglia, such as Parkinson's disease and Huntington's chorea can affect the ability to select responses, inhibit

unwanted responses, initiate voluntary movements, cognitive aspects of motor function, executive functions mediated by prefrontal cortex, and the capacity for learning and memory, particularly the incremental acquisition of habits or stimulus-response associations.

Neocortex (or isocortex) consists of six distinct layers of neuropil that form the outer shell of cortex (Latin for 'bark') of the cerebral hemispheres. The expansion of cortex in humans caused cortex to fold into a series of sulci (fissures) and gyri (ridges). Human cortex is divided into four main lobes (**Figure 2**). *Frontal cortex* is in front of the central sulcus. *Parietal cortex* is located behind the central sulcus (in front of occipital and above temporal cortices). *Occipital cortex* is at the back of the brain behind the occipito-parietal sulcus. *Temporal cortex* is located below the Sylvian fissure (lateral sulcus or fissure), in front of the occipital lobe and below the parietal and frontal cortices. There are extensive connections between homologous areas of cortex in the right and left hemispheres that travel through two white matter tracts. The *corpus callosum* is the main source of interhemispheric cortical communication. The *anterior commissure* carries fibers connecting portions of temporal cortex. Although all areas of neocortex have a comparable six-layer organization, there are systematic differences across different areas of cortex in the extent to which the six layers of cortex are developed. In motor cortex, for instance, layer V (which contains large neurons projecting beyond local areas of cortex) is well developed. By contrast, layer IV (which receives specific inputs from thalamus) is well-developed primary sensory cortices. Classic neuroanatomists mapped these differences in detail long before neuropsychologists described the localization of function in cortex. The results were maps based purely on structural anatomical differences. One of the great discoveries of twentieth century neuroscience was the recognition that maps based on subtle anatomical differences correspond to the localization of function in cortex. The most widely used map was developed by the German anatomist Brodmann in 1909 and still serves as a standard system to refer to different areas of cerebral cortex.

How do human brains differ? Humans have unique cognitive capabilities that include the abilities to communicate with language and to use tools flexibly in complex ways. Neuroscientists have long been interested in understanding how the human brain evolved to give rise to these abilities. It seems unlikely that human cognitive function reflects a fundamental change in the organization of the brain. The human brain follows a general blueprint shared with brains of other vertebrate species. Behavioral neuroscience studies have revealed similar functions in homologous brain structures in humans and in other mammalian species. Humans have relatively large brains for their body mass compared to other species. The fossil record reveals evidence of a tremendous increase that nearly tripled the size of the human brain within the last 2 million years. This increase must have conferred substantial evolutionary advantages as it came with a steep metabolic cost – brain activity consumes about 20% of our calories. Careful analyses have revealed important changes in cerebral cortex that may account for our unique cognitive abilities. The human brain has relatively large amounts of neocortex and subcortical structures that communicate with neocortex, including the lateral cerebellar

hemispheres, basal ganglia, and thalamus. Human cortex has relatively large numbers of cells/ unit area of cortex, particularly within later developing, more superficial layers thought to play a critical role in processing information. Human cortex is more clearly differentiated with more distinct signs of structural specialization from area to area. Human cortex has relatively less area dedicated to primary motor and sensory function and thus more association cortex available for integrative functions.

Functional Organization of the Brain

Sensation and Perception

Sensory systems consist of peripheral receptor cells specialized to detect and encode sensory signals, pathways by which this information is processed and transmitted to primary sensory cortex, and sensory association cortices that further process this information to give rise to perception. There are many potential sensory signals in the environment. Organisms sample and process a small fraction of the available signals, focusing on sensory information that fits species-specific needs.

Vertebrate *vision* begins with photoreceptor cells in the *retina*, a thin band of tissue at the back of the eye. Photoreceptor cells contain photopigments that absorb visible wavelengths of light and release neurotransmitters that affect the activity of second order visual neurons (bipolar cells). These interact with interneurons within the retina (horizontal and amacrine cells) to control the activity of ganglion cells, the output neurons of the eye. The wavelengths of electromagnetic radiation detected by vertebrate photoreceptors are in a narrow range that is ideal for detecting the objects in the external world including color information useful for finding food and detecting predators. Shorter wavelengths (X-rays) can penetrate the surface of objects. Longer wavelengths (radio waves) are better suited for detecting large distant objects (like planets). The physiological properties of visual neurons are likewise specialized to encode motions consistent with the speed of moving animals (rather than say a speeding bullet or a moving glacier). Axons originating in the eye terminate in the *lateral geniculate nucleus* of thalamus as well as in subcortical nuclei specialized to direct attention to objects of interest (superior colliculus) and to entrain the brain to daily rhythms of light and dark (suprachiasmatic nucleus). The projections responsible for visual perception run from the lateral geniculate nucleus to primary visual (*striate*) cortex in the occipital lobe (**Figure 2**). From here, the visual system diverges to areas of visual *association cortex*, extending from the occipital lobe ventrally into inferior temporal cortex and dorsally into posterior parietal cortex, responsible for processing specific aspects of vision, such as color, motion, and spatial relationships. Rare cases of brain disease will sometimes affect these discrete areas of cortex and leave individuals without the ability to perceive color (achromatopsia), motion (akinetopsia), or spatial relationships ('Balint's syndrome'). Lesions damaging visual association areas can sometimes interfere with the ability to recognize objects visually without affecting more elementary visual processes (visual agnosia).

The *auditory system* converts vibrations (pressure waves) to sound. Species differ in the range of both loudness (amplitude)

and pitch (frequency) of vibrations that they hear. The range of sounds heard by different species reflect use of sound for communication, detection of prey and avoidance of predators, and the media through which auditory signals travel (air, water, or the ground). In humans, pressure waves are collected by the *outer ear* and mechanically amplified during transmission through the eardrum and the three bones of the *middle ear* (the ossicles) to the oval window of the cochlea. The *cochlea* is a spiral shaped bony structure. Pressure waves travel from the oval window through fluid filled cavities of cochlea where they cause vibrations of the basilar membrane. Vibrations of the basilar membrane displace ciliary appendages of hair cells (stereocilia), which then activate terminals of the auditory nerve. The frequency (or pitch) of a sound is encoded by the point that the basilar membrane vibrates maximally (place coding) and by the timing of action potentials produced by the vibrations (volley coding). The pattern of activation that emerges from the cochlea is represented tonotopically as auditory information and is transmitted through the *cochlear nucleus* to the *inferior colliculus*, the *medial geniculate nucleus* in thalamus, and then primary auditory cortex (*Heschl's gyrus*) in superior temporal cortex extending into the Sylvian fissure. In tonotopic coding, different frequencies of sound are represented topologically as a spatial map. Conscious awareness of sound depends on activation of primary auditory cortex. Auditory association cortices adjacent to primary cortex play critical roles in the ability to perceive complex patterns of sound as music, language, or elements of a complex and changing environment.

Somatosensory information (touch) is transduced by different types of receptor end organs distributed across the skin. These include end organs specialized to detect different aspects of touch (pressure, vibration, stretch, tickle, itch) and temperature (warm, cool). *Pain* is detected by receptors with higher thresholds for activation (nociceptors) and by high levels of activation of somatosensory nerve endings. *Somatosensory* information travels through the dorsal columns of the spinal cord to the medulla where they synapse with neurons that send axons to the *ventral basal complex* in thalamus. From here, somatosensory information travels to primary somatosensory cortex in the *postcentral gyrus* and to somatosensory association areas in adjacent regions of parietal cortex (Figure 2).

Chemorensory information is detected by the olfactory (smell), gustatory (taste), vomeronasal, and trigeminal systems. What we commonly experience as flavor of foods or strong smells are often produced by stimulation of multiple chemorensory systems. Free nerve endings of the *trigeminal nerve* line the nasal cavities and respond to irritating concentrations of odorants (which can happen at low concentrations for particularly noxious chemicals). For the untrained observer, the sting associated with trigeminal stimulation is often perceived as an integral component of a strong smell. *Flavor* is a complex perception based on a combination of taste, olfaction (often through retro-nasal stimulation), and texture (somatosensory input from the mouth and tongue). There are five basic *tastes*: salty, sour, sweet, bitter, and umami. These are detected by receptors on taste buds in papillae on the tongue and at the back of the throat. Taste information travels over three different cranial nerves (facial, glossopharyngeal, and vagus) through axons that terminate in the *nucleus of the solitary tract*. From here, taste pathways are closely aligned with somatosensory areas in thalamus and

cortex. Axons from second order gustatory neurons terminate in the *ventral posterior medial thalamic nucleus*, which project in turn to the cortical taste area in somatosensory cortex.

Smells are detected by receptor molecules located on cilia projecting from receptor neurons into the mucus layer in the upper portions of the nasal cavity. Vertebrates have about 1000 different types of olfactory receptors, about 350 of which are functional in humans. The ability of humans to perceive novel synthesized molecules that are not found in nature demonstrates the ability of at least some of these receptors to respond to a wide range of novel stimulus substances. Axons from receptor neurons cross the cribriform plate and synapse with dendrites from mitral cells in the glomeruli of the *olfactory bulb*. Each glomerulus receives inputs from receptor cells that express the same receptor molecule. Mitral cell axons travel into basal areas of the forebrain where they terminate in primitive cortical areas collectively called *primary olfactory cortex*. The ability to discriminate diverse smells results from a diversity of receptor molecules that are organized to produce distinct topographic patterns of neural activity across the receptor epithelium. This topographic patterning is preserved within olfactory bulb and primary olfactory cortex. The *vomeronasal organ* is located in the base of the nasal cavity, just above the palate, in many animals. It is specialized to detect pheromones (chemical signals that trigger social responses). Although the vomeronasal organ has been identified in humans, recent evidence suggest that humans lack functional genes for vomeronasal receptor molecules and thus that the vomeronasal organ is vestigial in humans.

Acting on the External World

We act on the world by contracting muscles as Sir Charles Sherrington noted "whether in whispering a syllable or in felling a forest." Our ability to act purposively is organized hierarchically. In 1889, John Hughlings Jackson characterized three levels of organization that continue to guide modern thinking about motor control. The lowest level consists of the spinal cord and brainstem motor nuclei, the middle level of sensorimotor cortex, and the highest level of premotor and prefrontal cortex. Jackson emphasized the role of the brain in organizing movement and the ultimate control of lower motor centers by higher motor centers.

Spinal mechanisms: Skeletal muscles contract when *extrafusal muscle fibers* are excited by axons of α -motoneurons that are located in the ventral horn of the spinal cord. As muscles can only exert force in one direction (by contraction), they are generally organized in groups of *agonists* (or synergists) producing movement in one direction and *antagonists* that produce movement in the other direction. In limbs, these pairs consist of *extensors* (muscles that resist the force of gravity or straighten limbs) and *flexors* (muscles that bend limbs, moving them in the opposite direction as extensors). The spinal cord receives inputs from proprioceptors that provide information about muscle length and tension. *Muscle spindles* consist of intrafusal muscle fibers aligned in parallel with extrafusal muscles. Sensory endings in muscle spindles signal information about the length of muscles and provide the sensory component of the stretch reflex. *Golgi tendon organs* are located at the insertion of muscle fibers into tendons – in series with skeletal

muscles. They sense the force exerted on muscles and provide the sensory component of the autogenic inhibition reflex.

Spinal reflexes provide control over the activation of skeletal muscles by α -motoneurons. In the *stretch reflex*, activation of muscle spindles directly excites α -motoneurons producing contractions of agonist muscles to compensate for an increase in muscle length. At the same time, the spindles activate interneurons to reciprocally inhibit antagonist muscles that would otherwise resist the compensatory movement. The stretch reflex is what allows a waiter to hold a tray steady while it grows lighter as food is served or heavier as dishes are placed on it. The *autogenic inhibition reflex* occurs when Golgi tendon organs are activated by muscle force and excite spinal cord interneurons to inhibit agonist α -motoneurons. This was once thought to function as protective response, preventing muscles from being damaged by strong forces. It is now recognized that Golgi tendon organs are activated by much weaker forces, where the inhibitory reflex is thought to spread work out evenly across a population of muscle fibers. The spinal cord also contains circuits that mediate protective reflexes. The *flexion reflex* causes a limb to withdraw in response to a noxious stimulus (like stepping on a tack). Here, flexors are excited and extensors inhibited for the limb involved, while extensors are excited for the opposite limb (crossed extension) to maintain sufficient extensor activity to resist the force of gravity (and remain upright).

Central pattern generators are neural networks that activate motoneurons in rhythmic patterns to produce stereotyped movements. They spare higher motor centers the cost of programming individual muscles to produce routine, repetitive sequences of contractions. Some central pattern generators, like those that control breathing, are active at rest. Others, such as those that control locomotion or chewing, are activated by descending projections from higher motor centers. Central pattern generators are influenced by sensory feedback that can modify the duration of phases of the activity cycle to adapt responding to environmental conditions – for instance adjusting one's stride when stepping on a rock while hiking. Central pattern generators for locomotion are localized in spinal cord, while those controlling breathing, chewing, swallowing, and eye movements are located in brainstem motor nuclei.

Cortical control of movement is mediated by projections from *primary motor cortex* in the precentral gyrus (Figure 2) to the spinal cord (corticospinal tract) and to brain stem nuclei that project to spinal motor centers (such as the rubrospinal, vestibulospinal, and reticulospinal tracts). The corticospinal tract also contains projections from *supplementary* and *premotor* cortices, located just in front of primary motor cortex, and somatosensory cortex, in the postcentral gyrus. The supplementary and premotor areas project heavily to primary motor cortex and play important roles in planning movements, particularly complex sequential movements. While lesions of primary motor cortex have profound effects on muscular strength (particularly for the hands), lesions in premotor and supplementary motor areas impair the ability to develop sequential strategies for movement but have little effect on strength. Primary motor cortex contains populations of neurons that respond to the activation of specific muscles and others that code direction of movement regardless of the muscles involved. Neurons in primary motor cortex are coarsely tuned, exhibiting

responses coding movements in a large range of directions. The ability to make precise movements is thought to depend on the ability to sum responses across a large population of neurons to determine a precise average vector. The motor map is not rigidly fixed, but can be changed by motor learning. Larger areas of motor cortex are activated when well-trained movements are performed. This presumably reflects an increased level of precision for well-practiced motor skills like playing a musical instrument. Neurons in premotor and supplementary motor areas exhibit responses that seem consistent with a role in motor planning. They tend to respond earlier before the onset of movement, in response to stimuli that indicate the direction of an impending movement. Studies of brain-injured patients and results of functional imaging studies suggest that higher order motor skills such as skilled tool use or pantomime of tool use depend on large-scale distributed neural networks that connect the premotor and supplementary motor areas to association areas in prefrontal and parietal areas of cortex in the left (dominant) hemisphere of the brain.

The *cerebellum* and *basal ganglia* have important effects on motor function at multiple levels of the central nervous system. Virtually all areas of cerebral cortex project to *striatum*, the input area of the basal ganglia. Striatum projects back to much of frontal cortex through topographically organized pathways that pass through pallidum and thalamus. These cortico-striato-pallido-thalamo-cortical projections provide parallel pathways that link functionally related areas of cortex, basal ganglia, and thalamus. Current theories emphasize the role of the basal ganglia in action selection – deciding which of several possible actions to execute at a given point in time. Basal ganglia areas associated with motor cortex are thought to mediate sensory-guided responding, while areas associated with prefrontal cortex are thought to guide responding on the basis of information represented within the brain as working memory. The *cerebellum* guides responding on the basis of sensory input from sensory areas of cortex, peripheral proprioceptors, and the vestibular system. Cerebellum is divided into regions having distinct phylogenetic origins. The *vestibulocerebellum* (flocculomodular lobe) targets motor nuclei controlling axial muscles and primarily affects balance. It is well developed in fish and reptiles and is regarded as the oldest part of cerebellum in evolutionary terms. The *spinocerebellum* consists of the medial and intermediate zones. It projects to brainstem and midbrain motor nuclei and is primarily concerned with the modulation and execution of ongoing movements. The *cerebrocerebellum* consists of the lateral zone of the cerebellar hemispheres. These are particularly well developed in humans and project to thalamus to provide input to premotor cortex. These are regarded as the most recently evolved part of cerebellum and play an important role in the initiation, planning, and timing of movements.

Adapting to the Environment

Humans, like other mammals, have evolved mechanisms that allow us to adapt to changing conditions in external and internal environments. These include systems specialized to maintain homeostasis of internal conditions, to regulate behavioral states to maintain beneficial levels of wakefulness and arousal, to attend to critical tasks and information needed

to optimize cognitive and perceptual function, and to express and perceive emotions to facilitate social interactions.

Homeostasis

In the middle of the nineteenth century, the French physiologist Claude Bernard called attention to the importance of having a constant internal environment in the body. He emphasized the organic composition of blood as the nutritional medium of cells. In the 1920s, the American physiologist Walter Cannon drew attention to the role of coordinated physiological mechanisms in regulating internal state conditions. He coined the term homeostasis to characterize these functions. It is now well established that the *hypothalamus* interacts with brainstem nuclei to control homeostasis through actions of the peripheral nervous system and hormones released by the pituitary gland. *Thermoregulation* maintains body temperature within a narrow range for mammals and other homeotherms. Body temperature is sensed by cutaneous thermoreceptors and by temperature sensitive cells in hypothalamus. Regulator circuits in spinal cord, brainstem, and hypothalamus sense deviations from the setpoint (normally 98.6°F for humans) and trigger both compensatory behaviors (heat seeking/avoiding) and reflex actions (vasoconstriction/dilation, sweating, respiration, brown fat metabolism, thyroid hormone secretion) to restore homeostasis. *Fluid balance* is monitored by cardiac and kidney baroreceptors that signal hypovolemia (low blood volume) and hypothalamic osmoreceptors that signal increased concentrations of solutes in extracellular fluids. These signals are processed in hypothalamus to give rise to behavioral adaptations (motivated drinking, salt appetite) and reflex responses (water and salt retention by the kidneys, vasoconstriction to maintain blood pressure) that maintain homeostasis. *Energy balance* is a more complex process. Appetite is influenced by short-term factors signaling hunger, satiation, and the palatability of available food and by long-term factors related to the amount of energy stored in adipose tissue. The arcuate nucleus in hypothalamus acts as an appetite controller, responding to hormones released in the gut reflecting both short-term (insulin, ghrelin, obestatin peptide YY) and long-term (leptin) factors. Feeding behavior is regulated by nuclei in hypothalamus and hindbrain based on input from the arcuate nucleus, neural signals from the gut, and nutrient sensing neurons in the brain.

Behavioral state control

Almost all living species exhibit *circadian rhythms*, daily patterns of biochemical, physiological, or behavioral processes that allow organisms to adapt to regular changes in the external environment. Circadian rhythms result from internal circadian clocks that typically run slightly longer than 24 h and zeitgeber ('time giver') stimuli (most commonly light) that reset the clock in phase with the daily cycles of the external environment. The primary circadian clock in mammals is located in the *suprachiasmatic nuclei*. These are small nuclei located just above the optic chiasm (Figure 2). They contain neurons that exhibit endogenous circadian rhythms and receive direct input from specialized cells in the retina that allow light to serve as a zeitgeber. Circadian rhythms of the suprachiasmatic nuclei regulate daily patterns of sleep and wakefulness that are characteristic of most mammalian species. Mammalian brains exhibit different rhythms of neural activity that correspond to

states of vigilance (or alertness). In most general terms, these consist of the wake state, associated with a low amplitude, desynchronized EEG activity; slow-wave sleep, divided into four stages associated with slow-wave EEG activity; and rapid eye movement (REM) sleep, associated with small-amplitude, fast EEG waves, lack of muscle tone, and rapid eye movements. *Wakefulness* is regulated by neurons in the lateral hypothalamic area and posterior hypothalamus that release the neuropeptides orexin A and orexin B (also known as hypocretin1 and 2) in neurochemically specific wake-promoting nuclei that are located in the brainstem. These *wake-promoting nuclei* include noradrenergic neurons in locus coeruleus, serotonergic neurons in the raphe nuclei, cholinergic neurons in pedunculo-pontine tegmental and laterodorsal tegmental nuclei, glutamatergic neurons in the midbrain, dopaminergic neurons in tegmentum, and histaminergic neurons in the tuberomammillary nucleus. They produce arousal through direct effects on neurons throughout thalamus and neocortex and through actions on neuromodulatory systems in the basal forebrain. *Slow-wave sleep* results from decreased activity of wake-promoting systems by substances like adenosine that build up during prolonged periods of wakefulness and by descending inhibitory projections that originate in the preoptic area of hypothalamus. *Rapid eye movement sleep* is triggered by cholinergic neurons in the pons and maintained by cell groups in the brainstem that activate cortex and produce muscular atonia.

Attention

William James famously described attention in *The Principles of Psychology* (1890): "Everyone knows what attention is. It is the taking possession by the mind, in clear and vivid form, of one out of what seem several simultaneously possible objects of trains of thought. Focalization, concentration, of consciousness are of its essence. It implies withdrawal from some things in order to deal effectively with others, and it is a condition which has a real opposite in the confused, dazed, scatter-brained state ..." Modern theories have unpacked James' description into a number of components. *Top-down attention* (endogenous or voluntary attention) is the ability to deploy attention according to internal behavioral goals. *Bottom-up attention* (exogenous, involuntary attention) is the tendency for highly salient stimuli like the ring of a cell phone or a flashing light to attract attention automatically. Stimulus saliency depends on both the nature of the stimulus and the environment in which it is experienced. Working memory is a temporary store of information used to carry out cognitive functions like decision-making or planning complex behaviors. Working memory can hold only a limited amount of information at a given moment in time. Both top-down and bottom-up attention determine which of multiple types or sources of information is held in working memory (and is thus available for decision-making or planning). At the same time, working memory plays an important role in directing top-down control of attention. Convergent evidence supports a critical role for prefrontal cortex in working memory and prefrontal and posterior parietal cortices in both top-down and bottom-up attention. The capacity for attention depends critically on the level of alertness and arousal and thus many of the neurochemical systems that control wakefulness (see above). The relationship between arousal and attention is

characterized by an inverted-U (Yerkes-Dodson) function: too little arousal results in drowsy inattentiveness and too much arousal produces the frazzled, 'dazed, scatterbrained' state described by James.

Emotion

In 1872 Charles Darwin published *The Expression of the Emotions in Man and Animals* in which he characterized emotions as instinctive reflex actions that serve as an important means of communication and an efficient way to adapt to changing environmental demands or opportunities. Modern theories largely accept the idea that there are fundamental types of emotion that are expressed through stereotyped motor responses (primarily facial expressions in humans) and physiological changes. According to cognitive theory, emotions are activated by cortical mechanisms that perceive and interpret sensory stimuli within a particular context and separately trigger both emotions and autonomic nervous system responses. The autonomic responses are thought to influence how the emotion is experienced and this overall experience of emotion then provides feedback signals that affect subsequent interpretation of sensory inputs. Neurological theories emphasize the role of amygdala in processing socially and emotionally relevant stimuli. The amygdala receives sensory information from thalamus and cortex and contextual information from hippocampus required for this function. The central nucleus of the amygdala sends projections to brainstem areas that trigger visceral and somatic responses and to hypothalamic nuclei that control autonomic and hormonal responses. The role of amygdala in perception and expression of emotions has been confirmed by convergent evidence from studies of lesion effects on experimental animals and human patients and analyses of neural activity in animals and functional imaging in human subjects. The amygdala is interconnected with two regions of frontal cortex, the orbitofrontal and anterior cingulate areas, with which it interacts to produce normal patterns of emotion and social behavior.

Higher cortical functions in homosapiens

Localization of function in cerebral cortex: Nineteenth century neurology established beyond doubt that cerebral cortex is necessary for cognitive function. Controversy remains however over the extent to which cognitive functions are localized in discrete areas of cortex. Cortex is broadly divided into motor areas that give rise to voluntary movements, sensory areas that receive and process information in the senses, and association areas that lack direct sensory or motor connections and mediate cognitive functions like perception, attention, language, and memory. Apart from simple functions of primary motor or sensory cortex, like flexion of a finger or perception of visual stimuli in a discrete part of the retina, evidence of localized cortical function must be treated with caution. Association areas participate in large-scale distributed neural circuits that involve other areas of cortex and subcortical areas like thalamus, amygdala, and the basal ganglia. It may be misleading to identify discrete cortical locations with functions like reading, tool use, or working memory that depend on interactions between multiple brain areas. A second concern is that cognitive functions, as currently understood, may not accurately characterize what a particular brain area does. The human

brain is a biological system that evolved gradually over many millions of years. Cognitive functions are psychological constructs that do not necessarily reflect the physiological functions performed by a particular brain area. These concerns aside, there are strong arguments that support localization of function. Cerebral cortex is not a homogeneous mass. Human cerebral cortex is anatomically differentiated by cytoarchitecture (cellular composition), anatomical connections, gene expression, and neurochemistry. There are many compelling examples of structure–function relationships that suggest specialized functions of localized areas of cortex. Similarly, there are many examples of well-defined cognitive deficits that result from lesions damaging discrete areas of cortex and of local areas of cortex exhibiting alterations in neural activity, metabolic function, and early or intermediate gene expression when individuals perform specific cognitive tasks. The bottom line is that while there is abundant evidence that cerebral cortex is topographically organized into discrete areas that serve specialized functions, there are also good reasons to be cautious in identifying specific cognitive functions with discrete areas of cortex.

Language: Much of what we know about the organization of language in the brain has come from the study of aphasia, the loss of language ability as a result of brain damage. The modern study of aphasia began in the early 1860s when Paul Broca described several patients who lost the ability to speak ('aphemia') with lesions that damaged the third frontal convolution in the left hemisphere of cerebral cortex (now known as Broca's area). Broca noted that this inability to speak did not result from an inability to move muscles needed for speech, to understand spoken speech, or to communicate nonverbally. In 1868, Hughlings Jackson argued that the emissive symptoms described by Broca reflect a higher-level inability to express a proposition in words. He based this on observations that expressive aphasia commonly spares the ability to utter emotional oaths or overlearned phrases or to produce words in the context of automatic speech (saying 'no' to indicate something not to be done, while being unable to say 'no' as a voluntary answer to a question). He also noted that speaking and writing are often similarly impaired. In 1874, Carl Wernicke, a 26-year-old medical student, published a short monograph based on ten cases of aphasia (only four autopsied) that described a new type of aphasia and proposed a framework for understanding aphasia that remains relevant today. Wernicke described sensory aphasia, a syndrome characterized by diminished comprehension of speech (but not deafness), fluent and nonsensical speech, and frequent paraphasias (errors in speech production). Wernicke attributed sensory aphasia to lesions damaging the posterior portion of the superior temporal gyrus in the left hemisphere (now known as Wernicke's area). Wernicke predicted a third type of aphasia (conduction aphasia) primarily affecting the ability to repeat spoken language when lesions disconnect the anterior (Broca's) and posterior (Wernicke's) language centers. The current view of aphasia accepts Wernicke's view of functionally distinct anterior and posterior language areas located in the left hemisphere of most individuals (virtually all right-handed individuals). Current analyses emphasize the involvement of broader areas of cortex surrounding the classic Broca's and Wernicke's areas, particularly for cases in which severe symptoms persist. Current

descriptions of aphasic syndromes have also changed. Broca's aphasia is characterized by slow and effortful speech production, word-finding difficulty, and grossly intact comprehension of speech. Aphasiologists emphasize a fundamental deficit in grammar (agrammaticism) affecting comprehension of grammatically complex sentences, the lack of grammatical endings on words and words carrying grammatical meaning in spontaneous speech, and the difficulty of producing more than one or two word utterances (telegraphic speech). Wernicke's aphasia is characterized by a fundamental inability to use language to express ideas. This is reflected in fluent speech rife with paraphasic errors, naming errors (often bizarre misnamings), and impaired comprehension and repetition of speech.

Memory is defined by what we remember, that is the influence on ongoing thought processes or behaviors of information that is no longer present in the environment (and thus must be represented in the brain). Failure to retrieve is generally taken as evidence that a memory no longer exists. Memory is necessary for any cognitive process that is on the basis of more than information immediately available to the senses. For the most part, remembering is an automatic, effortless process. At a cellular level *synaptic plasticity*, the ability of synapses between neurons to change in strength, is thought to underlie learning and memory. Newly learned information exists in a labile state of altered synaptic strength for a limited period of time. With the passage of time information becomes consolidated in a more permanent form. When information is retrieved, it is reactivated into a labile form for a brief time before it is reconsolidated back into a more stable form. While synaptic plasticity seems to be a general feature of many neurons, neurons in memory circuits are organized to represent information in neural networks that allow for information to be retrieved and to influence systems that guide responding. Most information stored in memory is represented in cerebral cortex, particularly within association areas of cortex. Perceptual memories are stored in sensory association cortex while motor memories such as skilled tool use are stored in premotor and posterior parietal areas. Working memory, the ability to hold and manipulate information in consciousness, is encoded by the activity of neurons in prefrontal cortex. Cortical memories are accessed by different neural systems that mediate distinct types of memory. The cerebellum and basal ganglia mediate *procedural memories*, including habit learning, skill learning, and sensorimotor adaptation. The lateral cerebellum (cerebrocerebellum) receives its main inputs from parietal and premotor areas of cortex. The basal ganglia receive convergent corticostriatal projections from widespread areas of cortex. The amygdala mediates implicit (subconscious) *emotional memories*. The amygdala has prominent reciprocal connections with limbic-related areas of cortex (frontal, cingulate, and insular areas) and projections that control autonomic and hormonal aspects of emotional responses. Hippocampus and adjacent areas of parahippocampal cortex mediate *declarative (explicit) memories*. Parahippocampal cortex has extensive reciprocal connections with association areas of cortex and is

connected in turn with hippocampus. The hippocampal system is thought to facilitate the formation of associations between memories represented in different areas of association cortex. Declarative memories are of information like facts or events that can be consciously recalled. These include both episodic memories of specific personal experiences and semantic memory of facts that are not necessarily tied to a particular context.

Executive functions are core activities of prefrontal cortex that optimize behavioral performance, particularly in situations that place demands on cognition. Executive function is critical for cognitive flexibility, the ability to adapt ongoing behavior on the basis of the status of external events and internal intentions. Executive functions include working memory, supervisory (top-down) control of attention, and cognitive control. *Working memory* is active, short-term memory that has been related to activation of neurons in dorsolateral prefrontal cortex. Working memory holds information about external stimuli, intended actions, and internal goals in consciousness so that it can be used to guide both overt actions and covert thinking. *Supervisory (top-down) control of attention* promotes control over thoughts and actions by resolving conflicts between stimulus or response elements. Convergent evidence suggests that supervisory control of attention depends on interactions between dorsolateral and anterior cingulate areas of prefrontal cortex. *Cognitive control* reflects the ability to orchestrate thought and action in relation to internal goals. In a sense, it is an emergent property of working memory and supervisory attentional control. Cognitive control is thought to depend on lateral prefrontal cortex and to exert its effects through top-down control of premotor and posterior association areas of cerebral cortex. Cognitive control appears to be organized hierarchically in a caudal to rostral fashion with more caudal areas mediating sensory control and more rostral areas mediating higher-level aspects of cognitive control.

Glossary

Achromatopsia Also known as cortical colorblindness, it refers to the loss of ability to perceive colors.

Agnosia It is loss or diminution of the ability to recognize familiar objects or stimuli. Agnosia may refer to visual, auditory, or tactile perceptions.

Alexia It is the loss of ability to read.

Amusia It is the inability to produce or comprehend music.

Aphasia It is the loss or impairment of the power to use or comprehend words.

Aprosody It is the absence of the normal pitch, rhythm, and variations in melodic intonations of speech.

Declarative memory A type of memory that requires conscious recollection of information previously learned.

Dysarthria It is the difficulty in articulating words.

Hierarchical (serial) processing A type of processing where information is relayed in hierarchy from one center to the next.

Neuronal/synaptic plasticity The property of synapse and neurons to change their functionality, connectivity, and internal parameters based on activity level.

Nondeclarative memory A type of memory that does not require conscious or intentional recollection of what was learned.

Nuclei A collection of central nervous system gray matter (neuronal cell bodies) embedded in white matter.

Parallel-processing model Processing of different aspects of information simultaneously in different regions of the brain.

Prosopagnosia It is the loss or inability to recognize human faces.

Historical Background

From the time of Aristotle to the modern age, human behavior has been understood in the context of the ideological trends and philosophy of the historical period. During the last millennium, the natural sciences have developed testable theories, which explain observed phenomena in terms of physical laws. The development of this scientific method of inquiry has resulted in a shift from exclusively theological or philosophical explanations to those that are subject to measurement and testing.

The Greek physician, Hippocrates (460–377 BC), maintained that “not only our pleasure, our joy and our laughter but also our sorrow, pain, grief and tears rise from the brain and brain alone” (Figure 1). Hippocrates’ ideas were overshadowed by those of the influential Greek philosopher, Aristotle (384–322 BC), who proposed that the heart was the organ of thought and mental processes while relegating the brain to the role of a cooling organ for hot blood from the heart. The second century AD physician, Galen of Pergamum, advanced the theory that the brain was the seat of mental activity, and like the rest of the body, it functioned by the balance of the four vital humors. The bodily humors hypothesis proposed that differences in human moods come as a consequence of imbalances in one of the four bodily fluids: blood, yellow bile, black bile, and phlegm. According to Galen, an imbalance of each humor corresponded with a particular human temperament (blood-sanguine, black bile-melancholic, yellow bile-choleric, and phlegm-phlegmatic). Individuals with sanguine temperaments are extroverted and social. Choleric people have energy, passion, and charisma. Melancholics are creative, kind, and considerate. Phlegmatic temperaments are characterized by dependability, kindness, and affection.

For the next 1500 years until the time of the Enlightenment, the understanding of brain function was highly influenced by

the teachings of Galen. As Western Europe gradually emerged from the Dark Ages, the dissection of human cadavers became more common. From dissections, artists like Leonardo da Vinci prepared anatomic atlases of the human body and nervous system. The seventeenth century French philosopher and mathematician, René Descartes, argued that physical laws could not account for the full range of human behavior such as the intellect. From this hypothesis arose the modern formulation of the mind – body dichotomy, known as Cartesian Dualism, which to this day continues to be a point of philosophical debate (Figure 2).

The proponents of the mind–brain dichotomy have contended that human consciousness is unlike any other physical phenomena, and cannot be fully accounted for by mere biological processes. This mind–brain division led to the divergence of psychiatry and neurology in twentieth century medicine, with psychiatry focusing on the psychological and emotional underpinnings of behavior while neurology focused on brain physiology and pathology. Sigmund Freud (1856–1939), the founder of the psychoanalytic school of psychiatry and a neurologist by training, focused mainly on the psychological foundations of behavior (Figure 3). Freud did, however, believe that brain physiological studies would eventually lead to a better understanding of mental processes. Contemporary neuroscience views the brain as the source of all behavior and mental functions. Human cognitive abilities and behaviors are seen as having varying degrees of representation and homology with those found in other members of the animal kingdom.

By the nineteenth century, the gross anatomy of the human nervous system had been well documented. Through careful microscopic examination of brain sections, Santiago Ramon y Cajal (1852–1934) prepared drawings of brain cells, which continue to be referenced today. Korbinian Brodmann (1868–1918) defined regions of the cerebral cortex based on histological

Figure 1 Hippocrates. Engraving by Peter Paul Rubens, 1638. Courtesy of the National Library of Medicine.

Figure 2 Portrait of René Descartes by Frans Hals, Louvre.

characteristics. These regions, named Brodmann areas, correspond to functional regions (see [Figure 4](#)). The work of Paul Broca (1824–1880) and Carl Wernicke (1848–1905) contributed to our understanding that the brain has regions dedicated to the performance of discrete functions. The origin of such intricate specialization was a mystery but it would soon be less so. In 1859, in his book *On the Origin of Species*, Darwin proposed that natural selection was the means by which nature crafted biological specialization. This theory proposed that the

Figure 3 Sigmund Freud. Photograph by Max Halberstadt, 1921.

characteristics of organisms result from a long process of natural selection. Organisms, and therefore the nervous system, were shaped by adaptation to ever-changing environmental pressures. Since the introduction of this theory, scientists have analyzed physical and behavioral characteristics in terms of their adaptive advantages to the organism ([Figure 5](#)).

The substance that encoded biological evolutionary changes and allowed them to be transmitted from generation to generation was still unknown. In the mid-nineteenth century, a Catholic monk, Gregor Mendel, while experimenting with horticulture and insects, observed that organisms inherit traits via discrete units of inheritance. Mendel's observations served as a foundation for the modern science of genetics. It was not until 1953 that James Watson and Francis Crick, using X-ray diffraction data, deduced the double helix structure of the DNA molecule. In 1963, they were awarded the Nobel Prize for their discoveries which ultimately revealed how information was transferred from generation to generation in living organisms. Subsequent research has identified a genetic basis for numerous neurobehavioral disorders such as Huntington's disease, frontotemporal dementia, Down's syndrome, and Wilson's disease. The genetic factors that alter susceptibility to many diseases, such as Alzheimer's disease, schizophrenia, mood disorders, alcohol dependence, and certain personality disorders, have also been identified.

The germ theory of disease and the development of microbiology helped elucidate brain and behavior relationships as well. Although many individuals have made monumental contributions to the development of microbiology, it was Robert Koch who published a series of proofs in 1890 verifying the germ theory of disease. Microbiology research led to identification of the *Treponema pallidum* bacterium in 1905 by Shaudinn and Hofmann as the causative agent for syphilis. Eight years later, Hideyo Noguchi demonstrated the presence of the syphilis spirochete in the brain of a patient with generalized paresis of the insane (GPI). Before this, GPI was largely thought to be a mental illness caused by weakness of personality or defective moral character. After this discovery, it became the first neuropsychiatric syndrome caused by an identifiable infectious agent. A study published in 1930 looking at more

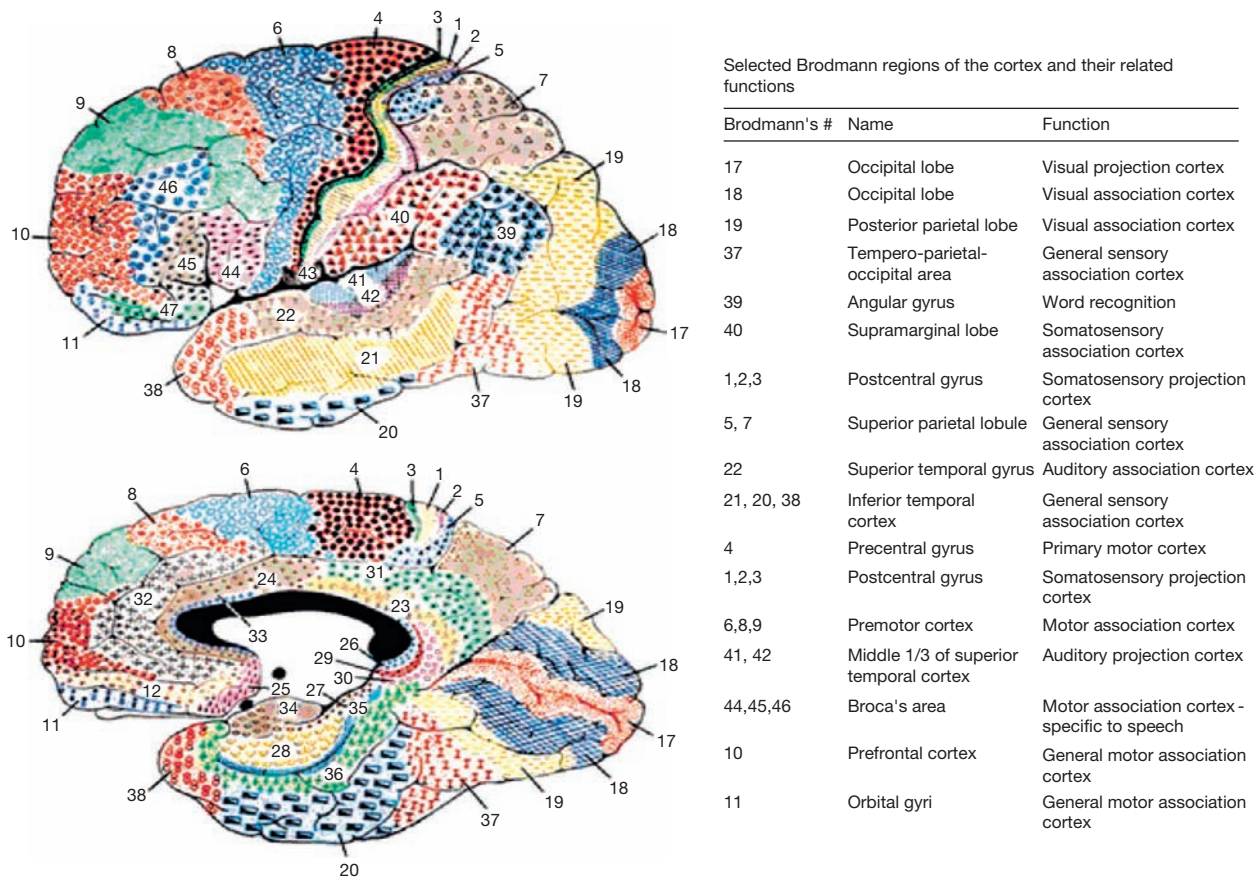

Figure 4 Selected Brodmann regions of the cortex and their related functions. Reproduced with modification from Mesulam MM (ed.) (2000) *Principles of Cognitive and Behavioral Neurology*. New York: Oxford University Press.

Figure 5 Charles Darwin 1868.

than 2000 consecutive admissions to an insane asylum estimated that one in six patients may have had syphilis infection. The 1930s and 1940s saw the beginning of the antibiotic revolution in medicine. The introduction of penicillin, an

effective treatment for syphilis, resulted in a dramatic reduction of syphilis-related psychiatric illness.

Principles of Behavioral Neuroanatomy

From simple reflexes to complex reasoning, behavior is generated in a hierarchal fashion in the nervous system. Many aspects of behavior are mediated almost reflexively, with more complex mental tasks requiring engagement and coordination of multiple higher brain centers. Simple reflexes, such as tendon stretch reflexes, are mediated at the level of the spinal cord, while brain stem structures control semiautomated motor aspects of behaviors such as crying, laughing, chewing, and sucking without the absolute requirement of cortical involvement. Anencephalic babies, born without the cerebral cortex, are able to suckle, chew, and cry just like their healthy counterparts. Nevertheless, there is a bidirectional modulation between subcortical and cortical centers, with the cortex exerting regulatory control over lower-level reflexes under normal circumstances. The hypothalamus is a subcortical structure which mediates homeostatic functions such as temperature, appetites, and sexual drive. The cortex regulates behaviors which address the biological needs arising from lower centers.

Cerebral function may be analyzed from the vantage point of a number of disciplines: neurochemistry, neurophysiology,

histology, and at the gross anatomical level. None of these alone is sufficient for achieving a comprehensive understanding of behavioral neurobiology. Neurotransmitters, receptors, synaptic plasticity, and neural connectivity form a continuum of elements which are the basis of nervous system function. On a higher organizational level, corticocortical and corticosubcortical brain networks link and coordinate distant brain regions. These networks function in parallel to generate our mental representations of the internal milieu and the external world.

Chemical and Neural Basis of Behavior

Neurotransmission

For millennia, various cultures have used perception and mood-altering substances in religious or shamanic rituals to facilitate healing, divination, communication with spirits, and to mark coming-of-age ceremonies. Some plant derivatives, such as opiates and cocaine, have been used in modern times for their medicinal benefits and abilities to induce euphoria. The misuse of drugs has resulted in medical, legal, and social problems for which society has not been able to find adequate solutions. Yet, they also have opened up new and profound opportunities to study human behavior. The mechanism of the profound behavioral effects of psychoactive ethnobotanical substances did not receive wide scientific attention until the twentieth century when, in 1938, Albert Hofmann synthesized a hallucinogenic drug, lysergic acid diethyl amide (LSD), from the ergot fungus. In 1943, Hofmann became inadvertently intoxicated by LSD and is remembered for his colorful description of his bicycle ride home while in an intoxicated condition. Early researchers observed that the drug's effects were similar to the naturally occurring symptoms of schizophrenia. In the decades that followed, psychiatrists developed an interest in the properties of hallucinogenic drugs as a model for understanding psychosis. The structural similarity of serotonin (5-HT) to LSD offered support to researchers who hypothesized that alteration of brain 5-HT might be involved in mental illness.

The early 1950s witnessed the birth of psychopharmacology with the serendipitous discovery that the administration of chlorpromazine reduced psychotic symptoms in patients. The introduction of first-generation antipsychotics, over three decades, significantly reduced the number of chronically psychotic patients institutionalized in long-term treatment facilities and returned them to the community. The antidepressant effects of antihistamine derivatives with a tricyclic structure led to a subsequent revolution in the pharmacotherapy of depressive illness. Julius Axelrod and his colleagues received the Nobel Prize for their work performed in the late 1950s describing the synthesis, storage, release, and inactivation of catecholamine (i.e., epinephrine, norepinephrine, and dopamine) neurotransmitters. Many classes of medications have since been developed for treatment of psychosis, depression, mania, anxiety, obsessive-compulsive disorder, and insomnia: selective serotonin reuptake inhibitors, serotonin-norepinephrine reuptake inhibitors, second-generation (atypical) antipsychotics, tetracyclic antidepressants, and monoamine oxidase inhibitors. This revolution in pharmacology opened new avenues for investigating the chemical mediation of behavior. Research clarified that

antipsychotic medications exert benefits through their ability to block dopamine D2 receptor binding. Amphetamines were demonstrated to increase brain norepinephrine and dopamine levels, and large doses or prolonged use of this medication were observed to cause psychosis. These lines of evidence converged to support the 'dopamine hypothesis' of schizophrenia. This hypothesis postulated that psychosis results from disturbed and hyperactive dopaminergic signal transduction. Another model based partly on the mind-altering effects of drugs, namely, phencyclidine (PCP) and ketamine, which act upon glutamatergic signaling systems, is that of the 'glutamate hypothesis.'

Learning and Memory

Connectivity between neurons is a dynamic process, continually being modified by the level of neuronal activity. Synapses with high activity levels are maintained and strengthened, while low activity leads to weakening of synaptic transmission or even dissolution of the connection. This process continues throughout life and is a critical substrate for learning, memory, and the brain's ability to adapt to environmental demands. In 2000, Eric Kandel was awarded the Nobel Prize in medicine for his work describing the physiological processes by which memory and learning occur in *aplysia* (sea slug). This work ultimately shed light on how individual personality styles might be shaped by experience, why children start to speak the language they are most exposed to, and why practice improves subsequent performance.

Localization of Brain Functions

The cortex has discrete regions dedicated to the processing of language, visual, auditory, and olfactory information as well as areas for cognitive and emotional processing. There are higher-order cortical association areas that are specialized to process color, form, fine details of visual objects, motion, and even areas specific to human face recognition. The brain has semantic stores, located in association cortices, where knowledge about the world is categorized and organized. These stores attach semantic knowledge to primary modalities of perception and action located in primary sensory and motor cortices. Hence, the brain is a collection of highly subspecialized, interconnected functional regions (see [Figure 6](#)). The processing of different characteristics of a stimulus in discrete brain regions may seem counterintuitive to our subjective experience. After all, when we see a red car speeding down the street, we do not perceive the color, shape, noise, or speed of the car separately. Rather, we see and hear the car as an integrated whole. How the brain binds these various percepts into one experience is not fully understood. It is clear that it is dependent on the rich reciprocal connections among distributed specialized cortical and subcortical regions which create a type of parallel processing network.

Early functional maps of the cerebral cortex were prepared from postmortem studies of patients with brain insults. Later, the famous neurosurgeon, Wilder Penfield (1891–1976), refined a technique of testing the function of various brain regions. While experimenting with ways to limit brain injury during surgery, he applied electrical stimulation to specific brain regions via small probes while the patients were

Figure 6 Positron emission tomography (PET) imaging of the brain demonstrating that different brain regions are activated when people perform four different language tasks, showing anatomical localization of the various language tasks. Courtesy of Marcus Raichle.

conscious on the operating table under only local anesthesia. Penfield observed their responses and accurately mapped the major sensory, motor, and language areas, thereby allowing some ability to minimize injury to these areas during surgery. He also charted the connections from sensory and motor cortices (homunculus) to the various limbs and organs of the body. Strikingly, he observed that in his epilepsy patients, stimulation applied to regions of the temporal lobes could trigger vivid recall of past experiences. As of yet this has not been reproduced in patients without epilepsy. The functional maps Penfield produced are still in use today. Functional magnetic resonance imaging (fMRI) and positron emission tomography (PET) scans are imaging technologies which have led to refinements of functional brain maps (see [Figure 6](#)). fMRI uses signal changes which arise from blood flow and/or oxygenation changes caused by local neural activity. These signal changes serve to indicate regional brain activity during the performance of a defined task. PET scans use radio-labeled tracer molecules which may target receptors, molecules, or be incorporated into metabolic processes to allow visualization.

Cognitive–Behavioral Neuroanatomy

Two general principles of brain organization can be discerned (see [Figure 4](#)). Perceptual areas such as the somatosensory, visual, and auditory cortices are located posterior to the central sulcus, while effector (output) areas such as the prefrontal and motor cortices are found anterior to the central sulcus. Speech production (Broca's area) and speech perceptual areas (Wernicke's area) also follow this anterior–posterior pattern of organization. In addition to anterior–posterior localization, the brain also shows lateralization of function between the hemispheres. The left and right hemispheres of the brain look similar but they are not exact mirror images of each other in terms of anatomy or function. Each hemisphere receives sensory information from and controls motor activity to the opposite side of the body.

The left hemisphere is dominant for language function in over 90% of all right-handed and about 60% of left-handed

people, while the right hemisphere is involved in the emotional content (prosody) of language. Hence, damage to the left Broca's area results in hesitant, agrammatical speech with short utterances consisting of few words. A lesion in the homologous right hemisphere will result in impairment of emotional inflection in speech. In such patients, speech may be flat, monotonous, and lacking in gestures, but with fairly normal content and grammar. The parietal, frontal, and cingulate cortices interact to generate attention to the opposite side of space. Lesions in these cortices produce contralateral sensory neglect, directional hypokinesia, and reduced motivational value, respectively. Neglect most often occurs with respect to the left side of space, indicating the importance of the nondominant hemisphere (usually, the right hemisphere) in spatial attention. Neglect syndromes show that focal lesions may affect specific aspects of self-awareness while sparing others. Focal lesions resulting in neglect syndromes illustrate that self-awareness is a composite consisting of the interconnected functions of many brain regions.

Cortical Organization

The cerebral cortex can be divided into five major functional subtypes: primary sensorimotor, unimodal association, heteromodal association, paralimbic, and limbic (see [Figure 7](#)). The primary sensory areas are the point of entry for sensory information into the cortical circuitry. The primary motor cortex conveys motor programs to motor neurons in the brain stem and spinal cord. Further processing of sensory information occurs as information moves from primary sensory areas to the adjacent unimodal association areas. The unimodal and heteromodal cortexes are involved in perceptual processing and motor planning. The complexity of processing increases as information is then transmitted to heteromodal association areas, which receive input from more than one sensory modality. Examples of heteromodal association areas include prefrontal cortex, posterior parietal cortex, parts of the lateral temporal cortex, and portions of the parahippocampal cortex. The highest level of cognitive processing occurs in regions referred to as transmodal areas. These areas are composed of heteromodal, paralimbic, and limbic regions, which are collectively linked in parallel to other transmodal regions. Interconnections among transmodal areas such as Wernicke's area, posterior parietal cortex, and the hippocampal–entorhinal cortex allow the integration of distributed perceptual processing systems resulting in perceptual recognition, such as scenes and events becoming experiences or words taking on meaning.

The limbic region has strong connectivity with the prefrontal cortex and is intimately involved with regulation of emotion, memory, motivation, and autonomic and endocrine function. Limbic system dysfunction has been described in several psychiatric syndromes such as schizophrenia, bipolar illness, and depressive disorders. The amygdala, located in the mesial temporal lobe, is important for both the acquisition and expression of emotions. Its strong connectivity with the hypothalamus is the underpinning for the autonomic and visceral manifestations and sensations accompanying emotions such as fear. The critical role of the amygdala for emotional processing is demonstrated in individuals who have Klüver–Bucy syndrome. Klüver–Bucy syndrome is a behavioral syndrome characterized by psychic blindness (visual agnosia), a tendency to

Figure 7 Showing major functional areas of the brain. Reproduced with permission from Blumenfeld H (2010) *Neuroanatomy Through Clinical Cases*, 2nd edn. Sunderland, MA: Sinauer Associates.

examine objects orally, distractability, hypersexuality, loss of aggressiveness (placidity), and a striking inability to display or experience fear or anxiety. Klüver–Bucy syndrome occurs with injury to the amygdale or medial temporal lesions on both sides. Potential causes include traumatic brain injury, anoxia, herpes encephalitis, and frontotemporal dementia. In contrast, seizures arising from the amygdala often produce intense anxiety or fear, through overactivation of this circuit.

Cortical Networks

Five distinct cortical network regions govern specific aspects of cognitive functioning: (1) the language network, which includes transmodal regions in Broca's and Wernicke's areas; (2) the spatial awareness network dependent on transmodal regions in the posterior parietal area, frontal eye fields; (3) the memory and emotional network located in the hippocampal entorhinal region and amygdala; (4) the executive function-working-memory network dependent on transmodal regions in the lateral prefrontal cortex and possibly in the inferior parietal cortices; and (5) the face–object recognition network based in the temporopolar and midtemporal cortices. Lesions of transmodal cortical areas result in global impairments such as hemineglect, anosognosia, amnesia, and multimodal anomia. Disconnection of transmodal regions from a specific unimodal input will result in selective impairments such as category-specific anomias, prosopagnosia, pure word deafness, or pure word blindness (alexia).

Cortical networks underlie the ability to empathize with another person's psychological and physical circumstances. Empathy is a necessary foundation for social and moral behavior. Originally identified in monkey premotor cortex, mirror neurons are a specific class of visuomotor neuron that discharges in a subject when a particular action is performed and when an action is observed in another individual. The human mirror neuron system is the neural network now postulated

to be involved in comprehending the actions of others and the intentions behind the actions. It may also provide the basis for observational learning. The parietofrontal mirror system, which includes the parietal lobe and the premotor cortex plus the caudal part of the inferior frontal gyrus, is involved in recognition of voluntary behavior in other people. The limbic mirror system, formed by the insula and the anterior mesial frontal cortex, is devoted to the recognition of affective behavior. Dysfunction of this system may underlie deficits in theory of mind and has been proposed as an explanation for the social deficits seen in autistic disorders. Theory of mind is a model of how a person understands and infers other people's intentions, desires, mental states, and emotions.

Frontosubcortical Networks

Cognition, behavior, and movement are dependent on five frontosubcortical circuits. All share the same principal components: (1) frontal cortex; (2) striatum (caudate, putamen, ventral striatum); (3) globus pallidus and substantia nigra; and (4) thalamus. While two of these circuits are concerned with somatic motor and oculomotor functions, the other three are intimately involved in cognition and behavior. These circuits originate in the dorsolateral prefrontal, orbitofrontal, and anterior cingulate cortices.

The dorsolateral prefrontal circuit governs executive functions, including the ability to plan and maintain attention, problem-solve, learn, retrieve remote memories, sequence the temporal order of events, shift cognitive and behavioral sets, and generate motor programs. Executive dysfunction is a principal component of subcortical dementias. Common deficits in subcortical dementias include slowed information processing, memory retrieval deficits, mood and behavioral changes, gait disturbance, dysarthria, and other motor impairments. Vascular dementias, Parkinson's disease, and Huntington's disease are examples of conditions that affect this circuit.

The orbitofrontal circuit connects frontal monitoring functions to the limbic system. This circuit governs appropriate responses to social cues, empathy, social judgment, and interpersonal sensitivity. It pairs thoughts, memories, and experiences with corresponding visceral and emotional states. This circuit is heavily involved in the process of decision-making and evaluating the costs and benefits of specific behavioral responses to the environment. The medial orbitofrontal cortex (OFC) evaluates reward, whereas the lateral OFC monitors and decodes punishment as it pertains to motivating behavioral change. There is an anterior–posterior gradient in which the reward value for more abstract and complex secondary reinforcing factors, such as money, is encoded in the anterior regions, and more concrete factors such as touch and taste are encoded in the posterior OFC areas. The posterior OFC is thought to have an important role in evaluating the emotional significance of stimuli. Dysfunction in this circuit can lead to disinhibition, irritability, aggressive outbursts, inappropriate social responses, and impulsive decision-making. Persons with OFC lesions may show deficits in both the production and recognition of emotional expression from the face, voice, or gestures. Bilateral OFC lesions may result in theory of mind deficits.

The anterior cingulate circuit includes the nucleus accumbens and has both afferent and efferent connections to the dorsolateral prefrontal cortex (DLPFC) and amygdala. It is involved in motivated behavior. Lesions in this circuit result in apathy, loss of the ability to act or to make decisions (abulia), and akinetic mutism (loss or impairment of voluntary activity and communication). Apathy can have affective (flat and unchanging facial expressions), emotional (loss of interest or excitement and lack of emotional reactivity), cognitive (lack of interest in learning and a decreased ability to understand new thoughts and participate in creative thought processes), and motoric dimensions (lack of effort, reduced productivity, and decreased ability to sustain activities). The medial prefrontal cortex is thought to play a significant role in the generation of emotions related to empathy, cognitive functions related to ‘theory of mind,’ and the ability to recognize a moral dilemma. The ventromedial frontal lobe evaluates the current relative value of stimuli helping to guide decision-making by determining the goals toward which behavior is directed and through judging outcomes. Various conditions that may affect this circuit include Alzheimer’s disease, frontotemporal dementia, Parkinson’s disease, and Huntington’s disease, head trauma, brain tumors, cerebral infarcts, and obstructive hydrocephalus.

Cerebrocerebellar Networks

Once thought to mainly coordinate movement, the cerebellum has been shown to have a role in the regulation of cognition, mood, and behavior. Cognitive processing tasks such as language, working memory, and spatial and executive tasks are associated with activation of the posterior cerebellar lobes. The posterior cerebellar vermis may function as a putative limbic cerebellum modulating emotional processing. Distractibility, executive and working memory problems, impaired judgment, reduced verbal fluency, disinhibition, irritability, anxiety, emotional lability or blunting, and obsessive–compulsive

behaviors as well as depression and psychosis have been reported in association with cerebellar pathology.

Neuropsychiatry

Neuropsychiatric symptoms can result from dysfunction in specific anatomic regions. Any disease, toxin, drug, or process that affects a region can manifest with changes in behavior mediated by the circuitry dependent upon that region. Brain pathologies may result in loss of function (negative symptoms, e.g., apathy), appearance of symptoms which should not be there (positive symptoms, e.g., hallucinations), or a combination of the two. **Table 1** summarizes neuropsychiatric symptoms and their anatomic correlates.

Not all brain lesions, however, will have observable behavioral consequences. There is also wide individual variability in the behavioral manifestations of focal brain lesions. Observational studies have shown that depression is common following left anterior or left subcortical stroke, but not all patients with such lesions develop depression. When temporal lobe epilepsy or Huntington’s disease begins in adolescence, a higher incidence of psychosis is noted than when their onset occurs later in life. This variability in behavioral manifestation of brain lesions may be due to factors specific to the lesion (e.g., size, location, laterality) and factors related to the individual such as the cerebral reserve, genes, and developmental stage of the brain (**Table 2**).

The case of Phineas Gage illustrates how regional brain injury may result in profound behavioral changes in the absence of

Table 1 Neuropsychiatric symptoms and proposed corresponding neuroanatomy

<i>Symptom</i>	<i>Neuroanatomic region</i>
Depression	Frontal lobes, left anterior frontal cortex, anterior cingulate gyrus, subgenum of the corpus callosum, basal ganglia, left caudate
Mania	Inferomedial and ventromedial frontal cortex, right inferomedial frontal cortex, anterior cingulate, caudate nucleus, thalamus, and temporothalamic projections
Apathy	Anterior cingulate gyrus, nucleus accumbens, globus pallidus, thalamus
Obsessive–compulsive disorder	Orbital or medial frontal cortex, caudate nucleus, globus pallidus
Disinhibition	Orbitofrontal cortex, hypothalamus, septum
Paraphilias	Mediotemporal cortex, hypothalamus, septum, rostral brain stem
Hallucinations	Unimodal association cortex, orbitofrontal cortex, paralimbic cortex, limbic cortex, striatum, thalamus, midbrain
Delusions	Orbitofrontal cortex, amygdala, striatum, thalamus
Psychosis	Frontal lobes, left temporal cortex

memory dysfunction, language deficits, or sensorimotor symptoms. Gage was the foreman of a railroad construction crew working in Vermont on September 13, 1848. He was known to be the company's 'most efficient and capable foreman' with a well-balanced mind and a shrewd business sense. He was tamping an explosive charge into the bottom of a borehole with a tamping iron when the charge accidentally exploded resulting in the tamping iron rocketing through his left cheekbone, prefrontal cortex, and anterior dorsal skull finally landing 25–30 yards away. Gage survived the massive penetrating injury but displayed personality changes which his physician, Dr. John M. Harlow, described in 1848 as follows: "He is fitful, irreverent, indulging at times in the grossest profanity (which was not previously his custom), manifesting but little deference for his fellows, impatient of restraint or advice when it conflicts with his desires." According to his friends, Gage 'was no longer Gage.' Demasio and colleagues performed an analysis using clues from the remains of Gage's skull and found that Gage's brain injury likely involved bilateral anterior orbitofrontal cortex, polar and anterior mesial frontal cortices, and the rostral portion of the anterior cingulate gyrus, with underlying white matter more extensively involved in the left hemisphere than in the right (see [Figure 8](#)).

Depression and Schizophrenia: Nature and Nurture

Depression and schizophrenia are conditions which both appear to result from a complex interplay of environmental and biological factors. Depression occurs with a prevalence of 20–60% in persons with stroke, neurodegenerative diseases, multiple sclerosis, headache, HIV, traumatic brain injury, epilepsy, chronic pain, obstructive sleep apnea, intracranial neoplasms, and motor neuron disease. It has been proposed that primary depression is due to dysfunction in a network that includes two known pathways: the orbitofrontal – basal ganglia – thalamic circuit and the basotemporal limbic circuit that links the orbitofrontal cortex and the anterior temporal cortex by the uncinate fasciculus. This has been expanded into a unifying depression circuit model which consists of four interconnected functional compartments. Each functional compartment consists of strongly interconnected anatomic structures upon which that compartment is dependent. The functional compartments are as follows: mood regulation (medial frontal, medial orbital-frontal and pregenual anterior cingulate cortex), mood monitoring (ventral striatum-caudate, amygdale, dorsomedial thalamus, midbrain-ventral tegmental area), interoception (subcallosal cingulate, ventral-anterior hippocampus, anterior insula, brain stem, hypothalamus), and exteroception

Figure 8 Damasio and colleagues' digital reconstruction of the penetrating brain injury sustained by Phineas Gage in 1848 which led to profound personality changes likely due to orbitofrontal cortical damage. (The metal rod shown in red.)

(prefrontal, premotor, parietal, mid-cingulate, and posterior cingulate cortices with dorsal-posterior hippocampus).

Efforts to link single genes to major depressive disorder (MDD) have been unsuccessful, despite exhaustive mapping attempts. Consequently, behavioral geneticists have turned to the study of genetic polymorphisms in establishing a predisposition to depression and in shaping the response to environmental stressors. The most extensive studies in this field have focused on polymorphisms in the serotonin transporter (5-HTT) gene. Behavioral genetics research based on diathesis-stress models of depression demonstrate that the risk of depression after a stressful event is enhanced in populations carrying genetic risk factors and is diminished in populations lacking such risk factors. Genotype-environment interactions are ubiquitous, because genes not only impact the risk for depression by creating susceptibility to specific environmental stressors but also cause individuals to persistently place themselves in highly stressful environments.

Among several etiological hypotheses for schizophrenia, the neurodevelopmental model is most prominent. This model generally posits that schizophrenia results from processes that begin long before the onset of clinical symptoms and is caused by a combination of environmental and genetic factors. Environmental factors include being a first-generation immigrant or the child of a first-generation immigrant, urban living, drug use, head injury, prenatal infection, maternal malnutrition, obstetrical complications during delivery, and winter birth. Genetic risks are clearly present but not well understood. The majority of patients with schizophrenia lack a family history of the disorder. The population lifetime risk for schizophrenia is 1%, 10% for first-degree relatives, and 4% for second-degree relatives. There is an ~50% concordance rate for monozygotic twins compared to that of ~15% for dizygotic twins. It is most likely that many

different genes make small, but important, contributions to susceptibility. The disease manifests only when these genes are combined or certain environmental factors are present. A number of susceptibility genes show association with schizophrenia. A small proportion of schizophrenia incidence may be explained by genomic structural variations known as copy number variants (CNVs). CNVs consist of inherited or de novo small duplications, deletions, or inversions in genes or regulatory regions. These genomic structural variations contribute to normal variability, disease risk, and developmental anomalies as well as acting as a major mutational mechanism in evolution. The most common CNV disorder, 22q11.2 deletion syndrome (velocardiofacial syndrome), has a 20-fold increased risk for schizophrenia and constitute about 0.9–1.0% of schizophrenia patients.

Functional imaging studies in schizophrenics show decreased cerebral blood flow in the DLPFC during specific cognitive tasks. Schizophrenic patients with prominent negative symptoms display reduced glucose utilization in the frontal lobes. Functional imaging studies suggest that disruption in distributed functional circuits is important in the development of schizophrenia. These functional circuit locations include the DLPFC, OFC, mediofrontal cortex, anterior cingulate gyrus, thalamus, temporal lobe subregions, and the cerebellum. Several conditions which may manifest psychosis, such as Huntington's disease, Parkinson's disease, frontotemporal dementia, and stroke, are commonly associated with frontal and subcortical dysfunction. Dorsolateral and mediofrontal hypoperfusion on functional imaging has been demonstrated in a subset of Alzheimer's disease patients with delusions.

Wisdom

The neurobiology of wisdom warrants special mention since it lies on the exciting frontier of our ability to model sophisticated cognitive processes. A consensus definition for wisdom is not available. Since the dawn of civilization, definitions have been advanced from different cultural, religious, and philosophical viewpoints. A theoretical definition that takes into account many cultural, religious, and philosophical themes is that wisdom represents a demonstrated superior ability to understand the nature and behavior of things, people, or events. This results in an increased ability to predict behavior or events which then may be used to benefit self or others. There is more often a desire to share the accrued benefits with a larger group for the purpose of promoting survival, cohesion, or well-being of that group. The benefits do not result from malicious or antisocial intents or inequitable behavior. Environmental factors, such as family, education, socioeconomic status, culture, and religion, are involved in generating the milieu in which the personal value system develops. Many of these same factors also influence how a given community decides whether wisdom is present or not.

This model of wisdom relies on the individual's ability to generate a mental representation of the self (cognitive, emotional, and physical), the external world, and the dynamic relationship of the self with the external world. The neural systems critical to enable these functions are distributed but heavily dependent on those that support memory, learning, understanding other people's mental states (Theory of Mind), and assigning relative value to information. The three

frontosubcortical neural networks, the limbic system, and the mirror neuron system are of particular importance for supporting these activities. These neural systems work in concert to weigh and estimate the risks and benefits of various mentally modeled courses of action to generate wisdom. The neural substrates of empathy may be conceptualized as biasing the information processing network in favor of valuing others, interpersonal communication, cooperation, and community.

Summary

Advances in the natural sciences and medicine have resulted in a shift from analysis with theological or philosophical explanations of human behavior to those that are subject to scientific methods. With this revolution in scientific thought has come the understanding that emotions, behavior, and cognition are produced and controlled by distributed neural networks. The brain and, in turn, behavior are shaped by genetics and a host of environmental factors throughout life. New technologies, such as fMRI and PET, enable scientists to study brain function in vivo and are beginning to yield insights into mental illness and normal cognitive functions such as empathy and wisdom which have traditionally been left to philosophical speculations. Advances in neuroscience will continue to change our understanding of ourselves and our relationship with the world around us.

Brain Chemicals: Global Projections of Ancient Aromatic Neurotransmitters

E C Azmitia, New York University, New York, NY, USA

Glossary

Aromatic structures They are usually six member carbon (benzene) or five (pyrrole) or six member (Pyridine) carbon–nitrogen ring structures having alternating single and double bonds. These ring structures are biologically important because they are able to absorb the energy from a photon which has the energy equivalent to that of a hydrogen electron. Aromatic (ring) hydrocarbons can be used as electron donors aerobically. The benzene-based amino acids (tyrosine, phenylalanine) do not lead to initiation of photosynthesis. However, indole-based amino acids (tryptophan), which have a five member aromatic ring with a nitrogen molecule attached to the benzene, donate an electron to a heavy metal and begin the process of photosynthesis.

Glial cells There are three main types of glial cells: the oligodendroglia cells, the astrocytes, and the microglia cells. These cells made their appearance in the brain as it became more complex during animal development. The oligodendroglia cells wrap themselves around axons and provide guidance, stability, and insulation to the axons of PTP neurons. The astrocytes function to support neurons by providing trophic factors (e.g., S100B, GFAP, and GDNF), energy (e.g., glucose), ions (e.g., K^+), and guidance factors (e.g., laminin). Microglial cells are of mesoderm origin (as opposed to the ectodermal origin of most other brain cells – blood vessels are also of mesodermal origin). These aggressive cells multiply, are mobile, and contribute principally to inflammation processes which occur after brain injury.

Global neurons These neurons are evolutionarily ancient and have extensive connections throughout the brain. They have their cells of origin in the brainstem regions but appear to connect with most neurons in the cortex, cerebellum, and spinal cord. These neurons use monoamines as neurotransmitters. These chemicals, made from indole or benzene structures, have powerful actions using a multiple number of specific receptors. Brain chemicals are indole and benzene ring-containing amino acids.

Interneurons These neurons are almost always inhibitory, using GABA as their neurotransmitter, and are mainly involved in the regulation of the local circuitry. The interneurons are involved in feedback inhibition and in defining the limits of neuron activity as best seen in sensory systems. The interneurons develop by a different pattern than that seen with either the global or PTP neurons. The interneurons principally use GABA, a derivative of the principal excitatory PTP chemical glutamate.

Limbic system James Papez first conceived the idea of a limbic system in 1937 after reviewing brain injuries in soldiers that resulted in emotional problems. The Papez circuit consisted of the hippocampus, mammillary bodies,

anterior thalamus, and the cingulate cortex. Over the years, many regions have been added to the emotional brain as part of the limbic system. These include the raphe serotonin system, amygdala, and septum; some even include the cerebellum, hypothalamus, parahippocampal gyrus, olfactory bulbs, and orbitalfrontal gyrus. As the number of structures increases in this 'emotional circuit,' its utility as an interesting concept decreases.

Medial forebrain bundle and lateral forebrain

bundle These two, largely unmyelinated, ancient fiber tracts have fibers extending to and from the midbrain-pons and the forebrain of the reptilian and mammalian brain. These tracts are used by the aromatic neurotransmitters systems (serotonin, dopamine, and noradrenaline) to reach all areas of the telencephalon and diencephalon, brain regions rostral to the midbrain. All cells of the forebrain are near one of these aromatic neurotransmitter axons.

Neuromuscular neurons These neurons project from the spinal cord and brainstem to innervate and activate skeletal muscle. These neurons use the brain chemical acetylcholine. Acetylcholine is also used by other PTP systems in the limbic system and also as a global cortical projecting system from the rostral brainstem.

Neurosecretory neurons These cells project from the hypothalamus to directly reach the posterior pituitary or the blood vessels going to the endocrine cells of the anterior pituitary. These neurons are part of the limbic pathway or in close association with the global neurons. The brain chemicals used by these secretory cells are almost predominately large peptides such as ACTH, oxytocin, anandamide, or vasopressin.

Photosynthesis This is a process whereby solar energy is converted to biological energy that converts carbon dioxide into organic compounds, especially sugars, resulting in the release of O_2 and the creation of ATP and reduced cofactors such as NADH. In the second stage of photosynthesis, ATP and NADH can be used to convert CO_2 to sugars.

Point to point (PTP) neurons These neurons are evolutionarily a more recent addition in that they are part of what is referred to as the hard wiring of the brain. The neurons have specific and localized projections and are used to relay specific bits of information into and out of the brain. These neurons use glutamate as the excitatory and glycine as the inhibitory neurotransmitters. Brain chemicals are amino acids with simple side chains such as glutamate and glycine.

Terminal neurons There are two types of neurons that are involved in transmitting the results of brain activity to the rest of the body. Motoneurons serve to move muscles and cause the body to move. The neurosecretory neurons release hormones (i.e., steroids and peptides) into the blood.

I was sitting writing at my textbook but the work did not progress; my thoughts were elsewhere. I turned my chair to the fire and dozed. Again the atoms were gambolling before my eyes. This time the smaller groups kept modestly in the background. My mental eye, rendered more acute by the repeated visions of the kind, could now distinguish larger structures of manifold confirmation: long rows, sometimes more closely fitted together all twining and twisting in snake like motion. But look! What was that? One of the snakes had seized hold of its own tail, and the form whirled mockingly before my eyes. As if by a flash of lightning I awoke; and this time also I spent the rest of the night in working out the rest of the hypothesis. Let us learn to dream, gentlemen, then perhaps we shall find the truth ... But let us beware of publishing our dreams till they have been tested by waking understanding. (August Kekulé, 1890)

Introduction

In the first edition of the *Encyclopedia of Human Behavior*, I presented an article on brain chemicals that focused on neurotransmitters and neurotrophic molecules. Neurotransmitters were placed into three different categories depending on the size, rate of synthesis, and binding characteristics to receptors. A fast system used acetylcholine, glutamate, or GABA, which are small molecules rapidly available to the neuron with minimal synthetic processing. These chemicals could bind to their receptors with relatively low affinity to enable quick on and off states. The slow systems used peptides such as enkephalin, oxytocin, substance-P, or anandamide, which are large molecules stored in dense core vesicles and slowly available for synaptic release. The synthesis of these peptides begins in the neuronal soma and involves extensive axonal processing. These chemicals bind to their receptors with high affinity to produce very slow on and off states and prolonged activation.

The intermediate system used the aromatic monoamines such as serotonin, dopamine, and noradrenaline. These aromatic neurotransmitters are available in limited quantities because the amino acids tryptophan (indole ring) and tyrosine (benzene ring) must be obtained from the diet. Once the aromatic amino acids are stored in the neurons, the synthesis

requires molecular oxygen and reduced cofactors (both chemicals important for mitochondrial production of ATP) to produce the final monoamine chemical. These transmitters are ancient and have multiple binding proteins in the human brain, ranging from low to high affinity to permit a wide range of actions. The intent of the present article is not to expand on the previous edition, but to focus on the brain aromatic chemicals required for the intermediate system as these brain chemicals form a global projecting system involved in brain homeostasis.

Obviously, the range of human behavior is dependent on the neural circuits contained in the human brain. Most of the research strategies utilized to study human behavior focus on the point to point (PTP) circuits (Figure 1). For example, to understand vision, the processes begin in the eye, but then the connections of the eye with the lateral geniculate and the visual cortex are followed and examined. Similar pathways are available for the behaviors involved in all the senses where there is a PTP progression from the principal sensory receptors to a final stop in a specific region of the sensory cortex, with relays occurring in thalamus or brainstem. The ancient system of olfaction is different, but still possesses a PTP circuit that can be drawn, usually utilizing black arrows. PTP diagrams are also available to illustrate the limbic system and cortical processing, with information transfer moving neatly from one point to another. The brain chemicals required for this type of network would be as vast as all the receptors needed, neurotransmitters released, and trophic factors required to build and maintain each PTP connection. It is not the intention of this article to discuss the neurotransmitters of the PTP circuits.

Rather, I will focus on the aromatic compounds – indole and benzene – which form the backbone of the amino acids of tryptophan and tyrosine. These are the essential chemicals needed by the global systems that utilize the monoamines. The unique properties of the aromatic chemicals were central to the unicellular process of photosynthesis, and regulated such processes as cell division and motility. The presence of these aromatic amino acids (AAA) and their derivatives enable the survival and growth of solar powered oxygen producing

Figure 1 The figure illustrates drawings showing global projecting system (a) and point-to-point (PTP) systems (b). The global systems are proposed to be more primitive and are called first-order systems while the PTP systems are a more recent addition and considered as second-order systems.

organisms. However, when the animal kingdom separated from the plant kingdom, the AAA could no longer be produced endogenously because of the loss of chloroplast and genes necessary for indole and benzene synthesis. These chemicals have to be obtained from the diet.

During the evolution of the brain, the AAA developed a global system for the distribution of aromatic neurotransmitters that depended on the medial and lateral forebrain bundles to reach target areas and then on multiple receptors to transmit their physiological actions. The important aspect of receptor-mediated actions is that the neurotransmitters are not degraded, and reuptake mechanisms are used to return these chemicals to the aromatic neurotransmitter axon. This extensive distribution of the global neurotransmitter system provides insights into many of the human behaviors influenced by these chemicals. Not only are many of these behaviors linked to the primitive networks of the limbic system but they also regulate many glial trophic factors necessary for the maintenance of the PTP networks throughout the forebrain. Thus, the concept is that these global neurons are involved in the homeostatic regulation of the brain itself, and its interaction with the rest of the body functioning within the external environment. Furthermore, an understanding of these brain chemicals in the global neurons provides fresh insights into concepts such as awareness, depression, and consciousness.

Aromatic Chemicals

Many of the chemicals found in the brain that are involved in important behaviors in humans also served important roles in the life, growth, and division of unicellular organs. Three billion years ago, unicellular organisms began to produce oxygen by the process of photosynthesis. To make the monoamine neurotransmitters, oxygen is needed (Figure 2). In the earliest geological times, the earth's atmosphere had little oxygen. Thus, the monoamines were made specifically in unicellular systems capable of photosynthesis and the cellular production of oxygen. The conserved monoamine biosynthetic pathway began in the unicellular systems of cyanobacteria, green algae, and fungi, and continually evolved to its current position in the human brain.

Benzenes

Two amino acids have a benzene backbone: phenylalanine and tyrosine. The delocalization of electrons is one explanation for the thermodynamic stability of benzene and related ringed molecules. It is likely that it is this stability that contributes to the peculiar molecular and chemical properties known as aromaticity, a term originally used to describe their fragrance. The concept of quantum-mechanical resonance was developed by W. Heisenberg in 1926 and applied to the benzene molecule by L. Pauling. Pauling wrote that benzene bonds 'would then be expected to be a sort of average of the properties of the individual molecules.'

Catechols

Benzenes can be oxidized by both bacteria and eukaryotes. In bacteria, the dioxygenase enzyme adds two oxygen molecules

Figure 2 This figure shows the molecular structures of benzene, pyrrole, and indole rings. Double bonds are illustrated as localized in the first two structures, and as being nonlocalized in the third structure of each set.

to the ring, and the unstable product is immediately reduced (by the cofactor NADH) to a cyclic diol with two double bonds, breaking the aromaticity. Next, the diol is reduced by NADH to form catechol. Catechol can be metabolized to acetyl CoA and succinyl CoA, used by organisms mainly in the Krebs Cycle for energy production. The catechol skeleton occurs in catecholamines, drugs derived from them (such as MDMA), urushiols (skin-irritating poisons found in plants like poison ivy), and catechin (found in tea).

Pyrrole

Pyrrole is an aromatic five-member ring containing four carbons and a single protonated nitrogen. There are two double bonds which alternate between the five atoms. It is an important component of such complex light gathering macromolecules as chlorophyll.

Indole

This ring structure is an organic compound consisting of a benzene ring and a pyrrole ring (Figure 3). The most reactive position on indole for electrophilic aromatic substitution is C-3, which is 10^{13} times more reactive than benzene. The origin of the first photosynthetic pathway is proposed to be the photooxidation of uroporphyrinogen (an indole-rich compound) by sunlight and this oxidation is accompanied by the release of molecular hydrogen. The indole structure can be found in the amino acid tryptophan. This molecule also forms the light-sensitive component of such molecules as, niacin, melatonin, tryptophan-containing enzymes and receptors, alkaloids, and pigments. The indole ring is electron rich and will easily lose a nitrogen electron (oxidized) to an electrophilic compound, like a heavy metal.

Figure 3 The biosynthetic steps are shown for the enzymatic conversion of tyrosine to dihydroxyphenylalanine (DOPA), dopamine, norepinephrine (noradrenaline), and epinephrine (adrenaline). The names of the enzymatic steps as well as the main cofactors are given.

Biosynthesis of Aromatic Amino Acids

Hydroxylation

Hydroxylase is the first enzyme in the synthesis of the aromatic neurotransmitters serotonin and catecholamines. In animals, tryptophan, phenylalanine, and tyrosine are obtained exclusively from the diet. Tyrosine can be converted from phenylalanine by the enzyme phenylalanine hydroxylase. The next step is also mediated by a hydroxylase enzyme, tyrosine hydroxylation. This enzyme produces L-DOPA, which retains the catechol structure.

The three enzymes involved in aromatic hydroxylation evolved from a single primitive enzyme that reacted with phenylalanine, tyrosine, and tryptophan, which were all sensitive to light. The hydroxylase enzyme was involved in the synthesis of large number of complex alkaloids in plants, all of which are potent antioxidants in their own right. Cellular oxidation is important for cell maturation and division, but excess oxidation results in cell death. The synthesis of pharmaceutically important indoles also involves decarboxylase enzymes (3.2), discussed below.

The hydroxylase enzyme, which utilizes molecular oxygen and H_4 -biopterin, is the first enzyme in the pathway for both serotonin and catecholamine synthesis. 5-HTP, the immediate precursor of serotonin, is formed from tryptophan and L-DOPA, the immediate precursor of noradrenaline, is formed from tyrosine. The ubiquitous carboxylase enzyme, working in reverse to function as an aromatic amino acid

decarboxylase, rapidly converts both these molecules to serotonin or dopamine (Figure 4).

Decarboxylase

The second enzyme in serotonin biosynthesis is tryptophan decarboxylase. The first organisms to contain this enzyme may have been the bacteria, *Enterobacteria cloacae* strains, which are normally associated with plant roots, and help produce the plant hormone auxin by using the enzyme indolepyruvate decarboxylase. Aromatic L-amino acid decarboxylase occurs in plants. For example, tryptophan decarboxylase in plants leads to the biosynthesis of pharmaceutically active indole alkaloids. These compounds are abundant throughout the plant kingdom, and are known to produce strong psychic or hallucinogenic responses in humans (see Figure 3). In animals, this enzyme loses its specificity for tryptophan and becomes a general aromatic acid decarboxylase. It is likely that as animal cells had a marked reduction in tryptophan because of loss of tryptophan synthesizing enzymes, there was less evolutionary need for a specific tryptophan decarboxylase enzyme.

Thus, enzymes commonly used in anaerobic organisms before O_2 was formed inside cells produce serotonin and the catecholamines. Besides the algae, fungi, and molds, the most efficient generators of O_2 and monoamines are plants. In humans, the collection of the AAA is quite complex because these structures are no longer made endogenously. A single transport system exists for phenylalanine, tyrosine, and tryptophan

Figure 4 The biosynthetic steps are shown for the enzymatic conversion of tryptophan to 5-hydroxytryptamine, serotonin, and 5-OH-indole aldehyde (5-HIAA). The names of the enzymatic steps are given as well as the main cofactors.

to carry these molecules to the brain. Once in the brain, the amino acids have specific uptake into the global neurons where they are converted into the neurotransmitter chemicals. This conversion occurs in the axon in the terminal areas of the brain. The neurotransmitters are released either in vesicles after an action potential or from the cytoplasm not in vesicles by a Ca^{2+} -independent process. These chemicals have multiple receptor systems to translate their biological actions without the metabolism of the neurotransmitter. The neurons also contain a very effective reuptake protein that removes the neurotransmitter from the synapse and either releases it again or retrogradely transports it back to the neuronal soma in the brainstem.

Derivatives of Aromatic Neurotransmitters

As bacteria and plants became very efficient at converting light into biological energy (NADH and ATP), the excess production of O_2 became a biochemical problem: oxygen can easily generate free radicals that are very destructive to the interior of the cell. The remedy was to have O_2 bind directly to tryptophan and tyrosine. Many of the biochemical derivatives of tryptophan and tyrosine evolved to function as antioxidant molecules in simple cells long before they assumed more complex functions in animals and humans as hallucinogens and mind-altering drugs.

Catecholamine

Catecholamine derivatives are known to serve important regulatory roles in plants and in humans. The sympathetic component of the peripheral nervous system (PNS) uses noradrenaline and the adrenal gland secretes adrenaline during stress response. Many of the benzene based alkaloid and synthetic compounds are also hallucinogenic. These chemicals act as dopamine and noradrenaline agonists with actions on both the central nervous system (CNS) and PNS. In addition to their hallucinogenic effects, they produce nausea, psychosis, racing, mania, and panic attacks (Figure 5).

Catecholamines

They are called catecholamines because they contain a catechol or 3,4-dihydroxyphenyl group. They are derived from the amino acid tyrosine. Catecholamines are produced mainly by the chromaffin cells of the adrenal medulla and the postganglionic fibers of the sympathetic nervous system. Noradrenaline neurons, part of the global neurons, are largely confined to melanin-pigmented cell bodies of the locus ceruleus in the Pons. Dopamine, a global neurotransmitter in the CNS, is largely produced in neuronal cell bodies in two areas of the brainstem: the substantia nigra and the ventral tegmental area.

Epinephrine (adrenaline)

It is a hormone and neurotransmitter. It increases heart rate, contracts blood vessels, dilates air passages, and participates in the fight-or-flight response of the sympathetic nervous system. Epinephrine acts on nearly all body tissues. Its actions depend on the receptor expression of the tissue. For example, epinephrine causes smooth muscle relaxation in the esophagus, but causes contraction of the smooth muscle that lines arterioles. Adrenaline is a nonselective agonist of all adrenergic receptors.

Mescaline

Peyote is found in high levels in the buds from the cactus pants in Mexico. This drug can produce deep introspection and insight described as being of a metaphysical or spiritual nature. This hallucinogen is rich in both visual and auditory effects (synesthesia). Mescaline was first isolated and identified in 1897. Its side effects include paralysis, breathing difficulty, vomiting, tremors in the legs, and anorexia.

Phenethylamine

The group of phenethylamine derivatives is referred to as the phenethylamines. Substituted phenethylamines, substituted amphetamines, and substituted methylenedioxyphenethylamines are a series of broad and diverse classes of compounds derived from phenethylamine that include stimulants, psychedelics, and entactogens, as well as anorectics, bronchodilators, decongestants, and antidepressants, among others.

Figure 5 The physiologically relevant derivatives from catecholamines are shown. These include the principal neurotransmitters dopamine and noradrenaline. Mescaline is a strong hallucinogen while the phenethylamines include ephedrine and selegiline. These are all alkaloids with mind-altering properties. Amphetamine, DOM (2,5-dimethoxy-4-methylamphetamine), methamphetamine, and ecstasy are designer drugs. They are synthetic phenethylamines with strong sympathetic and mind-altering properties.

Ephedrine

Chemically, it is an alkaloid derived from various plants in the genus *Ephedra* (family *Ephedraceae*). Ephedrine is a sympathomimetic amine. The principal mechanism of its action is on the nonvesicular release of noradrenaline in the sympathetic nervous system of the PNS. Ephedrine crosses the blood–brain barrier weakly. Behavior effects of this drug include mania, hallucinations, delusions, agitation, confusion, mild euphoria, paranoia, hostility, and panic.

Selegiline (deprenyl)

It is a synthetic phenethylamine which functions as a potent inhibitor of the enzymes MAOA and MAOB, the principle routes for the degradation of the aromatic neurotransmitters. The drug results in intraneuronal concentration of these aromatic neural transmitters and is commonly used as an adjunct to L-DOPA therapy or ecstasy and amphetamine abuse. Effects of these sympathomimetic stimulants include hallucinations, dizziness, dry mouth, severe headache, tachycardia, arrhythmia, and panic.

Designer drugs

They have been synthesized from using the amphetamine backbone. Many of these compounds were first synthesized by Alexander Shugun and are discussed in his book *PiHKAL (Phenethylamines I Have Known And Loved)*.

Amphetamine

It is a synthetic psychostimulant drug of the phenethylamine class. This drug effects the release of dopamine and noradrenaline in the CNS and PNS by a Ca^{2+} -independent nonvesicular release mechanism. The drug is a stimulant coupled with a

feeling of euphoria. The class includes prescription CNS drugs paradoxically used to treat attention-deficit hyperactivity disorder (ADHD).

Methamphetamine

It has high potential for abuse and addiction by activating the psychological reward system via increasing levels of dopamine, noradrenaline, and serotonin in the brain. The US Food and Drug Administration (FDA) has approved methamphetamine for the treatment of attention-deficit hyperactivity disorder (ADHD) and exogenous obesity. Methamphetamine is marketed in the United States under the trademark name Desoxyn.

DOM (2,5-dimethoxy-4-methylamphetamine)

It is also known as STP, an abbreviation for 'serenity, tranquility, and peace.' This is a powerful psychedelic (hallucinogenic drug) and a substituted amphetamine which has its hallucinogenic properties by stimulating serotonin receptors. DOM is a very potent agonist of the serotonin 5-HT family of receptors; mainly of the 5-HT₂ subtype. Effects of this drug include substantial perceptual alterations such as visual hallucinations, double vision, distortions, vibration of objects, slowing of time, and panic.

Serotonin

This is the principle substance used as a neurotransmitter in the nervous system of all animals, and has been found in nearly all photosynthetic organisms. Two major compounds with structural similarities to serotonin are auxin and melatonin, which serve important regulatory processes in plants and humans. Other structural derivatives of serotonin function as antioxidants, trophic molecules, or strong hallucinogenic drugs.

Auxin (hydroxyindole acetic acid)

It is also a protective, antioxidant compound found in unicellular organisms and functions to stimulate growth and survival. Auxin acts as an important phototropic hormone in plants and induces cell elongation and cell division, with all the subsequent results for plant growth and development. Its specific function in leaves is to move the entire photogenerating organ toward the source of sunlight.

Melatonin

It functions as a powerful antioxidant. Melatonin is found in all plants and animals, including algae and is involved in microtubule function in flagella and in mitosis. Melatonin levels have a diurnal rhythm in many protists and plants, as well as in humans. Melatonin functions as an antioxidant in plants and as a biological signal for the organization of day-length-dependent annual functions such as reproduction, behavior, coat growth, and camouflage coloring.

Indolamines

There are many natural psychoactive drugs synthesized in plants from tryptophan. All these compounds function as

antioxidants in single-cell organisms, and have been used by man as entheogens for thousands of years. The ability of these drugs to induce a feeling of closeness to God is a special property of the indoles and this property is attributed to activation of the cortical 2A serotonin receptor. Substituted indoles are derivatives of the tryptophan-based tryptamine alkaloids, such as serotonin, melatonin, and auxin; the hallucinogens psilocybin, DMT, and 5-MeO-DMT; and the ergots, such as ergotamine and LSD. *N*-Formylkynurenine, 5-methoxytryptamine, auxin, and melatonin in prokaryotes function as photosensors, antioxidants, and pattern generators for flagella movement, and in defense mechanisms. These alkaloids produced from tryptophan have powerful actions on the human brain by acting through the serotonin receptors or reuptake proteins. The structures of some of these compounds are shown in Figure 6.

Psilocybin mushrooms

Psilocybin mushrooms are found mainly in South and Central America. Native Americans (e.g., Aztecs, Mayans) used this hallucinogenic drug for thousands of years. It was almost always used in religious ceremonies with the users believing

Figure 6 The physiologically relevant derivatives from indolamines are shown. Auxin is a powerful plant hormone. Melatonin is a powerful hormone in humans and found in plants. The indoleamines are powerful hallucinogens. The alkaloids include psilocybin, *N,N*-dimethyltryptamine (DMT), 5-methoxytryptamine, ibogaine, and yohimbin. LSD is a semisynthetic psychedelic drug of the ergoline family, which is one of the most powerful mind-altering drugs known.

they were moving between the earthly and supernatural realms. Its properties are due to activation of the cortical 2A serotonin receptor.

N,N-Dimethyltryptamine (DMT)

This alkaloid occurs in many species of plants and in trace amounts in the human brain. *N,N*-Dimethyltryptamine (DMT) is a naturally occurring hallucinogenic drug of the indoleamine family and functions as a nonselective agonist at most or all of the serotonin receptors (including 5-HT_{2A}) with some affinity for dopamine adrenergic receptors. DMT can produce depersonalization, near-death experiences and mystical states.

Ibogaine

It is found in a number of plants, principally in a member of the dogbane family known as iboga (*Tabernanthe iboga*). Ibogaine-containing preparations are used in medicinal and ritual purposes within African spiritual traditions. Ibogaine experience occurs as two distinct phases: the visual phase and the introspective phase. The visual phase is visual distortion often accompanied by laughing, euphoria, fear, and temporary short-term memory impairment. The introspective phase is elevated mood, calm, and euphoria, and intellectual and emotional clarity.

Yohimbine

It is the principal alkaloid of the bark of the West-African evergreen *Pausinystalia yohimbe*. In Africa, yohimbine has traditionally been used as an aphrodisiac. Yohimbine is used as a dietary supplement in herbal extract form and as a prescription medicine in pure form for the treatment of sexual dysfunction. Yohimbine can produce hallucinations, anxiety reactions, rapid heart rate, high blood pressure, insomnia, seizures, and panic attacks.

Lysergic acid diethylamide (LSD)

LSD is a semisynthetic psychedelic drug of the ergoline family. The parent compound of the major hallucinogen LSD has long been known to be produced by a fungus, genus *Claviceps*. The hallucinogen was synthesized by the addition of diethylamide to ergotamine by the chemist Albert Hofmann at the Sandoz Laboratory. LSD is believed to be one of the most potent mind-altering compounds discovered to date. LSD causes hallucinations, distortions, and an altered experience of senses, emotions, memories, time, and awareness. There can be distortions of sensory perception such as synaesthesia, the experience of additional spatial or temporal dimensions, and temporary dissociation.

Homeostasis

In a discussion of brain chemicals and human behavior, the aromatic neurotransmitters are an important topic not only for the variety of behavior under their control, but also for the intensity and 'mind-altering' aspects of the induced states. Serotonin is involved in aggression, dominance, memory, mood, appetite, and sleep. Biologically, it is implicated in neurogenesis, movement, cell division, and apoptosis. Dopamine is directly implicated in addiction, pleasure, and repetitive motor activity. Noradrenaline has actions on all the

sympathetic responses in the PNS and CNS. The derivatives of these compounds, many found in plants, produce hallucinations and altered states of consciousness. To appreciate the spectrum and nature of these actions in human behavior, it helps to have an evolutionary perspective.

The aromatic neurotransmitters were found in very high levels in unicellular organisms and plants because of the availability of aromatic amino acids and oxygen. The aromatic amino acids were largely synthesized in plastids (chloroplast), which are the major organelles in the cells of plants and algae. Most proteins have an intrinsic UV fluorescence as a result of photoabsorption because of the aromatic amino acids in their structure, particularly phenylalanine, tyrosine, and tryptophan. Comparing the latter two aromatic amino acids, tryptophan has the higher fluorescence quantum yield, overshadowing markedly the emissions of the tyrosine. The amino acid tryptophan contains an indole backbone with a reactive pyrrole ring and absorbs light very effectively. Free tryptophan has characteristic fluorescence absorption at UVB (450–480 nm wavelength), and the fluorescence emission is in the range of UVA-blue light. This amino acid in proteins is needed for solar energy to drive photosynthesis in cyanobacteria, algae, and plants. The absorption of a UVB photon (energy of a photon of blue light of wavelength 450 nm = 2.76 eV) is equivalent to the energy of a hydrogen electron. Therefore, it appears that the primary photoionization pathway involves base ionization of tryptophan followed by deprotonation. The energy equivalent of solar energy conversion in photosynthesis involves electron transfer between an excited donor molecule and an acceptor molecule that are contained in the reaction center, an intrinsic membrane protein pigment complex. In the photosynthetic reaction centers of *Rhodobacter sphaeroides*, there are 39 tryptophan residues. The importance and abundance of tryptophan, as well as the catecholamines, have made these chemicals central to many cellular functions such as energy production and cytoskeleton stability that regulates cell mobility and cell division (Figure 7).

As cells began to produce large amounts of O₂, the formation of free oxygen radicals became a serious problem. The hydroxylation of aromatic amino acids removed not only a molecule of O₂, but also the aromatic amino acid. Over time, many of these aromatic amines became effective antioxidants and served to regulate the homeostasis of algae and plants.

When animals diverted from plants, the plant plastid organelle (chloroplast) was lost and with it the ability to produce aromatic amino acids. Animals could only survive if they were symbiotic to plants or algae or digest their material. The animals were still largely dependent on the aromatic chemicals, but now developed a new strategy for maximizing the effects from these compounds by evolving receptor molecules that could produce a metabolic response without metabolizing the neurotransmitter. The neurons developed global projections throughout the brain using the ancient forebrain bundles and the largely unmyelinated axons also traveled near blood vessels and in the ventricular space. The aromatic neurotransmitters were synthesized from products obtained in the target regions. They evolved reuptake proteins for retrieving any secreted aromatic amino acid and are able to transport chemicals made in the terminals back to the cell somas in the mid-brain and pons. Because of this extensive network and multiple receptors, the human brain has maintained a homeostatic role

Figure 7 This is a line diagram illustrating the close biological interactions between the aromatic amino acids in the production of neurotransmitters (serotonin and catecholamine) and hormones (melatonin and adrenaline). The key process of photosynthesis in producing oxygen and NADH in the biosynthesis of these chemicals is shown. The importance of chloroplast (plant plastid) and mitochondria organelles is illustrated. The hallucinogenic derivatives are included as these compounds are alkaloids and serve antioxidant functions in the algae and plant cells.

Figure 8 This drawing shows the central role of aromatic global neurons in the homeostasis of the brain. The various biological components that interact with these neurons are shown in small type and include vascular and digestive processes. The biological impact of these neurons can be seen on tissues from all three types of cells: endoderm, mesoderm, and ectoderm. The influence of these neurons affects CNS, PNS, and endocrine systems.

for aromatic neurotransmitters, despite an inability to synthesize the precursor amino acids. This is consistent with the early proposal of Brodie and Shore (1964). In their hypothesis, noradrenaline and serotonin modulated opposite systems in the brain on the basis of [Walter Hess's \(1949\)](#) concept of the functional integration of the autonomic system with the CNS. The PNS uses acetylcholine to mediate the sympathetic response and noradrenaline to mediate parasympathetic response. Serotonin was the modulator of the trophotropic system, which integrates behavioral patterns that are recuperative in nature. This was considered a recessive system, which normally functions during sleep or hibernation ([Figure 8](#)).

A new concept of consciousness proposes that the mind is an amalgamation of the actions of the PTP and global neurons. Therefore, not only do the aromatic amino acids serve homeostasis involved in cellular and behavioral processes, but deal with inner process of the mind. Many of the alkaloid and synthetic derivatives have mind-altering properties in humans. The actions of the aromatic amino acids in early life to capture solar energy may explain why decreases in aromatic

neurotransmitters in the human brain lead to feelings of worthlessness and suicidal ideation. In certain conditions, these states in humans are elevated by exposure to blue light. Brain chemicals are found in all the primitive cells, and the most interesting of these may be the aromatics.

Brainwashing and Totalitarian Influence

Glossary

Attitudes The evaluations, whether positive or negative, of social objects or persons, as linked to specific beliefs and ideas, and an alteration in this response based on exposure to new information or social cues.

Automatic thought Thought and association that occurs with little investment of mental effort, attention, and without the need for conscious control.

Conscious thought It is the processing of information in awareness versus without it.

Cult A group, usually of a religious or political nature, that tends to be all-consuming for members and is highly controlling of members' thoughts and actions, even if participation is voluntary.

Dissociative states Atypical states of consciousness with little or no self-awareness of one's own ordinary identity and that often accompany behavior that is atypical for the individual.

Heuristic processing This means responding to new information by taking recourse to simple, common rules (e.g., likeability = credibility) rather than engaging in careful systematic processing.

Hypersuggestibility It is the unusual suggestibility in one's own beliefs and actions to influence by the beliefs, actions, or commands of another.

Identity It is the person's own sense of self as an individual, and also in terms of his or her important relationships (relational identity) and identification with groups (social identity).

New religious movements These are new groups reflecting a nonconventional approach to religion and spirituality, not necessarily highly controlling and thus not precisely cults.

Systematic processing It is the conscious evaluation, integration, and weighing of new information.

Brainwashing can be defined, in succinct terms, as a process by which an individual's values, beliefs, and behaviors, usually of a religious or political nature, are systematically, intentionally, and forcefully compromised and replaced with those determined by another person by deceptive, manipulative, and coercive means. The term is most likely to be evoked when the brainwashing agent has the intention of totally controlling the other person, inducing him or her to engage in a sequence of actions at variance with the individual's prior beliefs, particularly in a relatively short time frame and with little awareness on the part of the person or preexisting familiarity with the change agent. The aim of brainwashing is to break down the individual's capacity for critical thought, systematic decision-making, and self-reflection involving long-held values, beliefs, preferences, and norms. At the same time, brainwashing remains sufficiently ill-defined that its existence is open to question.

The term brainwashing was first used by journalist and US intelligence agent Edward Hunter, who derived it from the Chinese term 洗腦 (*xǐ nǎo*), and popularized it through news articles and a book in the early 1950s. The term was purportedly used by a Chinese citizen, whom Hunter interviewed, to refer to reeducation experiences in Communist China, and although it was brought to the attention of Western society in a negative light, as a kind of mental rape of the person, adherents of Chinese Communism apparently viewed it in a more positive light, as a 'morally uplifting' process by which the person is freed from the grip of imperialist ideology.

Uses of the Term

Brainwashing has been applied to influence exerted by both small and large groups of people, including religious 'cults' and

political organizations, for example, Jim Jones' Peoples Temple movement in Jonestown where the mass suicide/massacre occurred in 1978, as well as one-to-one dyads, such as the case of Lee Boyd Malvo, the teenage sniper in the Washington, DC, suburbs in 2002. It has been termed a social weapon aimed at nonmainstream movements, such as religious 'cults,' or new religious movements. Legally, the concept has been evoked to defend the crimes committed by members of cults (or other kinds of groups) that allegedly employ brainwashing, as was presumed in the case of the members of Aum Shinrikyo, a Japanese group responsible for the 1995 Tokyo subway gas attacks.

Brainwashing is a concept commonly evoked by the media and the lay public to fill in gaps in their understanding of extreme experiences and transformations of individuals they care about as intimates, community members, or well-known individuals, including someone like Patty Hearst, the young American heiress kidnapped by the Symbionese Liberation Army in the 1970s who then confounded the public and police by proceeding to actively participate in a bank robbery with her captors. The term has been raised to try to explain any number of unconventional or hard-to-comprehend acts perpetrated by members of a particular group (e.g., by cult members), and as a label, it creates an illusion of understanding and delineates perpetrators relative to victims.

The concept has also been evoked to justify kidnapping and deprogramming of cult members who are loved ones and are presumed to have succumbed to untoward influence, and then this process is carried out with the aim of erasing the effects of the putative brainwashing and bringing the individual back into alignment with mainstream values, itself potentially a kind of brainwashing.

The Mythic Definition: Induced by Exotic Techniques

The most exotic techniques that laypeople assume are involved in brainwashing, whether severe exposure to drugs, sensory deprivation, or hypnosis, are often presumed to have the power to transform the human being into a programmed machine that enters dissociative states when cued by physical triggers (e.g., a code word) and will follow directives that would otherwise be refused based on individual identity and morality, and with no memory of doing so, as a kind of Manchurian Candidate. Although controversial at best, this definition of brainwashing involves exotic techniques that were purportedly developed, used, and researched by the erstwhile Soviet Union (e.g., revealed in the Moscow show trials of the 1930s), by German Nazi intelligence agencies in the Second World War, by China during the Communist Revolution and Korean War, by the Central Intelligence Agency (CIA) in research projects (e.g., MKULTRA) conducted after the Second World War, and by some religious or political cults. Since such activities tend to occur in secret, behavioral science researchers are generally not in a position to judge the veracity and comprehensiveness of the available accounts.

A distinguishing aspect of this definition of brainwashing seems to be its complete lack of regard for ethics, human rights, and the personhood of the individual, as evidenced by the extreme and sensational nature of the techniques used and their presumed results. The hallmarks are the complete control of thought and behavior that is sought, the direct harm to the recipient and to others, and the brainwasher's intent to use targeted individuals to engage in violent acts. The most vivid feature of such brainwashing is the intent of the brainwasher to systematically and persistently manipulate, through any available means, the individual's attitudes and behaviors to align them with the brainwasher's vision. Beyond changing the subject's attitudes and behaviors and achieving complete control over the individual, the goal can also be extracting secret information from a captive or creating a deployable agent who will carry out pro-organization tasks (e.g., a suicide attack) regardless of personal costs or moral or legal concerns. The results of the search for methods of brainwashing, defined as such, have at best been mixed.

These oft-discussed techniques include

- Pharmacological substances such as hallucinogens
- Hypnosis to produce dissociative states
- Physical exhaustion, sleep deprivation, heavy labor, withholding food and water, etc.
- Abuse and torture in the form of sensory deprivation, sensory overstimulation, extended confinement, spinning, supersonic vibrations, electroshock, lobotomy, extreme temperatures, cold-heat alternation, near-death experiences, oxygen deprivation, gasses, etc.
- Psychic driving (i.e., exposure to looped audio messages during drug-induced coma)

There is little doubt that efforts have been made to brainwash specific individuals using such procedures and to study the consequences of it. Existing evidence, however, does not support the claim that these efforts uncovered a set of exotic techniques that will render a person sufficiently robotic that he

or she can be programmed to carry out an elaborate sequence of actions without awareness, upon command, that he or she otherwise would not. This version of brainwashing, then, is essentially a myth. Such interventions in fact are better known for disorienting, disabling, or killing the person rather than effectively programming him or her to do one's bidding.

The Social-Psychological Definition: Coercive Persuasion Through Mundane Social Influences

Exercise of influence over the mental processes and behaviors of other individuals may be more profound and controlling when based on mundane social-psychological processes common in daily life (such as those typically employed by legitimate socializing agents like parents, the state, etc., and others in relevant social roles such as salespersons) than when reliant on exotic techniques. Although there is no consensually used term for this social-psychological understanding of brainwashing as contrasted with the mythic sense of this concept, the terms, coercive persuasion and mind control, are sometimes used to denote well-understood social influence processes that have been heavily researched in social psychology, as noted by Andersen and Zimbardo. The term coercive persuasion is the scientific term most commonly in use and we restrict ourselves to that term here. This conceptualization of coercive persuasion builds on classical work in social psychology, such as that of Asch, Sherif, Festinger, Milgram, and Zimbardo, whose research on conformity, compliance, obedience, the power of social roles, and cognitive dissonance is well known. Contemporary scientific research on social influence, persuasion, and attitude change is also central. For instance, Cialdini has identified numerous 'weapons' of social influence that can be considered the core aspects of coercive persuasion when used in combination and to an exaggerated extent, including use of a persuader who is an authority and is likeable, playing on norms of reciprocity, focus on the scarcity of the desired outcome, use of the social proof that 'everyone else is doing it, including those you trust,' and fostering a relevant commitment in order to tap people's need to respond consistently. These techniques are crucial in social influence and thus in coercive persuasion.

Whether this is an appropriate replacement for the otherwise mythic concept of brainwashing depends on the perceived goals of the brainwasher. For instance, Solomon has argued that the foundational techniques used by the Chinese should be distinguished from those used by the Russians because the former sought conversion, not mere compliance. In this view, the Chinese model may be better understood from a social-psychological perspective than from the perspective of the mythic brainwashing concept.

Social influence stems from the desire of a social system (e.g., a religious organization) to propagate itself, socializing recruits into its network of values and behavioral norms via systematic use of a combination of ordinary social influence tactics. An individual may choose to subject himself or herself to such tactics when he or she expects benefits such as in purchasing a used car or joining like-minded others for spiritual guidance and growth. However, when a social system, for various reasons (e.g., high ambitions and incentives for growth), comes to exert an unacceptable level of influence and control through the systematic and combined use of

nonexotic social-psychological influence techniques at exaggerated levels, this may be tantamount to coercive persuasion. Such influence techniques may be viewed as safe and legitimate under normal conditions, such as when used separately and at milder levels. Such coercive persuasion may or may not involve untoward, malignant intent or complete disregard for the rights of the target individual, unlike the more dramatic definition or version of brainwashing, which is virtually always considered to involve those factors and leads to no positive outcome for the individual.

While severe distress and duress would be a core aspect of brainwashing, coercive persuasion can proceed more subtly, relying exclusively on the psychological tactics. Through more subtle means of coercive persuasion, there is the potential to socialize the person into the organization in a way that leaves largely intact the individual's psychological integrity and his or her decision-making abilities, even while significantly limiting his or her personal freedom of choice and action.

Identifying Coercive Persuasion

When attempting to identify agents of coercive persuasion, a persistent problem is overcategorization of deviance from mainstream culture, religion, ethicality as involving untoward influence. When there is demonstrable harm to the individual or to society, however, the question of whether or not there is an intolerable control exerted over individual freedom, based, for instance, on the joint use of social-psychological techniques noted below, this can be a viable alternative. Coercive persuasion arises from a strong and uniform authority structure, and the elicitation of complete commitment by members, creating the potential for exploitation of individuals. When coercion and deception are also involved, the totalitarian aspects of the organization become increasingly evident. This may also be considered cult-like, though the use of this term, like brainwashing, is also fraught. Such an organization can be religious or political or may involve a dyadic familial structure, as with battered spouses.

Mundane influences on persuasion and compliance

- The illusion of common ground, that is, perceived similarity fostering the belief that the persuader (and other group members) shares the individual's values, needs, goals, etc., whether or not this is true
- Fostering a sense of belonging, acceptance, and relationship, appealing to the inner pressure to bond with others
- The illusion of free choice through offers to the individual of only prosystem choices, while legitimate options that do not fit the group's goals are omitted
- Limiting the information available (external sources of information), even as the individual is asked to choose freely
- Inducing complexity, uncertainty, and confusion via jargon, euphemisms, false analogies, rhetorical labels, semantic distortions, misleading abstractions, and so on to capitalize on the natural tendency to seek simple answers (e.g., from a strong leader or cohesive group, or simply for convenience), to engage in heuristic processing rather than reasoning critically
- Playing on norms about reciprocity (i.e., to reciprocate disclosures or gestures of another)
- Use of contingent social reward (e.g., love, support, emotional comforting) that depends on expressed beliefs and actions reflecting the preferred worldview or ideology
- Assigning the individual to one or more roles, ranks, or positions to bestow significance and guide behavior, possibly capitalizing on the tendency to take on a complementary social role (e.g., to become strong or the helper when somebody else is weak)
- Use of a step-by-step indoctrination strategy to render recruits unaware of the intended end results of the recruitment process
- Emotions, especially negative ones, like fear or guilt, induced, and then resolved, as when an insurance salesperson first makes the customer feel fearful and then offers the solution of an insurance policy
- Use of artificial pressures to create group unanimity (e.g., censoring, intolerance of diversity, discouraging questions), potentially resulting in groupthink, and poor decisions under the guise of consensus
- Restriction of communication and prohibition of certain linguistic expressions, in favor of a coded language, labels, or jargon
- Evoking reactance, as when a behavioral choice is presented as scarce and limited to only a select few, in order to induce the person to become more intrigued by it, desiring it more

Psychological coercion

In some combinations, social-psychological influence strategies can approach psychological coercion, if used systematically by the persuader, and hence, these are worthy of note as particularly controlling:

- Isolation of the individual from his or her usual social network and prior sources of social support
- Stripping the individual from familiar environments, symbols, and possessions that remind the individual of his or her identity
- Systematic induction of relatively intense psychological duress, whose simplest resolution is a further commitment to the group
- Division of the world into the 'good us' and the 'evil them,' and the dehumanization and possibly demonization of the other using facile, derogatory labels for outsiders
- Elicitation of confessions, potentially to obtain knowledge of the individual's deepest vulnerabilities, which can then be abused, possibly for blackmail
- Overstimulation by prosystem information (e.g., interactions or rehearsals with members, proselytizing activities, etc.)
- Exhaustion through extended labor and sleep deprivation
- Lack of or elimination of privacy
- Threat of sanctions for failure to adhere to the group view, whether subtle or overt
- Threat of psychological or spiritual punishment (e.g., to 'burn in hell')
- Threat of physical harm

The relevance of deception

The use of outright deception may also be present and exacerbate psychological coercion, making it most insidious. This can include

- Providing inaccurate information about the group in the form of overt lies about the group (e.g., via a front organization) or other misleading identification about the group presented to outsiders, for example, to potential recruits, family members of existing recruits, etc.
- Omitting crucial information about the group and its aims and activities.

Other factors

The groups or organizations that grab hold of an individual and exert special control over him or her may also enable persuasion by other factors, including

- The presence of a charismatic leader or guru, and referring to him or her as God or God-like
- The fostered belief that there is only one true authority (e.g., the group leader)
- Special appeals to individuals not anchored in social networks, who are alienated from society, and/or who feel excluded
- Love bombing (showering with love and praise).

Dyadic Coercive Persuasion

Coercive persuasion is not limited to groups. Spousal battery in marital relationships, for example, may make use of forms of coercive persuasion, by involving (1) verbal and/or physical dominance; (2) isolation or imprisonment; (3) fear arousal and maintenance; (4) guilt induction; (5) contingent expressions of 'love'; (6) enforced loyalty to the aggressor and self-denunciation; (7) promotion of powerlessness and helplessness; (8) pathological expressions of jealousy; (9) hope-instilling behaviors (that somehow the battering will end if...); and (10) required secrecy.

Coercive Persuasion in Organizations Involved in Terrorism

While coercive persuasion has often been discussed in the context of religious cults, and to a lesser extent, spousal abuse, the potential application of these ideas to terrorism is of special contemporary interest. In recent years, scholars have paid increasing attention to terrorism, especially in the Islamic world, following events such as 9/11 and the bombings in Madrid, London, and elsewhere. What is known about coercive persuasion has potential applicability to recruitment and training of individuals by extremist organizations, luring young people and readying them to conduct suicide attacks. Kruglanski and colleagues have argued that personal qualities (e.g., trauma, social exclusion, alienation, etc.) may heighten individuals' quest for personal significance and meaning. In the context of high levels of intergroup conflict and threat to the ingroup, terrorism-justifying ideologies may provide the means to restore significance and overcome death anxiety that stems from earlier traumas and lacking of a sense of belonging. Consistent with the foundational work of Lifton, Schein, and others, it is this

particular constellation of personal and social factors that may create vulnerability in the individual to the indoctrination techniques of terrorist organizations. Terrorist organizations are likely to make use of the same social-psychological influence strategies as other kinds of organizations do (see above) and to deliberately engineer their messages to fulfill the significant quest for potential recruits, seeking out individuals from the backgrounds noted (e.g., traumatized, alienated individuals). Like some religious groups, terrorist organizations may be led by a charismatic and megalomaniacal leader aiming to undertake spectacular acts.

Coercive Persuasion versus Ordinary Social Influence

The aforementioned techniques, used in moderation, may be common, if not ubiquitous, in modern society. However, when many social influence strategies are combined in extreme form and used systematically, this level of influence may constitute a qualitative difference that demarcates what is an acceptable level of relatively nonmanipulative social influence. This is akin to a mild versus severe exposure model, as in the example of radiation in which mild exposure can be tolerated well by the person (the body), whereas exposure from multiple sources over extended periods or in the extreme may result in cancer.

One reason that a combination of techniques results in a qualitatively different kind of social influence is their effect on attentional capacity. Robert Baron has argued, on the basis of social-psychological research, that the stress and emotional arousal that is a part of intense indoctrination experiences leads to significant decreases in attentional capacity, which in turn makes subjects highly vulnerable to social influence tactics. Research shows that factors that lessen attentional capacity increase (a) compliance, (b) heuristic (vs. systematic) message processing, (c) conformity, (d) stereotypical thinking, and (e) cognitive dissonance effects. For instance, individuals under intense indoctrination, even when they are motivated to do otherwise, should be less able (have less capacity) to process messages systematically (in the sense of Chaiken's attitude theory) and should be more influenced by heuristic qualities of persuasion and cues associated with heuristic processing. Minimally, the lure of engaging in relatively little thought (processing information automatically) without systematic deliberation is quite considerable in most situations, and further enabling this is not particularly difficult. Individuals under intense indoctrination should be more influenced by heuristic qualities in a persuasion context, such as the responses of others around them (who may be well-socialized members who have been trained to give a uniform response) and how confident or likeable the persuader appears, rather than critically scrutinizing the substance of the information provided. This kind of heuristic processing can lead to attitude change based on little conscious thought or deliberation, which is solidified later, for example through continued socialization into the group and reinforcing activities and discussions that enable the new information to be incorporated into aspects of one's own identity. Increased stereotypical thinking among indoctrinees suggests that individuals are easily led to endorse a stark 'us versus them' distinction and to have a fostered paranoia about outsiders and the outside world,

which the stereotyping measure may tap. Intense indoctrination situations increase conformity and reliance on authority, as manifested perhaps in the Stockholm Syndrome in which a captive becomes sympathetic to and collaborates with his or her captors.

Theories of Brainwashing

Foundational Work

The foundational research of Robert J. Lifton and Edgar Schein on Korean War prisoners of war (POWs) (and also those of others in the same era, such as Hinkle and Wolff) reached the conclusion that the Communists had no especially influential techniques at their disposal, and whoever among the POWs converted, defected, or refused repatriation (22 out of about 4500 American soldiers; none of the Turkish soldiers) under their influence did so either out of emotional and physical needs or due to prior ideological leanings. For instance, captors placed POWs under harsh conditions and rewarded them for their pro-Communist behavior by improving their conditions, such as giving them better food, blankets, and a more comfortable sleeping arrangement. While the behavior of some POWs changed to align with their captors' desire, for most of them, cognitive (e.g., beliefs, values) changes did not accompany. None of Lifton's and Schein's subjects actually converted to Communism, though a small number can be said to be influenced in the direction of their captors. It must be noted, however, that foundational research has been criticized for its small samples (e.g., $N = 40$ in Lifton's study). This foundational research attributed such influence (and conversion to Communist ideology, when it occurred) among POWs to personality characteristics that existed prior to the exposure to Communist messages and not to induced dissociation or to other more exotic factors.

Powerful social influence strategies are thus not particularly exotic, but rather, mundane in their influence on behavior and central to a social-psychological conceptualization of coercive persuasion. While early research did suggest a variety of potentially influential techniques, it also refuted an initial allegation by Hunter that a person's belief system can be completely replaced against his or her will by powerful, external influences. For this reason, both of the foundational researchers stayed away from the term brainwashing and instead used the term *coercive persuasion* (Schein) and the terms *thought reform* and *totalism* (Lifton). Despite this, the term brainwashing stuck in the public consciousness and continued to fuel paranoia about the Eastern bloc in the Western hemisphere, in the United States during the Cold War.

Foundational researchers like Schein also viewed thought reform or coercive persuasion in terms of stages such as unfreezing, changing, and refreezing (see also Kruglanski's work). Lifton in particular asserted eight stages of the process of thought reform and ideological totalism beginning with assault on identity and ending with final confession and rebirth. In particular, these proposed stages track well with techniques identified as influential earlier, and involve the following:

- Milieu control: Control of information and also internal dialog of the subject

- Mystical manipulation: Covertly orchestrating events while simultaneously making them appear spontaneous to argue for the special powers or divine status of the organization/leader
- Demand for purity: Imposing a dualistic view of the world in terms of us/them, good/evil, saved/damned, etc., and arguing that outgroups should be eliminated or otherwise prevented from contaminating the ingroup
- Cult of confession: Use of public confessions to destroy privacy and exploit the subject
- Sacred science: Imposing a view of organizational ideology as morally unchallengeable and scientifically exact
- Loading the language: Use of simple language (thought-terminating clichés) to reduce complexities regarding organizational ideology, thereby discouraging critical thinking and creating the illusion of group unanimity
- The primacy of doctrine over person: The view that nothing the person experiences can have more importance than, and potential to discredit, organizational ideology
- Dispensing of existence: The view that the organization has the right to determine the fates of its members and also its opponents.

Cultic Brainwashing Theory

A number of scholars, such as Singer and Ofshe (in the United States) and Abgrall (in Europe), have characterized brainwashing in the context of conversion to cults (and in related legal cases), and have referred to their approach as 'cultic brainwashing theory.' Owing to its tacit assumptions about personhood and free will, it has also been referred to as Robot Theory or the Involuntarist Theory of Brainwashing. While it references the foundational work of Lifton and Schein, its formulation is closer to the mythic definition of brainwashing than to the social-psychological definition. The gist of its understanding of brainwashing is that the unsolicited use of a set of techniques by cults on recruits can put the latter into disoriented or dissociative states of consciousness in which their capacity to make rational choices for themselves is vastly diminished or destroyed, and hypersuggestibility reigns that leads to the uncritical adoption of any propaganda imposed on them. The victim then may become addicted to the new set of beliefs programmed into his or her mind and thus may not be able to rationally contradict these beliefs unless deprogrammed by experts. Such brainwashing is assumed to be irresistible and potentially irreversible, and this is the approach that has been central in the anticult literature and movement, although empirical evidence for it is lacking and it has been roundly criticized.

Primitive states of consciousness (e.g., the dissociative, the hypnotic) were not central to or a part of Communist indoctrination and thus, the foundational researchers accorded no special role to them. The foundational researchers also recognized more complexity in human behavior and thus offered a 'soft determinism' rather than an exotic model in which human beings can be transformed into tools or robots ('hard determinism') by means of hypnosis. As criticism of the cultic brainwashing theory, scholars like Robbins and Richardson have argued that there is little evidence of any special illegality of religious 'cults' in terms of unacceptable means or levels of

influence (e.g., physical coercion) or other illegality, that these are protected under the First Amendment, and that the theory ignores findings showing that participation in some unconventional religious movements is beneficial to the well-being of recruits. These authors also argue that the theory overemphasizes and makes overly broad claims about hypnosis and its influence in the light of research that has discredited the notion that hypnosis can be used to obtain complete control over an individual's behavior, that it underemphasizes predisposing characteristics of religious converts, and that the recruitment process is typically entirely volitional (voluntary). Indeed, Richardson argues that parents, fraternities and sororities, marine boot camp, and juvenile detention halls – all use isolation for attitude and behavior change, so even the more dramatic strategies are not unprecedented. Use of such strategies, as in preventing a recruit from being exposed to dissenters, should thus be treated as no more problematic than a car salesman preventing a customer from talking to someone who previously refused the same offer, the great deal. Some argue then that cultic brainwashing theory is not a proper scientific theory in that it is ambiguous, internally contradictory, and not falsifiable.

Other scholars have sought to study brainwashing from a more scientific perspective. For example, Zablocki has argued that both those who claim that there is a pandemic of brainwashing and those who claim that brainwashing does not exist at all are both incorrect, and has attempted to construct a precise and falsifiable definition of brainwashing, reviewing ethnographic evidence on cults and interviews with ex-members and leaders to support it. This approach has been strongly criticized as well by anticultic brainwashing scholars, though Zablocki argues that ignoring the situation of former members of cults who were psychologically and/or physically harmed prioritizes legal proceedings and concerns about religious liberty over scientific study.

Activist View of Conversion: Eschewing the Brainwashing Concept

Based on such criticism, Richardson offered a view of the recruitment and conversion as an interactive negotiation, drawing heavily on Moreland and Levine's work on socialization in small groups. Other scholars, mostly sociologists of religion (vs. mental health professionals), support such a view. The main contrast between passivist views (such as cultic brainwashing theory) and the more activist (subject-centered) view of conversion is that the individual's capability to act autonomously and make choices to advance his or her own goals is intact and not entirely compromised, though it may be manipulated to whatever degree. This includes the active seeking of recruitment and the ability to withdraw from the group. The group is not seen as omnipotent. The group can also choose to withdraw from the effort to recruit the individual or may kick existing members out. The levels of commitment of individual to group and group to individual fluctuate over time, and recruits can exert minority influence on the group once they are members. This offers a more balanced view of a greater proportion of recruit-group interactions as may occur in non-traditional religious movements that does not take recourse in the brainwashing concept.

Difficulties with the Scientific Study of Brainwashing

There are a number of difficulties with the scientific study of brainwashing whether defined in mythic or social-psychological terms. The concept has suffered from loose definition as well as distortion in the mass media, in popular culture, and in political propaganda. As a result, its definition is less coherent and less widely agreed upon than is the case for other scientific constructs, and its scientific status is debatable. Some scholars have thus suggested that the concept be abandoned. Concepts at the heart of the brainwashing debate are themselves controversial, such as the nature of free will, consciousness, dissociative states, and the definition of pathological. Relatively few solid theoretical advances have emerged since the so-called foundational theories of brainwashing (such as Lifton's and Schein's) were developed, and these foundational theories themselves are often misinterpreted or presented in misleading ways. As a result of court cases making reference to brainwashing and in which a binary decision needs to be reached, scientific attempts to answer questions about brainwashing have also taken on an either/or flavor (e.g., Does it exist or not? Is it effective or not? Do religious movements use it or not?), whereas the answer to most pertinent questions along these lines is likely to lie in the gray area as with every other reasonable scientific question.

Because brainwashing cannot be created in the laboratory, for obvious ethical reasons at minimum, direct scientific evidence pertaining to it is scant. There remains no consensus on how to determine whether or not a person has been brainwashed, making the concept highly problematic to assess. For example, determining through interviews whether or not an individual who joined a movement did so by consent will be highly problematic after the individual is already a well-socialized member of the group. Indeed, some scholars have argued that the more successful the brainwashing is in any given case, the fewer the symptoms the person should show, making assessment all but impossible. Further, if brainwashing is thought to be psychologically damaging, those who were allegedly brainwashed may be seen as lacking psychological integrity and credibility. And, even if not psychologically compromised, a person who has had negative experiences in a religious group and thus exits the group may be motivated to go against it or even to take revenge on it, thus making evaluation of the veracity of their accounts highly problematic. Sound evidence on the matter thus clearly calls for longitudinal (pre-post) data collection, and yet it remains unclear how researchers should know in advance whom to follow based on the individual being likely to join such a movement.

Scholars interested in the brainwashing concept have tended to focus on movements that have clearly harmed individuals, such as Aum Shinrikyo, People's Temple, Heaven's Gate, Solar Temple, and Charles Manson's group, whereas those opposing the use of the brainwashing concept have tended to focus instead on movements that obviously contribute positive value and innovation to society. The difficulty in establishing a scientific consensus on the brainwashing concept is evidenced by the rejection, in 1987, of the report of the American Psychological Association's (APA) Task Force on deceptive and indirect techniques of persuasion and control (DIMPAC) by APA's board of social and ethical

responsibility for psychology (BSERP) on the basis that it did not provide sufficiently rigorous and evenhanded analysis of the issue.

Conclusion

Brainwashing is a sufficiently ill-defined concept that it may not be scientifically useful. There is a lack of evidence for it in its mythic form which is presumed to rely on exotic techniques and to lead surreptitiously to total control. Even half a century ago, the foundational researchers in this area eschewed the term brainwashing for good reason. Instead, the most fruitful approach has been to examine mundane but powerful social influence processes, which may, under some circumstances, take an extreme form in a particular social group or organization, whether religious, political, or otherwise, or even in a dyadic relationship. An alternative term sometimes used, rather than brainwashing, is coercive persuasion or thought reform, with grounding in basic social influence processes and factors that have an impact on human thought processes and persuasion, and the operation of which is well understood on the basis of the science in social psychology.

Bulimia Nervosa

J E Mitchell, K Steffen, T Ertelt, and J Marino, University of North Dakota, Fargo, ND, USA

© 2012 Elsevier Inc. All rights reserved.

Glossary

Binge eating Consuming a large amount of food in a short period of time accompanied by a sense of loss of control.

DSM-IV The 4th edition of the Diagnostic and Statistical Manual of the American Psychiatric Association.

Eating disorders not otherwise specified (EDNOS) An eating disorder that is clinically significant but does not meet criteria for anorexia nervosa or bulimia nervosa.

Incidence New cases per period of time.

Pharmacotherapy Drug treatment.

Prevalence Total cases at any given time.

Introduction

Bulimia nervosa (BN) involves three behavioral and cognitive components: binge eating, inappropriate compensatory measures, and body image disturbance. Binge eating is defined as (1) eating a large amount of food in a discrete amount of time which would be atypical of others in similar circumstances and (2) a sense of loss of control during these eating episodes. Binge-eating episodes are often followed by a negative emotional state, and often occur in response to stressors or after a period of fasting. The food consumed during binge-eating episodes is usually high in calories and often has fat content, for example, sweets. Research also suggests that the disorder has a significant financial cost (i.e., \$1599.45 per year in the United States) associated with purchasing the food that patients consume during their eating episodes.

Compensatory behaviors can involve multiple methods including vomiting; laxative, diuretic, or enema misuse; fasting; or overexercising. DSM-IV suggests that binge-eating and purging behaviors occur in combination and at least twice weekly for 3 months. Body image disturbance is defined such that self-evaluation is unduly influenced by body shape and weight. These symptoms must not occur during the course of anorexia nervosa (AN), which is marked by maintenance of low weight.

BN can be specified in two ways: purging and nonpurging. Purging behavior includes vomiting, and misuse of laxative, diuretics, or enemas. Nonpurging BN is diagnosed when the patient only engages in fasting or overexercise.

BN includes ~25.5% of outpatient eating-disorder (ED) diagnoses. Many ED patients tend to fall into the ED not otherwise specified (EDNOS) category, as many patients' symptoms do not meet the full criteria for BN. EDNOS is the most common ED diagnosis, constituting nearly 60% of outpatient ED cases. Given this large grouping which lacks specifying detail, many clinicians and researchers are looking to the DSM-V to define the diagnostic criteria for subgroups of EDNOS. A future direction for the next edition of the DSM may be to operationalize the amount of food needed to define an 'objectively' large binge-eating episode. Some ED patients report experiencing 'subjective' binge-eating episodes, wherein the amount of food consumed is not necessarily considered larger than what others would eat (e.g., two cookies); however, the patient reports a feeling of loss of control during the consumption of the food. Further research is needed to better

understand the caloric differences between objective and subjective binge-eating episodes. Additionally, recent attention has been paid to 'purging disorder,' which is similar to BN but is marked by compensatory behavior in the absence of objectively large binge-eating episodes. Limited research has explored this disorder, which is currently classified as a form of EDNOS.

Clinical Characteristics

BN most often occurs in females (i.e., 90%), although a research literature has developed on males and eating disorders. EDs have generally been studied, and likely are most prevalent in western cultures. Research has suggested, however, that the cultural bias on thinness is impacting other regions of the world as Western influences become more prevalent. Individuals suffering from BN are typically of normal weight. Patients can experience comorbid substance abuse, especially alcohol abuse, mood disturbance, anxiety disorders, and personality disorders.

BN often first appears during adolescence or in the early 20s. Patients tend to begin restricting food intake, which is followed by episodes of overeating and subsequent purging. These behaviors become cyclical. As mentioned, the binge-purge cycle appears to become a means to cope with negative emotional states. The most commonly used method of compensating for binge eating is vomiting, which can occur somewhat effortlessly after recurrent vomiting. Oftentimes, the pattern of purging can lead to medical complications such as electrolyte imbalances, edema, and dental complications such as erosion of dental enamel. Laxative abuse can engender various gastrointestinal complications. Given the sometimes chronic course of BN, ongoing medical complications can occasionally become life threatening.

Epidemiology

The DSM-IV estimates the prevalence of BN to be between 1 and 3% for women and between 0.1 and 0.3% for men. As numerous epidemiological studies have indicated, the prevalence and incidence of BN and its subthreshold variants are considerably more complicated issues. There have been a

number of significant difficulties and methodological limitations inherent in studying the epidemiology of EDs, including the relatively low prevalence of eating disorders in the overall population and the general reluctance of individuals affected with EDs to seek professional help. Considerations of this nature must be taken into account when discussing epidemiological issues in BN.

The incidence of BN has been estimated in several studies in industrialized nations. In the United States, the incidence of BN has been estimated at 13.5 affected individuals per 100 000 people for the period between 1980 and 1990. An incidence of 12.2 per 100 000 was observed in the United Kingdom in 1993 by Turnbull and colleagues.

Several prevalence studies of BN have also been conducted in industrialized nations. Fairburn and Beglin in 1990 provided the generally accepted prevalence of estimate of 1.0% when taking into account BN as it was defined in DSM-III, DSM-III-R, and Russel's original description in 1979. Kendler and colleagues in 1991 reported a lifetime prevalence of the narrow BN phenotype at 2.8% in the United States. In 2006, a replication of the National Comorbidity Survey reported in a paper by Hudson and colleagues a lifetime prevalence of 1.5% for women and 0.5% for men and a point prevalence of 0.5% in women and 0.1% in men.

In addition, it is important to consider individuals affected by subclinical variants of BN when discussing epidemiological issues. The prevalence of subclinical BN is ~3–4 times that of full-syndrome BN.

Longitudinal Course

The course of BN is highly variable. One-quarter of individuals with BN who do not receive treatment still improve, while upwards of 70% who are treated respond. Literature has suggested that there may be considerable crossover among AN, BN, and EDNOS. In fact, it is likely that many individuals fluctuate between these disorders, and in the severity of their psychopathology. Research generally has focused on full-threshold disorders (e.g., AN and BN). However, it has been suggested that AN and BN may in fact exist on a continuum with EDNOS. Indeed, patients with AN often cross over to BN. Although BN patients can also cross to AN, it is less common. Periods of symptom remission are also possible. For example, research suggests that nearly 30% of BN patients and 12–30% of patients with EDNOS resembling BN or purging disorder had a previous diagnosis of AN. Most women who transition to AN from BN appear to meet criteria for AN-B/P, and fewer transition from AN-R. It appears most likely that patients with BN tend to fluctuate to partial remission or full resolution of symptoms. These changes in diagnostic classification and in symptom severity speak of the importance of continued monitoring of symptoms and assessment of treatment effectiveness throughout the course.

Psychotherapy

Cognitive behavioral therapy (CBT) is generally considered the treatment of choice for patients with BN. The treatment can be

delivered in either group or individual formats. Recently, the NICE guidelines in the United Kingdom assigned the grade of A for CBT for BN, attesting to the efficacy of this treatment. Interpersonal therapy (IPT) has also been monitored in two large studies, and although the effectiveness is substantial, the therapy appears to take longer to have an effect. From a theoretical standpoint, this is quite interesting. IPT was developed to be used as a maintenance treatment for depression and does not include a focus on the specific symptoms of BN. A third treatment, which has also been modified from its original application for use with ED patients, is dialectic behavior therapy (DBT). This therapy was originally given to patients with self-injurious behavior and suicidality but has subsequently also been shown to be effective in BN. While CBT focuses on specific bulimic behaviors and IPT focuses on interpersonal relationships, DBT focuses on both behavioral change and self-acceptance. Several other treatments have been suggested in the literature but have not been empirically validated.

Unfortunately, the treatment of choice, CBT, often results in low rates of complete remission, usually in the range of 30–40% in most studies. For this reason, increasing emphasis is being placed on the development of new therapies. One such therapy is an enhanced form of CBT (CBT-E) developed by Fairburn, Cooper, and Shafran at Oxford University. This therapy expands on the existing form of CBT to embrace four additional domains that are assumed to be maintaining mechanisms: clinical perfectionism, interpersonal difficulties, low core self-esteem, and mood intolerance. This therapy is designed to be transdiagnostic and may be used for patients with any ED. Another new therapy developed at the Neuropsychiatric Research Institute and the University of Minnesota also appears promising. This therapy, called Integrative Cognitive-Affective Therapy (ICAT), expands on traditional CBT by placing greater emphasis on cultural factors, self-oriented cognitions, interpersonal schemas, interpersonal patterns, and emotional experience.

CBT rests on the cognitive view of the maintenance of BN, which assumes that low self-esteem generates extreme concerns about weight and shape; this leads to strict dieting which subsequently leads to binge eating and then to self-induced vomiting. Each level of this cascade then feeds back on the other levels. Traditional CBT is delivered in 20 sessions over 16 weeks with twice-weekly appointments in the initial month. There are generally three treatment phases. The first 8 sessions focus on explaining the rationale for CBT and replacing binge-eating behavior with a stable eating pattern. The second treatment phase, from sessions 9–16, continues to focus on behavioral strategies but also focuses on cognitive issues, including an examination of all forms of 'dieting,' weight and shape issues and cognitive distortions, and includes training in behavioral problem solving. The third phase, from sessions 17–20, focuses on relapse prevention. There is a strong emphasis on self-monitoring in this treatment.

Pharmacotherapy

The first report of pharmacotherapy as a treatment method for BN appeared in 1983, 4 years after Gerald Russell first

described the condition. Over the last 30 years, several pharmacological agents have been shown to have efficacy for BN, beginning with early trials with tricyclic antidepressants (TCAs) and continuing through more recent trials with the antiepileptic drug topiramate. Despite the presence of positive efficacy data with several classes of medications in BN, significant room for improvement in the pharmacological treatment of this disorder remains, as remission rates are low, often only around 10–15%.

Typically, patients with BN fall within the normal weight range and are likely to have at least one comorbid psychiatric condition. For example, approximately half the patients with BN have a lifetime diagnosis of major depressive disorder. In addition to targeting the recurrent binge eating and compensatory mechanisms that characterize this condition, pharmacotherapy trials have also investigated the impact of medication on comorbid psychopathology and body weight.

A number of placebo-controlled trials of TCAs were published in the 1980s and early 1990s, including imipramine, desipramine, and amitriptyline. With a few exceptions, the results of these trials demonstrated the ability of TCAs to reduce the frequency of binge eating in patients with BN. A secondary outcome measure in many of these studies was a reduction in depression symptoms. The TCAs generally, although not always, led to a significantly greater reduction in depression symptoms relative to placebo.

Despite research showing overall favorable efficacy with the TCAs, tolerability was not optimal. With varying degrees of potency, the TCAs act as antagonists at muscarinic, α -1 adrenergic, and histamine-1 receptors. These pharmacological attributes can generate adverse effects including anticholinergic effects (e.g., dry mouth, urinary retention, and constipation), orthostatic hypotension, sedation, and weight gain. These drugs are also known to have serious or fatal consequences in overdose. Also beginning in the mid-1980s, several controlled trials with monoamine oxidase inhibitors (MAOIs) were reported. Later, the selective, reversible MAOIs brofaromine and moclobemide were investigated. Neither of the latter two MAOIs are currently available in the United States. Similar to the TCA trials, most, although not all, of the placebo-controlled MAOI trials demonstrated efficacy for reducing the frequency of binge eating. Also in similarity to the TCAs, the MAOIs have unique tolerability and safety concerns. While the TCAs and MAOIs may remain effective and appropriate options for selected patients, the marketing of the first selective serotonin reuptake inhibitor (SSRI), fluoxetine, in the late 1980s resulted in a shift toward the use of newer antidepressant medications for BN.

Investigations shifted to the SSRIs in the 1990s. The US Food and Drug Administration approved fluoxetine 60 mg day⁻¹ for BN treatment. Romano and colleagues examined whether fluoxetine could prevent relapse in BN following successful acute treatment. Although the data were positive, the study suffered from a high drop-out rate.

Two novel treatment approaches, ondansetron and topiramate, have also been investigated in controlled trials over the past decade. Ondansetron, a serotonin-3 receptor antagonist used for the prevention and treatment of nausea and vomiting, was shown to significantly reduce binge-eating and vomiting episodes in a 4-week, placebo-controlled trial at a daily dose of 24 mg, divided into six 4-mg doses.

Topiramate, an anticonvulsant medication with a complex mechanism of action, has been examined in two 10-week, placebo-controlled trials for BN. Results from both these trials showed a reduction in binge-eating and purging frequency along with a reduction in body weight with topiramate relative to placebo.

Interspersed throughout the timeline of the previously discussed studies were trials that examined an assortment of other compounds. Results from clinical trials with the opioid receptor antagonist naltrexone have been mixed. Rebexetine, a selective norepinephrine reuptake inhibitor that is not currently available in the United States, has been reported to reduce symptoms of binge eating, vomiting, and depression in a small case series and subsequent uncontrolled pilot study. A variety of other medications have also been explored in BN, including D-fenfluramine, flutamide, phenytoin, an anti-androgenic oral contraceptive, spironolactone, and methylphenidate. Concerns over efficacy, safety, tolerability, or the need for additional data exclude these compounds from routine clinical use for the treatment of BN at the present time.

Although pharmacotherapy trials for BN have consisted of a variety of medications and have often resulted in positive efficacy data, the majority have been of short duration. For many of these medications, it is unclear whether improvements gained during the acute treatment are sustained over a longer duration of treatment.

Psychobiology

EDs in general and BN in particular in our discussion here are probably best considered as examples of gene–environment interactions. Clearly environmental factors are important, but the available study suggests a strong influence of genetic factors for the liability for this disorder. Relative to specific genetic risk factors, seven linkage regions have been identified in genome-wide screens of patients with AN and BN, but no consistent association between a candidate gene and BN has been identified. These problems can be overcome only with larger genetic association studies involving multicenter collaborations. Also, the heterogeneity of eating disorders (ED) phenotypes represents a major problem, and it will be necessary for future studies to focus on more homogenous groups using selective phenotypes and perhaps focusing on specific ED traits. Also, there is some interesting work suggesting poor treatment response in patients with bulimic syndromes who have low functioning alleles of 5-HTTLPR and -1438 G/A, suggesting hereditary factors involving the serotonin system. Relative to the psychobiology of BN, several areas have developed over the last few decades. One such area has been an examination of baseline concentrations and physiological responses of various gut peptides in patients with eating disorders. This work has been recently reviewed. Results in these studies have been somewhat inconsistent as have the conclusions that have been drawn from these studies. Some results suggest elevations in gut peptides such as ghrelin, PYY, and cholecystokinin. Others have not replicated these findings. There has also been an interest in examining biogenic amines and their metabolites in various bodily fluids. Also various brain imaging techniques have been used to examine possible structural and

functional changes in the CNS including magnetic resonance imaging, positron emission tomography and single photon emission computed tomography. CT studies have generally found some evidence of decreased cortical mass in patients with BN. There have also been studies in general showing the significant correlations between measures of harm avoidance and binding for the 5HT_{1A} and 5HT_{2A} D2/D3 receptors in certain brain areas such as the mesial temporal lobe, and harm avoidance appears to be elevated after recovery from BN. There also appear to be interesting changes in frontal striatal circuits across multiple childhood psychopathologies including BN as well as altered striatal responses to reward in recovered women with BN.

Conclusions

BN is a prevalent, serious, ED among young women. It can be associated with serious medical and psychosocial complications. Many patients with BN have other psychiatric problems. Antidepressant drugs improve the symptoms of BN. However, CBT appears to be more effective and is the treatment of choice. Both genetic and environmental factors play a role in the etiology of this disorder.

Glossary

Bully/victim continuum Bullying behaviors are depicted on a continuum of four behaviors: bullying, victimization, experiencing both, and watching bullying occur.

Bullying A relationship that occurs between two or more individuals, with repeated interactions characterized by an imbalance of power and the intent to harm.

Cyberbullying An individual or a group willfully using information and communication involving electronic technologies to facilitate deliberate and repeated harassment or threat to another individual or group by sending or

posting cruel text and/or graphics using technological means.

Dating aggression Physical, sexual, and/or emotional aggression carried out by a dating partner.

Direct behaviors A form of bullying that includes behaviors that are overt, usually involve a face-to-face interaction, and can be either physical or verbal.

Indirect behaviors A form of bullying that includes behaviors that are covert, possibly relationally aggressive, including cyberbullying.

Intimate partner aggression Physical, sexual, and/or emotional aggression carried out by an intimate partner in the context of control.

Definition

Bullying is most commonly defined as any form of aggression in which one or more individuals repeatedly verbally or physically harass a victim without provocation. According to the American Psychological Association, bullying is persistent, threatening, and aggressive behavior directed toward others, especially those who are smaller or weaker. There are three common characteristics found in most definitions of bullying: (a) an imbalance of power, (b) the intent to harm, and (c) the display of repetitive behavior. An imbalance of power is stereotypically characterized as a physical issue, with the bully being much larger and stronger than the victim. While this is the stereotypical image of bullying, an imbalance of power can also include characteristics such as intellectual ability, social status, or social prowess. To illustrate this issue, consider the example of a high school senior who is physically shorter and weaker than a high school freshman; however, the freshman does not believe he can defend himself because he is an underclassman. Because of the senior's greater social status, he is able to repeatedly make the freshman stand in a hallway trashcan. Thus, the senior's behavior is considered as bullying, despite his physical size.

The behaviors that constitute bullying can be divided into two forms: (a) direct behaviors and (b) indirect behaviors. Direct behaviors are more overt, can be both physical and verbal, and involve face-to-face interactions between the bully and the victim (e.g., hitting, shoving, and calling names). Indirect bullying behaviors can be relationally aggressive, are typically covert in nature (e.g., spreading rumors, excluding someone from a group), and can also include cyberbullying (e.g., bullying through technology such as cell phones and computers). The underlying factor distinguishing direct forms of bullying from indirect forms is whether or not there is a face-to-face interaction between the bully and the victim.

Bullying behaviors exist on a continuum and are not permanently set in fixed roles in individuals. There are four

behaviors along the bully/victim continuum: (a) bullying, (b) victimization, (c) experiencing both (bullying-victimization), and (d) watching bullying take place. Bullies are those individuals who exhibit only bullying behaviors, while victims are those who are targeted by bullies. Bully-victims are those individuals who both bully others and are bullied by others. Relative to only bullies or only victims, bully-victims are typically more impulsive, have greater difficulty regulating their emotions and reactions, and experience the greatest psychological impact from their involvement in the bullying continuum. Bystanders are those who witness bullying but are involved neither as a bully nor as a victim. Individuals involved in bullying may move between roles or hold multiple roles on the bully/victim continuum. Thus, bullying/victimization should be considered a dynamic, evolving experience, and not a static, fixed experience.

Prevalence

Bullying is a worldwide phenomenon. Studies have shown that bullying behaviors exist with similar prevalence rates across countries (e.g., Australia, United States, Japan, Italy, the Netherlands). Bullying occurs in rural and urban populations, across social classes, large and small schools, single-sex and coeducational schools, romantic relationships, and the workplace. In short, bullying is an issue that is present in the majority of the world. Although the fact that bullying exists is clear, the determination of reliable and valid prevalence rates of bullying is more difficult.

The prevalence rates of bullying in schools vary based on the definition and methodology used in the research. One of the largest samples of bullying behavior in the United States found that, of 15 686 students in grades 6 through 10, 13% reported frequent involvement as bullies, 10.6% as victims, and 6% as bully-victims for a total rate of 29.9% for frequent involvement in bullying. However, when examining students

who were bullied 'regularly,' a separate study found victimization rates to be between 5% and 9%. Participants across cultures or countries may also report differing prevalence rates. In Australia, for example, within a sample of 2680 students with an average age of 13, 33% of students reported being bullied at one time. A study of over 5000 Swedish students, however, found that 20.2% were repeatedly victimized every month. Cultural differences may partially explain the differences in prevalence rates found between countries. For example, Japan is considered to be a more collectivist country compared to the United States and the topography of bullying is influenced by this cultural difference. In Japan, bullying is referred to as 'ijime' and is rarely a one-to-one interaction. The majority of bullying incidents that occur in Japanese schools involve multiple students directly or indirectly bullying an individual student. Given these differences, perhaps it is not surprising that such different prevalence rates have been found across studies.

At this time, there is no universally accepted method for measuring bullying. The most common methods used for measuring bullying behaviors are self-report from students, teachers, and parents, direct observations, and teacher and peer nominations. Each method has strengths and limitations, making it difficult for one method to be considered the 'gold standard.' Additionally, other factors can influence reported prevalence rates. For instance, some studies assess relational bullying, while others only examine more direct behaviors such as hitting or name-calling. Despite the differing cultures, methodologies, and definitions, the overall range of prevalence rates in the majority of research on bullying suggests that bullying is an important issue.

Development

When examining bullying across students' school career, we see that it typically increases at the end of elementary school (grades 4 and 5), peaks in the middle school years (grades 6–8), and begins to decline in high school (grades 9–12). Despite this developmental trend, research on the bullying behaviors of younger children (under age 6) and adults is less abundant. The method of bullying may also change depending on the age of a student. In earlier grades, bullying is typically more direct and physical, while relational bullying increases as students progress through school. Furthermore, as children become more cognitively and socially mature, the topography and methods they use to bully others change.

Although the majority of research begins measuring bullying in middle childhood, bullying behaviors have been found as early as preschool. Relative to older students, preschoolers show higher rates of physical aggression. This is often explained by the lack of social skills and problem-solving abilities children have at younger ages. Supporting this argument is the finding that at the beginning of the school year, preschool children typically show increased rates of physical and verbal aggression, which decline over the year. Relational bullying does occur during preschool, but it is less frequent and more direct than in older children (e.g., 'You can't play with our group unless you give me your toy'). Preschool bullying behavior has also been linked to future behavioral problems. More

specifically, preschool children who bullied others were more likely to be diagnosed with Conduct Disorder in adolescence. This suggests that as early as preschool, children engage in bullying behaviors, and the effects of those experiences are carried forth into adolescence.

As students enter middle school, the topography of bullying begins to change. By middle school, bullying tends to become more covert and relational. A student might replace the overt physical bullying behavior of hitting with the more covert behavior of spreading rumors. As students enter early adolescence, their social group is increasingly used for emotional support. Thus, bullying behaviors target these social areas as they are important for adolescents. It is also during this time that cyberbullying becomes more prevalent. As parents give their children more independence and privileges (e.g., cell phones, less restrictive Internet access), the opportunity for bullying increases. Additionally, romantic relationships begin to play a role in the experience of bullies at this time. Bullies have been shown to begin romantic relationships earlier than students not involved in bullying. While bullies begin dating earlier, and in more advanced forms, they also report less emotional support in their relationships. On the basis of this research, bullies appear to be at a greater risk for developing unhealthy romantic relationships (e.g., domestic violence and sexual harassment).

During middle to late adolescence, bullying behaviors once more begin to change. Physical bullying becomes even less frequent as the consequences for physical aggression become more severe. With the increased cross-sex interactions that occur during adolescence, a new context for bullying emerges. For example, in high school, rumors may be spread that a female student is pregnant. While these types of bullying behaviors do occur in earlier grades, it is during high school that they become more prevalent. Also during this time, and into adulthood, bullying behaviors may transfer into romantic relationships. Research has suggested, for example, that bullying may turn into sexual harassment as students become more aware of their own and others' sexuality. Additionally, bullying in the workplace does occur, although less frequently than during the primary and secondary school years.

Impact

The experience of being victimized has been found to be associated with a wide range of consequences. Children who are victimized by their peers have been found to show more internalizing (e.g., anxiety and depression) and externalizing (e.g., delinquent and aggressive behaviors) problems. Similarly, adolescent victims have reported more trauma symptoms, a higher rate of substance abuse, lower levels of self-esteem, poorer health, and higher rates of suicidal ideation. The experience of being a victim of bullying may be linked to students' decisions to carry out physical attacks, and even lethal attacks. Clearly, there are a variety of negative, even potentially fatal, short- and long-term effects of bullying. However, the adverse effects of bullying may be dependent on the type of victimization one experiences. It has been found, for example, that students who experienced verbal victimization, physical victimization, or sexual harassment had a higher risk of

experiencing behavioral problems, while being relationally victimized was not associated with these negative effects.

Research has shown that individuals who bully are also at risk for adverse effects. Both bullies and victims of bullying have been found to be more likely than their nonbullying peers to experience depressive symptoms. Additionally, students who bully others have shown higher general misconduct in a variety of settings, greater levels of impulsivity, significantly greater levels of anger, and more feelings of depression compared to peers who do not bully. Such negative effects may be even more pronounced for students who are bully-victims, as one study found that such students were significantly more likely to show symptoms of depression compared to their peers who bullied, were victims, or were not involved. In fact, compared to other groups, bully-victims were four times more likely to lack a positive self-image and three times more likely to report feeling insecure within the school setting.

Research suggests that negative psychosocial outcomes exist for those individuals who bully, those who are victimized, and those who are bully-victims. The same appears to be true for bystanders. One study found that adults who witnessed workplace bullying were more likely to suffer poor mental and physical health compared to employees who neither experienced nor witnessed workplace bullying. Additionally, a recent study found that people who had witnessed a great deal of bullying in their youth reported clinical levels of distress and psychological trauma similar to the levels exhibited by people who had witnessed catastrophic events such as earthquakes. This evidence is used to support the claim that if bullying was truly a normal, natural part of growing up, it would not result in such devastating levels of distress and psychological trauma. Thus, it is clear that bullying can cause serious harm to all the parties involved, even to those who 'simply' witness the bullying incident.

Gender Differences

At this point of time, there is little consensus regarding whether or not boys and girls differ in the frequency with which they bully. After analyzing seventh- and eighth-grade students' responses to questionnaire items assessing the frequency with which they bullied, one study found that males were significantly more likely to bully others than their female peers. However, Crick and Grotpeter found that approximately equal numbers of boys and girls (27.0% and 21.7%, respectively) were classified as aggressive, meaning that they engaged in some type of bullying. Therefore, it is not clear whether boys and girls bully at similar rates.

Furthermore, it is not clear whether boys and girls use different types of bullying with similar frequencies. When measuring overt types of aggression, which included physical and verbal aggression, Crick and Grotpeter found that 15.6% of boys but only 0.4% of girls were classified as overtly aggressive. In addition, when examining relational aggression, defined as attempts or threats to harm another's peer relationship, 17.4% of girls but only 2.0% of boys were classified as relationally aggressive. Thus, boys were significantly more likely than girls to be overtly aggressive, while girls were significantly more likely than boys to be relationally aggressive.

This is consistent with other research findings that females are more likely to be involved in relational and indirect forms of bullying, while males are more likely to be involved in direct forms of bullying.

However, other research studies suggest that gender differences in relational aggression are not as clear. When the study undertaken by Crick and Grotpeter was replicated using a sample of third- and sixth-grade students, the results showed that there were no gender differences in the percentage of boys and girls found to be relationally aggressive. Furthermore, although the replicated study, like that of Crick and Grotpeter, found that boys were more overtly aggressive than girls, it acknowledged that their definition of overt aggression included only physical aggression and theorized that had they included verbal aggression in their measure of overt aggression, they would not have found gender differences either.

Aside from school-age children and adolescents, gender differences with respect to bullying have been studied among adult populations as well. One study found that, within a sample of male and female university students, males reported using physical aggression significantly more often than females but there were no gender differences in the reported use of relational aggression. A separate study measuring workplace bullying among a sample of adults employed in nine companies in Iceland, found that men reported bullying significantly more often than women. Although men and women reported being victimized at similar rates, gender differences emerged in the manner in which these adults responded to such victimization. Specifically, women were more likely to seek help, while men were more likely to confront the perpetrator(s) of the aggression.

Additional evidence shows that there may be gender differences in the effects of bullying. While some studies have found a significant relationship between bullying others and depressive symptoms for both genders, others have found that females were more likely to develop internalizing symptoms due to bullying. Looking at specific types of bullying separately, Crick and Grotpeter found that relationally aggressive girls reported significantly higher levels of loneliness and significantly lower levels of peer acceptance compared to relationally aggressive boys, nonaggressive girls, and nonaggressive boys. Relationally aggressive boys did not experience these problems at significantly higher levels than their peers. It appears as though girls, but not boys, who perpetrate acts of relational aggression, are at a higher risk for feelings of loneliness and low peer acceptance. Furthermore, in one study, female university students who were physically aggressive were more likely to be depressed than their nonaggressive peers, while physically aggressive males were no more likely than peers to be depressed. Thus, physical aggression, too, seems to be associated with negative outcomes for females but not for males.

Although it is difficult to conclusively say that gender differences exist in any area of bullying, it is clear that (a) both boys and girls engage in bullying, (b) the use of physical, verbal, or relational aggression is not limited to just one gender, and (c) the act of bullying is associated with negative outcomes, females being more likely to experience these outcomes. Further research is needed to clarify the remaining questions surrounding potential gender differences in bullying.

Cyberbullying

Cyberbullying is a relatively new medium through which bullying occurs (e.g., chat rooms, text messages). Cyberbullying has been defined as an individual or a group willfully using information and communication involving electronic technologies to facilitate deliberate and repeated harassment or threat to another individual or group by sending or posting cruel text and/or graphics using technological means. Many of the methods used in traditional bullying are used in cyberbullying. Direct cyberbullying can occur when one person calls another a name through an electronic message. Relational bullying can also occur online. For example, with the numerous social networking sites now online (e.g., Facebook, MySpace), 'hate groups' have become a popular approach to bullying. In a hate group, a student creates an online social group against a schoolmate, allows others to join, and collectively the group posts negative comments about the student. Fortunately, social networking sites have begun taking action against the creation of hate groups. When creating a group on Facebook, for instance, a warning is placed near the bottom of the page that reads, "Note: groups that attack a specific person or group of people (e.g., racist, sexist, or other hate groups) will not be tolerated. Creating such a group will result in the immediate termination of your Facebook account." There are several similarities between cyberbullying and traditional bullying. Examining the overlap between cyberbullying and traditional bullying, one study found that 56% of online victims were also victims of traditional bullying. Unfortunately, no information exists on whether the cyberbully was the same person who also bullied the victim in traditional ways. Interestingly, this also means that some victims are targets of only online bullying. One explanation that has been proposed for this phenomenon involves the anonymity an individual has on the Internet. In traditional bullying, the person bullying a victim is almost always known. Online, however, individuals are represented by screen names that do not necessarily correspond with their real-life identity. The psychological outcomes of bullies and victims of cyberbullying are also similar in relation to traditional bullying. Approximately 38% of youth who are harassed online report emotional distress about the event. Additionally, the type of harassment perpetrated has an effect on the degree of emotional distress one experiences. One of the most emotionally distressing types of harassment mentioned by youth includes being propositioned to send a picture of oneself.

Some research has shown that there are also differences between cyberbullying and traditional forms of bullying. As with traditional bullying, prevalence rates of cyberbullying vary depending upon the method of assessment and the definition of cyberbullying. A synthesis of research findings suggests that 10–30% of youth are involved in cyberbullying. There are also gender differences in cyberbullying. One study found that the gender of online harassers was split evenly between males and females. These findings, however, may be influenced by the lack of physical bullying that can occur on the Internet. In another contrast to traditional bullying, in which prevalence rates decrease with age, cyberbullying has been shown to increase with age. This may be due to the increased availability of the Internet to older students. With

an increasing number of adolescents and younger children going online, cyberbullying is an important area for further research.

Workplace Bullying and Sexual Harassment

Bullying is a very common occurrence in schools, but it is not limited to this domain. In fact, bullying has been found to occur in a variety of contexts, including among adults within the workplace. A 2001 study found that nearly half (i.e., 46.5%) of a sample of 5288 employees reported being bystanders of workplace bullying in the past 5 years. Workplace bullying is known by many names, such as mobbing and harassment, and has been defined in a multitude of ways. It is a complex phenomenon that has yet to be consistently defined.

For their purposes, Baillien, Neyens, De Witte, and De Cuyper defined workplace bullying as negative behaviors in the workplace that persist for a minimum of 6 months and may be psychological, physical, or sexual. To explore individual and work-related factors that may lead to workplace bullying, Baillien et al. interviewed 87 informants who reported that they had knowledge of bullying occurring in the workplace. The results showed three 'pathways' that could lead to the development of workplace bullying: (a) frustration and ineffective coping, (b) interpersonal conflict, and (c) a negative culture and/or harmful habits within the organization. A better understanding of these antecedents may lead to more efficient ways of preventing workplace bullying from occurring.

In order to further understand workplace bullying, it has sometimes been studied in conjunction with sexual harassment, another form of workplace aggression. Sexual harassment has been defined as behaviors with sexual content that negatively affect one or more people by humiliating, ridiculing, and/or intimidating them. Sexual harassment can be verbal (e.g., telling sexual stories or making sexual comments about a person), nonverbal (e.g., wolf whistling or other gestures with sexual connotations), or physical (i.e., unwanted touching) and can range from telling jokes with sexual content to criminal actions such as rape. When considering the range of aggressive behaviors in the workplace, it has been theorized that these could be thought of as residing upon a continuum, with acts as harmless as channeling aggression into effective work practices on one end of the continuum and something as violent as homicide in the workplace on the other end. Workplace bullying would fall somewhere in the middle of this continuum, as would sexual harassment.

To explore the relationship between sexual harassment and workplace bullying, one study queried male and female employees at a large university to complete questionnaires that asked about several work-related subjects. Path analysis revealed that the occurrence of workplace bullying was closely related to aspects of work organization for both men and women but that sexual harassment was related to work organization for women only. Specifically, the relationship between workplace bullying, conflicts at work, and gender differences was significant for men and women, although it was stronger for women. Informal decision structures were related to bullying for men, while lack of equality and conflicts were related to

sexual harassment for women. In addition to these gender differences, a greater number of women experienced both sexual harassment (9% of women vs. 2% of men) and bullying (13% of women vs. 9% of men).

The relationship between sexual harassment and bullying has also been studied among adolescents in the school context. In one study, middle and high school students completed questionnaires measuring bullying, sexual harassment, and sexual orientation. The results were analyzed to explore whether the frequency and/or health effects of bullying and sexual harassment differed by gender and/or sexual orientation. Bullying was found to occur more frequently than sexual harassment and members of sexual minorities reported higher rates of both bullying and sexual harassment. While both bullying and sexual harassment had adverse effects on students' health, sexual harassment had more negative effects on health than bullying, especially for girls and members of sexual minorities. Although this study is limited by the small numbers of ethnically and racially diverse students as well as students of sexual minorities, it helps to demonstrate the need to study bullying in conjunction with sexual harassment.

Intimate Partner Aggression

Like sexual harassment, intimate partner aggression and dating violence are unfortunate realities for adults as well as adolescents. These forms of aggression are of particular concern because, in addition to causing direct harm to the victims, children who witness such aggression appear to be more likely to engage in bullying (see section 'Cycle of Aggression'). Within a sample of 1059 elementary and middle school children in one study, a substantial proportion (17.4%) reported witnessing intimate partner aggression between their parents at home. Rates of intimate partner aggression appear to be even higher when women are directly asked about their experience or lack thereof with such aggression over their entire lifetimes. On interviewing 1401 women from 18 to 65 years of age, over half (55.1%) reported having experienced intimate partner aggression with a past or present male partner. Clearly, a woman's lifetime risk of experiencing intimate partner aggression is alarmingly high.

Equally disturbing is the fact that such aggression is not limited to adults. According to ninth- through twelfth-grade students' responses on the Youth Behavior Risk Survey, 10.3% of girls had experienced dating aggression, defined as being intentionally, physically hurt by a dating partner. Dating aggression was also found to be associated with involvement in other types of violence, substance use/abuse, risky sexual behavior, experiencing sad/hopeless feelings, and contemplating or having attempted suicide. Espelage and Holt found that the experience of dating aggression was also closely related to the experience of bullying for a sample of 685 male and female seventh- through twelfth-grade students. Specifically, students who reported being bully-victims reported experiencing higher levels of physical dating aggression than students who reported being bullies, victims, or uninvolved in bullying. Bully-victims also reported experiencing higher levels of sexual harassment compared to members of the other three groups and higher emotional abuse within a dating relationship

than victims and students uninvolved in bullying. Given this overlap between bullying, sexual harassment, and dating aggression, it appears as though a substantial proportion of adolescents are being victimized in numerous ways.

Cycle of Aggression

Existing research has shown that bullying, as well as other types of violence and aggression, may follow a cycle of aggression that begins at home. For instance, one study found that young adults who were maltreated as children were more likely to perpetrate acts of general aggression as well as intimate partner aggression. Furthermore, among a sample of 43 death row inmates convicted of homicide, childhood maltreatment was extremely prevalent. Over half of the inmates reported experiencing sexual abuse, 95% had been physically abused, and a substantial proportion (75%) had experienced multiple forms of victimization, including verbal, physical, and sexual abuse, neglect, and having witnessed others being victimized.

Additional evidence supports the notion that being a bystander is associated with later aggression. In addition to early childhood physical abuse, witnessing a parent suffer domestic abuse predicted later perpetration of intimate partner aggression. It has also been found that there is a significant association between children witnessing intimate partner aggression between their parents at home and bullying others at school. This association could be explained by Bandura's Social Learning Modeling Theory, which states that people, particularly children, learn certain behaviors by watching the adults in their lives model them. In other words, children who see themselves or others being victimized may learn to victimize, be it via bullying or other aggressive acts.

Not all children who witness or experience such aggression will later exhibit these same or similar violent behaviors, however. The pathway between the witnessing/experiencing of aggression and later perpetration of violent acts is not certain and, thus, the witnessing and/or experiencing of aggression does not guarantee that such people will fall prey to this 'cycle of aggression' and perpetrate violent acts themselves. Yet, as a whole, evidence seems to suggest that witnessing and/or experiencing aggression, particularly multiple forms of aggression, may be risk factors for the later perpetration of violent acts.

Conclusion

Bullying is a prevalent phenomenon that causes harm to those who perpetrate acts of bullying, experience acts of bullying, or witness bullying occurring. While bullying is frequently studied in middle childhood and in the context of schools, bullying occurs in a variety of contexts across the life span, from preschool to adulthood. Bullying also shares a close relationship with sexual harassment, intimate partner aggression, and childhood maltreatment. Such aggressive acts have been theorized to occur within a vicious cycle in which those who experience aggression are more likely to perpetrate acts of aggression in the future. In short, bullying can and does affect the lives of countless children and adults.

Glossary

Adenosine A neuromodulator associated with regulating the degree of alertness in central nervous system functioning. A1 adenosine receptors inhibit excitatory neurotransmitters, while A2 receptors facilitate neurotransmission by inhibiting A1 receptors.

Affect The feeling state associated with an emotion. Affect is typically used in terms of direction of approach (positive affect) and avoidance (negative affect). It is most typically measured by self-reports of positive and negative affect.

Arousal A construct used to organize the common behavioral effects of exercise, stimulant drugs, sleep deprivation (negatively), time of day, and time on task. Arousal is associated with feelings of energy and tension. It is better thought of in terms of the two independent dimensions of energetic arousal and tense arousal. It typically involves increases in heart rate, blood pressure, skin conductance, and other autonomic indicators.

Caffeinism Chronic psychological distress, including sleep and anxiety disorders, associated with high levels of caffeine consumption.

Dose response The shape of the relationship between increasing dosage levels (measured in mg of caffeine/kg of body weight) with physical or psychological responses.

Energetic arousal One of the two dimensions of arousal, associated with self-reports of feeling energetic, lively, alert versus sleepy, tired, and drowsy. It is correlated with but separable from positive affect.

Negative affect A second unipolar dimension of affect. It is associated with self-reports of feeling sad, blue, unhappy, and depressed.

Positive affect One of the two unipolar dimensions of affect. It is associated with self-reports of feeling happy, pleased, delighted, and satisfied.

Tense arousal A second dimension of arousal, associated with self-reports of feeling scared, tense, nervous, afraid versus calm, relaxed, and at ease. It is correlated with but separable from negative affect.

Vigilance task It is a monotonous task, typically requiring a rapid response to the detection of an infrequently occurring event. Most vigilance tasks require sustained performance over a long period.

Withdrawal Symptoms associated with an abrupt cessation of consumption of a drug (e.g., caffeine).

Introduction

Caffeine and its fellow xanthines, theophylline and theobromine, are the most consumed drugs in the world, surpassing alcohol and nicotine for popularity and universality. Caffeine, normally associated with coffee, is also a major ingredient of tea, as is theophylline, and is even found in chocolate, a source of theobromine. Caffeine may also be found in the kola nut (chewed in Africa), yerba mate (taken with hot water in South America), and guarana seeds (primarily added to soft drinks in Brazil but also included in various 'natural food supplements'). Moderate doses of caffeine enhance mood, alertness, and physical endurance, but at the cost of increased tolerance with use and withdrawal symptoms of severe headache, fatigue, and dysphoria. The affective, behavioral, and cognitive consequences of caffeine consumption are generally positive for moderate doses, but can lead to clinical diagnoses of anxiety disorder, as well as to physical tremor, twitching, and cognitive impairment at higher levels. Besides the obvious sources of coffee and tea, caffeine is also included as an active ingredient of colas, energy drinks, and energy bars, sold in over-the-counter pill or lozenge form, and is added to many over-the-counter and prescription drugs to alleviate other side effects.

Perhaps because of its common usage and lack of apparent danger, caffeine is generally not even considered a drug. Indeed, its very ubiquity makes it very much a part of modern society and hard to think of as a psychoactive drug. However,

given that its effects are similar to those of many other psychoactive drugs, if caffeine were to be discovered today, it is quite likely that it would be illegal or at least seriously regulated. Indeed, unsuccessful attempts at regulating caffeine have occurred since coffee's first introduction into Arabia and Europe.

Coffee came to Europe and then the rest of the world from Arabia (probably starting in Yemen) or Ethiopia where the legendary Ethiopian goat herder, Kaldi, saw his goats chew on the red berries of a bush and then show great energy. Trying the berries himself is said to have led him to the joys of coffee. More likely is that warriors of Ethiopia used a mixture of ground coffee beans and animal fat to provide nourishment and energy while conducting raids on their neighbors. This mixture spread to Arabia and then by the late sixteenth century to the rest of the world. However, tea had been consumed in India and China for millennia before being introduced to Europeans searching for spices. The guarana seed was a source of caffeine in pre-Columbian South America and remains a major source of caffeine in South America and in 'health food' stores. The introduction of coffee and tea into Europe as sources of caffeine had a revolutionary impact.

The ubiquity of caffeine and its cousins as drinks and candies around the world testifies to the ease of preparation and its perceived benefits for thinking clearly and feeling alert. Some attribute the European Enlightenment and subsequent Industrial Revolution to the introduction of coffee to Europe

in the early seventeenth century and the resulting replacement of beer by coffee or tea in workers' and intellectuals' diet. (The boiling of water necessary for tea and coffee purified the drinking water, making it a safe alternative to beer for breakfast. Workers could thus work longer and intellectuals argue with greater logic than had they started their day with beer.) Joining the classic association with writers and musicians who praised (and used) the powers of coffee (cf. Balzac, Johnson, Bach, Mozart), it is difficult today to think of software developers or college students without a nearby espresso maker, cans of cola, or more powerful forms of caffeine ('energy drinks'). A wonderful statement about the powers of caffeine frequently is attributed to the Hungarian mathematician, Erdos, although probably was made by his colleague, Rényi, who claimed that 'A mathematician is a machine for turning coffee into theorems.'

A negative consequence of the introduction of coffee and tea to Europe and then to the rest of the world was similar to the later introduction of electric lights: By allowing people to stay awake when tired or when it is dark, caffeine and the electric light have modified our sleep patterns in a manner that leads to sleep deprivation and insomnia. A society without caffeine or electricity is bound to the natural rhythms of day-light and spends more time sleeping than does one with caffeine and artificial lighting.

Sources and Consumption of Caffeine

Caffeine is typically consumed by drinking coffee or tea, although it is also found in chocolate, many soft drinks, and a variety of over-the-counter medicines. The amount of caffeine in these various preparations differs drastically with more variance in tea (at least a factor of 10 between the weakest and the strongest tea in one study) than in coffee (only a factor of 4 between the weakest and the strongest coffee). What makes estimates of caffeine consumption difficult is that the standard 'coffee cup' unit of 5 oz (150 ml) is probably used less often than a 'coffee mug' of 8 oz (237 ml) or the 'Grande' size (16 oz or 473 ml) of some coffee chains. A further difficulty is that coffee differs in the way it is prepared. In a comparison of coffees, home-brewed filtered coffee tends to be stronger than does instant coffee, perhaps because the process of making the latter is more efficient in extracting caffeine, as well as some of the other bitter flavors than found in a cup of freshly brewed and filtered coffee. (Table 1)

In the United States, 95% of the adult population consumes caffeine in some form, with an average daily consumption increasing with age to the late 50s and then declining slightly (Figure 1). Typically taken with breakfast, the serving of coffee or tea to visitors is an expected custom for many. In Europe and North America, the social aspect of caffeine consumption began with the establishment of coffee houses in seventeenth century Britain and continues to this day with the popularity of various coffee shop chains. Given caffeine's prevalence in modern society, it is hard to believe that four centuries ago, coffee and tea were considered revolutionary, and there was a move to ban coffee houses as sources of rebellion.

There are vast individual differences in the consumption of caffeine, probably due to self-titration, in that people

self-administer as much caffeine as they find to yield the positive effects on mood and alertness but not enough to produce some of the negative side effects of tension. As is true of most psychological variables, there are reliable individual differences in caffeine consumption and these differences are moderately heritable ($h^2 \geq 0.4$) with a higher heritability for heavy use ($h^2 \geq 0.7$). In addition to individual differences within countries, the consumption of caffeine varies a great deal between nations. While the average intake in the United States is roughly 2–3 mg kg⁻¹, this varies drastically, with the top 10% of the population consuming as much as 5 mg kg⁻¹. In the United Kingdom, the per capita consumption is about 4 mg kg⁻¹, with the top 10% consuming as much as 7 mg kg⁻¹, while in Scandinavia, the average is about 7.5 mg kg⁻¹, with the top 10% consuming almost 15 mg kg⁻¹!

Although given GRAS status (generally recognized as safe) by the US Food and Drug Administration as a supplement to cola-like beverages, in 2009, the FDA announced that it did not view it as GRAS as an additive to alcoholic beverages. This led to some controversy, as a variety of alcohol-producing and -marketing companies complained that this would limit their sale of caffeinated alcoholic beverages (CABs). The US Center for Disease Control has issued warnings about the use of CABs, as well as the mixing of 'energy drinks' containing caffeine with alcoholic beverages. The warning is that the stimulating effects of the caffeine when combined with the disinhibiting effects of alcohol can lead to binge drinking and increase the likelihood of driving under the influence of alcohol or to unsafe or undesired sexual behavior.

Physiology of Caffeine

The full chemical name for caffeine is 1,3,7-trimethylxanthine, and its chemical formula is C₈H₁₀N₄O₂. Caffeine is a member of the purine family of compounds, meaning that it has a double-ringed, crystalline organic base, C₅H₄N₄. When consumed orally, caffeine is rapidly and completely absorbed into the bloodstream through the gastrointestinal tract. Individual differences in the amount of time it takes to achieve peak plasma levels in the bloodstream can range from 15 to 120 min, with the majority of individuals reaching peak plasma levels approximately about 30–60 min after ingestion. Caffeine is broken down extensively by the liver into three primary metabolites, paraxanthine (84%), theobromine (12%), and theophylline (4%), each of which have their own effects on the body. The liver further breaks down these three metabolites into xanthine by removal of methyl groups. Xanthine is either excreted in urine or reused by the body. The average half-life of caffeine, the time it takes for half of the caffeine consumed to be eliminated, is 2.5–4.5 h. The half-life may vary depending on a number of factors; it is much longer in individuals with liver disease, reduced by up to 50% in smokers, may be doubled in women taking contraceptives, and increases throughout pregnancy (reaching a maximum time of 15 h during the last trimester of pregnancy). The half-life also depends on the amount of caffeine consumed. The pharmacokinetics for ~70–100 mg of caffeine are linear, but the clearance of caffeine is significantly reduced and its elimination half-life is prolonged at higher doses of 250–500 mg, indicating nonlinearity. Caffeine has no nutritional value.

Table 1 Common sources of caffeine

Source	Serving	Dose/serving	Dose per ml
<i>Coffee & tea</i>			
Espresso, generic	30 ml	30–90 mg ^a	1.00–3.00 mg ml ⁻¹
Coffee, generic, drip	237 ml	96–288 mg ^a	0.41–1.22 mg ml ⁻¹
Coffee, generic, percolated	237 ml	64–272 mg ^a	0.27–1.15 mg ml ⁻¹
Coffee, generic instant	237 ml	27–192 mg ^a	0.11–0.81 mg ml ⁻¹
Starbucks brewed coffee (Grande)	473 ml	320 mg	0.68 mg ml ⁻¹
Dunkin' donuts medium coffee	473 ml	206 mg	0.50 mg ml ⁻¹
Starbucks vanilla latte (Grande)	473 ml	150 mg	0.32 mg ml ⁻¹
Black tea, 1 teabag brewed 3 min	237 ml	25–110 mg ^b	0.11–0.46 mg ml ⁻¹
Starbucks chai tea latte (Grande)	473 ml	100 mg	0.21 mg ml ⁻¹
Oolong tea, 1 teabag brewed 3 min	237 ml	12–55 mg ^b	0.05–0.23 mg ml ⁻¹
Snapple-flavored iced teas	473 ml	42 mg	0.09 mg ml ⁻¹
Green tea, 1 teabag brewed 3 min	237 ml	8–30 mg ^b	0.03–0.13 mg ml ⁻¹
Arizona iced tea, black	473 ml	32 mg	0.07 mg ml ⁻¹
Coffee, generic decaffeinated	237 ml	3–12 mg ^a	0.01–0.05 mg ml ⁻¹
Arizona iced tea, green	473 ml	15 mg	0.03 mg ml ⁻¹
<i>Soft drinks</i>			
Jolt Cola	355 ml	140 mg	0.39 mg ml ⁻¹
Mountain Dew	355 ml	54 mg	0.15 mg ml ⁻¹
Diet Coke	355 ml	47 mg	0.13 mg ml ⁻¹
Dr. Pepper	355 ml	41 mg	0.12 mg ml ⁻¹
Pepsi	355 ml	38 mg	0.11 mg ml ⁻¹
Coca-Cola	355 ml	35 mg	0.10 mg ml ⁻¹
Diet Pepsi	355 ml	36 mg	0.10 mg ml ⁻¹
Guarana sodas	355 ml	30 mg	0.08 mg ml ⁻¹
<i>Energy drinks</i>			
AMP Energy	237 ml	80 mg	0.34 mg ml ⁻¹
Monster Energy	473 ml	160 mg	0.34 mg ml ⁻¹
Red Bull	250 ml	80 mg	0.32 mg ml ⁻¹
<i>Chocolate</i>			
Hershey's special dark chocolate bar	41 g	31 mg	
Hershey's unsweetened baking chocolate	14 g	15 mg	
Hershey's milk chocolate bar	43 g	9 mg	
Hershey's chocolate milk	237 ml	4 mg	0.02 mg ml ⁻¹
Starbucks coffee ice cream	101 g	40 mg	
<i>Over-the-counter medications</i>			
NoDoz (maximum strength)	1 tablet	200 mg	
Excedrin (extra strength)	2 tablets	130 mg	
Anacin (maximum strength)	2 tablets	64 mg	
<i>Other</i>			
AMP caffeinated gum	2 pieces	80 mg	
Enerjets lozenges	1 lozenge	75 mg	
GU energy gel	32 g pack	20 mg	

Adapted from the Center for Science in the Public Interest, the USDA National Nutrient Database for Standard Reference, Release 22 (2009), the International Coffee Organization, and company Web sites.

^aFactors affecting the range of caffeine in coffee include the type and origin of the coffee bean, roasting method, grinding method, and brewing method.

^bFactors affecting the range of caffeine in tea include the type, origin, and age of the tea plant, the location of the leaf on the plant, the method of steeping (loose leaf, bagged, etc.), and the length of steeping time (where longer steeping times release more caffeine). 1 fluid oz = 30 ml; 1 oz weight = 28 g.

Not only does caffeine rapidly disperse to all cells in the body, its chemical structure also allows it to easily cross the blood–brain barrier. Once in the brain, the principal mode of action is as a nonselective antagonist of adenosine receptors. The caffeine molecule is structurally similar to adenosine and binds to adenosine receptors on the surface of cells without activating them, therefore acting as a competitive inhibitor or 'antagonist' of adenosine. Caffeine's physiological and psychostimulant effects are thought to derive largely from inhibiting the effects of adenosine, particularly at the A1 and A2a

adenosine receptors. The A1 receptors are located in all parts of the brain with the heaviest concentration in the hippocampus, cerebral cortex, cerebellum, and certain thalamic nuclei. The A2a receptors are located in the dopamine-rich areas of the brain, including the striatum, nucleus accumbens, and olfactory tubercle. Adenosine transmission normally decreases the neuronal firing rate and inhibits both synaptic transmission and the release of most neurotransmitters; it promotes sleepiness, dilates blood vessels, reduces the contractions of the stomach and intestines, slows the reaction to stress, and lowers

Figure 1 Caffeine consumption increases by a factor of 21 with age and differs between men and women. However, when considering body weight, the sex difference is diminished, and the increase with age is less than a factor of 5.

the heart rate, blood pressure, and body temperature. After caffeine connects to the A1 and A2a receptors, an adenosine blockage forms, thus reversing the effects of adenosine. Caffeine is classified as a psychostimulant because it produces heightened central nervous system (CNS) arousal, which increases the dominance of the sympathetic branch of the autonomic nervous system. The result of this shift is to increase the levels of activity in physiological systems that mobilize the body for aggressive or defensive activity, including the cardiovascular system, the respiratory apparatus, and the digestive system. Under continued stress, the pituitary gland is instructed by the hypothalamus to increase the release of hormones that cause the adrenal glands to produce epinephrine and cortisol. These hormones cause increased heart rate, dilation of the bronchi, a release of sugar into the bloodstream from the liver, increased blood flow to the muscles, and a tightening of muscles for action.

Caffeine also affects dopaminergic transmission. By inhibiting adenosine A2a receptors, caffeine reduces the negative modulatory effects of adenosine receptors on dopamine D2r receptors, thus causing potentiation of dopaminergic neuro transmission. This mechanism is thought to be related to the ability of caffeine to induce a positive mood state that includes mild euphoria. However, in contrast to the drugs of abuse that selectively lead to a release of dopamine in the shell of the nucleus accumbens, caffeine increases dopamine release in the caudate nucleus. Dopamine release in the caudate nucleus relates to the stimulatory properties of caffeine on locomotor activity. Only at doses not likely to be consumed by humans does caffeine cause release of dopamine in the nucleus accumbens; however, this dose is associated with nonspecific activation in the brain and aversive effects such as anxiety. Repeated administration of caffeine quickly leads to tolerance of the physiological effects previously described; tolerance refers to an acquired change in responsiveness after repeated exposure to a drug. Usually developing within a few days, tolerance to caffeine's effects on blood pressure, heart rate, diuresis, plasma

epinephrine and norepinephrine levels, renin activity, tension, anxiety, jitteriness, and nervousness has also been demonstrated. Tolerance to sleep disruption can develop within 1 week with doses as low as two cups of coffee per day. Nonhuman animals also develop a tolerance to caffeine-induced locomotor stimulation, cerebral electrical activity, and reinforcement thresholds for electrical brain stimulation. The alerting and attentional focus effects of the drug do, however, continue.

Withdrawal

Physiological dependence is a state induced by repeated drug use that results in a withdrawal syndrome when the drug is discontinued or an antagonist is administered. It is important to distinguish a withdrawal syndrome from a rebound phenomenon. Withdrawal comprises a number of signs and symptoms not present during administration of the drug, whereas rebound refers to a single sign or symptom that is the reverse of the drug effect. Additionally, withdrawal most often occurs after discontinuation of repeated drug administration; rebound can occur after single administrations of a drug. The most oft-reported symptoms of caffeine withdrawal are headaches, fatigue, weakness, drowsiness, impaired concentration, work difficulty, depression, anxiety, irritability, increased muscle tension, decreased energy and activeness, decreased alertness, drowsiness, and irritability. Onset of symptoms can appear within only 3–6 h after abstinence and can last for one week, although the incidence or severity of the symptoms increases with increases in daily dose; symptoms can appear with doses as low as 100 mg day⁻¹. It is important to note, however, that the intensity of withdrawal symptomatology is subject to substantial individual differences, based, in part, on genetic predispositions. Some people experience quite extreme withdrawal symptoms, while others experience almost none.

Although there is an overall, general withdrawal factor, withdrawal symptoms can be grouped into lower-level factors

of fatigue/headache, dysphoric mood, and flu-like symptoms. The effects of withdrawal are most clearly dose-dependent for the first two sets of symptoms: compared to light caffeine consumers (less than 100 mg day⁻¹), heavy consumers (greater than 200 mg day⁻¹) are more than four times as likely to report headache and fatigue as well as more than three times as likely to report dysphoric mood.

The effect of acute withdrawal from caffeine is seen commonly in headache and fatigue. Indeed, office workers who consume high doses during the week and then do not consume caffeine on the weekend find that the resulting weekend headaches are easily treated with pain relievers that contain caffeine. Perhaps one cause of postoperative headache is the preoperative withdrawal from caffeine rather than the acute aftereffects of anesthesia.

Some of the physiological underpinnings of common withdrawal effects have just recently been discovered. Acute caffeine abstinence results in increases in blood flow velocity in middle and anterior cerebral arteries and decreases in variability of blood flow velocity in the middle cerebral artery. These effects suggest that a vascular mechanism causes the caffeine withdrawal symptom of headache. Acute caffeine abstinence also produces significant changes in electrical activity in the brain corresponding with increased drowsiness and decreased alertness.

Withdrawal effects complicate the study of caffeine effects on mood and performance. Because most participants normally consume caffeine, it has been proposed that the beneficial effects of caffeine on mood, behavior, and cognitive performance are actually due to antiwithdrawal effects. That is, caffeine does not elevate mood or improve alertness, but rather withdrawal leads to tension and sleepiness. The logic of this position is that most double-blind caffeine studies are done after 12–24 h of caffeine withdrawal (e.g., participants are requested not to consume any caffeine after 8 pm prior to a morning study), and thus, participants are in acute caffeine withdrawal. Evidence against this proposal comes from comparing predrug administration measures of mood and performance for heavy and light caffeine consumers as well as the observation that both nonconsumers and normal consumers of caffeine report increased alertness following caffeine consumption when compared to a placebo. Further evidence against the withdrawal hypothesis comes from the pattern of cognitive performance effects of caffeine as they interact with personality and the time of day.

Affective, Behavioral, and Cognitive Effects of Caffeine

Caffeine is most commonly consumed because it improves alertness, attentional focus, and mood and fights off the effects of fatigue, though it is also used by athletes because of its effects on motor speed, power, and endurance. However, as with most things, moderation is important, for too much caffeine will mimic the symptoms of anxiety, induce hand tremor, and hinder performance in a variety of ways. Though the cognitive, affective, and behavioral effects of caffeine are addressed in turn in the following sections, it is important to acknowledge that the distinct causal mechanisms for these effects are often complicated by the fact that caffeine affects

several physiological systems simultaneously. In addition to the central nervous system, each of the cardiovascular, muscular, pulmonary, hormonal, and metabolic systems are affected by the presence of caffeine in the bloodstream.

Affective Effects of Caffeine

Coffee and tea are part of the morning routines for many around the world because they help people to feel more awake. In low to moderate doses, caffeine consumption enhances mood, increases levels of self-reported alertness, and decreases self-reported fatigue. While some effects of caffeine consumption decrease with increasing tolerance, this is generally not the case with enhancements to mood and mental alertness, though considerable evidence suggesting an interaction effect of caffeine and expectancy may play a role in the preservation of these effects.

The effect of caffeine on affect needs to be considered in terms of at least four distinct but correlated constructs. Energetic arousal (EA), indicated by such terms as alert, energetic, and wide awake as contrasted to tired, sleepy, or drowsy, is increased with caffeine. This is, after all, why coffee and tea are consumed! Orthogonal to EA is Tense arousal (TA), which is indicated by words such as tense, anxious, nervous, or afraid as contrasted with calm, relaxed, or at ease. State levels of TA are seen as a response to stressful situations, while more stable individual differences (trait levels) are associated with anxiety and neuroticism. TA increases with caffeine, particularly at higher doses (i.e., ≥ 4 mg kg⁻¹). Positive affect (PA), although highly correlated with energetic arousal and indexed by words such as cheerful, pleased, and happy, is an interactive effect of caffeine and situational cue for happiness. Without such cues, caffeine has a small positive effect on PA. The dimension of negative affect (NA) as indicated by unhappy, depressed, and blue, is highly positively correlated with TA and slightly negatively correlated with PA. NA is less affected by caffeine than it is by situational manipulations of affect (e.g., sad or depressing movies or other negative mood inductions).

In higher doses, and among individuals with lower tolerances, caffeine also increases 'jitteriness,' nervousness, and general anxiety, and these side effects are more common among clinically anxious individuals. Indeed, caffeinism is a recognized anxiety disorder associated with high levels of caffeine intake. The current diagnostic and statistical manual of mental disorders (DSM-IV-TR) lists four caffeine-related psychiatric disorders: caffeine intoxication, caffeine-induced anxiety disorder, caffeine-induced sleep disorder, and other caffeine disorders not otherwise specified. Caffeine intoxication is shown by having recently consumed more than 250 mg of caffeine and showing at least five of the following symptoms: restlessness, nervousness, excitement, insomnia, flushed face, diuresis, gastrointestinal disturbance, muscle twitching, rambling flow of thought and speech, tachycardia or cardiac arrhythmia, periods of inexcitability, or psychomotor agitation. For a diagnosis, these symptoms must be causing clinically significant distress or impairment of functioning. Caffeine-induced anxiety disorder includes symptoms of anxiety associated with high levels of caffeine intake. Caffeine-induced sleep disorder is associated with high caffeine consumption and sleep disorders not otherwise explained. Because the symptoms of high levels of caffeine

consumption are similar to those of the anxiety disorders, physicians are encouraged to inquire about the level of caffeine intake for patients complaining about anxiety symptoms.

Behavioral Effects of Caffeine

Of course, many of these affective effects carry over into more overtly physical behaviors. The most renowned behavioral effect of caffeine is increased alertness. Performance on monotonous tasks that require detection of rare events (e.g., vigilance tasks such as long distance truck driving or looking for weapons in airport scanners) normally deteriorates over time. Moderate doses of caffeine ameliorate this decrease. A more subtle, but equally reliable effect is the speeding up of reaction time, particularly when choice is not required.

In addition to these benefits, moderate doses of caffeine enhance physical endurance by increasing both work output and the time to exhaustion. Caffeine's effect on shorter-term physical behavior is less well documented, perhaps because shorter durations make effects more difficult to reliably detect. Nevertheless, the effect of caffeine on physical exercise of short duration suggests that peak power output, speed, and isokinetic strength are improved for very short bouts (lasting less than 10 s). For longer bouts (greater than 15 s), which rely on the glycolytic system, these same improvements are not maintained; in fact, some findings suggest a detrimental effect of caffeine on power for bouts of 15 s to 3 min. These discrepancies reflect the likelihood that the effects of caffeine result from a combination of mechanisms at work simultaneously. In addition to the central nervous system, these mechanisms result from changes to the cardiovascular, muscular, pulmonary, hormonal, and metabolic systems.

The effects of caffeine on physical performance have led to its widespread use among elite athletes and performers, even though the benefits are not well established across activities. With respect to elite athletic performance, it is important to note that very small variations in performance are the difference between being on the victory stand and being one of the crowd. The unit of analysis is thus not the percent change in performance so much as change as a percent of the coefficient of variation in performance, that is, the size of the effect in terms of the standard deviation rather than in terms of the raw performance.

In an effort to maintain parity, the International Olympic Committee classified caffeine as a doping agent in 1984 by setting an acceptable threshold level of $15 \mu\text{g ml}^{-1}$ in urinary samples (the level was reduced to $12 \mu\text{g ml}^{-1}$ the following year). In 2004, however, this prohibition was revoked when doping for most international sporting events (including the Olympics) fell under the administration of the world anti-doping agency (WADA). Under the current WADA policy, the concentration of caffeine in the bloodstream is monitored through urine samples for signs of potential abuse, though the threshold level constituting abuse has not been officially declared. In the past, threshold levels have been subject to criticism on the basis that they fail to take into account high interindividual variability in terms of caffeine metabolism (several studies suggest a 15–20-fold range across individuals) as well as the fact that most performance-enhancing benefits of caffeine have been documented at levels consistent with

moderate daily use. Estimates vary dramatically depending on many factors, but peak urinary caffeine concentrations of $12 \mu\text{g ml}^{-1}$ would be expected to occur 105 min after a mean caffeine intake of at least 10.5 mg kg^{-1} of body weight.

Cognitive Effects of Caffeine

The effects of caffeine on cognitive performance are not as clear-cut as they are for feelings of alertness. They are complex, for they depend upon the type of task, the situational demands, and characteristics of the individual. To make it more complicated, there is reliable evidence for systematic interactions with the various combinations of person, situation, and task variables.

To understand these effects, it is useful to organize a number of cognitive tasks along three dimensions: the requirements for sustained attention, the requirements for working or immediate memory, and the requirements for integrating long-term memories with immediate memory. Tasks can be high or low on each of these three dimensions. The positive effects of caffeine on the first (sustained attention) are quite clear, whereas effects on the latter two dimensions are more complicated.

Sustained attention tasks such as long distance truck driving, security scanning at airports, or other examples of vigilance that require detection of rare events in the presence of many repetitive but nontarget signals are correlated with general alertness. Performance on these tasks is hindered by manipulations that lead to lower alertness: alcohol, sleep deprivation, the time of day (the optimal time depends upon the participant), or the time on task. In particular, performance on these tasks decays over time, with very good performance upon starting with a (negatively accelerating) exponential decay over time. Performance may be indexed by reaction time or by accuracy. Reaction time increases and accuracy diminishes over time. Caffeine as well as brief exercise, or even an increase in the signal frequency inhibits this decay, although effort instructions ('try harder' or 'do not go to sleep') do not. The clearest evidence for caffeine effects on vigilance are found following sleep deprivation and after a period of time on the task. That is, caffeine helps the most when the subject is most fatigued. These effects are associated with increases in energetic arousal.

Although the effect of caffeine on vigilance is quite clear, the pattern on working memory tasks is much less so. Part of the confusion is that caffeine facilitates alertness which is, in turn, related to detection of the material to be remembered. In addition, caffeine enhances speed of performance which in turn can reduce accuracy. Thus, in some studies, memory for recent events is enhanced, probably because the detection was better, rather than improvements in storage or retrieval. An example of the complexity of the results may be seen in proof-reading where caffeine hinders the detection of interword errors (e.g., subject-verb agreement) which requires more working memory than does the detection of intraword errors (e.g., spelling or broken typography) which has a more complicated relationship with caffeine (a small decrease in detection is associated with an increase in the speed of processing).

Information acquired when one is alert is recalled better later (after at least a day) than is information acquired when

one is sleepy. This effect may be shown using sleep deprivation, the time of day, exercise, and variation in personality dimensions associated with arousal (impulsivity and extraversion). Similar effects are found with caffeine: caffeine taken when learning new material facilitates long-term recall and recognition of that material.

For complex cognitive tasks, similar to the sort of ability tests given for admission to graduate school, the effects of caffeine are even more complicated and are an interactive function of individual differences in impulsivity and the time of day. In a series of studies using these complex tasks, it was shown that caffeine facilitated the performance of subjects thought to be less aroused (high impulsive participants in the morning, low impulsive participants in the evening) but had deleterious effects for those thought to be more highly aroused (low impulsiveness in the morning, high impulsiveness in the evening.)

The general conclusion for cognitive performance is that caffeine facilitates performance on tasks that require (sustained) attention, particularly among participants who are fatigued or less aroused. The beneficial effects of caffeine are harder to detect for alert subjects or for tasks that require more memory. For especially complicated tasks with highly aroused participants, caffeine can have a deleterious effect.

Caffeine as a Tool for Psychological Research

Much of the research on caffeine is just that: studies of the effects of caffeine on various psychological variables. A less recognized use of caffeine is as a tool for psychological research. By increasing the ways in which a participant's

energetic and tense arousal may be manipulated, caffeine allows the careful researcher to tease apart the effects of putative arousal and motivational-related variables such as the time of day, introversion–extraversion, impulsivity, exercise, or incentives. For example, in the study of the association between positive affect and energetic arousal, and negative affect and tense arousal, the differential effect of caffeine on these variables as contrasted to more typical mood manipulations allows for distinctions that would otherwise be difficult to achieve.

Conclusion

Caffeine, particularly in the form of coffee or tea, is used by a majority of adults worldwide. The benefits on feelings of alertness and positive affect, as well as on endurance and simple cognitive performance are clear, particularly in situations that would otherwise normally lead to fatigue or when sleep-deprived. However, the benefits come with some cost, in that performance on complex reasoning tasks can be hindered, and that high doses lead to unpleasant levels of tension. Although the effects of low to moderate doses seem positive, higher doses can lead to discomfort and impaired cognitive performance.

Career Development

S H Osipow, The Ohio State University, Columbus, OH, USA

© 2012 Elsevier Inc. All rights reserved.

Glossary

Career The succession of vocational activities through the life span.

Negative reinforcer Environmental event that reduces a positive response.

Occupational stereotype The image an occupation holds in the view of society in general.

Positive reinforcer Environmental event that satisfies an individual's needs.

Vocational maturity The degree to which an individual's vocational activities are congruent with the expectations of his/her life stage.

Vocational self-concept The individual's personal image in terms of work.

How It Began

Career development involves a lifelong series of vocational activities. It represents a series of work activities which may or may not have continuity. It is important to recognize that the work activities are a sum of specific tasks. The accumulation of these tasks makes up what is called a job. The sum of jobs engaged in represent a vocation. One's vocational history across the life span becomes a career. One can infer a person's career only in retrospect. The process begins with a decision about educational objectives. This results in a chain of events which leads to vocational entrance. For some people, the vocational activity that follows may have little variance. That is, the vocation chosen may not change much over the course of a lifetime. For others, there may be considerable change, as skills develop and opportunities present themselves.

History of Career Development

The concept of career development is a relatively new one, generally thought to have its origins in the early part of the twentieth century. Prior to that time no one thought that careers were developmental in nature. Careers, or rather jobs and work, were thought to be discrete. In other words, for upper class or professional workers, some training might occur such as in law or medicine, after which the worker would enter and remain in the vocation doing essentially the same thing throughout the entire work life. For middle class workers such as small business owners, jobs were largely inherited. A family business, for example, a store, a farm, or a trade, was usually passed along from parent to child. For lower class workers there was little continuity from job to job. Work was obtained where it could be found and when it was exhausted jobs were sought elsewhere. While some transferability of skills and experience might occur from one job to another, no one thought that there was that significant continuity in work tasks. The question of choosing a career was hardly considered. Except for the professional level jobs, choice was not a factor to be considered. Even in these limited circumstances individual choices were likely to be somewhat constrained depending on family background.

As the Industrial Revolution continued to develop, discrete industries were developed. Except for the lowest skill level jobs, some training and/or experience was needed for entry and advancement. As industries became increasingly differentiated, the degree to which individual choices were possible increased. However, the choices were still constrained to a significant degree. Furthermore, what choices existed were limited to males for the most part, since women were not significant players in the work place outside of the home. Except for careers in teaching or in nursing, women did not have a similar range of choices available to them as did men. Not until the late nineteenth century when office technology created the typewriter and the telephone were women seen in office jobs, and even then for a long time men did those jobs because the work was considered to be too hard for women.

In the early part of the twentieth century more attention was given to the role that inherent abilities played in work effectiveness, along with that individual interests might be differentially satisfied in different kinds of work. Interests and abilities were of increasing interest as methods to measure them were developed. As a result, the concept of fitting people to jobs (e.g., round pegs for round holes) as Parsons proposed, became a cornerstone in the creation of the concept of career development. Institutions devoted to the 'test them and tell them' approach to careers began to occur. However, even then, the notion that there might be life stages or phases which would significantly influence career directions did not occur to those practicing career planning for men. Women were still excluded for the most part from career planning, again, except for nursing and teaching, typically seen to be women's work.

World War I accelerated the attention paid to differential psychology as applied to careers because the rapid mobilization of the work force into a war machine made it necessary to classify people (mostly men) according to their abilities in order to assign them to tasks most closely allied to their potential. World War II further accelerated this process because the number of candidates to be sorted was larger and the jobs more diverse and specialized. Furthermore, the methods of assessing people became more sophisticated.

With the advent of the 1920s and 1930s the measurement of interests became more sophisticated and became an equal

partner to the use of abilities in understanding the issues underlying career choices and ultimate adjustment to work.

Life Stages and Career Theories

Using knowledge developed from differential psychology it was but a small step to thinking about careers as associated with life stages. Adding to differential psychology was the knowledge based on psychometrics and developmental psychology, and, thus, gradually the concept of career development took shape. These developments largely took the form of theoretical ideas about how people choose, implement, and adjust to their career possibilities across the life span.

One of the first of these theories relied heavily on developmental psychology. It focused on stages of development through childhood, and adolescence into early adulthood, later extending into middle adulthood and into the retirement years. Career development was seen to be a process of growth, stability, and decline. The most influential advocate of this approach was Donald E. Super. According to Super, the earliest life stage critical to career development is exploration, during which individuals become increasingly aware of their physical and psychological environment in general and later as it applies personally. This process leads to a series of vocational developmental age related stages, each of which has tasks to be mastered.

To the degree that these tasks, called vocational developmental tasks, are mastered, the individual is seen to be vocationally mature. Later stages named by Super were crystallization (starting at age 14–18), specification (18–21), implementation (21–24), and stabilization (25–35). Less clearly described are the stages after stabilization. To the degree that an individual successfully negotiates the stages in an age appropriate way, he/she is seen to be vocationally mature. The vocationally mature individual presumably has a smoother and relatively trouble free career pattern.

Adequate vocational development requires the individual to fit his/her emerging self-concept with an increasing awareness of the world of work. In order to include individual continuity in career development, Super added the self-concept. The self-concept involves the integration of experiences that give feedback to the individual in terms of his/her interests, abilities, and values. The emerging self-concept leads to a more sophisticated way of fitting round pegs into round holes, as suggested by the early work of Parsons. In the approach proposed by Super, the development of a person's self-concept provides one-half of the equation while increasing knowledge about the world of work provides the other half. Career choice is, thus, the process of increasing the accuracy of self-concept implementation, which in turn leads to career development.

Measuring Vocational Interests

Vocational interests and their measurement have played a significant role in understanding the career development process. Starting with the early work of E.K. Strong, the measurement of interests has occupied the attention of investigators of career development. The rationale for their importance is obvious: if one is able to implement one's career interests in work,

then the only missing variable is the assessment of one's abilities. When interests and abilities do not coincide, the career development process is derailed.

Holland's Approach to Career Development

Another way to view the manner in which self-concept implementation occurs is the approach proposed by J.L. Holland to understanding career development. Holland has described the world of work as consisting of six occupational environments (i.e., realistic, investigative, artistic, social, enterprising, and conventional.) These environments correspond to six personal types having the same names. As an individual matures, his/her experiences lead to the development of a personality, which can be described in terms of the six personal types. People are seen to seek occupational environments that correspond to their personal type. This idea is similar to the self-concept implementation in work as described by Super. While Holland's theory does not explicitly describe the way these personal types occur, they do seem to have a developmental aspect.

Values and Career Development

The role of values in the career development process is another significant variable. Values seem to be an intervening variable having a shaping effect on interests. In other words, interests first develop based on individual reactions to activities. There is some reason to believe interests are shaped by success or failure experiences. That is, as the individual gets feedback from the environment about how his/her abilities interact with satisfaction resulting from engaging in various activities, interests flow from success experiences. At a later point in the process, the notion that some activities have more intrinsic value than others begins to play a role in the early expression of occupational choices.

Life Stages

Developmental psychologists have postulated that human development can be described in terms of stages of life. Specific stages and their names vary according to the investigator. Career psychologists have adopted some of the names and stages and also have described stages in ways that apply specifically to careers.

As noted earlier, the most prominent career development stage theorist is Super. Knowledge of life stages can direct career psychologists in useful ways. For instance, the career developmental stage determines issues such as the content of the tasks of career development that are to be faced, how they take shape, and how they shift over time. Thus, an individual in the earliest stage would largely be focused on information gathering and integration, while at a later stage, say midlife, would be dealing with the ability to maintain his/her career status.

The Theory of Work Adjustment

Rene Dawis and Lloyd Lofquist created a theory of work adjustment which postulates that a hierarchy of personal needs

develops as a function of the individual's interactions with the environment. The outcome variable of interest in this theory is the correspondence between work requirements and personal requirements. The degree to which these are in accord results in what the authors call work adjustment, which can be viewed as a developmental process over the life span.

The theory offers a substantial number of psychometric instruments designed to measure personal needs that are to be potentially satisfied in work as well as measures to assess the degree to which these needs are satisfied in different occupations. Where the individual's needs are satisfied in their occupation, job tenure is predicted to be high. As the individual's needs change through the life span, satisfaction in different jobs changes, leading the individual to strive to alter his/her occupation. People strive to maintain a correspondence between their work needs and work requirements. The degree to which these correspond is called work adjustment, which is measured in terms of job tenure, satisfaction, and effectiveness.

Social, Economic, and Technological Influences on Career Development

Not to be denied is the impact of society on how one's career develops. This includes the state of the economy, social mores, and technology. Thus, an individual from a simple, primitive society would have fewer choices and less control over them than an individual from a complex society.

Underlying the social context of choices is the state of the economy. In a thriving economy the range of career choices available exceeds that in a stagnant or declining economy. Not only is the range of choice larger in an expanding economy, but new industries are spawned, which, in turn, create new kinds of work opportunities and eliminate other, older jobs. Thus, for example, the invention of the cell phone has dramatically changed the communications industry. Jobs for telephone operators have changed. Not only are there fewer of them, but the nature of the work itself has changed. Office technology has had other significant effects on jobs. There are fewer secretaries, and those jobs that remain are different than they were formerly. There is less need for shorthand skills. The invention of the personal computer has reduced the number of typists, since workers can do their own typing. An examination of the total range of occupations demonstrates how technology has created new jobs in the health professions, among others.

Social conditions interact with the individual's life stage. The state of the economy when one first enters the labor market, affects the range of possible initial decisions. This range, in turn, has a long-term effect on what follows in later life, even when the economy may have changed significantly. Another example of how technology has changed career development is the existence of the automobile. Before the automobile, people were limited in the range of their choices to those occupations which could be performed within a short distance from their homes. After the car came into widespread use, people were able to travel extensively and so they could live at some distance from their place of employment. This made it possible for more drastic changes in one's career than possible earlier.

Another example of how technology has effected career development can be seen in how the computer has and

continues to create new kinds of jobs, and job settings. For the first time since the industrial revolution, the computer enables people to work at home, or to work at long distances from their primary place of employment.

Social changes have affected careers in a multitude of other ways. Women's entrance into the labor force in significant numbers changed existing jobs by creating new careers (such as child care) in large numbers, the need for married couples to accommodate to each other's careers, and because two income families resulted in greater affluence, more and different consumer goods on which to spend this new money. Issues that occur throughout one's career are subject to various interventions. Career counseling, an entirely new profession, has been developed to help people deal with the problems described below.

Issues Involved in Choice

Numerous events can cause difficulty in determining an individual's initial career choice. Among those are personal, familial, and society barriers to implementing a person's career choice.

Barriers Blocking Entrance to Desired Vocations

People may encounter barriers to their entrance into desired occupations. These barriers may include lack of appropriate abilities, unrealistic interests, lack of resources for training, social discrimination, and lack of family support, to name but a few. Clearly, some of the barriers are external to the individual, such as social, economic, and new technologies.

Other issues may interfere with advancement. These include poor performance, limited job opportunities, interpersonal barriers, and social discrimination, for example.

Issues that are involved in premature or untimely vocational termination are sometimes within the individual and others external. For example, one reason for termination may include failure to meet employers' goals, physical or mental limitation, employment in obsolete industries, and reaching retirement age.

Comparison of Theories

Examination of the various theories reveals some major similarities of their major concepts. For example, Super's notion of self-concept implementation in work choice has some of the overtones of Holland's concept of correspondence between an individual's personal type and the type of the work environment experienced. And both the Holland and Super approaches share similarities with the Dawis and Lofquist notion of satisfaction/satisfactoriness of jobs as related to the degree to which the work setting reinforces an individual's primary psychological needs. This trend toward similarity of concept and outcomes suggests that the theoretical approaches, different as they may seem superficially, are converging.

Catecholamines and Behavior

L A Trevino, K Lorduy, M Natishyn, A L Dougall, and A Baum[†], The University of Texas at Arlington, Arlington, TX, USA

© 2012 Elsevier Inc. All rights reserved.

Glossary

Catecholamines A class of neurohormones that are involved in various central and peripheral processes; includes epinephrine, norepinephrine, and dopamine.

Dopamine A catecholamine that is an important neurotransmitter in the central nervous system involved in movement, mood, and learning.

Epinephrine A catecholamine that is a neurotransmitter and hormone that is produced from activation of the sympathoadrenal-medullary axis with its primary effects in the periphery including increased heart rate, dilation of blood vessels in the skeletal muscular system, opening of airways, and constriction of blood vessels in the skin.

Learning Involves establishing a conditioned response to a stimulus that did not illicit the behavior prior to a series

of interactions providing a conditioned reinforcement and/or punishment.

Norepinephrine A catecholamine that acts as a neurotransmitter and hormone in the periphery, and is produced from activation of the sympathoadrenal-medullary axis. In the central nervous system, norepinephrine acts as a neurotransmitter affecting many behaviors such as mood, learning, and arousal.

Stress Is experienced when an organism perceives harm, loss, or threat to their homeostasis or well-being. Activation of the sympathoadrenal-medullary axis and release of catecholamines along with activation of the hypothalamus-pituitary-adrenal axis and release of glucocorticoids are the primary physiological responses associated with stress and drive many of the other physiological, cognitive, and psychological changes that occur.

Introduction

There has been a substantial focus on the relationship between catecholamines and behavior. Researchers have examined a number of topics, including catecholaminergic pathways in the brain that promote stereotypical behavior, motor abilities, operant learning, psychopathology, and other higher-order behavior. As newer methods have become available, we have been able to understand behavior at a more basic level. Technology has allowed research to explore the functions of catecholamines, how they are synthesized, how they influence the function of particular areas in the brain to promote behavior, and how imbalances in particular regions produce pathology (e.g., Parkinson's disease, depression, schizophrenia). Comprehension of the relationship between catecholamines and behavior is best facilitated using a step-wise approach. We start with basic knowledge regarding catecholamines, and then discuss how they are measured centrally and peripherally. The role catecholamines play in stress, mood, learning and reward, and movement is also discussed.

What are Catecholamines?

The most prevalent catecholamines are dopamine (DA), norepinephrine (NE), and epinephrine (E). Dopamine acts as a neurotransmitter in the central nervous system (CNS) and is a precursor for NE and E. Epinephrine and NE are the primary catecholamines responsible for peripheral changes. Norepinephrine also acts as a neurotransmitter in the CNS. Before discussing the widespread effects of catecholamines on behav-

ior, the types of catecholamines and how they are synthesized and transmitted, as well as their central pathways, are described.

Dopamine

Dopamine is synthesized from a tyrosine molecule into L-dihydroxyphenylalanine (L-DOPA) by tyrosine hydroxylase, which is a rate-limiting enzyme that determines the overall rate of DA synthesis and the subsequent synthesis of NE and E. (Figure 1) Tyrosine hydroxylase activity is regulated by (1) the quantity of catecholamines present, such that high levels of catecholamines will inhibit the rate of tyrosine production, and (2) the rate of neural activity. L-DOPA is then converted into DA by the enzyme, L-aromatic amino acid decarboxylase. The location of synthesis occurs in the presynaptic terminals (i.e., the sender) of central dopaminergic neurons and begins with the activation of these neurons through action potentials. Dopamine is released into the presynaptic cleft following the influx of calcium ions into the presynaptic terminal and the synthesis of dopamine from tyrosine. Once released into the presynaptic cleft, DA activates dopaminergic receptors on the postsynaptic terminals (i.e., the receiver). Areas of high dopamine activity are (a) the arcuate nucleus projecting to the infundibulum of the hypophysis (pituitary gland), (b) the ventral tegmental area (VTA) projecting to the limbic system, and (c) the substantia nigra that projects to the striatum. These differing projections are implicated in various behaviors such as homeostasis, motivation, and movement (these behaviors are further discussed later in this article).

Projections from the arcuate nucleus through the tuberohypophyseal to the adenohypophysis (anterior pituitary gland) comprise the tuberoinfundibular DA pathway. This system serves the regulation of releasing and inhibiting factors

[†]Deceased.

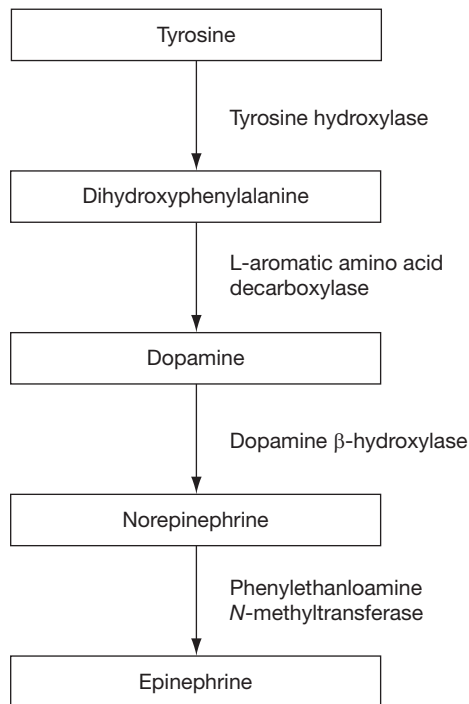

Figure 1 All catecholamines are derived from the precursor tyrosine. Its conversion by tyrosine hydroxylase is the rate-limiting factor in catecholamine synthesis and is highly regulated by catecholamine levels.

(hormones) that in turn synthesize their target hormones in the adenohypophysis and release them into the bloodstream. The hypothalamus exerts downstream effects from these hormonal pathways that include the regulation of food and water intake and thermoregulation. Damage or dysregulation of the tuberoinfundibular DA pathway therefore has serious consequences. For example, prolactin, one of the hormones regulated by this pathway, is responsible for lactation in nursing females. The production of prolactin is inhibited by DA, and a condition called hyperprolactinemia (too much prolactin) manifests when this inhibitory mechanism is disrupted. Symptoms of hyperprolactinemia for both sexes include inappropriate lactation, abnormal menstruation, and sexual side effects.

Dopaminergic projections originating from the VTA to cortical regions yield the ventral DA pathway. Additionally, there are two closely related subsidiaries of this pathway, the mesolimbic and mesocortical pathways. The mesolimbic pathway originates in the VTA and makes projections to the nucleus accumbens, septum, amygdala, and the hippocampus. The amygdala is involved in the emotional evaluation of a stimulus, whereas the medial prefrontal cortex modulates the mesolimbic pathway and facilitates both reward- and punishment-related motivation. Without adequate NE synthesis in the medial prefrontal cortex, dopaminergic transmission in the nucleus accumbens is abolished. This finding is supported by many studies that have demonstrated the suppressive effects of NE depletion on learned aversion behaviors and reversal learning. It is well established that the dopaminergic projections from the nucleus accumbens are responsible for reinforcement by activating reward and punishment neural regions. It has more recently been discovered that adrenergic projections from the medial

prefrontal cortex are a necessary forerunner in mediating this function. The mesocortical pathway connects the VTA to the frontal lobes, particularly the dorsolateral prefrontal cortices. These pathways are implicated in cognition, motivation, and reward circuitry. Particularly, psychiatric disorders, such as bipolar disorder and schizophrenia, have been associated with dysregulation of the ventral DA pathway.

The nigrostriatal or dorsal DA pathway originates from the substantia nigra to the striatum (both regions that comprise the basal ganglia). This pathway controls movement and dysfunction results in pathological conditions such as Parkinson's disease. Furthermore, medications, such as antipsychotics (e.g., haloperidol or thiorazine) can inhibit DA pathways and produce side effects such as tardive dyskinesia (Parkinson's-like symptoms).

Dopamine serves both inhibitory and excitatory functions in its pathways. For example, in the dopaminergic nigrostriatal pathway, there are both inhibitory and excitatory synapses with γ -aminobutyric acid (GABA) neurons: an inhibitory effect on the striatal GABA-ergic neurons of the lateral segment of the globus pallidus and an excitatory effect on the striatal GABA-ergic neurons of the medial segment of the globus pallidus and the pars reticulata of the substantia nigra. Essentially, these integrated networks provide a neural substrate for complex behaviors in organisms.

Norepinephrine

Norepinephrine acts as a neurotransmitter and as a hormone. The synthesis of NE occurs when DA is converted to NE by dopamine β -hydroxylase. This synthesis occurs in noradrenergic neurons in the central and sympathetic nervous systems (SNS), as well as in the cells in adrenal medulla. Peripherally, the main sources of NE are the sympathetic ganglia and the adrenal medulla.

There is a dorsal and a ventral NE pathway in the CNS. The dorsal NE pathway originates in the locus coeruleus (LC) and projects to the hippocampus and neocortex. The LC also has projections to the medulla oblongata that project to the SNS. The dorsal pathway is involved in the activation of the SNS following exposure to stressful stimuli. Conversely, the ventral NE pathway originates in the lateral tegmental field and projects to the diencephalon, particularly the hypothalamus. The major function of the central NE systems is to regulate arousal and modulate reward circuitry. In particular, these pathways constitute critical neural circuitry in reward and positive reinforcement. Many antidepressant drugs thus target noradrenergic projections to alleviate symptoms of depression. Additionally, nicotine stimulates significant increases in catecholamine activity in noradrenergic projections, contributing to its mood elevation properties.

Epinephrine

Epinephrine is synthesized from NE by the enzyme, phenylethanolamine *N*-methyltransferase (PNMT). Synthesis of E occurs primarily in the adrenal medulla and is released in conjunction with NE following activation of the SNS. Eighty percent of catecholamines released from the adrenal medulla following activation of the SNS are E; however, only 10% of

circulating catecholamines are E, indicating that additional sources of catecholamines lie outside the adrenal medulla. While the concentration of PNMT is highest in the adrenals, production of E still occurs in the rostral medulla oblongata. Consequently, E is the least ubiquitous catecholamine in the brain, and its neurochemical circuitry is isolated to the medulla oblongata. Nevertheless, it is important to consider that it does in fact exist in the CNS. Functionally, this region of the brainstem is particularly important in autonomic nervous system modulation, heart rate, and respiration. Glucocorticoids are often released in conjunction with catecholamines during stress responses. Glucocorticoids increase the expression of PNMT, thereby increasing the production of E.

Measurement of Catecholamines

Measurements of catecholamines can be used to determine the role they may play in behavior. Several techniques are used for measuring catecholamines, depending largely on whether central or peripheral measures are desired. Animal models are commonly used to directly measure catecholamines in the CNS. Brain dissection methods and tissue punching allow for rapid dissection of brain nuclei along major nerve terminal fields; however, these methods for measuring catecholamines and their neural pathways in the human brain are limited. Positron emission tomography (PET) is a current tool used to detect the radiofrequencies of neurotransmitters or the molecular weights of chemical substances in the human brain through the use of highly selective radiotracers. Otherwise, the detection of catecholamines in humans is muddled by the lack of available methods for distinguishing catecholaminergic function in the brain from that in the periphery.

Catecholamines, especially in humans, are more commonly measured in the periphery. Several common techniques are used for detection, including enzyme-linked immunosorbent assays (ELISA), radioimmunoassays (RIA), and high-performance liquid chromatography (HPLC). ELISA and RIA methods involve binding isolates of catecholamines to antibodies and use either color change (ELISA) or radioactive tracers (RIA) to detect levels. HPLC involves isolating catecholamines from proteins using electrospray ionization time-of-flight mass spectrometry and detection typically using an ultraviolet detector. Although HPLC is very sensitive and selective, it is also complicated and time-consuming. In comparison, ELISA is also sensitive and can be readily performed, especially by using commercially available kits.

Catecholamines and Stress

Catecholamines are an integral component of the stress response, in particular the release of NE and E from sympathoadrenal–medullary (SAM) axis activation. From an evolutionary perspective, the stress response is adapted out of the necessity for additional resources (energy) to be present in order to better prepare an individual to attend to a threatening stimulus or stressor. Following exposure to a stressful stimulus, the paraventricular nucleus (PVN) of the hypothalamus is activated. Activation of the PVN, in turn, activates two

neuroendocrine systems that release hormones into the periphery. The hypothalamic–pituitary–adrenal (HPA) axis is activated and releases corticosteroids from the adrenal cortex. Additionally, the PVN has projections to the LC, that then projects to the medulla oblongata, and ultimately to the SNS. Once the SNS is activated, NE is released from the sympathetic terminals that innervate certain vital organs, such as the heart and lungs. Additionally, activation of the SNS also causes the release of NE and E from the adrenal medulla. Circulating NE and E then have effects on the same vital organs, innervated by the SNS. The cells that comprise the organs in each system have β -adrenergic receptors or α -adrenergic receptors that bind selectively to NE or E, producing a myriad of effects, depending on the receptor subtypes. Although it is beyond the scope of this article to describe each of the subtypes, a general description of these SNS effects is provided subsequently.

When NE is released from the sympathetic ganglia and both NE and E are released from the adrenal medulla, these circulating levels of catecholamines can have profound effects on many important systems. For example, when the SNS is activated following stress, the release of these catecholamines results in increased heart rate and strength of cardiac contractions. Additionally, there is an increase in blood pressure by increased cardiac output and vasoconstriction of small arterioles. This occurs when NE binds to β -adrenergic receptors that are located on the cardiac muscle. This effect is further reinforced by E binding to these same receptors. The release of these catecholamines also leads to bronchodilation via β -adrenergic receptors to increase respiration. Glandular activity during SNS activation is greatly decreased with the exception of sweat glands. Increases in sweat gland activity follow activation of the SNS via α -adrenergic receptors. Additionally, during the stress response, NE and E influence smooth muscle of the gastrointestinal and urogenital tracts. The smooth muscles in these tracts will either contract due to activation of α -adrenergic receptors or relax due to activation of β -adrenergic receptors. Metabolic changes occur due to activation of the SNS, such that glucose and glycogen synthesis are favored in the liver, and lipid oxidation is favored as a primary function to provide energy to cells. The SNS activation also causes dilation of the pupils, increased saliva production, and inhibited digestion and sexual reflexes. Collectively, these physiological changes prepare an organism to fight the threatening stressor or flee from impending danger. These adjustments are adaptive and motivate individuals to function (physically and psychologically) effectively as they interact in a changing environment.

Catecholamines and Mood

Depression

Norepinephrine has a significant impact on neural activity, mainly through the extensive connections of the LC to various brain regions involved in mood, arousal, and endocrine functions. Epinephrine is involved in the peripheral response to SNS activation that triggers the ‘fight or flight’ response. Dopamine is involved in the reward pathway and movement. Studies have identified changes in the function of these neurotransmitters in patients with depression and anxiety disorders.

Additionally, serotonin has been shown to be involved in the pathophysiology of depression. There is evidence that in depressed patients, altered autoreceptor functions impair NE release, and that the response of second messenger systems to NE binding is blunted. In addition, some patients demonstrate blunted responses to exogenous activation of the SNS. These changes are seen in peripheral tissues, but some have also been identified in the frontal cortex of patients who committed suicide. Unfortunately, evidence of these changes is inconsistent in the literature, and there appears to be a distinction between patients with depression alone versus those with depression and anxiety or panic disorder. Preclinical studies have attempted to replicate these findings in animal models of depression that involve chronic mild and/or unpredictable stress. Animals subjected to chronic stress demonstrate changes in adrenergic receptor levels and functionality similar to those seen in depressed patients, lending further credence to the role of NE in depression.

Genomic studies have identified variants in some of the genes involved in catecholamine synthesis and metabolism that are associated with depression. Polymorphisms exist for the genes encoding tyrosine, hydroxylase, and dopamine beta-hydroxylase, and catechol-O-methyltransferase (COMT) as well as the genes encoding D₂ and D₄ dopamine receptors. From this, it is clear that genetic vulnerabilities exist for depression and that future treatments could target specific deficiencies – a model currently in use for chemotherapy drugs.

Several classes of drugs are used to treat depression: monoamine oxidase inhibitors, tricyclic antidepressants (TCA), selective serotonin reuptake inhibitors (SSRI), receptor antagonists, serotonin-norepinephrine reuptake inhibitors (SNRI), and norepinephrine-dopamine reuptake inhibitors (NDRI). Monoamine oxidase inhibitors, such as phenelzine, inhibit the action of monoamine oxidase, which is an enzyme that breaks down monoamines (NE, E, and DA) following release into the synaptic cleft. Tricyclic antidepressants like amitriptyline work by blocking several neurotransmitter receptors, such as adrenergic, noradrenergic, and serotonergic, to name a few. The SSRIs, such as sertraline, work by blocking serotonin reuptake following release from the presynaptic terminal of the neurons. The SNRIs (i.e., duloxetine) and NDRIs (i.e., bupropion) work in similar fashion to those of the SSRIs by blocking serotonin and NE, and NE and DA, respectively.

Studies comparing antidepressants that target monoamine functions have demonstrated similar efficacies for drugs that target NE and/or DA versus those that are serotonin-specific. Although older versions of these drugs were hindered by side effects (mainly due to peripheral adrenergic activity and toxicity due to monoamine oxidase deficiency), current treatments are much safer and demonstrate fewer side effects. The only concern when using antidepressants that target catecholamine activity is that some patients may experience increased anxiety as a result of enhanced NE binding.

Additional treatments are used for depression, including electroconvulsive therapy (ECT) and deep brain stimulation (DBS). Both of these therapies are invasive to the patients, so they are used as a last resort when pharmacological and talk therapies have not worked. Electroconvulsive therapy involves inducing a seizure in a patient through the use of electricity and requires several sessions in order to fully alleviate

depressive symptoms. The course of ECT begins with marked improvements in appetite and drive that is believed to be caused by an increase in DA receptor function. Following additional sessions of ECT, patients experience an increase in energy and attention, which is believed to be the result of an increase in synaptic NE. The final sessions of ECT see improvements in cognition and resolution of anxiety that is associated with depression. This is believed to occur through increased serotonin function. Deep brain stimulation involves the implantation of an electrode into the brain and stimulates that area with low-frequency electrical stimulation. This procedure is a new treatment for depression, so the areas that are stimulated are still being mapped. However, there has been some success in relieving depressive symptoms by stimulating Brodmann's Area 25. It is believed that this therapy works by inhibiting this area of the brain, which causes increased activation in other areas of the brain that have been implicated in the cause of depressive symptoms.

Through manipulation of the various neurotransmitter systems in the brain, alleviation of depressive symptoms is achieved. However, it is believed that certain neurotransmitters are responsible for the alleviation of certain symptoms. For example, manipulation of the NE system may be related to improvements in alertness, energy, and interest in life. Therapies targeted to the DA system show improvements in attention, motivation, pleasure, and reward. Additionally, negative affect is improved by changes in the NE and serotonin systems, whereas loss of positive affect is improved by manipulations of the NE and DA.

Current research is examining the role of HPA axis dysregulation in depression, and novel targets for pharmacotherapy have been identified in preliminary studies. Dysregulation of the HPA axis leads to excess catecholamine release and could cause the pathological changes in catecholamine functions seen in depressed individuals. Altered catecholamine activity and HPA axis dysregulation have both been found in studies of suicide victims. However, catecholamine markers have been found to differ between suicide victims and patients with depression who are not suicidal. This suggests that altered HPA axis and catecholamine functionality is a risk factor for suicide in patients with depression but not an indicator of depression alone. Continued research into the relationship between catecholamines and mood disorders may shed light on the underlying mechanisms that trigger the development of these conditions.

Schizophrenia

Schizophrenia is a psychotic disorder that involves positive symptoms, such as hallucinations, delusions, and disorganized thoughts, and negative symptoms, including lack of speech, cognitive deficits, and depressive symptoms. Dopamine has been identified as one of the neurotransmitter systems that contribute to this debilitating disorder. The different dopaminergic pathways contribute in different ways to both positive and negative symptoms. For example, increased dopaminergic activity in the mesolimbic pathway is thought to underlie the hallucinations, delusions, and disordered thoughts that are the positive symptoms. Additionally, decreased dopaminergic activity in the mesocortical pathway and function in the

prefrontal cortex have been associated with negative symptoms. Memory deficits that are common in schizophrenic patients may also be associated with decreases in D₁ receptor transmission in the dorsolateral prefrontal cortex. With available technology and strides in the creation of animal models, additional neurotransmitter systems, such as NE, serotonin, GABA, and glutamate, have been implicated in maintenance of schizophrenic symptoms.

It has been well established that an increase in DA in critical sites in the brain play a major role in psychosis. However, there is a growing interest in examining the role of NE dysfunction. Recently, it has been found that individuals with schizophrenia whose psychotic symptoms returned while on medication produced more dopamine- β -hydroxylase (the enzyme that synthesizes NE from DA) than those that did not relapse. Also, increases in NE were strongly correlated with increases in both negative and positive symptoms in schizophrenic patients. Research demonstrates that when NE is not synthesized proportionately with DA, the emotional valence is increased. The disproportion between DA and NE is thought to explain the extreme fear experienced in schizophrenic individuals.

Treatments for schizophrenia fall into two categories of drugs: typical and atypical antipsychotics. Typical antipsychotics, such as Chlorpromazine, are used to treat positive symptoms, and can exacerbate negative symptoms. Typical antipsychotics are similar to DA and bind to D₂ receptors in the mesocortical and nigrostriatal dopaminergic pathways in the CNS. Atypical antipsychotics are more effective in eliminating negative symptoms; however, they do not have as high affinity for D₂ receptors as typical antipsychotics. There has been some debate regarding how to effectively treat negative symptoms of schizophrenia. Recently, there have been some questions on the advantages of treating these symptoms with atypical antipsychotic drugs versus neuroleptics. These classes of drugs are not solely specific to manipulation of dopaminergic pathways, but also improve imbalances in the other neurotransmitters, such as serotonin, glutamate, and GABA, that are associated with schizophrenic symptoms.

The DA hypothesis of schizophrenia is further supported by the fact that normal individuals will experience some psychotic symptoms that mimic those involved in schizophrenia when they take DA agonists such as cocaine and amphetamines. Also, when the DA agonist, L-DOPA, is administered in Parkinsonian patients at too high a level, it can potentially induce schizophrenic-like symptoms, including hallucinations, paranoia, and the stereotypic behaviors. In another study, the ability to modulate auditory filtering, a hallmark of schizophrenia was lost when amphetamines were administered in an animal study. Further, there have been studies that demonstrate the use of monoamine- β inhibitors (mirtazapine) to inhibit DA that could potentially help in treating the negative symptoms of this disease. Together, this evidence supports the role of catecholaminergic function in the pathogenesis of schizophrenia.

Learning and Reward

Learning is associated with acquiring new skills and behaviors through a series of stimulus–response associations. Recall of these associations is important for the expression of future

behaviors and adaptations that are important for survival, such as locating high-quality food sources and avoiding areas where predators reside. The process of differentiating rewarding stimuli from those that have negative consequences aids in the ability to make predictions about the surrounding environment and serves as a foundation for goal-directed behavior. Catecholamines are intrinsically involved in learning as well as reward and motivation, as demonstrated by studies employing genetic knockouts, drugs that modify catecholamine synthesis, metabolism, and functionality, and behavioral paradigms designed to evaluate reward and aversion. Alterations in noradrenergic and dopaminergic pathways produce changes on behavior. For example, damage to the nigrostriatal areas reduces eating and drinking behaviors, while damage to the mesolimbic dopaminergic pathway causes deficits in movement that would facilitate these goal-directed behaviors. The central DA pathways facilitate learning and reward goal-directed behavior, such as seeking out food, water, or drugs, as demonstrated by numerous studies that have observed increases in consumptive behaviors with the administration of DA agonists. Additionally, DA antagonists reduce or block the rewarding nature of food, water, cocaine, and amphetamines.

Both noradrenergic and dopaminergic neurons fire when paired with a novel or unpredictable stimulus, and their activation is inhibited by a predictable stimulus. Levels of these catecholamines are also dose-dependent for learned behavior, in that both high and low doses of NE impair learning. Therefore, there is an optimal range to facilitate learning. The major difference between NE and DA in learning appears to be that NE is needed to start learning or changing of behavior. Its continued release is not needed to sustain the expression of a behavior, but DA is necessary to maintain the continued expression of such behaviors. In contrast, behavioral suppression occurs when the DA or NE functioning is impaired.

Other neurotransmitters appear to exert effects on the catecholamine pathways in learning, such as glutamate, GABA, and even serotonin. Glutamate is highly important in learning, as long-term potentiation is necessary for memory formation in the hippocampus. Many of the dopaminergic projections involved in learning interface with glutamatergic projections to the hippocampus, and both NE and DA terminals implicated in learning are regulated by glutamate receptor activity. Serotonin can also moderate catecholamine-dependent behavioral learning by changing the dose-dependence of catecholamines to initiate a learned behavior. Finally, drugs such as cocaine and amphetamine activate these same pathways for reward and learning. For example, amphetamine has a similar chemical structure to that of NE and produces similar effects in the reward and learning pathways.

Projections from the basal ganglia to the hypothalamus play a role in conditioning responses by reinforcing behaviors through stimulation of reward centers in the brain. The endogenous reward system yields a highly positive experience as evidenced by numerous studies that demonstrate that animals will voluntarily stimulate areas of their brain involved in reward by pressing a lever that applies an electric current to electrodes implanted on neurons in reward centers in the brain. The use of self-stimulation paradigms revealed that electrical stimulation associated with activation of central dopaminergic pathways is rewarding, despite the fact that no intrinsic

drive (such as hunger or thirst) is present. Additionally, administration of DA agonists increases self-stimulation and DA antagonists decrease it. Under normal circumstances, an activity associated with the reduction of a biological drive state would activate these same pathways, reinforcing the action as well as environmental cues associated with the reward.

Drugs of addiction directly or indirectly act upon the central dopaminergic pathways to produce a pleasurable sensation that is inherently rewarding. The response is so strong that the administration of drugs such as cocaine enhances self-stimulation and reduces the stimulus intensity required to reinforce this behavior. Unfortunately, repeated activation of the reward pathway by cocaine or amphetamines alters the postsynaptic response to dopamine release, and eventually, tolerance develops to the initial dose of drug, and the original euphoria can only be achieved through increased consumption. Eventually, the brain adapts to the continual presence of the drug, and addiction develops as an individual finds it necessary to continue using in order to achieve normalcy instead of euphoria.

Movement

The basal ganglia is an area of the brain responsible for the organization, execution, and timing of voluntary movements, such as writing on a chalkboard. The basal ganglia consist of several different nuclei, including the caudate nucleus, putamen, globus pallidus, substantia nigra, and the subthalamic nucleus. The circuitry of these different nuclei is responsible for the execution of voluntary movement. (Figure 2) The substantia nigra has projections to the putamen via two different dopaminergic pathways. The direct pathway that uses the D₁ dopamine receptors facilitates movement, whereas the indirect pathway that uses the D₂ dopamine receptors, inhibits movement. The direct pathway begins when the putamen receives excitatory dopaminergic projections from the substantia nigra. The putamen then sends inhibitory GABA projections to the

internal globus pallidus that sends inhibitory GABA-ergic projections to the thalamus. In the indirect pathway, the substantia nigra sends inhibitory dopaminergic projections to the putamen. The putamen sends inhibitory GABA-ergic projections to the external globus pallidus. The external globus pallidus sends inhibitory projections to either the internal globus pallidus or the subthalamic nucleus. The subthalamic nucleus sends excitatory glutamatergic projections back to the internal globus pallidus. The internal globus pallidus sends inhibitory projections to the thalamus. When projections from the internal globus pallidus reach the thalamus, the result is inhibition of thalamic neurons. Both of these pathways from the subthalamic nucleus are vital in the coordination of voluntary movement.

Parkinson's disease is a debilitating disorder that is marked by characteristic tremors at rest, difficulty initiating movement, and rigidity in movement. Additionally, there can be some emotional and cognitive deficits associated with the disease. Parkinson's disease is characterized by a depletion of dopaminergic neurons in the substantia nigra that projects to the putamen. Depletion of these neurons causes deficits in both the direct and indirect pathways. Activation of the dopaminergic neurons that contain D₁ receptors that project to the putamen from the substantia nigra causes a reduction in neuronal activity to the internal globus pallidus. This ultimately leads to increased neuronal activity in the projections from the internal globus pallidus to the thalamus. When this occurs, there is less inhibition of thalamic neurons. In the indirect pathway, the inhibition of dopaminergic neurons from the substantia nigra is greatly reduced, leading to increased neuronal activity to the external globus pallidus. The increase in neuronal activity of the external globus pallidus leads to decreased neuronal activity to the internal globus pallidus and the subthalamic nucleus. The reduction in neuronal activity ultimately leads to increased neuronal activity to the thalamus. The increases in thalamic activity following destruction of the dopaminergic neurons in the substantia nigra would lead to the characteristic rigidity that is the hallmark of Parkinson's disease.

Figure 2 Neural circuitry of movement. This is simplified to include the dopaminergic pathways discussed in the text. Solid lines reflect excitatory activity and dashed lines reflect inhibition. SN, substantia nigra; STN, subthalamic nuclei; GPE, external globus pallidus; GPI, internal globus pallidus; and D1/D2 refer to specific dopamine receptor types.

In order to treat Parkinsonian symptoms, several treatments have been targeted to improve depleted DA levels in the basal ganglia. L-DOPA, which is the precursor to dopamine, is commonly used in Parkinsonian patients to regain motor control. L-DOPA influences the ability of damaged dopaminergic neurons to metabolize DA along the nigrostriatal path, a pathway largely involved in motor function. Recently, another DA agonist, pramipexole has been experimentally challenged as an adjunct to L-DOPA in order to improve motor deficits along with the depressive behaviors (e.g., dysphoria, social withdraw, cognitive deficits) that accompany the dopaminergic dysfunction associated with Parkinson's disease. Although L-DOPA is a common method of treatment for Parkinsonian symptoms, administration of this drug at too high a level can potentially induce schizophrenic-like symptoms, including hallucinations, paranoia, and the stereotypic behaviors. Deep brain stimulation of the basal ganglia has shown remarkable and immediate improvements in symptoms associated with Parkinson's disease.

Summary

The catecholamines, DA, NE, and E, are essential not only for survival during times of crisis but are also involved in learning, motivation, and reward processes that contribute to an organism's adaptive prowess. The actions of NE and E as part of the body's stress response system trigger an immediate response to threatening stimuli through increased arousal, priming of the cardiovascular system, and changes in blood flow that favor skeletal muscles over the organs of digestion. Mood is greatly affected by NE and DA, and disruptions to these systems can lead to depression, anxiety disorders, or schizophrenia. Dopamine's role in motivation and reward enables an organism to identify pleasurable events and also learn to avoid aversive conditions, a distinction that is vital for long-term survival. In addition, the delicate balance of DA and NE in

the CNS is responsible for voluntary movement, and any disruption to these neurotransmitters can lead to disorders of movement as seen in Parkinson's disease. Continued research into the factors that influence both central and peripheral catecholamines and disease states is essential for the creation of novel therapies that could prevent dysfunction and deleterious consequences.

Glossary

Amusia A selective impairment of the ability to appreciate music related to damage to the central nervous system.

Attention deficit hyperactivity disorder

A neurodevelopmental disorder characterized by inattentiveness, hyperactivity, and impulsivity.

Auditory agnosia A collection of disorders associated with loss of the ability to recognize sounds that is not attributable to sensory difficulties.

Auditory evoked potentials A series of minute electrical potentials that reflect the neurophysiologic activity generated in the auditory system in the course of processing an auditory stimulus.

Auditory processing disorder (APD) Disorders of auditory processing in children resulting from functional compromise of the central auditory processes underlying the analysis of auditory information.

Central deafness A broad term referring to conditions in which the detection of sound is impaired due to dysfunction of the central auditory nervous system.

Cortical deafness A relatively rare condition usually associated with bilateral temporal lobe damage resulting in functional deafness.

Developmental dyslexia or reading disorder (RD)

A neurodevelopmental disorder characterized by specific deficiencies in decoding written language.

Dichotic listening A task that evaluates a listener's ability to process competing signals by delivering different information simultaneously to each ear.

Hyperacusia Heightened sensitivity to auditory stimulation associated with an aversion to or intolerance for certain sounds at their typical sound levels.

Planum temporale An area on the dorsal surface of the superior temporal gyrus posterior to Heschl's gyrus thought to play a role in processing the rapid spectrotemporal cues in sound, including speech.

Pure word deafness A subtype of auditory agnosia characterized by severe difficulties in understanding spoken language with intact speech production, nonauditory language, and relative preservation of nonverbal sound recognition and identification.

Specific language impairment (SLI) A neurodevelopmental disorder characterized by problems in understanding or producing language in the absence of causal factors such as hearing impairment, mental retardation, neurological deficits, primary emotional disorder, or social deprivation.

Tinnitus The perception of sound in the absence of an external acoustic stimulus.

Introduction

The complexity of the central auditory nervous system (CANS) is unrivaled by other human sensory systems. Comprised of multiple parallel pathways consisting of many intricately interconnected nuclei, the system is capable of processing information with remarkable speed and efficiency. While information processing in other sensory modalities usually occurs on a timescale of milliseconds, the CANS is capable of coding time-based acoustic cues on the order of microseconds. Detailed knowledge of the function of the CANS has been slow to emerge and correspondingly there is also limited understanding of the central auditory processing disorders (CAPDs) that arise when its operation is impaired by disease, damage, or maldevelopment. Nevertheless, significant progress has been made in recent years both in recognizing these disorders and in developing a workable framework for their diagnosis and treatment.

The term CAPD encompasses a broad range of deficits that occur when neural processes underlying the analysis of auditory information by the brain are functionally compromised. Currently, it is defined by deficiencies in one or more of the following auditory behaviors: sound localization and lateralization, auditory discrimination, auditory pattern recognition, auditory temporal processing (e.g., resolution, integration,

masking, ordering), and performance with competing or degraded acoustic signals. Given the paramount role of hearing in everyday human communication, CAPD often comes to attention as difficulties in processing speech.

We begin this overview of CAPD with a brief synopsis of the organization and function of the CANS. This is followed by a summary of acquired syndromes that arise with lesions to the CANS. We then discuss idiopathic and developmental forms of CAPD and conclude with a discussion of treatment approaches.

Neural Architecture of Central Auditory Processing

The three primary functions of the auditory system are to detect sounds, localize their source, and determine their identity and meaningfulness. For the brain to interpret what we hear, sound vibrations must first be transduced into patterns of neuronal excitation. This is accomplished by ~3500 inner hair cells (IHCs) (see [Figure 1\(a\)](#)) that are organized in a single row on the ribbon-like basilar membrane that runs down the cochlea of the inner ear. Analogous to the arrangement of the strings on a piano, there is an orderly relationship between the frequency of a sound and the location of IHCs on the basilar

Figure 1 (a) Schematic drawing of a cross-section of the cochlea showing inner and outer hair cell on the basilar membrane. The fine filaments protruding upward from inner hair cells toward the tectorial membrane represent clusters of cilia of varying length. Movement of a bundle back and forth causes cycles of depolarization and hyperpolarization of the hair cell. These occur at a preferred time during the stimulus wave cycle resulting in pulsatile release of neurotransmitter and phase locking of the postsynaptic potentials of spiral ganglion cells. (b) Schematic diagram of the major nuclei of the ascending pathways. Colored lines represent the chief ipsilateral and contralateral pathways from the left cochlea to the auditory cortex. The same pathways from the right cochlea are not depicted here to allow a clear view of the anatomy of the brain stem. Similarly, no attempt is made to illustrate subdivisions of nuclei and connections within regions that transmit information both ipsilateral and contralateral to the ear of stimulation. (c) Coronal view of the brain illustrating the location Heschl's gyrus and secondary auditory cortex on the dorsal surface of the superior posterior temporal lobe. Courtesy of Patricia Hearons.

membrane that a sound maximally stimulates. This tonotopic organization enables the cochlea to act as a frequency analyzer, essentially decomposing spectrally complex sounds into constituent frequencies.

Stimulated IHCs release neurotransmitters that are detected by receptors on axons of nearby inner ear spiral ganglion cells, causing action potentials to be propagated along these axons toward the brainstem. Approximately 30 000 of these fibers comprise the bulk (95%) of the eighth cranial nerve, also known as the vestibulocochlear nerve (VN). Given that each spiral ganglion nerve cell axon carries action potentials originating from stimulation of a single IHC, the VN is also tonotopically organized. Indeed, tonotopy is preserved up to and including auditory cortex.

The frequency of a stimulus is coded not only by the location of the stimulated IHC on the basilar membrane, but also in the timing of the intervals between spikes. The firing rate of IHCs encode the intensity of sound which, up to a certain sound level (~ 50 dB), translates to an increase in the discharge rate and the number of spiral ganglion cells firing. Thus, critical information on the frequency, intensity, and timing of a stimulus is coded in activity of these afferents to the brainstem.

Ascending Auditory Pathways

VN fibers enter the brainstem at the posterior pontomedullary junction, bifurcate, and synapse with neurons of the cochlear nucleus (CN), the gateway to the CANS (see [Figure 1\(b\)](#)). Neurons of the CN begin the process of extracting and coding features of acoustic input, setting the stage for more refined processing of acoustic features at progressively higher levels of the CANS.

From the CN, coded impulses ascend the CANS in multiple, parallel, and hierarchically organized processing pathways that carry information regarding different aspects of sound to the auditory cortex. [Figure 1\(b\)](#) provides a highly simplified schematic representation of the flow of information. In reality, the system is exceedingly complex, involving at least nine nuclei in the ascending system. Each major division is characterized by a distinctive composition of cell types functionally specialized for performing particular computations on sensory input.

As shown in [Figure 1\(b\)](#), ascending fibers leave the CN and decussate, sending information to both the ipsilateral and contralateral superior olivary complex (SOC). Since each SOC receives input from both ears, critical binaural analyses

occur here relating to sound localization. Neurons in the lateral superior olive (LSO) process interaural sound level differences (ILDs), a cue used in the spatial localization of high-frequency sounds. By contrast, cells in the medial superior olive (MSO) assist in sound localization by detecting microsecond level disparities in the arrival time of sound at the two ears (intra-aural timing differences, ITDs). Overall, approximately five nuclei of the ascending CANS are involved in some aspect of sound-source localization.

Nearly all of the ascending auditory fibers converge in the central nucleus of the inferior colliculus (ICC) in the midbrain. The IC plays a critical role in integrating spectral and temporal information in order to localize sound sources and code dynamically varying stimulus attributes, such as changes in frequency and amplitude.

Two nuclei, the external nucleus of the IC (ICX) and the dorsal cortex of the IC (DCIC), comprise components of the so-called nonclassical or extralemniscal auditory system. This system receives its primary input from the ICC and follows a parallel course to the classical auditory pathway up to the thalamus, synapsing with the dorsal and medial parts of the medial geniculate body (MGB). The pathway then diverges from the classical pathway, which projects to primary auditory cortex (PAC). Instead, the extralemniscal system projects to secondary and association cortices and to regions not directly contacted by the classical auditory pathway, such as the basolateral nucleus of the amygdala and the cerebellum. Neurons of the nonclassical system differ from neurons of the classical auditory pathways in that they are not as sharply tuned to stimulus features and they respond to input from the auditory, visual, and somatosensory systems.

In the classical auditory system, the main target for projections of ICC neurons is the ventral nucleus of the MGB (MGv). From the MGv, projections go on to the PAC via the auditory radiations. These connections allow for extensive convergence and divergence of information. A single cortical locus can receive inputs from large regions of the thalamus and conversely individual axons can establish synaptic contacts spanning up to 7 mm of cortical surface.

Cells in MGv demonstrate greater selectivity of responses to stimulus features than neurons lower in the system. Many appear unresponsive to simple acoustic stimuli but show vigorous responses to specific parameters of complex time-varying stimuli (e.g., direction or rate of frequency change). The responses of neurons in MGv, to some degree, are tuned by cortical influences (directly or through the thalamic reticular nucleus) aimed at optimizing the processing of dynamic aspects of auditory input used to identify, localize, and ascribe meaning to sounds.

Auditory Cortex

Many computational transformations related to the processing of an auditory stimulus are completed before activation reaches the PAC, located on Heschl's gyrus in the superior temporal lobes (see [Figure 1\(c\)](#)). Nevertheless, further processing and integration occurs at the cortical level, evidenced by sensitivity of various cortical fields to a range of basic stimulus attributes such as frequency (tonotopic organization), bandwidth, intensity level, spatial location, and movement or

motion. Some response properties of PAC neurons are inherited from thalamic inputs while others undergo significant transformation or are generated intracortically. While most neurons in PAC are binaurally influenced, 10–20% show no evidence of binaural interaction.

Surrounding the PAC are so-called belt and parabelt regions, which are responsible for secondary and tertiary levels of cortical processing, respectively. While PAC responds to all types of auditory stimuli, secondary and association auditory cortex in anterolateral and ventral auditory areas show particular sensitivity to spectrally and temporally complex sounds, including speech. These areas form part of a hierarchically organized processing stream involved in auditory object and speech perception. This auditory analog of the so-called 'what' pathway in vision includes connections from anterior belt areas directly to ventrolateral prefrontal cortex (PFC). By contrast, a posterodorsal stream, analogous to the 'where' pathway in visual system, is involved in the perception of auditory space and motion as well as aspects of processing speech and language. This pathway extends from PAC to the posterior superior temporal gyrus, inferior parietal cortex, and eventually projects to dorsolateral PFC.

Experience plays an important role in determining the functional circuitry of the auditory cortex. Processing in the auditory cortex is dynamic, with reorganization occurring to optimize the apprehension of relevant stimuli. This plasticity is reflected in cortical tonotopic maps that can adaptively change in response to reinforcement, or fill in areas that may be otherwise deprived of input from cochlear lesions.

Ontogenetically, synaptogenesis of PAC peaks at 50 months of age and myelination of thalamocortical projections continues until ~6 years of age. Hence, auditory cortex function continues to evolve throughout early to middle childhood, maturing late relative to other sensory cortex. Many cortically mediated aspects of central auditory function are dependent on processing by secondary and association cortex and their intra- and interhemispheric connections. Consequently, some functions of the CANS do not fully mature until adolescence.

The auditory cortices of humans possess some hemispheric specialization of function. Auditory processes distributed in the left cerebral hemisphere appear to be particularly adept at processing rapid dynamic changes (up to a few tens of milliseconds) in the spectrotemporal form of sound, whether or not stimuli are speech. The right hemisphere appears to preferentially process stimulus features that vary more slowly or require integration over longer periods of time (e.g., melody, prosodic contours in speech, emotions in voice).

Efferent Auditory Pathways

The CANS contains an extensive network of structures and pathways that allow higher order auditory processing centers to exert 'top-down' influences over the activity of lower nuclei. The auditory corticofugal system (ACS) takes the form of descending cortical projections that reach every major element in the auditory system, extending as far as the cochlear hair cells. This system forms important feedback loops designed ultimately to adjust and improve input to the cortex for signal processing. The ACS temporarily or permanently influences the filtering, tuning, and response plasticity of the CANS.

CAPD: Diagnostic Considerations

Individuals diagnosed with CAPD present with a variety of symptoms that can range in severity from a lack of responsiveness to sound (cortical deafness) to a constellation of more subtle problems reflecting impaired listening skills or difficulties discriminating slight differences in sounds. The latter problems include difficulties attending to and remembering orally presented information, following multistep directions, and perceiving speech when it is presented in a noisy environment (e.g., classroom, cocktail party), at a rapid rate, or when signals are degraded (e.g., indistinctly articulated, transmitted via intercoms, public address systems, cell phones).

In considering the diagnosis, it is necessary to establish that a peripheral hearing loss cannot account for a presenting problem. Quantification of peripheral hearing sensitivity typically entails standard audiometric testing, such as pure tone and speech audiometry. This may be combined with immittance audiometry, otoacoustic emissions and possibly brainstem auditory evoked potentials. It is also necessary to evaluate potential 'top-down' contributions to auditory processing problems such as difficulties with attention, memory, linguistic processing, or other specific cognitive domains. The diagnosis of CAPD therefore often requires multidisciplinary input.

Three complementary approaches are used to identify the presence of deficits consistent with CAPD. The most common initial approach is behavioral assessment, which examines a listener's performance on structured auditory tests that evaluate several dimensions of processing commonly impaired individuals with CAPD. Behavioral assessments can be supplemented, when necessary, with electrophysiological testing measures and/or neuroimaging techniques. The essentials of these approaches are discussed in the following sections.

Behavioral Assessment

Behavioral assessments utilize psychoacoustic measures and norm-referenced, performance-based tests to identify deficiencies in auditory skills linked to CAPD. There is no standard approach to the assessment of CAPD, although some guidelines have been established. The tests can be conceptualized as falling into five broad categories of auditory behavior. A number of the measures commonly used in assessing CAPD are listed in [Table 1](#) along with the auditory skill to which they broadly relate. It is not possible to precisely match the behaviors associated with CAPD with specific measures in a one to one correspondence, in part due to the multifactorial nature of task demands.

The choice of diagnostic measures is driven by a careful review of the patient's history and presenting problems, but also by the characteristics of the tests themselves, such as the quality of the normative data and the discriminant validity. Details of the specific nature of the presenting problem(s), onset, progression, consistency, and the circumstances of manifestation help to define the scope of an evaluation. In addition, it is necessary to consider variables such as age, gender, medical and psychological history, and the presence of coexisting conditions or concerns.

Implicit in the overall approach is the notion that different patterns of auditory processing impairment can emerge depending on the location, extent, and nature of compromise of the

CANS. Pathophysiology of the brainstem frequently results in problems of binaural convergence and integration. As a consequence, conditions such as multiple sclerosis or brainstem stroke are associated with highly abnormal performance on tests examining sensitivity to ILD or ITD, due to both the need for integration and the microsecond level timing requirements for accurate ITD perception. Interestingly, sound localization can also be impaired in conditions such as albinism where the development of decussated pathways to the SOC is atypical.

By contrast, patients with unilateral lesions often but not invariably retain some ability to process either ILD or ITD measures, although their performance may differ from normal controls. Left hemisphere lesions can result in particular difficulty with ITD judgments. However, unilateral patients are more likely to have difficulty localizing sounds in the vertical plane or when spatial localization cues must be integrated with mental representations of space (as in free-field localization). They may have particular difficulty in localizing sound sources in the side of space contralateral to their lesions. This is most strikingly evident following right parietal lobe damage which acutely can result in auditory neglect. Individuals with neglect may be unresponsive to voices and environmental noises emanating from the left side of space or they may demonstrate alloacusis, systematically localizing these sounds to the right side of space.

Auditory discrimination is a fundamental skill necessary for a listener to consistently assign meaningful properties to an acoustic object. Auditory discrimination is typically tested by prompting the listener to decide whether two stimuli are the same or different, or by matching an auditory stimulus to one of several pictures of acoustically confusable objects. Stimuli may be contrasted in a number of domains including pitch, duration, intensity, and phonetic cues.

Dysfunction of the CANS often results in difficulty discriminating brief auditory temporal events in sound. These difficulties commonly become evident in poor speech perception, because phonemic discrimination and identification requires resolution of brief or rapidly changing acoustic cues in the speech signal such as consonantal bursts, formant frequency transitions, and voice onset time. These cues occur on the order of milliseconds to tens of milliseconds.

Discriminating the duration of particular cues is essential for recognition of voicing contrasts in stop consonants (e.g., /p/ vs. /b/, /t/ vs. /d/, /k/ vs. /g/), the timing of silent bursts in fricatives and vowel length. Resolution of rapid changes in frequency is essential for distinguishing acoustic cues related to the place of articulation in stop consonants and manner of articulation in stops and glides. Problems discriminating these temporal cues lead to errors in discrimination even though speech audiometry thresholds are normal.

Basic temporal resolution is commonly measured using psychoacoustic tasks such as click fusion, click differentiation, or gap detection. In click fusion, very brief (< 1 ms) spectrally broadband stimuli (clicks) are presented in rapid succession separated by a short intervening period of silence. When the silent interstimulus interval is extremely brief, the temporal boundary between each click is insufficient to result in separate percepts, so listeners fuse two clicks and report hearing only a single click. Extending the duration of the interstimulus interval beyond a threshold value results in the perception of two

Table 1 Summary of auditory behaviors and assessments for CAPD

<i>Auditory behavior</i>	<i>Assessment measure</i>
1. Localization and lateralization	Interaural intensity difference, interaural time difference (e.g., Kaga et al., 1997 [^])
2. Temporal processing	Click fusion, click differentiation (e.g., Lackner and Teuber, 1973; Stefanatos et al., 2005 [^])
Resolution, integration, discrimination, temporal ordering	Auditory fusion threshold test (McCroskey and Keith, 1996) Within and between channel gap detection (e.g., Phillips, 1999; Stefanatos et al., 2007 [^]) Random gap detection test (Keith, 2000) Gaps in Noise Test (Musiek et al., 2005) The Duration Pattern Test (DPT) (Musiek et al, 1990) Pitch Pattern Sequence Test (PPS) (Pinheiro, 1977)
3. Auditory discrimination	Newcastle Auditory Battery (Griffiths et al., 2001) Phoneme discrimination (Wepman and Reynolds, 1986; Benton et al., 1983) Test of Auditory Perceptual Skills (TAPS-R) (Gardner, 1997) [<i>Word Discrimination</i>] Environmental sound discrimination (e.g., Schnider et al., 1994 [^])
4. Processing low redundancy or degraded auditory signals (separation, closure) Time compressed, filtered, interrupted, competing with noise	Multiple Auditory Processing Assessment (MAPA) [<i>Monaural-Selective Auditory Attention Test (M-SAAT)</i>] (Schow et al., 2007) MAPA [<i>Speech in Noise for Children and Adults (SINCA)</i>] (Schow et al., 2007) Test for Auditory Processing Disorders in Children (SCAN-C) [<i>Filtered Words, Auditory Figure Ground</i>] (Keith, 2000) Performance Intensity for Phonetically Balanced Words (PIPB) (Boothroyd, 2008) Speech in Noise (SPIN) (Bilger et al., 1984) Bamford-Kowel-Bench speech in noise test (BKB SIN) (Nyquette, 2005) Willeford Battery [<i>Competing speech, filtered speech, binaural fusion, and rapidly alternating speech</i>] (Willeford, 1977) Compressed Speech Test (Beasley et al., 1972) Synthetic Sentence Identification (SSI-ICM) (Speaks and Jerger, 1965)
5. Processing auditory signal with competing acoustic signals (binaural competition) Consonant-vowel syllables, digits, words, and sentences	MAPA [<i>Dichotic Digits Test, Competing Sentences</i>] (Schow et al., 2007) SCAN-C [<i>Competing Words</i>] (Keith, 2000) Hugdahl Dichotic Listening Test (Hugdahl and Andersson, 1986) Staggered Spondaic Words (SSW) (Katz, 1968)
6. Auditory pattern recognition	MAPA [<i>Pitch Pattern Test, Auditory Fusion Test-Revised, Duration Patterns Test, Tap Test</i>] (Schow et al., 2007) Frequency (Pitch) Pattern Test (Musiek, 1994). Montreal Battery of Evaluation of Amusia (MBEA) (Peretz et al., 2003)

distinct clicks. For normal hearing adults, this threshold is in the order of 2–3 ms. By comparison, several studies have shown that patients with bitemporal lesions require prolonged periods of silence (15–300 ms) between two clicks before they are able to reliably discriminate one from two clicks. In rare instances, temporal lobe lesions can result in palinacousia, in which the percepts of sounds continue or recur beyond their cessation, leading to an echoing effect.

Gap detection is a similar but potentially more refined measure in which listeners must identify the presence or absence of brief gaps of silence inserted between two sounds (e.g., tones, noise bursts) lasting tens to hundreds of milliseconds. This paradigm allows the examination of the effects of gap duration as well as the influence of the frequency and duration of the sounds that precede and follow the gap (called markers). When the frequency characteristics of markers differ sufficiently, determination of whether or not a gap is present requires integration across frequency-specific channels. This so-called central gap detection task requires longer gap durations for detection of the intervening silent interval.

Gap detection is an auditory capacity that can be impaired with bilateral temporal dysfunction but also in individuals with aphasia secondary to left hemisphere stroke. Interestingly, impaired gap detection performance in children can be predictive of poor language development. Other temporal tasks sensitive to cortical lesions include the ability to judge the temporal order of rapid tonal sequences and the direction of rapid frequency sweeps.

Individuals presenting with possible CAPD commonly complain of difficulties with listening to speech in noisy environments. This is often a specific instance of more general problems detecting and processing a sound when it occurs in the presence of competing sounds. Formal assessment may involve the determination of masking level differences (threshold for tone detection in the presence of noise). Alternatively, a more direct approach would entail the presentation of speech (e.g., words) embedded in noise or measured amounts of background ‘cocktail party’ conversation. Interestingly, the use of a linguistically relevant background stimulus such as cocktail party chatter is more effective a masker than speech spectrum noise, white noise, or narrow band noise.

Many speech-in-noise or ‘auditory figure-ground’ tests of central auditory processing utilize low-redundancy monaurally presented stimuli. The low redundancy limits a listener’s ability to utilize compensatory mechanisms or strategies, while monaural presentation allows comparisons of the performance of the left and right ear. Comparing the ears can sometimes be informative since cortical lesions tend to impair performance in the ear contralateral to the lesion more so than the ipsilateral ear. However, relatively depressed performance can be observed in the ear ipsilateral or contralateral to subcortical lesions. While these tests are sensitive to functional compromise of the CANS, they are generally limited in their localization value. Other low redundancy monaural stimuli include low pass frequency-filtered speech, time-compressed speech, and time-expanded speech.

While auditory figure-ground measures assess the ability to hear target sounds in the presence of competing noise presented within the same ear, other measures assess the ability to isolate and separate different streams of information

presented to both ears. Dichotic tasks evaluate a listener’s ability to process competing signals by delivering different information concurrently to each ear. A dichotic words test, for example, may present a different word simultaneously to the left and right ear and require a listener to report both words if he/she can (free recall), just the stronger percept, or just the word from a predesignated ear.

In the vast majority of neurologically healthy right-handed individuals, free recall of verbal stimuli is better in the right ear than the left, reflecting hemispheric specialization of the contralateral (left) hemisphere for language processing. Unilateral temporal lobe damage commonly results in difficulties processing speech presented to the ear contralateral to the lesion. Indeed, patients may demonstrate extinction of the ear contralateral to the lesion, failing to recall most if not all of the stimuli presented to that ear. A related task, the Staggered Spondaic Word test, entails presentation of temporally overlapping bisyllabic compound words presented to the two ears (e.g., hotdog in one ear, baseball in the other, with only dog and base presented simultaneously).

One of the higher level demands on the auditory system involves auditory pattern recognition. Because of the complexity of tests of temporal pattern recognition, they are highly sensitive to a wide variety of cerebral lesions, including temporal, temporoparietal, frontoparietal, insular cortex as well as diffuse cerebral damage. These tasks are less sensitive to damage to the brainstem. Due to their differential sensitivity, such factorially complex tests are often useful for screening purposes.

Like speech processing, musical ability may be selectively impaired in neurological disease. The recent development of assessment measures specifically designed to examine the breakdown of musical ability provides an important expansion of the repertoire of measures used to evaluate pattern processing.

Electrophysiological Assessment

Electrophysiological measures examine the electrical potentials produced by the central auditory system in response to auditory stimulation. Auditory brainstem responses (ABR) have become a mainstay of the electrophysiological assessment of central auditory function. These far-field electrical potentials, recorded with electrodes placed on the vertex of the head and the mastoids, reflect neural activity generated by the auditory system in a 10-ms period following presentation of a stimulus (usually clicks) over headphones. The earliest components (Waves I and II) of this multiwave response occur within the first 3 ms and are thought to represent electrical activity generated in the distal and proximal portions of the VN, respectively. Wave III arises at about 4–5 ms from second-order neuron activity in or near the CN, while Wave IV likely reflects third-order neurons located in the vicinity of the SOC with possible contributions from the CN and the nucleus of the lateral lemniscus. Finally, Wave V, which follows Wave III by about 2 ms, is believed to originate in the vicinity of the IC, although it too likely has contributions from multiple anatomic structures. The actual site of generation of Waves VI and VII remains unclear, but they are believed to be thalamic in origin.

The procedure can disclose dysfunction of brainstem auditory nuclei and their afferents. For example, the existence of

eight cranial nerve tumors can be detected with ABRs in ~90% of cases. Specifically, Wave I is present but subsequent components (Waves III or V) are absent (10–20% of cases) or delayed. A prolonged interval between Wave I and Wave III is also common (40–60% of cases).

Later potentials in the range of 20–70 ms post stimulus comprise the so-called middle-latency responses. These potentials reflect a combination of diencephalic and cortical generators. They are small potentials that have received variable use in clinical settings.

Cortical dysfunction can be assessed using long-latency auditory event-related potentials (ERPs) such as mismatched negativity (MMN). This complex, evident between 150 and 250 ms poststimulus, reflects automatically generated preattentive cortical responses to a detected change in a stimulus. A late positive wave occurring at 300 ms, called the P300, can be an excellent neurophysiological marker of attention to auditory events and processes related to updating of working memory. Auditory steady-state responses provide a useful method of assessing the processing of rapidly changing auditory features such as amplitude and frequency modulations.

Structural and Functional Neuroimaging

Recent advances in magnetic resonance imaging permit the acquisition of very high resolution structural images of the brain and brainstem which correspondingly has improved the capacity to detect small lesions. Contrast agents such as gadolinium can further enhance detection of small lesions or masses (e.g., tumors) which can be missed with electrophysiological procedures alone or MRI without contrast. However, small lesions can still be missed with structural neuroimaging.

In the past decade, there has also been a dramatic increase in the use of functional magnetic resonance imaging (fMRI) which can examine metabolic changes in oxygen utilization in different areas of the brain related to neural activity produced in the performance of auditory tasks. Recent advances in the production of nonmagnetic transducers (e.g., electrostatic, piezoelectric) allows good quality sound in the MRI environment and sparse sampling sequences allow presentation of stimuli at a time when noise generated by the scanner during image acquisition does not interfere with perception.

Central Deafness

Central deafness (CD) is a broad term referring to conditions in which partial or complete loss of hearing occurs due to damage or dysfunction of the CANS. The model for this class of disorders is cortical deafness, a relatively rare condition that typically results from bilateral lesions of auditory cortex or auditory radiations. The impairments associated with cortical deafness are summarized in Table 2. Patients initially show substantial elevations of hearing thresholds when assessed with pure tone and speech audiometry, yet have normal or near normal function of the middle and inner ear as indexed by tympanograms, stapedius reflex, and otoacoustic emissions. Brainstem auditory evoked potentials also commonly reveal evidence of normal peripheral hearing, while middle-latency and cortical evoked responses are either variable, abnormal or absent. These cases emphasize the importance of objective electrophysiological assessments to accompany standard behavioral audiometry.

Deficits in hearing sensitivity are accompanied by profound difficulties in understanding or responding consistently to both speech and environmental sounds. While appearing deaf, some subcortically mediated reflex responses, such as orienting toward a sudden loud sound may be preserved. Hearing sensitivity sometimes improves over time, but generally remains clinically elevated. In some cases, the speech of affected individuals acquires the inflection and prosodic characteristics typically associated with profound peripheral hearing loss.

The most severe and persistent forms of cortical deafness arise from subcortical white matter lesions, involving the thalamocortical auditory radiations. These strategically placed lesions result in total or near total interruption of thalamocortical projection fibers from the medial geniculate bodies to primary and secondary auditory cortex (likely disrupting both classical and nonclassical auditory pathways).

Bitemporal lesions can result from a variety of circumstances but when caused by stroke, the history often reveals consecutive cerebrovascular events. An initial unilateral temporal lobe lesion may result in a selective cortical auditory processing disorder (APD) such as an auditory agnosia for environmental sounds, word sound deafness (WSD), or aphasia (discussed in later sections of this article). Cortical deafness

Table 2 Summary of impairment in classical syndromes of CAPD

Function	Cortical deafness	Word sound deafness	Word meaning deafness	Nonverbal auditory agnosia	Receptive amusia
Speech comprehension	✓ ✓ ✓	✓ ✓ ✓	✓ ✓ ✓	⊙	⊙
Speech repetition	✓ ✓ ✓	✓ ✓ ✓	⊙	⊙	⊙
Writing to dictation	✓ ✓ ✓	✓ ✓ ✓	⊙	⊙	⊙

Reading comprehension	⊙	⊙	⊙	⊙	⊙
Spontaneous writing	⊙	⊙	⊙	⊙	⊙
Recognition of familiar nonspeech sounds	✓ ✓ ✓	⊙	⊙	✓ ✓ ✓	✓ ✓
Recognition of melody	✓ ✓ ✓	⊙	⊙	✓ ✓ ✓	✓ ✓ ✓
Hearing sensitivity	✓ ✓ ✓	⊙	⊙	⊙	⊙

Severity of impairment: ⊙, none/mild; ✓ ✓, moderate; ✓ ✓ ✓, Severe. Expanded from Bauer RM and McDonald CR (2003) Auditory agnosia and amusia. In: Farah MJ and Feinberg TE (eds.) *Patient-Based Approaches to Cognitive Neuroscience*, pp. 257–270. Cambridge, MA: MIT.

emerges when a second lesion occurs some time later and causes damage to PAC or subcortical afferents in the contralateral hemisphere. The syndrome can also emerge in children and has been described in association with a severe closed head injury and herpes encephalitis.

CD has also been described in individuals with subcortical lesions involving the MGB and the IC. Subcortical forms of CD can occur from a variety of etiologies including stroke. This generally entails a single event involving the vertebralbasilar artery system which perfuses the pons, midbrain, and thalamus, rather than the consecutive middle cerebral artery strokes implicated in cortical deafness.

Since virtually all ascending and descending auditory pathways synapse in the IC, bilateral lesions that result in complete destruction of the ICs should, in theory, result in complete deafness, since such a lesion presumably isolates the auditory cortex from information encoded at the ear. However, available clinical reports present a mixed picture. In two case reports, IC lesions resulted in complete deafness, while in three other reports, there was mild elevation of pure tone thresholds, but profound impairment of word recognition. In these cases, pure tone perception may have been mediated by the extralemniscal auditory brainstem pathway, whereas functional integrity of the IC is critical for speech processing, given its role in processing frequency modulation and other dynamic acoustic features.

General Auditory Agnosia

The term agnosia is derived from the Greek words for 'not knowing.' Auditory agnosia refers to a collection of disorders associated with the loss of the ability to recognize auditory objects that cannot be attributed to sensory difficulties. Auditory agnosia can be fairly selective, affecting particular classes of auditory input. Specifically, auditory agnosia can preferentially disrupt the processing of verbal information, music or environmental sounds. These specific forms of the disorders are discussed below. The term general auditory agnosia refers to a condition in which a neurologically based auditory recognition disorder is evident to both speech and nonverbal stimuli. Unlike cortical deafness, the processing impairment is not associated with clinically significant audiometric thresholds.

Verbal Auditory Agnosia

Word Sound Deafness

Word deafness is characterized by severe difficulties in understanding and reproducing spoken language, with otherwise intact speech production and nonauditory language comprehension (e.g., reading). In the context of marked deficits in processing speech sounds, words, phrases, and sentences, there is relative preservation of musical appreciation and the recognition of environmental sounds. The deficiencies in decoding language occur at an early stage of analysis and are relatively specific to the auditory modality. Given this, the condition has more recently been called WSD to distinguish it from other forms of verbal auditory agnosia, such as word meaning deafness (discussed below).

Phenomenological descriptions have implicated a range of disturbances of perceptual processing. In some cases, particularly those with bitemporal lesions, the dissolution of auditory perceptual processing is sufficient in severity to impede recognition of the acoustic characteristics of the human voice. Speech is described in such terms as 'a noise,' 'a garbled sound,' such as 'wind in the trees' or 'the rustling of leaves.' In others, spoken communications are recognized as speech, but a breakdown occurs in the process of mapping speech sounds to appropriate stored mental representations. Discourse sounds like 'jabbering,' 'a foreign language' or simply does not 'register.' There are frequent suggestions that perceptual resources are incapable of keeping up with the rate at which speech is produced: 'words just run together' or 'come too quickly.'

Some studies have noted systematic error patterns in speech discrimination and identification that implicate problems at phonetic levels of analysis, a stage of auditory processing specific to speech. Problems particularly impede the discrimination of stop consonants (e.g., /p/, /b/, /t/, /d/, /k/, /g/) while differentiation of vowels is relatively spared. This pattern of phonemic imperception is common in WSD but not necessarily specific to it.

Several reports have suggested that the symptoms characteristic of WSD are secondary to fundamental problems in basic aspects of auditory temporal processing. Problems noted in WSD include deficient intensity-duration functions and poor resolution of temporally distinct auditory events (click fusion, gap detection). In addition, individuals with WSD have difficulty detecting frequency modulations in sound and in judging the temporal order of sequential auditory stimuli. Based on such findings, some have argued that WSD is associated with general limitations in auditory temporal resolution that are particularly detrimental to language comprehension because they impede the ability to perceive brief spectrotemporal cues in speech necessary for the derivation of linguistic meaning.

There is disagreement regarding the anatomical basis of the syndrome. The majority of cases reported in the literature demonstrate bilateral temporal lobe lesions, particularly involving the mid portion of the superior temporal gyrus. However, WSD was first described in patients considered to have deep lesions confined to the left posterior temporal regions and a number of case reports have confirmed that a strategically placed unilateral left hemisphere lesion is sufficient to result in WSD. Unilateral lesions can impede the analysis of formant frequency modulation in speech sounds without causing impairment on basic temporal resolution tasks such as click fusion. WSD can also occur developmentally, and is the most common pattern of impairment associated with the Landau-Kleffner syndrome, a rare epileptic syndrome in childhood.

Word Meaning Deafness

Individuals with word meaning deafness have severe difficulties in understanding auditory language, yet can repeat and write to dictation sentences that they cannot comprehend. Curiously, they can also read and understand those sentences that they could write to dictation but not comprehend. The preservation of repetition and writing to dictation distinguishes this

condition from WSD and suggests that the analysis of phonological information is relatively intact. Rather, the breakdown in language comprehension appears to occur at the level of lexical access, possibly secondary to a failure to match the intact phonological code with corresponding representations in the lexicon or as a 'post access' failure of lexical items to activate corresponding representations in the semantic system.

Phonagnosia

Phonagnosia refers to disorders of familiar voice recognition. These individuals experience problems identifying coworkers, friends, and relatives by the sound of their voice. This deficit was first noted in patients with right hemisphere lesions who had difficulty recognizing the voice of famous individuals. A follow-up study revealed that temporal lobe damage of either hemisphere impaired the ability to discriminate famous voices, while deficits in discriminating and recognizing familiar voices was correlated with right parietal lobe damage.

Problems with familiar voice recognition typically occur in the context of other disorders of auditory processing, such as a broader auditory agnosia, amusia, or word deafness. However, some case reports suggest that it can occur in the context of unimpaired recognition of environmental sounds. Phonagnosia and amusia may be more closely tied, as both depend on auditory mechanisms required to distinguish the timbre of a sound. A developmental variant of the disorder has been described.

Nonverbal Auditory Agnosia

Sensory Amusia

Receptive amusia is associated with deficits in the ability to appreciate various characteristics of music such as pitch, harmony, and melody. While the disorder can occur as a fairly specific impairment dissociated from the perception of speech and environmental sounds, it is more commonly seen in the context of a broader nonverbal auditory agnosia. It has also been reported in cases of aphasia, suggesting that the left and right cerebral hemispheres contribute differentially to the multicomponent processes involved in music appreciation.

The right cerebral hemisphere appears to play an important role in the processing of some aspects of music such as the appreciation of melody. The left cerebral hemisphere appears particularly important for the processing of sequential, temporally organized information included in a series of musical notes. The left hemisphere's role may therefore increase with greater analytic analysis or with more attention to temporal patterns such as timing and rhythm. For example, there are reports of professional musicians who suffer from an amusia subsequent to a left temporoparietal stroke. These individuals may show normal performance on all aspects of melody processing but lose the ability to discriminate or produce rhythms. This arrhythmia is specific to auditory input and cannot be attributed to the impairment of supramodal temporal processing.

Other clinical studies also suggest a distinction between time-dependent processes governing melody recognition, such as the appreciation of rhythm or duration and the more instantaneous features of music, such as the pitch, harmony, timbre, and intensity. For example, double dissociations have

been described between pitch perception and the processing of temporal sequences. Similarly, the ability to appreciate expressive patterns of music indexed by pitch, timbre, and intensity (musical connotation) can be dissociated from the ability to appreciate the significance of lyrics (musical denotation). It has been further suggested that timbre-dependent skills such as recognition of specific voices and musical instruments can be distinguished from pitch-dependent skills, such as recognition of tunes.

A developmental form of amusia occurs in ~4% of the population. These individuals have difficulty discriminating pitch changes in melodies that cannot be explained by peripheral sensory impairment. The disorder, referred to as tone deafness or congenital amusia (CA), is frequently manifested by an individual's inability to carry a musical melody but seems unrelated to problems with musical time.

There is compelling evidence suggesting that CA is based in a congenital musical pitch disorder. The disorder is thought to have a genetic contribution insofar as in the families of individuals with CA, 39% of first-degree relatives have the disorder whereas only 3% have it in control families.

Neuroanatomical studies have suggested that CA is associated with abnormal gray and white matter in auditory cortex and the inferior frontal cortex. Neurophysiological evidence derived from recording auditory ERPs, has suggested that these individuals are capable of near-normal processing of musical pitch incongruities, suggesting that, similar to the visual phenomenon of blindsight, subjects with CA can process stimuli yet not have conscious access to that information. Their behavioral deficits therefore appear related to a limited awareness of pitch representations and a disconnection of these representations with their knowledge of pitch.

Environmental Sound Agnosia

Some clinical reports suggest that auditory agnosia can be restricted to environmental sounds. One case report with consecutive hemorrhagic lesions (left then right) sustained bilateral damage in the region of the putamen extending to the thalamocortical auditory radiations. Following the second infarct, the patient experienced a brief period of cortical deafness associated with bilateral sensorineural hearing loss of 55–100 dB at 1 kHz, in the context of normal brainstem-evoked responses. At this time, she could not distinguish broad categories of sounds, such as speech, music, or environmental sounds. However, this resolved over a 3-month period and was followed by a reportedly selective auditory agnosia for environmental sounds. Errors appeared discriminative rather than associative in nature. Processing of speech was relatively intact at this point. Unfortunately, neither this report nor previous reports directly compared environmental sound recognition to the perception of music. Consequently, they serve mainly to illustrate that environmental sound recognition can be impaired with relatively intact perception of speech.

Cortical Motion Deafness

A recent study described a patient with a selective deficit for the reception and discrimination of auditory motion. The disorder emerged following resection of the right anterior temporal lobe

and posterior temporal gyrus. While the patient could correctly identify and localize auditory objects in space, he failed to reveal normal responses indicative of the ability to process auditory movement.

Idiopathic Acquired CAPD

Hyperacusis

Hyperacusia is a term used to refer to raised sensitivity to auditory stimulation often associated with an aversion to or intolerance for certain sounds at their typical sound levels. A person with severe hyperacusis may have difficulty enduring the sound of everyday objects, such as a vacuum cleaner, a hair dryer or a food blender, indicating that they are unpleasantly loud when they are easily tolerated by others. While hyperacusis can occur with peripheral damage, it can also result from dysfunction or damage to the CANS. It is thought that efferent mechanisms from the SOC to the cochlea involving the auditory nerve (olivocochlear bundle) may be functioning abnormally in a proportion in these individuals.

It has been suggested that hyperacusis can be a symptom of a serotonin dysfunction, leading to suggestions that selective serotonin reuptake inhibitors (SSRI) may be helpful in treating the disorder. Though some case studies report improvement of hyperacusis from SSRIs, it has yet to be robustly clinically validated. Other etiologies associated with hyperacusis include exposure to certain medications or drugs, head trauma, and migraine. It is commonly described in children with autistic spectrum disorders and William's Syndrome. Finally, hyperacusia tends to accompany tinnitus.

Tinnitus

Tinnitus is the perception of sound in the absence of an external acoustic stimulus. It is often described as persistent ringing or buzzing in the ear and is commonly associated with presbycusis, a hearing loss due to aging. Indeed by 70 years of age, over 10% of all adults report episodes of tinnitus. Of those who experience tinnitus, 79% report hearing sounds like tones, while 21% report hearing a hissing or rushing noise. It is also a symptom of Ménière's disease and is common in individuals with tumors (acoustic neuroma or vestibular Schwannoma) growing in the space between the pons and cerebellum. Tinnitus may additionally occur as a result of exposure to loud noise (e.g., artillery fire, rock concerts) or after the use of certain antibiotics.

In ~60% of tinnitus cases, there is no known cause. Because of the association between cochlear pathology and tinnitus, it has been assumed that tinnitus is caused by hyperactivity of cochlear hair cells. It has often been compared to chronic pain, specifically phantom limb pain. However, evidence such as the persistence of tinnitus after cochlear ablation and a strong central effect of ototoxic medication suggests a central origin for persisting tinnitus.

Recent research has implicated the nontraditional extralemniscal auditory pathway in the disorder. Because the thalamic nuclei (medial and dorsal nuclei of the MGB) of the extralemniscal system project directly to the basolateral nucleus of the amygdala, involvement of this pathway may be fundamental

to understanding why some individuals experience tinnitus as a debilitating problem with affective symptoms.

Due to the commonalities between hyperacusis and tinnitus, SSRIs have also been proposed as a treatment for the latter. However, a recent randomized placebo-controlled study found that most subjects showed no consistent benefit from SSRIs.

Etiologic Heterogeneity/Diversity

Acquired forms of CAPD such as CD and the agnosias typically represent the sequelae of ischemic or hemorrhagic cerebrovascular accidents. Such syndromes can also result from a variety of other conditions such as head injury, herpes simplex encephalitis, tumor, and epilepsy. Less severe forms of CAPD have been described in association with aphasia, encephalitis, seizures disorders, brain tumors (e.g., cerebropontine angle tumors), as well as degenerative disorders (e.g., Alzheimer's disease), demyelinating disorders (e.g., multiple sclerosis), metabolic disorders (e.g., adrenoleukodystrophy), bacterial meningitis, Lyme disease, and drug toxicity.

A similar range of severity can be seen in children. Classic forms of either generalized auditory agnosia or verbal auditory agnosia are typical features of Landau-Kleffner syndrome, a relatively uncommon form of childhood epilepsy associated with continuous spike and wave activity. However, most children with CAPD have a developmental variant that is associated with less florid disturbances. In some of these cases, the disorder is specific to auditory processing, while in others CAPD is comorbid with other developmental disorders, such as attention deficit hyperactivity disorder (ADHD), specific language impairment (SLI), dyslexia, and autism.

Below, we briefly review the concept of developmental forms of CAPD as a distinct diagnosis and discuss its relation to various comorbid conditions.

Developmental CAPD

APD as a Distinct Diagnostic Entity

Children with CAPD often first come to attention when they experience difficulties in an academic setting, where success is dependent on absorbing highly structured auditory information, often in the presence of poor classroom acoustics and abundant background noise. An estimated 2–7% of school-aged children exhibit problems suggestive of the existence of a developmental form of CAPD. These children have difficulty attending to the teacher for an appropriate length of time and in following, remembering, or understanding verbal instructions. They often need to have spoken information repeated and are easily distracted or influenced by extraneous sounds in their environment. Though these children are intelligent and capable of attaining academic success, these deficits impede their academic performance and have the potential to be interpreted as a behavioral or motivational problem.

In 2000, a consensus statement by a group of 14 prominent scientists and clinicians on the problems related to diagnosing these disorders in school-aged children suggested relabeling the problem 'auditory processing disorders' (APDs) in order to 'keep with the goals of maintaining operational definitions,

avoid the imputation of anatomic loci, and (to) emphasize the interactions of disorders at both peripheral and central sites.' Many continue to utilize the qualifier 'Central,' if only parenthetically, with recognition of equivalence between the terms. Existing criteria that define APD are the same as those discuss for CAPD in the introduction to this articles.

Numerous controversies surround the concept itself and the pragmatic issues concerning its diagnosis. These issues include the extent to which a deficit must be restricted to the auditory domain to be called an APD and whether testing with nonspeech stimuli, such as tones is sufficient to indicate an APD, since evidence suggests that speech processing is computationally more taxing than other sounds, particularly with respect to the temporal processing demands. Moreover, given that speech processing is a special case of auditory processing, there is disagreement over where an APD ends and linguistic or neurocognitive impairment (e.g., memory, executive function) begins. Finally, the concept of APD in children is complicated further by comorbid presentation with developmental disorders, such as autism, dyslexia, SLI, and ADHD.

Despite objective evidence of normal peripheral hearing sensitivity, children with APD demonstrate a variety of deficits in behavioral batteries measuring central auditory function. In addition, their difficulties in remembering phonemes and manipulating them can result in problems with learning to read and spell. They may also have difficulty understanding persons with unfamiliar accents and may struggle in second language learning. Auditory memory span and sequencing auditory information can be problematic. Correspondingly, they may also demonstrate poor sense of rhythm and musical ability.

In a portion of children with CAPD, problems in central auditory processing may be confirmed using electrophysiological measures. While abnormal ABRs are observed in less than 10% of children with CAPD, as many as 42% show abnormal auditory middle-latency responses or P300 responses.

It is uncommon for individuals with developmental forms of CAPD to demonstrate an obvious structural lesion. Nevertheless, a recent case study is noteworthy insofar as it reported some characteristic anomalies in a developmental case of CAPD. The structural MRI revealed selective atrophy evident bilaterally in auditory cortex and subcortex. Positron emission tomography (PET), a functional neuroimaging procedure that can measure neural activation by imaging the brain's use of glucose, found bilateral hypometabolism in primary and secondary auditory cortices including Heschl's gyri. These findings underscore the potential future role that neuroimaging may play in the differential diagnosis of CAPD.

APD and Autism

Autism is a developmental disorder distinguished by impairment of social interaction and communication, accompanied by restricted interests and repetitive behaviors. Reports of auditory processing abnormalities are common, frequently including an absence of orienting reflex to sound, a lack or inconsistency in response to familiar sounds and noise, intolerance for certain sounds at their typical sound levels (hyperacusis), overselectivity when listening to multiple auditory streams, difficulty listening in the presence of background

noise and deficits in perception of emotional content and prosody in the human voice. In severe cases, the impairment can be as severe as functional deafness.

Neurophysiological and neuroimaging studies have implicated neurodevelopmental anomalies at multiple levels of the CANS, from the superior olive to auditory association cortex. Brainstems of children with autism are significantly smaller than typically developing peers and although findings are inconsistent, several studies have reported that auditory brainstem-evoked potentials show decreased amplitude and greater latency.

Functional neuroimaging studies have shown diminished activation of the auditory cortex when presented with nonverbal auditory stimuli. When listening to speech, a neurotypical brain shows bilateral activation in the superior posterior temporal lobes with a left-sided asymmetry involving posterior language areas. Studies of individuals with autism have shown a lack of activation in speech areas entirely or a reversal of the usual left hemispheric asymmetry. While failing to show activation of the superior temporal sulcus in response to the human voice, these studies generally report normal patterns of activation to nonvocal sounds.

APD and SLI

SLI is a neurodevelopmental disorder characterized by problems in understanding or producing language in the absence of causal factors such as hearing impairment, mental retardation, neurological deficits, primary emotional disorder, or social deprivation. A number of studies have suggested that these children have particular difficulties in discriminating speech sounds characterized by rapidly changing acoustic information (e.g., stop consonants) as well as in judging the temporal sequence of rapid presented complex tone patterns. These findings have prompted suggestions that a basic impairment of auditory temporal processing contributes to their difficulties with language acquisition, presumably resulting in unstable phonemic processing, which may interfere with encoding and producing spoken language.

Theories advocating a direct causal relationship of CAPD to SLI have been criticized. Several studies have found that while rapid auditory processing deficits are common in SLI, they are not universal. There also seems to be little or no relationship between the severity of a rapid auditory processing deficit and the SLI.

While the causal relationship between auditory processing difficulties and language problems remains in dispute, there appears to be ample evidence that auditory processing difficulties exist in a significant percentage of these children. Indeed, neurophysiological evidence of these deficits has been shown in the form of attenuated or absent MMN responses to vowel sounds and tones. In cases with severe receptive involvement, abnormal steady-state responses to rapid frequency changes may be observed. Recent studies have shown that impaired electrophysiological responses in some children with SLI may approach typicality as the child reaches adulthood. This eventual advance has led some to interpret these electrophysiological findings as evidence for a more general immature auditory processing system as a contributory factor to SLI.

APD and Dyslexia

There is also ongoing debate about the relationship between an auditory processing deficit and a specific reading disorder (dyslexia). Again, it has been suggested that children with dyslexia have low-level auditory and visual perceptual deficits, possibly related to anomalies impacting magnocellular visual and auditory systems. These deficits are thought to result in subtle perceptual problems that interfere with the development of phonology, reading, and spelling ability.

While numerous studies have provided evidence in support of magnocellular deficits in the visual system, data supporting comparable auditory system involvement are less compelling partly due to methods of subject selection and inadequate controls over potentially comorbid attentional problems. However, postmortem cytoarchitectural studies of a small number of brains of people with dyslexia have revealed smaller left MGN and planum temporale than expected. In addition, ectopias, and microgyria have been observed bilaterally in perisylvian cortex (including auditory cortex), greater on the left side. These findings suggest anomalies in cell migration during neurodevelopment that would impact auditory function in addition to language and reading. Some association has been observed between deficits in auditory temporal processing and problems with phonological processing, although this appears to be a weak or indirect association.

APD and ADHD

ADHD and APDs share many features which make their clinical presentation similar. Overlapping symptoms include poor concentration, distractibility, fidgetiness, and poor academic achievement. These similarities have led to the question of whether APD and ADHD are in fact distinct disorders. Though some authors have suggested that they are variants of the same disorder, noting that they share some prenatal and postnatal etiological factors, there is a general consensus that the two disorders are dissociable and discrete diagnostic entities.

The focus of the relationship between ADHD and APD has therefore shifted to diagnostic differentiation. Several approaches to differential diagnosis have been proposed, though none have been satisfactorily validated at this point in time. It has been suggested that a diagnosis be made only after comparing performance on a visual task with an auditory analogue, such as visual and auditory continuous performance tests, which examines a person's ability to sustain attention on a task. Others have attempted to differentiate ADHD from APD using electrophysiological measures with little success thus far. Finally, while stimulant medication such as methylphenidate has been used to control hyperactivity, impulsivity, and distractibility in ADHD, there is little evidence to suggest it improves deficits specific to CAPD.

Treatment

Because of the variability in presentation of CAPDs, intervention should be personalized to address each individual's specific deficits while building on their strengths. CAPDs may

be treated through environmental modification, teaching of compensatory strategies or direct treatment of the deficit. Intervention should be planned and executed by an interdisciplinary team.

Environmental modifications increase access to the acoustic information itself or facilitate learning through modified teaching methods. This can be achieved through assistive listening devices such as FM systems, removal of competing noise or preferential seating in a classroom environment. Instruction may be modified to include preteaching, reduced linguistic complexity, slower rates of speaking, and ample use of repetition/rephrasing. In addition, supplementing auditory information with visual presentation of information either in writing or using gestures is often helpful.

Teaching an individual with CAPD to use compensatory strategies is key to successful intervention in many cases. Compensatory strategies might include teaching an individual to ask for repetition of information if he/she did not comprehend it, independently choose seating away from noise or near a speaker, and to look at a speaker's mouth while listening. Individuals often need to take a proactive approach to becoming more aware of the impact of their deficits and the need to manage potential problems in different situations.

Direct treatment for CAPDs involves auditory training. This approach is designed to take advantage of brain plasticity to effect changes in the circuitry of the system through appropriate and often repeated practice. There is evidence indicating that sufficiently frequent, intense, and challenging auditory training can result in neurophysiologic and functional improvements in auditory skills. Many formal auditory training programs are available as commercial computer software packages.

Glossary

Amnesia Partial or total loss of memory; anterograde amnesia occurs when an individual has no memory for events that happened after a traumatic event or surgery, while retrograde amnesia is the inability to recall earlier experiences, especially those preceding a traumatic injury.

Aphasia Impairment in the ability to express or comprehend language due to injury or disease of the brain.

Central nervous system The brain and spinal cord.

Executive functions A set of cognitive abilities that control and regulate other abilities and behaviors, including the ability to evaluate a problem, plan a response, carry out the

plan, and assess the adequacy of the response within the context of ongoing environmental cues.

Neurons The basic unit of the nervous system or the nerve cell that sends and receives electrical signals over long distances within the body. The neuron includes the cell body (soma), dendrites, and an axon.

Neurotransmitters Chemicals that regulate nervous system functioning. The chemicals are released from a nerve cell which thereby transmits an impulse from a nerve cell to another nerve, muscle, organ, or other tissue.

Synapse The synapse contains a small gap separating neurons. Information from one neuron flows to another neuron across a synapse; it is at the synapse that biochemical transmission occurs.

The central nervous system (CNS) consists of the brain (encephalon) and spinal cord (medulla spinalis). The brain is located in the cranial cavity and is protected by the skull. The spinal cord lies in the vertebral canal and is protected by the vertebrae. The CNS is distinguished from the peripheral nervous system, which is composed of the remaining network of neurons throughout the body. First, we review the basic neuroanatomy of the CNS. Next, we examine both reflexive and voluntary behaviors that are derived from the CNS. Specifically, behavioral domains that include sensation, perception, motor activity, and language are described.

Neuroanatomy

Basic Structures

The CNS consists of neurons and glial cells. Neurons consist of the nerve cell body and its processes – the dendrites and axons. Neurons constitute about 10% of the cells in the CNS while glial cells make up the remainder. Neuron cells conduct information while glial cells both protect and provide a variety of support information to neurons. The CNS may be divided into regions of gray matter that consist of densely packed glial cells, neurons, and white matter. White matter consists of myelinated fiber tracts that connect parts of the CNS. The long processes of neurons, which are termed axons, are also located in the white matter. Axons are responsible for carrying outgoing messages from the cell.

The brain is surrounded by three membranes known as the meninges, which are located beneath the cranium and vertebral column. The first membrane is a tough, outermost layer,

or the dura mater, which is closely attached to the inner surface of the skull, beneath the subdural space. Epidural hematomas are triggered by injury to the middle meningeal artery and are formed between the dura and the skull. Subdural hematomas form between the dura and arachnoid and are caused by rupture of bridging veins. The arachnoid mater is the second membrane, which is thin and delicate and resembles a cobweb, and beneath this is the fluid-filled subarachnoid space that is part of the cerebrospinal fluid system. The rupture of an aneurysm of a cerebral artery can result in a subarachnoid hemorrhage between the arachnoid and the pia. The third layer, or pia mater, is the thin and transparent innermost layer of the meninges and is attached to the brain and dips down into the fissures or sulci. The pia mater forms the inner boundary of the subarachnoid space.

Neural Tube and Ventricular System

The neural tube is an embryonic structure that is formed when the lips of the neural groove fuse and is the basis for the development of the entire CNS. This process generally begins around the fourth week of development. Differential growth along the walls of the neural tube occurs during development and gives rise to the four primary subdivisions of the embryonic brain: (1) the prosencephalon (forebrain), (2) the mesencephalon (midbrain), (3) the rhombencephalon (hindbrain), and (4) the spinal cord. As the fetus develops, the prosencephalon goes on to develop into the telencephalon and the diencephalon. The mesencephalon develops into the midbrain. The rhombencephalon develops into the metencephalon (the pons and cerebellum) and the myelencephalon (the

medulla oblongata). The spinal cord develops from the most caudal (toward the rear) portion of the neural tube.

The ventricular system develops from the cavity of the neural tube in the embryo and consists of interconnected fluid-filled cavities located in the core of the forebrain and brainstem. There are four ventricles including two lateral ventricles, the third ventricle, and the fourth ventricle. Each of the ventricles is filled with cerebrospinal fluid and is lined throughout the ependyma. The paired lateral ventricles communicate with the third ventricle through the interventricular foramina. The third ventricle is connected to the fourth ventricle by the cerebral aqueduct. At its caudal end, the aqueduct opens into the fourth ventricle. Cerebrospinal fluid is a clear and colorless fluid that acts as a buffer to protect the brain and the spinal cord from mechanical trauma. It is present in the ventricles as well as the central canal of the spinal cord and in the subarachnoid space that surrounds the brain and spinal cord. Each ventricle contains a choroid plexus that produces the cerebrospinal fluid which is continually being produced and reabsorbed as it circulates through this intricate system. The cerebrospinal fluid is reabsorbed via the arachnoid villi into the venous sinuses when the cerebrospinal fluid pressure exceeds the venous pressure in the sinus.

Major Subdivisions of the Brain

Diencephalon

The diencephalon is located deep within the cerebral hemispheres and encloses the third ventricle. The four major subdivisions of the diencephalon include the thalamus, hypothalamus, subthalamus, and the epithalamus. The primary function of the thalamus, which is the largest division, is the recognition of sensory stimuli and the relay of sensory impulses (other than olfaction) to the cerebral cortex. The thalamus is the chief relay station for all output to the cortex that comes from the cerebellum and basal ganglia. The thalamus also plays an integral role in motor and limbic functions. The thalamus contains a Y-shaped sheet of fibers termed the internal medullary lamina that may be divided into three large cell masses, anterior, mediodorsal, and lateral, each of which contains several discrete nuclei that are interconnected with specific cortical regions. The anterior and mediodorsal cell masses are associated with the thalamic division of the limbic system, and the lateral cell mass belongs to the sensory and motor systems. Problems from damage to the thalamus may include sensory abnormalities, visual-field deficits, and behavioral changes.

The hypothalamus is located below the cerebral cortex at the base of the diencephalon. The primary role of the hypothalamus is the central regulation of homeostasis, which occurs through interfacing with the endocrine system, the autonomic nervous system, and the limbic system. The hypothalamus controls the nervous system by synthesizing and releasing neurohormones at regular intervals. Homeostatic functions associated with the hypothalamus include energy and temperature regulation, water balance, appetite, cardiovascular functioning, sleep and circadian rhythms, reproduction, emotional behavior, stress response, blood pressure, and respiration. Autonomic, emotional, or endocrine dysfunction is associated with lesions in the hypothalamus.

The subthalamus and epithalamus are small divisions of the diencephalon, with the subthalamus situated under the optic thalamus, while the epithalamus is superior and posterior to the thalamus. The subthalamus contains fiber tracts and the subthalamic nucleus. The subthalamus and epithalamus are involved in secretion of melatonin by the pineal gland, the motor functions of the basal ganglia, and the control of the circadian rhythms.

Telencephalon

The telencephalon is the rostral part of the embryonic forebrain and consists of the cerebrum and the limbic system. The cerebrum is the uppermost and largest part of the human brain and is situated at the top of the cranial cavity. The cerebrum includes the cerebral cortex, which is the outermost layer, and is responsible for controlling complex motor and mental activity. The cerebral cortex includes the left and right cerebral hemispheres, separated by the median longitudinal fissure, a large crevice that runs from front to rear. The cerebral cortex, which contains billions of neurons and multitudes of interconnections, is involved in higher order intelligence, sensory perception, movement, language, memory, consciousness, emotion, and personality. Although the left and right hemispheres appear to be physically similar, they control different types of processes and also are anatomically different.

The cerebral cortex has both gray and white matter. Gray matter is located on the surface of the cerebral cortex, while a large mass of white matter is located below the gray matter. The white matter contains axonal fibers that provide input to and output from the cortical matter. The fiber tracts are identified as follows: (1) association fibers, which link one area of the cortex to another area within the same hemisphere; (2) commissural fibers, which link the two hemispheres; and finally, (3) projection fibers that connect the cerebral cortex with the subcortical centers, the brain stem, and the spinal cord.

The cerebral cortex consists of four lobes: frontal, parietal, temporal, and occipital. The frontal lobes are located superior to the lateral sulcus and in front of the central sulcus (i.e., over the eyes), and contain the motor cortex, which coordinates voluntary motor activities. Specifically, activities of the voluntary muscles on the right side of the body are controlled by the left part of the motor cortex, while voluntary activities on the left side of the body are controlled by the right part of the motor cortex. Motor intention is regulated by the dorsolateral frontal lobe as increased activity is apparent when animals are about to make movements. Damage to this area is associated with motor or autonomic disturbances, including contralateral limb akinesia, or failure to use one limb in order to respond to a stimulus, not caused by inattention or weakness of the limb. The frontal lobe is also involved in important mental activities such as planning, association of ideas, emotion, and self-awareness. Finally, the frontal lobe is also concerned with personality, so lesions in the frontal lobe produce alterations in character and behavior.

The parietal lobes lie posterior to the central sulcus, but above the lateral sulcus on the lateral surface of the brain. The parietal lobe contains the somatosensory cortex, which is involved in body sensations such as pain, cold, heat, touch, pressure, and body movement. Damage to the posterior frontal or anterior parietal lobes can result in the loss of the ability to

express emotion by modulation of speech patterns resulting in aprosody or aprosodia. Individuals with aprosodia speak in a monotone regardless of the situation, but nonetheless experience normal emotional feelings. Lesions involving the parietal lobe may also result in a disturbance or loss of function in perception of size, shape, and texture (agnosia), as well as writing and memory difficulties.

The temporal lobes are located behind the ears and below the lateral sulcus. The functions of the temporal lobes are still being defined, but they are primarily involved in hearing, smell, and taste, with some involvement also occurring in vision and memory. Lesions involving the temporal lobe may produce disturbances in hearing and memory and in the regulation of emotional behavior. The occipital lobes are located at the extreme back of the head, and contain the visual cortex, which is involved in visual perception. Damage to the cortical visual areas of the occipital lobes may result in blindness.

The limbic system is a set of brain structures located at the top of the brainstem and buried under the cortex. The structures of the limbic system are highly influential in complex functions of emotional behavior such as stress, motivations, emotional responses, and memory. Structures of the limbic system include the following: amygdaloid complex (amygdala), hippocampal formation (hippocampus, dentate gyrus, subicular region), hypothalamus, thalamus, olfactory cortex, basal ganglia, and septum. The amygdala is located deep in the dorsomedial portion of the temporal lobe and is involved in emotional responses, the detection of threat, and sensory input about olfaction. Lesions in the amygdala can cause behavioural outbursts such as rage or docility. The hippocampus, located within the parahippocampal gyrus on the medial surface of the temporal lobe, is the major regulator of the limbic system. The hippocampus is involved in the formation and encoding of memory, including emotionally charged memories. Damage to the intrinsic structure of the hippocampus, such as occurs with individuals with Alzheimer's disease, results in impaired memory for the recall of facts and events (i.e., declarative or episodic memory). Emotional functioning is also associated with the cingulate gyrus, the septum, and areas in the hypothalamus. The cingulate gyrus, situated above the corpus collusum, is composed of a five-layered cortex as well as the neocortex. The hypothalamus is responsible for overseeing autonomic physiological and hormonal regulation. The olfactory cortex, responsible for our sense of smell, is located in the temporal lobe. The olfactory cortex is composed of the pyriform cortex, periamygdaloid area, and part of the entorhinal area. The olfactory cortex is concerned with conscious perception of olfactory stimuli.

Brainstem

The brainstem connects the spinal cord to the cerebral cortex and consists of three major parts: (1) the midbrain (or mesencephalon), (2) the pons (or metencephalon), and (3) the medulla oblongata (or myelencephalon). The brainstem has three main functions: (1) it is responsible for transmitting information between the spinal cord and cerebrum; (2) it controls consciousness as well as vital functions such as respiration and cardiovascular functioning through its reflex centers; and (3) it contains many cranial nerve nuclei, responsible for much of the movement in the face and neck.

The midbrain is the smallest part of the brainstem and is located directly inferior to (underneath) the diencephalon and superior to (above) the pons. The midbrain has two parts, the tectum and the tegmentum, which are separated by the aqueduct of Sylvius, or cerebral aqueduct. The tectum, located dorsal (toward the back) to the aqueduct of Sylvius, is comprised of four rounded protrusions termed the corpora quadrigemina. The corpora quadrigemina is further divided into two parts, the superior (upper) colliculi and the inferior (lower) colliculi. The corpora quadrigemina controls the position of the head and eyes in response to visual, auditory, and somatic stimuli as well as transmits auditory signals to the auditory center in the cerebral cortex. The tegmentum, located ventral (toward the front or belly) to the aqueduct of Sylvius, contains the red nucleus that controls motor function, the oculomotor nerve, and the trochlear nerve which are both involved in eye movement. Another important structure in the midbrain is the substantia nigra that is involved in reward seeking, addiction, and movement. Degeneration of the substantia nigra is implicated in Parkinson's disease. Finally, the cerebral peduncles, located in the tegmentum, are bundles of nerves that run from the cerebrum to the spinal cord and are responsible for motor control.

The pons is located between the midbrain and the medulla oblongata. It is ventral to (in front of) the cerebellum and is responsible for relaying information between the cerebellum and the cerebrum. Part of the reticular formation, which is responsible for maintaining an awake state, is housed within the pons. Lesions in the pons may cause a coma-like state called 'locked-in syndrome' which is characterized by weakness of the extremities and the face, with a limited level of consciousness.

The medulla oblongata is the lowest structure of the brain and connects to the spinal cord at the foramen magnum. Because of its location, the medulla is responsible for transmitting information from the spinal cord to the higher centers of the brain. The medulla oblongata contains the respiratory, cardiac, vomiting, and vasomotor centers. The medulla also contains part of the reticular formation and controls vital autonomic functions such as breathing, heart rate, and blood pressure. As such, any damage to this portion of the brain may result in respiratory failure and/or death.

Cerebellum

The cerebellum sits dorsal to the brainstem and directly posterior to (or toward the back of) the pons and the medulla oblongata and is connected to all three parts of the brainstem through large bundles of nerve fibers called peduncles. The peduncles connect the cerebellum to the rest of the nervous system. Similar to the cerebrum, the cerebellum has two hemispheres that are covered by a folded surface layer, called the cortex. Both white and gray matter comprise the cortex, which also houses deep nuclear structures. The cerebellum is primarily responsible for motor functions, such as coordination and stabilization of movement, and is involved with maintaining balance. The cerebellum is able to fine-tune movements using the extensive neural connections from the motor cortex of the cerebrum to the spinocerebellar tract (located in the spinal cord). These neural connections allow the cerebellum to gather information regarding intended and actual movement and

make adjustments as needed. Individuals with cerebellar disease may demonstrate slurred speech, poor coordination, and disrupted gait.

Spinal cord

The spinal cord is the lowermost part of the CNS and connects with the brain through the medulla oblongata at the foramen magnum. The spinal cord is shorter than the bony vertebral canal that surrounds it and runs from the foramen magnum to the second or third lumbar vertebra. The spinal cord consists of inner gray matter, containing the nerve cell bodies, and outer white matter, containing the axons of the nerves. In the center of the spinal cord is a space called the central canal, which is filled with cerebrospinal fluid.

The spinal cord has 31 segments of paired spinal nerves and ends with a thin, fibrous thread called *filum terminale*, in the coccyx. The 31 segments are divided into regions: (1) the top 8 segments comprise the cervical region such that C1–8 nerves exit the spinal cord in the cervical region or in the neck; (2) the next 12 segments are part of the thoracic region such that T1–12 nerves exit the spinal cord in the thoracic region or the chest; (3) the next 5 segments make up the sacral region such that L1–5 nerves exit the spinal cord in the lumbar region or the lower back; (4) the S1–5 nerves exit the spinal cord in the sacral region or near the pelvis; and finally, (5) the last segment consists of the coccygeal nerves which exit the spinal cord near the coccyx, or tailbone. The main purpose of the spinal cord is to transmit and receive information between the brain and the rest of the body (muscles and glands). The spinal cord also has some of its own neural circuits that are responsible for reflexes and rhythmic movements, such as locomotion and respiration.

Spinal cord injuries affect the whole body; however, impairments in sensation and/or motor ability typically occur below the site of the injury. For this reason, some persons have altered functioning in their legs and lower body only (paraplegic), while others have altered functioning involving all four limbs (tetraplegic). As such, spinal cord injuries are classified according to the affected individual's degree of loss of motor and/or sensory function.

Behavior

Sensation and Perception

All human contact with the outside world is contingent upon sensation and perception. Sensation is the process of receiving physical stimulation through specialized sensory organs. Perception is the process of becoming aware of, modulating, integrating, and interpreting sensory stimulation. Perception represents the modification and organization of incoming stimuli. Specialized receptors convert sensory stimuli (e.g., light waves) into neural activity in the form of either graded potentials or action potentials, which is a process called transduction. The sensory systems include vision, audition (hearing), taste, olfaction (smell), and somatic sensation (touch).

Visual system

The sensory organ of the visual system is the eye, which detects and focuses stimuli. Light enters the eye through a transparent

outer covering known as the cornea. Subsequently, light travels through the pupil, an adjustable opening in the iris (the colored part of the eye), is focused by the lens, and finally falls on the light-sensitive area of the eye, referred to as the retina. Within the retina are two visual receptor cells: rods and cones. Rods are visual receptors that are sensitive to low-intensity light and are involved in night and peripheral vision; cones are mainly found in the central region of the retina and permit color vision.

Once the rods and cones are stimulated, they carry visual impulses via the optic nerve, the large nerve that carries visual impulses from the retina to the visual processing areas of the brain, to the optic chiasm. At the optic chiasm, approximately one-half of the fibers from each eye's optic nerve cross to the other side of the brain. These fibers cross to the other side of the brain from the nasal portions of each retina. As a result, information from each eye reaches both sides of the brain, with signals from the left visual field terminating in the right hemisphere and signals from the right visual field being sent to the left hemisphere. Finally, these optic tracts travel to the thalamus and ultimately to the primary visual cortex of the occipital lobe.

Auditory system

The ear is the sensory organ of the auditory system. From the outer ear, sound waves enter the auditory canal and travel to the thin membrane known as the eardrum (tympanic membrane). Sound waves cause the eardrum to vibrate, which creates movement in the three ossicles (tiny bones) of the middle ear: the malleus, incus, and stapes. The ossicles amplify vibrations and then transmit these higher-pressure sound vibrations to the oval window, the membrane that leads from the middle to the inner ear. The oval window then sends the sound information in wave form through the fluid of the inner ear to the cochlea. Attached to the basilar membrane of the cochlea is the organ of Corti which contains auditory receptor cells known as hair cells. The hair cells are compressed between the basilar membrane and the tectorial membrane. Fluid sound waves in the cochlea move these two membranes in such a way that the hair cells are bent and distorted, thus transforming the fluid waves into neural impulses in the adjacent auditory nerve. The impulses follow pathways from the cochlea via a series of nuclei to the thalamus; finally, the signal ends in the primary auditory cortex, which is located in the temporal lobe. The auditory system is bilateral, meaning that each ear projects to both sides of the brain.

Taste and smell

Taste and smell (olfaction) are referred to as chemical senses because both transduce chemical signals into perception. The primary receptor cells for taste are located in the taste buds (gustatory calyculi), concentrated on the upper surface of the tongue. The taste buds are sensitive to five basic tastes: bitter, sweet, sour, salt, and umami (savory). Other tastes are considered to be a combination of these five qualities and/or a mixture of taste and smell. In humans, signals from the taste buds are conveyed to the brain through three different cranial nerves (facial, glossopharyngeal, vagus) that, combined, form the tractus solitarius in the medulla oblongata. From here, the signals cross the midline and continue, via the thalamus, to the

insula and the somatosensory cortex (tongue area), ultimately leading to the experience of taste. A second branch of the tractus solitarius projects to the lateral hypothalamus and the amygdala, areas that are involved in feeding.

In contrast to taste, there are hundreds of olfactory receptors, each of which binds to a particular molecular feature. The primary receptor cells for olfaction are located within the olfactory epithelium, the membrane that lines the roof of the nasal cavity. The axons of these olfactory receptor cells synapse in the olfactory bulb. From there, the olfactory nerve passes through the pyriform cortex and subsequently to the thalamus and the orbital frontal cortex. Olfactory receptor cells are not specific to single odors; instead, each odor molecule possesses a variety of features that excite specific receptors in varying degrees. In fact, it is believed that the combination of multiple signals from different receptors is processed in the olfactory system to form the experience of a particular smell.

Somatosensory system

The somatosensory system includes the following cutaneous or skin senses: pressure (touch), pain (nociception), vibration and temperature, position sense (proprioception), and body movement (kinesthesia). The somatosensory system reacts to diverse stimuli and skin sensations through the mechanical, chemical, and thermal properties of the tissue in which the sensory nerves terminate. The quality of sensation is also due to variations in temporal and spatial patterns of neural discharge in the sensory nerves. Axons that carry information from cutaneous receptors gather together in nerves that enter the spinal cord through the dorsal roots; these nerves are organized into two systems in the spinal cord, the posterior column–medial lemniscus pathway and the spinothalamic tract. Both systems ascend to the posteroventral nuclear complex of the thalamus, which, in turn, sends projections to the somatosensory cortex. The posterior column–medial lemniscus pathway is responsible for transmitting pressure and position senses; the spinothalamic tract mediates the sensation of pain and temperature. The arrangement of these projections in the postcentral gyrus generally represents the body parts topographically, with the legs at the top and the hand at the bottom of the gyrus.

Motor System

The motor system is the part of the CNS that is involved in movement. The motor system consists of a number of subsystems including the spinal cord, the brainstem, the cerebellum, the basal ganglia, and the neocortex. These structures are all closely interconnected and do not function in isolation. In fact, some of these connections are arranged in parallel and hierarchical systems exist within the motor system. The brainstem and cortex each influence the spinal cord autonomously for the purpose of invoking movements, but each system is also interconnected with the other system, thereby permitting them to influence each other. The cerebellum is a crucial coordinating center in the motor system; it directs balance and posture. Along with the basal ganglia and motor cortex, the cerebellum is essential to the performance of coordinated and refined motor movements. Damage to the cerebellum can result in ataxia, a lack of muscle coordination during voluntary

movements that can affect movement, speech, balance, and gait. The basal ganglia represent another level of the motor system. These substantial subcortical nuclei are important in the initiation and control of voluntary movements, particularly in the regulation of muscle tone. Damage to the basal ganglia and the regulation and initiation of motor commands can result in either decreased motor activity (e.g., akinesia) or generation of involuntary movements. These disruptions are most prominently observed in the tremors and rigidity of Parkinson's disease or the uncontrollable limb movements of Huntington's chorea.

The motor cortex follows two different major pathways to descend into the spinal cord; these are referred to as the lateral and ventromedial systems. These pathways allow each hemisphere to control the trunk on the corresponding side of the body and the arms and legs of the opposite side of the body. Ultimately, both pathways synapse with motor neurons located in the nuclei of the cranial nerves and in the ventral horns of the spinal cord. The motor neurons are the final link in the pathway, projecting directly into the muscles. The lateral system projects from both the cortex and the brainstem in one hemisphere to the spinal cord of the opposite side. The lateral system contains the axons of the cortical neurons that are responsible for the muscles and the extremities. Specifically, the lateral system includes the corticospinal and rubrospinal components. The corticospinal component connects directly with motor neurons and is involved in the movement of distal musculature (i.e., fingers and hands) on the contralateral side of the body. The rubrospinal component connects with interneurons and then with motor neurons that control the musculature of the shoulders, arms, and hands. The other major pathway, the ventromedial system, projects to interneurons of the spinal cord from the cortex and the brainstem. Unlike the lateral system, the ventromedial system does not change sides when it enters the spinal cord. This system descends directly into the ventral and medial part of the spinal cord, where it innervates motor neurons that control the musculature of the trunk.

For both motor and sensory cortex, a topographical relationship exists between body parts and locations within the neocortex. This relationship is often demonstrated schematically in texts by cartoon men or homunculi drawn over the motor and sensory areas to represent this type of organization. The face and the hands of the homunculi are larger than other body parts, as they are capable of finer perceptions and movements. Thus, relative to other body areas, they require proportionately more neocortex to be represented accurately.

Cerebral Lateralization

While both hemispheres play a role in most behavior, cerebral lateralization refers to the preferential use of one hemisphere (i.e., left and right hemisphere) of the brain to perform certain cognitive functions. Although on initial examination the left and right cerebral hemispheres appear to be quite similar, a detailed examination reveals numerous anatomic differences that are believed to support functional asymmetries. For example, the superior temporal portion of the planum temporale, a cortical region posterior to the auditory cortex, is larger on the left side in the majority of

individuals and this difference in size is believed to reflect left-hemisphere specialization for language.

Information about hemispheric contributions to cognitive function and hemispheric specialization was initially obtained from studies of split-brain patients whose corpus callosa were severed as treatment for severe epilepsy. Additional evidence from studies of patients with lateralized brain lesions and normal individuals evaluated under specialized laboratory conditions also suggest differences. Specifically, for most people, the left cerebral hemisphere is dominant in the control of speech, language and analytic processing, and mathematics. In contrast, the right hemisphere appears to be specialized in spatial-relational processing, creativity, and facial recognition. Although the two hemispheres may be specialized for different types of stimuli, each hemisphere also might have a characteristic processing style that is best suited for analyzing those stimuli. For example, the left hemisphere may process information in a serial, sequential manner, which is conducive to the analysis of language. Alternatively, the right hemisphere has been described as a parallel, holistic processor, more appropriate for handling complex configurations.

Whereas the majority of individuals fit this functional model of lateralization, individual variability is clearly present and is generally related to factors such as handedness and gender. Neuroimaging techniques recently provided support for gender differences in language lateralization, with males utilizing only the left hemisphere and a majority of females activating both the right and left hemispheres on language-related tasks. However, a majority of research supports that some degree of functional asymmetry appears to be present from birth. For example, newborns can accurately discriminate speech from nonspeech sounds and demonstrate greater activation of the left hemisphere in response to human speech.

Language

Language is considered a function that is both lateralized and localized in the brain. The association between damage to the left hemisphere and language impairments is most widely credited to the discoveries of French neurologist Paul Broca and German neurologist Carl Wernicke. Broca found that lesions in the left frontal lobe in an area now known as 'Broca's area' affected speech production. Wernicke discovered that damage to the left temporal lobe results in different language impairment, specifically a difficulty in understanding language. Collectively, these are early descriptions of aphasia, or acquired language disorders that can be traced to damage of specific areas of the brain. Aphasias are classified by different patterns of impairment of language processes. Patients may exhibit disorders of comprehension of speech or written language, or they may exhibit deficits in the production of language. These disorders may affect speech fluency, speech repetition, syntax, grammar, word retrieval, or writing. For example, in all cases when comprehension remains intact,

Broca's aphasia (motor/expressive aphasia) is associated with repetitive speech, phonemic paraphasias (one sound is incorrectly substituted for another), and disrupted grammar and syntax. On the other hand, patients with Wernicke's aphasia (sensory/receptive aphasia) demonstrate fluent speech with adequate syntax and grammar but often include contrived or inappropriate words; thus, problems are largely associated with comprehension.

Studies of split-brain patients have assisted in the identification of the independent function of each hemisphere in language. Specifically, the right hemisphere is largely responsible for prosodic elements, or the emotional elements of language. The right hemisphere also plays a role in rudimentary speech and is largely responsible for spatial abilities. Research on individuals who are deaf, who use sign language, reveals that similar areas of the brain are involved in sign production. This line of research also indicates that damage to the left-hemisphere language area is more likely to produce signing aphasia than damage to the same area in the right hemisphere. As such, the lateralization of language is preserved in deaf individuals.

In addition to clinical investigation of patients with brain damage, the major brain regions involved in language have also been identified by using cortical stimulation during brain surgery and functional brain injury. Other areas associated with language include the primary sensory and motor regions of the face and the supplementary motor area.

Glossary

Attachment Developed by John Bowlby and Mary Ainsworth, it is an innate emotional and behavioral system of protection for children that includes a child's attachment system and a parent's protection system.

Child neglect It is the failure of a parent or caregiver to provide for a child's basic emotional, medical, educational, and physical needs. Forms of neglect include emotional, medical, educational, and physical.

Child sexual abuse Sexual abuse involves an adult engaging a child in sexually explicit conduct, including direct sexual contact, simulation of sexual contact, or visual representation of sexual contact. This may include rape, molestation, prostitution, child pornography, incest, or other forms of exploitation.

Emotional abuse Also called psychological abuse, it is a pattern of parenting or caregiving that degrades a child or impairs healthy development.

Human trafficking It is the recruitment, transportation, transfer, harboring, or receipt of persons by means of threat, or use of force or other forms of coercion, of abduction, of fraud, of deception, of the abuse of power or position of vulnerability, or the giving or receiving of payments or benefits to achieve the consent of a person having control over another person, for the purpose of exploitation.

Physical abuse It is nonaccidental injury, inclusive of all levels from bruises to death, as a result of harm from a parent, caregiver, or adult responsible for a child's care.

Introduction

Throughout history, most cultures prohibited the abuse of children. Since the future of families, groups, and nations depends on the success of children to move forward and bear their own children to continue the species, most cultures have stated or implicit values about protecting children from harm. Children are generally valued for their representations of emotional connections between parents or others and serve as profound symbols of hope for the future as concrete protectors of traditions, caregivers of elders, and producers of new resources and subsequent generations. In addition, children are the rejuvenators of families and communities, renewing adults' senses of possibility.

Human children are altricial mammals, vulnerable at birth and unable to survive outside the care and support of a caregiving adult, usually a mother or parent. In this sense, there is no individual infant or young child independent of a dyad or family. On his or her own without a responsive and protective parent, caregiver, or community of caregivers, an infant or young child will not survive. Thus, millennia of evolution created complex and strong caregiving and protection systems for human children that are part of the fabric of all communities.

Nonetheless, child abuse remains a serious social problem, as children are some of the most vulnerable members of our societies and prone to victimization by those stronger than them or on whom they depend for care and protection – adults. While abuse against children is often perpetrated by nonfamily members, it is the exception rather than the rule. Outside areas of conflict such as war zones, children are more likely to be harmed, or put in harmful situations, by a family member or someone close to them in their community.

In this article, we provide an overview of child abuse as it pertains to intrafamilial child abuse or child maltreatment

perpetrated by a family member or a person close to a child. This includes four general types of child abuse: physical abuse, sexual abuse, neglect, and emotional abuse. However, we have also included information on human trafficking, which may be the result of intrafamilial or extrafamilial maltreatment, as it is an area of child exploitation, affecting children and mothers, that warrants further investigation and concern.

The theoretical framework used for this article is attachment and parent–child relationships with the view that child abuse is an extreme form of relationship-disruptions for children. As such, child abuse risk factors and protective factors for children, parents or caregivers, and community is reviewed with a particular focus on the role of relationships in contributing to maltreatment, ameliorating its traumatic impact, and preventing its occurrence. Child abuse treatment models reviewed here focus on interventions that repair a child's capacity, and a parent's or alternative caregiver's capacity, to enter into trusting and emotionally responsive relationships.

Attachment

Young children rely on their mothers or other caregivers for protection and guidance. Ideally, when a young child calls out for help or appears to need assistance, a mother or other caregiver will respond with support, nurturance, and protection. This emotional response is believed to be part of innate emotional and behavioral systems of protection – a child's attachment system and a parent's protection system.

Over time, the repeated expression of needs from a child and appropriate responses of emotional and physical support from a parent or other caregiver contribute to a child's feeling of a safe haven with that parent or caregiver. A parent's consistent signaling of emotional availability to a child affirms the stability of a child's safe haven. With a secure attachment

system between a child and a parent or caregiver, a child is able to use the relationship as a secure base from which he or she can explore the world and engage in other relationships based, in part, on the initial attachment system. A child is able to seek assurance and emotionally refuel as needed with a secure base, a responsive parent or caregiver.

In essence, a secure attachment system can create a template for future healthy and emotionally responsive relationships. It is believed that internal working models of relationships are based on early attachments systems between a child and a parent or caregiver. When those attachment systems are secure, derived from emotionally and physically responsive support from a parent or caregiver, a child can integrate a secure internal working model of attachment, encouraging his or her healthy development of autonomous emotional regulation and adept social skills.

If a parent or caregiver is not responsive, emotionally unavailable, abusive, or neglectful, a child is likely to develop an insecure attachment pattern and corresponding insecure internal working model of attachment. Child abuse and neglect can be the result of or contribute to insecure attachment systems. In the long term, children with insecure attachment systems are more likely to have social, cognitive, and mental health deficits.

Attachment Patterns

Four attachment patterns can be predicted from a child's attachment systems: secure, anxious, avoidant, and disorganized. Secure attachment usually emerges from a relatively normal functioning, nonabusive, child–parent relationship and attachment system. Additionally, secure attachment tends to correspond with stable physical, academic, and social development, and a general absence of anxiety and frustration.

Anxious attachments

Anxious, avoidant, and disorganized attachment patterns are classified as forms of insecure attachment and are associated with behavioral, relationship and mental health problems. Anxious attachment is usually produced from anxious, uncertain, and unreliable parenting from a caregiver who may have experienced similar anxious attachment patterns with his or her parents. The anxiety arises from a sense that a parent or caregiver is not reliably there to meet a child's needs. Such anxious attachments emerge from neglectful or inconsistent caregivers, resulting in a child doubting support from others and demanding more attention and reassurance.

Avoidant attachment

When a child's requests for comfort and nurturance are consistently met with insensitivity and unresponsiveness, he or she is likely to develop avoidant attachment patterns. A child with avoidant attachment patterns may exhibit uncertainty and anger resulting from a view of others as unhelpful, cold, or uninterested when a child needed help or support. Avoidant attachment patterns tend to be associated with people who do not trust others and may not be able to fully consider the needs of others.

Disorganized attachment

The most recently identified classification of attachment systems, disorganized attachment, arises from scenarios where a child's attachment figure or parent is observably frightened or frightening when a child needs comforting or reassurance. Disorganized attachment involves frightening and violent behaviors from parents or caregivers and is, therefore, more common with families suffering from combined or distinct problems of child abuse, domestic violence, and family instability. The severe long-term consequences for disorganized attachment systems include later dissociative disorders, anxiety disorders, and serious behavior problems.

Cultural Variations

Though there is general cultural pressure worldwide toward the selection of secure attachment systems, more cross-cultural and contextual attachment research is needed. Attachment theory and research focuses on Western culture models of parent–child relationships, but it continues to expand in consideration of other cultural and subcultural variations of child caregiving. Emerging models of social network support and plural caregiving referencing multiple attachment figures are in the process of being tested and will warrant further consideration in future reviews on attachment.

Types of Child Abuse

Most cultures recognize four major areas of child abuse: physical abuse, sexual abuse, neglect, and emotional abuse. These categories are not fully inclusive of all harm perpetrated on children, and most maltreated children are abused in various forms and not exclusively in one type or another.

Physical Abuse

Physical abuse is nonaccidental injury, inclusive of all levels from bruises to death, as a result of harm from a parent, caregiver, or adult who is responsible for a child's care. The exact detail of what constitutes physical abuse varies by jurisdiction or culture, but usually hinges on the intent of injury to be classified as abuse. Physical discipline is not considered abuse as long as it is culturally and physically reasonable and does not cause bodily injury to a child. However, infants are an exception, and physical discipline of an infant is usually viewed as abuse.

Sexual Abuse

Sexual abuse involves an adult engaging a child in sexually explicit conduct, including direct sexual contact, simulation of sexual contact, or visual representation of sexual contact. The acts of sexual abuse may include rape, molestation, prostitution, child pornography, incest, or other forms of exploitation of a child for the sexual gratification of an adult. Though there are varying legal definitions for child sexual abuse across cultures and jurisdictions, sexual abuse of a child can lead to trauma and stigma for a child and his or her family. Long-term health of a

sexually abused child usually depends on the support of the family or community and protection from further harm.

Child Neglect

The usual hallmark of child neglect is the omission of care rather than the commission of any particular act of maltreatment. Neglect is the failure of a parent or caregiver to provide for a child's basic emotional, medical, educational, and physical needs. Interpretation of child neglect depends on community standards and cultural values, as well as prevailing resources within a community. For example, lack of indoor plumbing or safe housing may be viewed as substandard living arrangement in many communities, leading to a potential assessment of neglect of children living in such conditions. However, in a community that lacks resources and standard housing does not always include indoor plumbing, child neglect may not be an appropriate assessment based on these particular elements.

Emotional neglect

Emotional neglect involves inattentiveness to a child's emotional and development needs. This may take various forms, including allowing independence inappropriate for a child's development needs. For example, permitting a child to use drugs or alcohol could be considered neglectful of a child's emotional and physical development. Interpretations of emotional neglect must also include cultural contexts, as plural or collective caregiving in some cultures and communities may allow for greater variation in emotional responsiveness based on shared caregiving practices. More specifically, a parent's potential lack of attentiveness to a child may be balanced by caregiving and attachment systems with other caregivers, such as grandparents, who are able to respond adequately to a child's needs.

Physical neglect

Physical neglect means a parent or caregiver fails to provide necessary shelter, food, or supervision. In these situations, resources and poverty are important considerations, as a parent or caregiver doing his or her best with meager resources to care for children is not physical neglect. In fact, poverty itself should never be considered physical neglect. Rather, physical neglect involves a risk to a child's health and safety and may involve parents failing to use the resources available to them to support children's needs.

Examples of physical neglect include

- *Unsanitary living conditions:* Home is unsafe or set near unhealthy or unsanitary conditions, which may cause sickness or harm to a child, and a parent or caregiver does not respond to a child's needs.
- *Unstable living arrangements:* A parent or caregiver does not have a stable home (e.g., homeless), and the instability presents a danger to the health and well-being of a child.
- *Abandonment:* A child is left without adequate care and supervision or without a plan for the child's care, leaving a child at risk of harm.
- *Exposure to drugs and alcohol:* Parents' or caregivers' addiction to drugs and alcohol presents a host of risk factors for children. Children exposed to drugs or alcohol prenatally

have special medical needs that require ongoing attention, and parents or caregivers who continue to use drugs and alcohol may be very challenged to fully address an infant's needs.

Medical neglect

Not providing for a child's medical or mental health needs may be considered medical neglect. Of special sensitivity are those situations where a child has a life-threatening condition that requires medical intervention and a parent or caregiver does not or will not attain professional services. The contextual considerations for these matters include parental or caregiver resources and the capacity to care for a medically fragile child and religious beliefs that may be counter to recommended courses of action. In the latter case, court intervention may be needed to obtain the right balance between community and familial standards in consideration of the best interest of the child.

Examples of medical neglect include

- *Inadequate or delayed health care:* A parent or caregiver is not able to care for a child's acute or chronic medical condition, physical, or mental disability that if left untreated causes harm or danger to a child.
- *Inadequate nutrition:* A parent or caregiver is unable to provide for a child's basic nutritional needs or purposefully withholds food and water.
- *Lack of treatment for mental health:* A parent or caregiver does not provide for necessary mental health concerns causing potential health and emotional impairment for a child.

Educational neglect

Inattention to a child's educational needs or failing to attend to a child's special education needs may be viewed as educational neglect. Considering community standards and resources as well as the mandatory education requirements of a culture, educational neglect involves deliberate lack of attention to a child's educational needs even when a parent or caregiver has been fully informed of his or her responsibility for that child's education and services have been made available. In these instances, a parent or caregiver may lack the physical or mental capacity to help a child with educational needs so efforts may be necessary to ameliorate both a child's and parent's or caregiver's needs.

Examples of educational neglect include

- *Unmet special education needs:* A parent or caregiver is unable or unwilling to have a child participate in special learning or remedial education programs, contributing to a child's learning disabilities.
- *Chronic truancy:* A parent or caregiver does not provide for a child's learning needs by not enrolling a child in school or not supporting a child's attendance.

Emotional Abuse

Emotional abuse, or psychological abuse, is a pattern of parenting or caregiving behavior that degrades a child or impairs healthy emotional development. This may involve constant demeaning or belittling comments and criticisms that impede a child's capacity to function and causes emotional strain for a

child. Withholding of parental or caregiver love, support, and guidance may also be considered emotional abuse if it causes undue strain and anxiety for an involved child.

Examples of emotional abuse include

- *Isolation*: A parent or caregiver does not allow a child to interact with peers or others causing undue dependency and potential harm to a child's physical and emotional development.
- *Ridiculing and degrading*: A parent or caregiver constantly belittles, degrades, and ridicules a child causing emotional harm and shame.
- *Witnessing violence*: A parent or caregiver allows a child to repeatedly witness criminal activities between caregivers and others.

Human Trafficking and Exploitation

Human trafficking is a modern-day form of slavery and is increasingly recognized as an emerging type of child abuse. It is estimated that 600 000–800 000 people worldwide are trafficked annually. No country in the world has been exempted from human trafficking. The Palermo Protocol adopted by the United Nations provides the most commonly recognized definition of human trafficking described as

the recruitment, transportation, transfer, harboring, or receipt of persons by means of threat, or use of force or other forms of coercion, of abduction, of fraud, of deception, of the abuse of power or of a position of vulnerability, or the giving or receiving of payments or benefits to achieve the consent of a person having control over another person, for the purpose of exploitation. Exploitation shall include, at a minimum, the exploitation of the prostitution of others or other forms of sexual exploitation, forced labor or services, slavery or practices similar to slavery, servitude, or the removal of organs.

The primary forms of human trafficking are sex trafficking, sex trafficking of minors, and labor trafficking. Other forms of human trafficking include the trafficking of children for adoption and trafficking of organs. Women and children are the most vulnerable groups of individuals trafficked, with ~50% of all persons trafficked being children under the age of 18 years.

Causes and Contributing Factors

The underlying causes of human trafficking are issues of poverty that have been compounded by the rapid growth of communication technology and globalization. Victims are trafficked within countries of origin and transported across international borders. Collapses of economic systems in some governments and regions have left large segments of the population desperate for money for survival. Women and children have been hit particularly hard by poverty. It is estimated that internationally 70% of all persons who are living in poverty are women. Desperate for work and a way to support their families, many women have been lured into slavery through employment agencies and false advertisements that promise work abroad. Many women who have responded to these false advertisements have disappeared and are assumed

to have been trafficked. In poor countries, children are left alone to parent themselves and younger siblings. The issue of families without an adult parent or caregiver is so relatively common in some parts of the developing world (e.g., areas of extreme poverty) that the term 'child-led families' is used to describe parent-less families. Children, left to fend for themselves, have become victims of traffickers and have also disappeared without a parent, family, or community to protect them or seek assistance when they disappear.

In the United States, many children who have run away from child welfare services (e.g., foster care) have become victims of traffickers and prostituted. Adolescents have been found to have been blackmailed into prostitution by gangs who first provide them with drugs, and when addicted require payment to support the addiction. Some traffickers take pornographic photos of victims, then threaten to expose them to their parents unless they cooperate, causing some adolescents to be secretly forced into prostitution while still living at home.

Psychological and Health Issues

Human trafficking has consequences that interfere with the developmental milestones expected during childhood and adolescence. Captivity interferes with the development of one's identity and the establishment of societal or cultural morals and values. They experience psychological distress that includes depression and posttraumatic stress disorder. The psychological stress is so great that many captive women and children commit suicide. The overall psychological impact of the abuses of human trafficking can profoundly change the development of one's character and personality.

During captivity, victims are exposed to sexually transmitted diseases and other health problems that worsen due to a lack of appropriate medical care. Women become pregnant and experience lasting health problems as a result of poorly performed or botched abortions, the lack of adequate medical care, and poorly met nutritional needs. As a result, those who are released from bondage are often seriously incapacitated or terminally ill.

Long-Term Consequences

Children born into captivity are exposed from birth to inconsistent care. From the earliest period of awareness, babies experience deeply traumatized and despairing mothers creating insecure attachment systems and poor internal working models of relationships. They experience their mothers as powerless and unable to protect them from their abusers. Born into captivity, these psychological conditions leave many children to identify with a detached and emotionally absent mother.

Many women who give birth during captivity are minor children and unable to parent. For these women, their children are a reminder of the rape and abuse they experienced while in captivity and the men who abused them. These issues interfere with the emotions of giving and receiving love as well as a capacity to establish secure attachment systems for self or others.

There are long-term consequences for children born into captivity. If a captive mother is unable to psychologically

nurture a child, that child is at risk of becoming detached, limiting the emotional capacity for giving and receiving love. Some captive mothers are able to give and receive love from their children. When this happens, a child's need for safety may cause a mother to risk the consequences of an attempt to escape captivity. In other, more desperate situations, the love returned by a child may keep a mother from committing suicide. The loss of psychologically healthy women able to nurture the next generation of children will have long-term consequences on society. Consequently, emerging research and information about human trafficking is worthy of additional consideration in future reviews of child abuse both as a distinct type of child abuse and as a consequence of other forms of child maltreatment.

Risk Factors and Protective Factors

While child abuse is found in all cultures and all socioeconomic strata, social science data and research, mostly from Western countries, reveal some general risk and protective factors relative to child abuse. Risk factors are the individual and familial variables that appear associated with children, individuals, and families for whom child abuse has been a problem. Protective factors represent the variables that seem to thwart occurrences of child abuse for individuals and within families or communities. These factors should be considered global indicators, as the presence of, or lack of, any factors does not predict, or counteract, child maltreatment. Rather, risk and protective factors can guide assessment of child abuse and planning for programs to ameliorate its effects on children and families.

Some suggest that risk and protective factors are additive features that can be simply balanced out as needed. Specifically, an increase in protective factors and a reduction in risk factors would theoretically reduce the chances of harm to a child. This may be true in some cases but it has yet to be determined across all aspects of child abuse. Instead, risk factors should be viewed as signals of concern and protective factors as areas of strength. The following review of risk factors and protective factors summarizes some of these factors in the contexts of parents or caregivers, children, and community.

Risk Factors

Parents or caregivers

For parents or caregivers, risk factors generally correspond to a lack of resources, materially, emotionally, and socially. Many parents or caregivers who abused their children were themselves victims of abuse or had insecure attachments with their parents or primary caregivers. Relatedly, abusive parents have less knowledge or understanding about the emotional or developmental needs of their children, expecting more than what might be appropriate for their children's age or attributing negative attitudes of feelings to their children. These mismatches of developmental expectations may be exacerbated by a parent's own poor romantic relationships or high conflict within the home with other adults or other children.

Mental health issues are clear risk factors for a parent or caregiver, especially depression and anxiety. Coupled with

social isolation, single parenthood, and poor social support, compromised mental health can contribute to elevated stress that can manifest in child abuse. Moreover, a parent or caregiver with a history of being abused or neglected is more likely to repeat that approach with his or her own children when there is an accumulation of other risk factors.

Alcohol and drug addiction is a major risk factor that seems increasingly correlated with numerous other social problems in addition to child abuse and neglect. It is difficult to disentangle other risk factors from drug and alcohol addiction, but it is the one risk factor most associated with child abuse, possibly because it is both an outcome and a contributor to other child abuse risk factors. Additionally, it creates a social scenario and lifestyle for a parent or caregiver that contains risk for the adults involved, let alone for the dependent children living with them and relying on their good judgment.

Children

Risk factors for children begin in utero where a forming child may be exposed to toxins from a mother's use of drugs or alcohol. The effects of these toxins can have profound impacts on a child's lifetime capacity to regulate intellectually and emotionally. Fetal Alcohol Spectrum Disorder, for example, can seriously alter a child's ability to read social cues, including verbal and nonverbal, contributing to challenging social interactions with family and others.

Children with difficult temperaments are prone to abuse and neglect because they tend to be more challenging behaviorally than other children. In fact, behavior problems or externalizing behavior (acting-out behavior) from children are often cited by nonabusing parents as well as abusing parents as the most challenging part of parenting. Also at greater risk of abuse are children with developmental, intellectual, and physical disabilities as they can be less responsive to caregivers and may cause additional stress given their special needs. Further, children who have experienced trauma, including those maltreated by a parent or caregiver, respond to caregivers in ways that appear to reject affection and care creating new risks of maltreatment for those children with histories of being abused.

Community

Stressful environments or neighborhoods can contribute to disruptions in parent-child relationships and create contexts for maltreatment of a child. Parental unemployment and other stressful family life events, including uncertain housing and homelessness, can be environmental risk factors for child abuse. Racial, economic, or cultural discrimination also form a broad context of systemic risk for children and families that may potentially elevate risks for child abuse.

Protective Factors

Parents and caregivers

In contrast to risk factors, protective factors for parents and caregivers correlate with material, emotional, and social resources. Strong, early parent-child relationships defined by secure attachment systems can help inoculate a child against maltreatment from a parent or caregiver. This protective factor depends on a parent's or caregiver's own attachment systems

with his or her own parents or significant others. In fact, marriage or parenting with another supportive caregiver can be a protective factor. Networks of supportive friends and family who can serve as substitute caregivers and with whom a child can develop independent, secure attachment relationship help protect a child from incidents of abuse. Further, parental, familial, or community knowledge of child development and associated parenting skills connected to a child's varying needs at different periods of life can help protect a child against episodes of maltreatment.

Children

Healthy development including a stress-free prenatal period helps protect a child against child abuse as well as a range of other health, cognitive, and social challenges. Meeting or exceeding developmental milestones supports a child's capacity for normative emotional skills and his or her ability to form a secure attachment system with a parent or caregiver. An agreeable temperament and adequate cognitive abilities can also help a child with a range of social tasks with peers and adults, potentially reducing stress and conflict with a parent or caregiver.

Community

Supportive extended family and neighborhoods can help form protective environments for children and families. Formal and informal community networks, especially those that offer judgment-free support for parents or caregivers, can help alleviate stress at home and help potentiate healthy relationships between children and their parents or caregivers. Additionally, positive peer relationships for children and adequate educational and extracurricular resources are essential components of a healthy community.

Treatment and Support

Safety

The first step in treating issues of child abuse is child safety. This may take the form of removing a perpetrator of child abuse from a home or placing a child temporarily in alternative care with a safe kin or nonkin foster family. In most cultures, these initial moves are viewed as temporary to allow for additional planning to assess the core issues underlying the history of maltreatment. Viewed in the context of relationship-disruptions and potential insecure attachment systems, child abuse interventions reviewed here will be those targeting young children and their parents or alternative caregivers (e.g., kin or nonkin foster parents, adoptive parents).

In advance of relationship-enhancing interventions, specialized treatment may be needed for a maltreating family, especially the perpetrator as the source of continuing danger, relative to reabuse. For example, child sexual abuse requires specialized treatment for perpetrators, usually addressing sexual deviancy with a combination of cognitive-behavioral and medical methods. Similarly, families and perpetrators of physical abuse need ongoing treatment addressing cycles of rage and assault. In these instances, it is likely and necessary that court or criminal jurisdiction will be applied to a child abuse matter, creating additional external accountability.

Interventions

Abused children need individual support and interventions to address issues of trauma associated with abuse and the potential familial disruptions associated with it. While stability of a safe home and a secure relationship with a caregiver who will protect him or her are paramount to the emotional needs of a child, attention must also be paid to the individual traumatic events of abuse. Mental health professionals skilled in trauma counseling should be engaged to support a child's needs as soon as possible following interventions due to maltreatment.

Maltreatment has dire effects on a child's health and well-being. Children who are abused are at far greater risk for developmental, health, and educational problems than the general population of children. Abused children have more behavioral and mental health problems than nonabused children and are more likely to use mental health services. Attention to the unique mental health needs of these children is a critical component of their long-term health.

Using an attachment framework, the following interventions have been demonstrated to be effective with maltreated children and their parents or caregivers in repairing or improving parent-child relationships. These interventions are described here as representations of potential models for professionals treating abused children and their families. The categories of parental internal working models, parental behavior, and parent-intervener relationship reflect the general approach of the interventions.

Parental internal working models

Child-parent psychotherapy (CPP) is a dyadic intervention for young children and their parents. It is intended to help parents come to grips with their own compromised childhood attachment systems to help prevent child maltreatment and improve current parent-child relationships. In general, CPP helps address insecure attachment issues that undermine parental capacity and contribute to risks of maltreatment.

Attachment and Bio-behavioral Catch-up is a brief home visiting program for foster parents and young foster children. Paying close attention to a foster parent's own attachment history, home visitors help address a foster child's need for security and help foster parents understand behavior from a child in their care that may appear to be rejecting the foster parents. It helps address problematic internal working models for the foster parent, redirecting attention to the emotional needs of a foster child.

A group-based educational approach, circle of security, helps parents or caregivers better understand a child's relationships needs. Using guided reviews of parent-child interactions, parents or caregivers learn to better read a child's cues for security and exploration. Initial studies with families who experienced the trauma of child abuse indicate that insecure attachment patterns were significantly reduced following interventions.

Parental behavior

Parent-child interaction therapy is designed for families with children who are behaviorally disruptive or have mental health concerns. Using in vivo coaching, parents learn new techniques to address a child's externalizing behavior. Treatment

concludes once parents or other caregivers master the techniques for managing a child's behavior.

Triple P – Positive Parenting Program promotes positive parenting approaches through a variety of sources: multimedia, professional consultations, and self-directed modules. Triple P originated in Australia, and its multilevel program is intended to prevent severe emotional and behavioral problems in children by helping parents or other caregivers manage difficult behaviors. Triple P has been successful in reducing parent-reported child behavior problems and parenting problems.

In the Netherlands, models of short-term intense home visiting have helped mothers of irritable infants and young children with externalizing behavior problems. After learning sensitive disciplinary practices and reviewing cues about their children's behaviors, mothers appeared to be more securely attached to their children than those who did not participate, and the effects of the interventions persisted over time. These models may have broader application across cultures as they are short term and simple for both the involved parent or caregiver and home visitors.

Parent–intervener relationship

Two similar interventions with at-risk mothers and their babies, the UCLA family development project and Minding the Baby, use the relationship of the intervener with a mother to establish secure attachment with a baby or expected baby. Through an established secure base with an intervener, a participating mother was able to build reflective capacity to address the emotional needs of her child. With both approaches, early interventions in support of expectant mothers' emotional and relational needs helped prevent development of risk factors for abuse by strengthening protective factors of secure attachments.

Summary

Child abuse is a global social problem defined broadly as physical abuse, sexual abuse, neglect, and emotional abuse of children by adults who are usually family or community

members. Human trafficking involves exploitation of children who are vulnerable due to extreme poverty, child abuse, and other difficult social pressures. Maltreatment by parents and caregivers contributes to insecure attachment systems for children, potentially leading to unhealthy internal working models of relationships that may be transmitted to maltreated children's subsequent relationships, including those with a new generation of children. Risk factors relative to child abuse can help intervening professionals identify those children who may potentially be harmed, while protective factors can help families and communities build personal and environmental strengths toward preventing child maltreatment. Evidence-based treatment programs aimed at enhancing relationship capacity for children and parents or caregivers are available to help maltreated children and their families address severe relationship-disruptions characteristic of child abuse.

Glossary

Child psychopathology The study of psychological and behavioral disorders in children and adolescents, taking into account developmental processes and milestones.

Comorbidity The diagnosis of more than one mental disorder in any given individual.

Diagnostic and Statistical Manual of Mental Disorders (DSM-IV) A manual published by the American Psychiatric Association that provides a common

language and criteria for the diagnosis of mental disorders.

Prevalence The proportion of individuals in a population diagnosed with a specific disorder.

Prognosis The likely outcome associated with a diagnosis or disorder.

Somatic complaints Unexplained medical symptoms.

Taxonomy The science of classifying plants, animals, and microorganisms into increasingly broader categories based on shared features.

Introduction

The current field of study for childhood mental disorders is often referred to as child psychopathology, which involves the study of psychological and behavioral disorders in children and adolescents. In order to be considered as meeting the definition of a mental disorder, there must be a pattern of symptoms that leads to some level of distress, disability or interference with daily functioning, and an increase in risk for pain, suffering, or loss of freedom (e.g., institutionalization). In addition, the symptoms are not consistent with the norms of the culture, though they may appear to be exaggerations of normal behavior or can occur in adaptation to some unusual circumstance (e.g., chronic illness, maltreatment).

The Diagnostic and Statistical Manual of Mental Disorders (DSM) was originally developed as a taxonomy to categorize these patterns of behaviors into distinct mental disorders. Currently, the DSM is in its fourth edition (DSM-IV) and a fifth edition is expected to be released in 2013. The DSM-IV lists numerous disorders as 'usually first diagnosed in infancy, childhood, or adolescence,' and these disorders will be discussed in the current article. Mood disorders and anxiety disorders are also common in children and adolescents, though in some instances they may not be diagnosed until adulthood. This review will focus on childhood mental disorders that are commonly seen in clinic populations, including the mood and anxiety disorders, attention-deficit and disruptive behavior disorders, and pervasive developmental disorders (PDDs).

Recent estimates suggest that 10–20% of youth meet criteria for a specific psychological disorder. Unfortunately, the majority of children with mental health problems do not receive services. About 20% of children with mental health problems will have significant difficulty throughout their lives, suggesting that childhood psychological disorders are long-lasting and continue into adulthood.

Anxiety Disorders

Anxiety in children is often an unrecognized and undiagnosed problem because some symptoms of anxiety are normal in

development (e.g., stranger anxiety in toddlerhood), many symptoms are not easily visible (e.g., increased heart rate), and the effects are not as damaging as those arising from disruptive behavior disorders (e.g., fighting, property destruction). While not easily identified, anxiety disorders in young people do exist and can be chronic.

Anxiety is a mood state that is often viewed as having three interrelated components – physical, cognitive, and behavioral. The physical component is mediated by the sympathetic nervous system and the endocrine system, and essentially involves the chemical and stress reactions that mobilize the body for action. This response is sometimes referred to as the fight/flight response, and prepares us to either flee or defend ourselves in dangerous situations. The cognitive component includes mental processes that allow us to search for potential sources of threat. This component can lead to worry or nervous apprehension. Finally, the behavioral component includes acts associated with anxiety, particularly aggression, avoidance or escape of the situation, and other nervous behaviors (e.g., finger tapping). Therefore, anxiety is characterized by a strong negative emotion accompanied with bodily fight/flight symptoms, apprehension of future danger, and a desire to avoid the feared situation.

In general, anxiety is thought to have some evolutionary survival value by preparing individuals physically and psychologically to cope with potentially dangerous situations. Some anxiety, therefore, is necessary for normal adjustment and coping. When anxiety becomes excessive and disabling, however, the child may have an anxiety disorder. Multiple anxiety disorders are specified in the DSM-IV and they will be reviewed here.

In general, the onset of anxiety disorders has been attributed to biological, behavioral, and social influences that lead to the dysregulation of the normal anxiety response. This disruption then results in undifferentiated anxiety, and ultimately distress and impairment. For example, being bitten by a dog may result in an animal phobia, being teased by classmates at school may result in social anxiety, and biological vulnerability may result in panic disorder. More specifically, the biological mechanisms associated with the onset of anxiety include an overactive behavioral inhibition system, overactive amygdala, increased cortisol levels, increased heart rate, blood pressure and electrodermal responding, as well as genetic influences

(i.e., 33% of the variance in anxiety is believed to be genetic). Family influences include excessive parental control, rejection, overprotection, or modeling. In terms of temperament, children who are born with a low threshold for novelty and unexpected stimuli are at greater risk for anxiety disorders. Countless influences have been identified as playing a role in the onset of anxiety disorders in children and a few of these mechanisms have been reviewed here.

Separation Anxiety Disorder

Separation anxiety disorder (SAD) is the only anxiety disorder in the DSM-IV that is specified as usually the first diagnosed in infancy or early childhood. SAD involves age-inappropriate, excessive, disabling anxiety about being away from home or from those individuals to whom the child is attached. According to the diagnostic criteria in the DSM-IV, the disturbance must last at least 4 weeks and begin before the child is 18 years old.

Separation anxiety is typical in toddlerhood, and so this disorder may be difficult to distinguish from anxiety that is developmentally normal. SAD occurs in about 4–10% of children and is equally common in boys and girls. Children with SAD may experience excessive distress when separated from their major attachment figures. They often need to know the location of their attachment figures and need to stay in frequent contact with them. They may become very ‘homesick’ when away from home and may become worried that something tragic will happen to their attachment figures while they are separated. Because of these fears, the children may avoid traveling independently away from home. For example, they may refuse to attend school, camp, or a sleepover at a friend’s house. Children with SAD may also refuse to engage in activities where they are alone, such as sleeping in their room. These children may sometimes have nightmares about their separation fears (e.g., being kidnapped), and they may also have physical complaints such as stomachaches and headaches.

Of all the anxiety disorders, SAD has the earliest onset. It often occurs after the child has experienced a stressful event (e.g., the hospitalization of a parent). SAD generally has a good prognosis, although it persists into adulthood for about one-third of children and adolescents. Friendships and academics may suffer as the child avoids school or other typical social events where they may be separated from their parent. In addition, children with SAD are at risk for developing other anxiety disorders or a secondary depression in reaction to their distress.

Generalized Anxiety Disorder

Generalized anxiety disorder (GAD) is excessive, uncontrollable anxiety and worry about numerous aspects of the child’s day-to-day life. According to the DSM-IV, it must occur on more days than not for more than 6 months. The onset of GAD is often around 10–14 years of age. Many people with GAD report having felt this way all their lives. It occurs in 3–6% of children, with equal rates in boys and girls, and is one of the most common anxiety disorders in children.

Children with GAD often find it difficult to control their worry, which is far out of proportion to the actual likelihood or

negative impact of the feared event. While adults with GAD tend to worry about everyday matters, children with GAD tend to worry about their own competence (e.g., grades). They may have excessive concerns about being punctual and about catastrophes, such as earthquakes. Children with GAD may also be overly conforming, perfectionistic, and uncertain of themselves, thus often requiring approval and excessive reassurance. In addition to this apprehension, the disorder is accompanied by at least one additional symptom, such as restlessness, fatigue, difficulty concentrating, irritability, muscle tension, and disturbed sleep (three of these symptoms are required in adults). It is commonly accompanied by physical symptoms such as headaches, twitching, shakiness, or muscle tension. GAD has a high comorbidity with other anxiety disorders, mood disorders, and substance related disorders. The course is chronic, but appears to fluctuate and worsen in times of stress.

Specific Phobia

Specific phobia is the extreme, disabling fear of specific objects (e.g., a dog) or situations (e.g., flying) that pose little or no danger. For example, if a child’s fear of costume characters impedes their ability to attend a friend’s birthday party, it may be considered clinically impairing. According to the DSM-IV, for individuals under 18 years old, the marked and persistent fear must occur for more than 6 months. Exposure to the feared stimulus is typically accompanied by an immediate anxiety response, which in children may be expressed as a temper tantrum or clinging to an attachment figure. In adults, DSM-IV criteria require that the individual recognizes that the fear is excessive or unreasonable; however, this characteristic is often absent in children and is not required for diagnosis. The onset of specific phobias can occur at any age, but the highest prevalence of specific phobias in children occurs between the ages of 10 and 13. Specific phobias occur in 2–4% of children, however only a small number of children are referred for treatment. Specific phobias are more common in girls than in boys, and the symptoms tend to occur at younger ages in girls than in boys.

Social Phobia

Social phobia is the marked, persistent fear of and desire to avoid being the focus of attention or scrutiny, or doing something humiliating in front of others. Subsequently, individuals with social phobia avoid situations where they may experience embarrassment or be perceived as stupid, including eating in public or speaking in front of the class. In children, the DSM-IV further specifies that there must be evidence of age-appropriate social interactions with familiar people (e.g., parents), but the child must become markedly anxious in peer social situations (e.g., school). Similar to the diagnosis of specific phobias, the DSM-IV specifies that, unlike adults, children frequently do not recognize that the fear is unreasonable, and for individuals under 18 years old, the fear must occur for more than 6 months. Social phobia in children may also take the form of selective mutism or the failure to speak in specific situations. The onset of social phobia typically occurs in early to mid-adolescence because of the greater emphasis on self-focus and -consciousness. It occurs in 1–3% of children, appears to

increase with age, and is slightly more common in girls than in boys. Younger children experience more somatic complaints, such as stomachaches, whereas adolescents report more concern about visible signs of anxiety, such as trembling or sweating.

Obsessive–Compulsive Disorder

Obsessive–compulsive disorder (OCD) is a disorder that is characterized by two types of symptoms: obsessions and compulsions. Specifically, individuals with OCD exhibit repeated, intrusive, irrational, and unwanted thoughts that cause anxiety (i.e., obsessions), which are often accompanied by ritualized behaviors or compulsions to relieve the anxiety (i.e., compulsions). For instance, experiencing irrational and repeated fears of germs (i.e., obsession) may lead a child to engage in hand washing (i.e., compulsion).

To be diagnosed with OCD, an individual must experience the symptoms for more than 1 h a day and the symptoms must cause marked distress or impairment in everyday life. In fact, OCD is typically associated with severe disruptions in health, social and family relations, and school performance. For instance, children with OCD frequently evidence declines in grades because of the secondary impairment in their concentration. Children diagnosed with OCD are extremely resistant to reason, even in instances where they recognize the irrational and obsessive nature of their fears and rituals.

The onset of OCD typically occurs between 9 and 12 years of age and tends to be gradual. The disorder is twice as common in boys than in girls during childhood, but the gender ratio equalizes by adolescence. Approximately 2–3% of children are diagnosed with OCD, the prognosis is poor, and there is a high rate of comorbidity with other anxiety disorders, depression and disruptive behavior problems. Fortunately, most children with OCD show some improvement in functioning following treatment.

Panic Disorder

Panic disorder is characterized by the presence of recurrent and unexpected panic attacks, as well as at least 1 month of persistent and marked worry about having another attack or worrying about the implications of having another attack. Panic attacks are sudden and overwhelming periods of intense fear or discomfort accompanied by the flight/fight response. Thus, panic disorder includes physical (e.g., elevated heart rate) and cognitive (e.g., fear of going crazy) elements of anxiety. Furthermore, situational avoidance may lead to agoraphobia, which is worry about being in situations where it would be difficult for one to escape or get help, if one were to have a panic attack. If agoraphobia is present in addition to panic disorder, then the diagnosis is coded as panic disorder with agoraphobia. Conversely, if the individual's symptoms do not meet DSM-IV criteria for panic disorder, then the symptoms are labeled as agoraphobia without history of panic disorder.

Panic attacks are fairly common in the population; however, panic disorder is relatively rare (i.e., 0.6%). The typical onset of panic disorder is 15–19 years old and is more common in girls. It is interesting that studies show that 95% of

adolescents with the disorder are postpubertal, supporting the importance of considering developmental milestones. Research suggests that panic disorder has the worst prognosis of all of the anxiety disorders, evidenced by the lowest rate of remission.

Posttraumatic and Acute Stress Disorders

Posttraumatic stress disorder (PTSD) is a disorder characterized by the development of symptomatology following direct exposure to a traumatic stressor during which an individual perceived a threat of death or serious injury, or after learning about the unexpected or violent death or serious injury of a close associate, such as a family member. Examples of traumatic stressors include natural disasters, car accidents, witnessing war, being kidnapped and experiencing sexual abuse. A diagnosis of PTSD involves three core features. First, individuals must report persistent reexperiencing of the event (e.g., flashbacks, nightmares). Second, PTSD is associated with the avoidance of associated stimuli and numbing of general responsiveness (e.g., dissociation). Third, individuals with PTSD experience extreme arousal, including increased autonomic reactivity. To meet DSM-IV criteria, the individual must experience symptoms for more than 1 month and the symptoms must cause significant distress or impairment.

PTSD in children may take a different form than the responses typically seen in adults. With regard to reexperiencing the event, children may engage in repetitive play involving themes from the trauma or they may report having nightmares without distinguishable content. Furthermore, PTSD in adults is associated with a response of fear, helplessness or horror following the trauma; however, children may exhibit disorganized or agitated behavior. This last criterion is being recommended for removal from future DSM editions, as it is difficult to operationalize in children.

Acute stress disorder is the development of symptoms within 1 month of being exposed to a traumatic stressor, during which the symptoms last for 2 days but no longer than 1 month. Thus, acute stress disorder is a short-lived stress response that involves many of the characteristics associated with PTSD.

PTSD occurs in ~3.7% of boys and 6.3% of girls in the United States. Furthermore, 75% of individuals diagnosed with PTSD also display comorbid depression and/or substance abuse. Prognosis following the diagnosis of PTSD is influenced by pretrauma child characteristics, exposure to additional traumatic stressors, features of the posttrauma environment, and specific PTSD symptomatology reported. For example, social support following exposure to a traumatic stressor is associated with better prognosis, whereas continued sexual abuse is typically associated with worse adjustment.

In sum, anxiety disorders in children are associated with cognitive disturbances, physical symptoms, social and emotional deficits, and high rates of comorbid mental disorders. These characteristics result in significant impairments in multiple areas of their lives, including academic difficulties, family conflict and peer problems. There are several therapeutic approaches that are used to address anxiety symptoms in children, such as behavior therapy, cognitive-behavioral therapy, medications, and family intervention.

Mood Disorders

Mood disorders, including depressive disorders and bipolar disorder (BD), are primarily categorized by a disturbance in mood and typically involve some form of depression. In the past, it was mistakenly believed that depression did not exist in children in a form comparable to adults; however, it is now known that children do in fact experience depression. Much of the confusion in the past occurred because childhood depression frequently co-occurs with more visible disorders and difficulties, such as aggression and attention-deficit/hyperactivity disorder (ADHD). Thus, the depression was typically masked under more observable symptoms. There is evidence now suggesting that depression is one of the most disabling childhood disorders. Furthermore, the prevalence of depression in children is increasing and the age of onset is decreasing. Although depression in children has many of the same features as the disorder seen in adulthood, the features and nature of the disorder change with age. For example, depressed preschoolers typically present as withdrawn and somber. Conversely, school-age children with depression tend to be argumentative and combative. Thus, it is important to take age into account when examining mood symptomatology.

Numerous causes of mood disorders have been identified. First, neurobiological influences have been implicated, such as a heightened stress reaction. Also, brain activity appears to be attenuated in areas associated with attention and sensory processes, but is more active in brain regions linked to recognizing and regulating emotions. Second, heritability estimates for depression range from 0.35 to 0.75, suggesting moderate genetic influences. In fact, if a parent has major depressive disorder (MDD) then their child is two to three times more likely to have depression. Family characteristics, such as more anger and conflict, poorer communication, parental over-involvement, less warmth and support, more disorganization, and higher levels of stress are also associated with mood disorders. Finally, stressful life events, including frequent moves, death of a parent, family illness, divorce, and violence may increase the likelihood that a child develops a mood disorder. In sum, no one influence has been linked to the onset of mood disorders, but several mechanisms have been identified that may increase the probability that a child develops a mood disorder, such as depression.

Depressive Disorders

The depressive disorders include MDD and dysthymic disorder (DD). MDD is a disorder that is characterized by one or more major depressive episode, which is a period of at least 2 weeks during which the individual experiences depressed mood or the loss of interest in almost all activities. To meet DSM-IV criteria, the individual must also report four additional symptoms, such as significant weight change, insomnia or hypersomnia, psychomotor agitation or retardation, fatigue, feelings of worthlessness, diminished ability to concentrate, or recurrent thoughts of death. For diagnosis, it is also necessary to exclude the presence of prior manic episodes, organic causes, normal bereavement, and underlying thought disorders. In childhood MDD, it is common to see academic difficulties unrelated to intellectual deficits, few close friendships, and poor relations with parents and siblings. Evidence supports

suicidal ideations in most young people with depression, with between 16% and 30% attempting suicide.

Although the DSM-IV criteria for MDD are the same for all ages, children with depression often present differently than adults. For example, although children with depression may be sad, they typically cannot verbalize their emotions in the same way adults frequently do. Therefore, they may attempt to express their feelings through withdrawal or irritability. Depressed children are more likely to report somatic complaints than adults, such as headaches. Also, anhedonia, psychomotor retardation, psychosis, lethality of suicide attempts and impairment of functioning increase with age. Relative to adults, children also are more likely to be experiencing their first episode of depression, tend to recover faster, and are at increased risk of developing BD.

The average length of a depressive episode is 8 months, and almost all children recover from the episode, but recurrence is highly probable. Furthermore, even after recovery, children typically continue to exhibit adjustment and health problems, and appear to display mild symptoms of depression.

MDD occurs in ~2–8% of children between the ages of 4–18 years old. It is less common in preschool and school-age children (1–2%), but the prevalence increases to 8% by adolescence, which is the typical onset age of adult depression. The increase in prevalence of MDD from preschool to school-age has been attributed to the child's growing sense of self-awareness, cognitive capacity, verbal ability, and performance and social pressures. The subsequent drastic increase in prevalence that occurs during adolescence is likely due to biological maturation. There are no gender differences until puberty, after which girls are two to three times more likely to be diagnosed with MDD. The lifetime prevalence of MDD is between 10–25% in women and 5–12% in men. Comorbidity is very common, with as many as 70% of individuals with MDD reporting at least one other disorder, such as conduct problems or ADHD. Most co-occurring disorders precede MDD and persist after the child is longer depressed.

DD is similar to MDD, but is less severe and more chronic. Specifically, individuals with DD exhibit depressed mood more days than not for at least 1 year, have at least two additional symptoms of depression, and are never symptom-free for more than 2 months. This criterion is different than in adults, which requires a duration of at least 2 years. DD is also associated with less anhedonia, social withdrawal, impaired concentration, death thoughts, and physical complaints than MDD. Conversely, children with DD tend to display more constant sadness, self-depreciation, low self-esteem, anxiety, irritability, anger, and temper tantrums. Individuals that have both MDD and DD are said to have 'double depression,' which is associated with longer, more severe depressive episodes, higher rates of other mental disorders, more suicide attempts, and worse social impairment. DD is less common than MDD, with prevalence rates of ~1% in children and 5% in teenagers. The onset of DD is earlier than MDD (11–12 years old) and the average episode length is 2–5 years. Most children with DD recover, but they are then at greater risk of other disorders, particularly MDD.

Bipolar Disorders

The essential feature of BD is periods of depression alternating with or accompanied by abnormally and persistently elevated,

expansive, or irritable mood. During this time, individuals with BD may display symptoms of overexcitement, restlessness, agitation, sleeplessness, pressured speech, flight of ideas, sexual disinhibition, inflated self-esteem, and reckless behavior. Manic episodes in adolescents are more commonly associated with psychotic features, school truancy, school failure and substance abuse than MDD.

There are several subtypes of BD differentiated based on whether the child displays a manic (i.e., elevated or irritable mood lasting at least 1 week or requiring hospitalization), mixed (i.e., both manic and depressed episodes within a 1 week period), or hypomanic episode (i.e., manic for 4 days but with no deterioration of functioning). Bipolar I is having one or more depressive episodes alternating with one or more manic/mixed episodes. Bipolar II is having one or more depressive episodes alternating with one or more hypomanic episodes. Cyclothymia is at least 1 year of numerous hypomanic and depressive symptoms that do not meet full criteria for manic, mixed, or depressive episodes, no more than 2 months without symptoms, and significant distress or impairment.

The lifetime prevalence of BD is 0.4–1.2%, and is less common than MDD in children. BD is rare in young children, but the prevalence rate increases after puberty when it becomes comparable to adult rates. Research suggests that early signs of BD include irritability and anger difficulties, as well as fluctuations in energy levels. However, it is important to note that these symptoms are also associated with other psychiatric disorders. Typically, the first episode occurs during adolescence (15–19 years old) and depression normally appears first. In fact, ~50% of individuals experience depression first, 25% report mania and 25% report a mixed episode. In young people, it is common to exhibit milder Bipolar II and cyclothymia rather than Bipolar I. BD is equally common in males and females; however, early onset is more common in boys. Comorbidity is common with anxiety disorders, ADHD, conduct disorders (CDs) and substance abuse. BD is chronic and resistant to treatment, with poor long-term prognosis.

Pediatric BD is quite controversial and although it only appeared in the literature during the past decade, the rate of diagnosis has increased exponentially. In fact, prior to 1990, BD was not thought to exist in children. Specifically, in 1996, BD was the least frequently diagnosed psychiatric disorder among inpatient children; however, in 2004, it was the most frequently diagnosed disorder. This increase in the prevalence of pediatric BD is thought to be largely due to a shift in the definition of the disorder. That is, since DSM-IV, a milder form of mania (i.e., hypomanic) is recognized, which is referred to as Bipolar II. As previously noted, Bipolar II is more common in children. Prior to the aforementioned change, children who are now diagnosed with BD would likely have been diagnosed with CD or ADHD. This broadening of the symptomatology of BD has therefore resulted in a greater prevalence of BD, particularly in children, because Bipolar II is more common in this age range than Bipolar I.

Attention-Deficit and Disruptive Behavior Disorders

Attention-Deficit/Hyperactivity Disorder

ADHD is a persistent pattern of severe inattention and or hyperactivity-impulsivity that persists for at least 6 months.

Some of the symptoms need to have been present prior to 7 years of age. Moreover, impairment in functioning must occur in at least two settings (e.g., in school and at home). ADHD is estimated to occur in 4–8% of all school-aged children. It is three times more likely to occur in boys and is more prevalent in groups of lower socioeconomic status.

Difficulties with attention seem especially prominent during activities that are long, repetitive, and tedious. The child may fail to pay attention to details, make careless mistakes, produce messy work, appear as though they are not listening, frequently forget or misplace things, and have difficulty completing work. Children with ADHD tend to perform better on self-paced tasks that they have chosen, in novel settings, in one-to-one situations, and when the activity is especially engaging or offers immediate reward.

In the DSM-IV, hyperactivity and impulsivity are considered to be a single dimension and reflect a deficit in behavioral inhibition. This factor refers to behavior that is excessively energetic, intense, and not goal-directed. Hyperactivity or overactive motor behavior includes fidgeting, difficulty staying seated, moving, running, climbing about, excessive talking, and appearing as if driven by a motor. Impulsive behaviors include difficulty in stopping an ongoing behavior, inability to resist immediate gratification, responding too quickly or blurting out answers, interrupting others, and difficulty waiting for one's turn.

The DSM-IV specifies three subtypes of ADHD, depending upon the predominant symptoms in the last 6 months. The first subtype is the combined type, which accounts for most children with ADHD. The combined type is classified when six or more symptoms of inattention and six or more symptoms of hyperactivity-impulsivity have persisted for the last 6 months. The predominantly inattentive type (ADHD-PI), which occurs in about 1% of schoolchildren, is diagnosed if at least six symptoms for inattention have persisted, but the child displays fewer than six symptoms of hyperactivity-impulsivity. Finally, the predominantly hyperactive-impulsive types (ADHD-HI) is used when six or more symptoms of hyperactivity-impulsivity have persisted, but the child displays fewer than six symptoms of inattention. ADHD-PI is frequently associated with learning disorders, slow processing speed, difficulties with information retrieval, and anxiety/mood symptoms. The combined and ADHD-HI types are associated with aggressiveness, defiance, peer rejection, and placement in special education classrooms. Literature on the various subtypes is ongoing, and it is not yet clear if these subtypes are clearly distinct, or if they represent different stages in the developmental course of the disorder.

Although children with ADHD may have normal levels of intelligence, studies have indicated that IQ scores range about 5–9 points lower than children without ADHD. Lower IQ scores may be due to deficits in working memory, speed of processing, sustained attention, and test-taking behaviors. Many children with ADHD experience difficulties with school, including academic underachievement, being held back a grade level, placements in special education classrooms and increased school dropout. About 25% may have a diagnosable learning disorder and 30–60% may have speech and language impairments.

Many children with ADHD have difficulties with sleep, and may also experience motor clumsiness or repetitive motor movements (i.e., tics). Impulsivity may lead to accidents and

risk-taking behaviors, including more pedestrian and traffic accidents, unsafe sex practices and increased use of substances. Others may perceive the child as noncompliant or annoying, which can lead to high levels of conflict with family members and peers. It is also likely that children with ADHD will display symptoms of oppositional defiant disorder (ODD) (about 50%) or CD (about 30–50%), which further increases their social difficulties. They may also experience comorbid anxiety (about 25%) and depression (about 20–50%). Finally, many children with ADHD report a higher level of self-esteem than would be expected in light of their behavior. That is, they have an exaggerated perception of their own competence, and this has been referred to as a positive illusory bias.

Developmentally, hyperactive–impulsive symptoms tend to appear first, especially in the preschool years. In retrospect, parents may report that their child had a ‘difficult’ temperament. Although the disorder may be present at this early age, and possibly from birth, difficulties are usually not identified until the school-age years (around ages 5–7), when the child is faced with the demands of school and is required to engage in activities that are long, tedious, and repetitive. The prognosis is poorer for children with co-occurring behavioral problems. As the child matures into adolescence, about 25–50% of children outgrow the disorder or learn to cope with its symptoms. However, most children still exhibit the disorder into adolescence. In general, hyperactive–impulsive symptoms tend to decline with age, while inattention remains stable over time.

It is not clear what causes ADHD, though it is currently viewed as a neurobiologically based disorder. Genetic evidence suggests that ADHD runs in families, with a concordance rate of ~35%, and twin studies show heritability estimates as high as 80%. Pregnancy and birth complications, smoking and substance abuse during pregnancy, and minor physical anomalies have also been implicated, suggesting neural maldevelopment. In particular, the prefrontal cortex, basal ganglia and cerebellum appear to be involved, which are associated with attention, executive functions, delayed responding and response organization.

ADHD symptoms and associated impairments are often treated with stimulant medications. These medications are effective in about 80% of children with ADHD by increasing sustained attention, impulse control, and persistence of work effort, and by decreasing task-irrelevant activity and disruptive behavior. It is clear, however, that symptoms are never completely brought to normal levels, and they return as soon as the medication is stopped. Behavior therapy via parent management training and classroom management also have been found to be effective in making short-term behavioral gains and improving relationships with parents and teachers.

Oppositional Defiant and CDs

Oppositional defiant and CDs involve age-inappropriate actions and attitudes that violate family and societal rules and rights of others. Behaviors vary widely and may range from defiance and noncompliance to assault and murder. While general surveys indicate that antisocial acts are relatively common among youth (i.e., about 30–50% of children report some antisocial act), it is less common for children and adolescents to engage in persistent and serious rule breaking.

It is this small percentage of youth, ~3–5% of youngsters, which is of particular concern. Their antisocial behavior tends to remain stable over time and lead to a myriad of associated problems such as physical injury, academic underachievement, peer rejection, exacerbated family conflict, and psychopathology. Moreover, this small number of youth contributes to a disproportionately large number of antisocial acts.

In the DSM-IV, children with these sorts of persistent rule-breaking and antisocial behaviors fall under the categories of ODD and CD, which have prevalence rates ranging from 6% to 16% and are more likely to occur in males. In order to be diagnosed with ODD, the child must show four or more symptoms of age-inappropriate stubborn, irritable, and defiant behavior that persisted over 6 months. Symptoms include losing temper, arguing with adults, active defiance or noncompliance, deliberately annoying others, blaming others for mistakes or misbehavior, being touchy or easily annoyed, anger and resentfulness, and spitefulness or vindictiveness.

CD reflects a repetitive and persistent pattern of behavior in youth that violates the rights of others. Criteria for the disorder include aggression toward people and animals (i.e., bullying, threatening, intimidating others; initiating physical fights; using a weapon to cause harm; using physical cruelty; stealing while confronting the victim; and forcing someone into sexual activity), property destruction (i.e., deliberately setting a fire or destroying another's property with the intent to cause damage), deceitfulness or theft (i.e., breaking into another's house, building or car; lying or conning to avoid obligations or to get something; stealing without confronting the victim), and serious rule violations (i.e., repeatedly staying out past curfew beginning before age 13; running away from home at least twice or for a lengthy period; being truant from school beginning before age 13). Three or more symptoms must have been present for the last 12 months, with at least one in the last 6 months.

CD is further broken down into childhood-onset type and adolescent-onset type, based upon the age of onset. Childhood-onset represents those children for whom at least one symptom began prior to age ten. These children are usually male, display frequent physical aggression, have disturbed peer relationships, have had ODD in early childhood, and usually show full symptoms for CD before puberty. Adolescent-onset represents those for whom no symptoms were present prior to age 10. Relative to the childhood-onset type, these youth are less aggressive, have a lower male to female ratio, have more normative peer relationships, and are less likely to persist in their conduct symptoms. This typing is based upon work looking at the development of antisocial behavior, which suggests a better prognostic picture for the adolescent-onset type.

Children with ODD or CD tend to have normal levels of intelligence, but scores generally fall about eight points lower than their peers, with greater deficits in verbal intelligence. Some studies also indicate difficulties with executive cognitive functions, which may interfere with the ability to learn from consequences. Academic underachievement and learning disorders are also common, which can lead to grade retention and school dropout. These cognitive deficits are sometimes, but not always, accounted for by the presence of ADHD. Youth with conduct problems may also show inflated self-esteem (i.e., positive illusory bias) that is easily threatened. They may have

difficulty with peers due to their aggressive and threatening behavior. Other associated problems include family conflict, instability in the home, and harsh discipline or deficient parenting practices. Finally, these youth have a higher rate of premature death, risk of personal injury, early onset of sexual activity, substance abuse, and comorbidity with ADHD, depression and anxiety.

Studies on the course of conduct problems from childhood to adolescence suggest that ODD developmentally precede CD in the majority of cases. These children begin with minor behavior problems in early childhood that develop into more serious problems in later childhood and adolescence. These studies also indicate that typically, without intervention, conduct problems tend to remain stable or worsen over time. Of all children with ODD, ~25% desist from further antisocial behavior, ~50% maintain a diagnosis of ODD, and ~25% progress to a diagnosis of CD. The course of development may also differ between childhood-onset and adolescent-onset CD, with greater persistence and escalation of behavior occurring in childhood-onset type.

Antisocial behavior in youth is likely to have multiple causes, any combination of which may be acting in a given child. Biosocial models suggest that the interplay of biological, psychological, and social influences contribute to severe and persistent antisocial behavior problems. Twin and adoption studies support a genetic contribution, suggesting that traits such as impulsivity or difficult temperament may be inherited. Neurobiological studies have implicated frontal lobe deficits leading to executive cognitive dysfunction and the perseveration of inappropriate behavior. Psychophysiological studies have also implicated low heart rate in individuals who are aggressive, suggesting that low arousal may lead to sensation-seeking and risky behaviors such as aggression. Low arousal may also indicate a fearless attitude, in which the child does not become anxious at the thought of punishment or negative consequences for their behavior. Cognitive influences could include a biased way of processing social information, so that the child makes hostile interpretations of other's actions or views antisocial behavior as a means to a positive outcome. Family influences include coercive interaction patterns, in which parent-child dyads learn to use increasingly intense behavior to coerce the other person into submitting to their demands. Family instability and stress, harsh or abusive discipline, parental criminality, and parental psychopathology are also commonly associated risk factors for ODD and CD. Finally, societal influences include neighborhoods with criminal subcultures, community violence, poverty, or high social disorganization.

There are few effective interventions with empirical support. Parent management training is especially useful for younger children with ODD. This behavioral intervention teaches parents skills for managing their child's behavior through the use of ignoring, attention, reinforcement, and punishment. Cognitive problem-solving skills training also has some support. It is typically used in school settings and teaches children a specific strategy for finding nonaggressive solutions to problems. Finally, multisystemic treatment has support as a treatment for severely troubled youth. Based on a systems approach, this treatment is carried out with all individuals in all settings of the child's life to address shortcomings at multiple levels.

Pervasive Developmental Disorders

PDDs include an array of chronic and lifelong neurodevelopmental disorders that affect children's social interactions, language/communication, and behavior. In the DSM-IV, these disorders include autism, Asperger's disorder, Rett's disorder, childhood disintegrative disorder (CDD), and PDD-not otherwise specified (NOS). They affect whether children develop speech, form social relationships, and process sensory information.

Autism Spectrum Disorders

Together, autism, Asperger's disorder, and PDD-NOS are referred to as autism spectrum disorders (ASDs). They are considered spectrum disorders because children vary in the symptoms they display and the severity of the disorder. High functioning autism and Asperger's disorder are often similar in presentation and there is a controversy over whether they are truly distinct disorders. Autism is thought to be the fastest growing developmental disability in the country. Recent statistics from the Centers for Disease Control and Prevention indicate that as many as 1 in 110 children are affected with an ASD. As such, more children are being recognized and require services.

The diagnosis of autism requires impairments in three key areas – social functioning, communication, and repetitive behaviors, interests or activities – with onset prior to age three. The primary difference between the diagnosis of autism and Asperger's disorder is that Asperger's disorder does not require delays in communication. Also, in Asperger's disorder, there is no clinically significant delay in cognitive development, self-help skills, adaptive behavior, and curiosity about the environment. However, research has not clearly shown distinctions between Asperger's disorder and high functioning autism in outcome, course/outcome, etiology, neurocognitive profile, or treatment needs. As such, current recommendations are that Asperger's disorder be subsumed under the autism category in future editions of the DSM.

Impairments in social interaction include nonverbal behaviors (e.g., eye contact, gestures) to regulate social interaction, peer relationships, spontaneous sharing of enjoyment, and social or emotional reciprocity. Impairments in communication include delay or lack of spoken language, initiating or sustaining a conversation, stereotyped or repetitive language, make-believe or social imitative play. Impairments in behaviors include preoccupation with an interest that is abnormal in intensity or focus, inflexible adherence to routines or rituals, motor mannerisms (e.g., hand-flapping, twisting), and persistent preoccupation with parts of objects.

Children with ASDs often evidence skills that are scattered, meaning that they may have deficits in some areas and strengths in others. Up to 80% of children with autism fall in the mental retardation range of intellectual functioning, with particular weaknesses in verbal IQ (using traditional tests, which may not be appropriate). About 25% have splinter skills (above average skills in one area like math) and 5% have savant abilities (extraordinary or supernormal talent). Other cognitive deficits might include difficulty in understanding social situations, impairments in the ability to understand

others' and their own mental states (Theory of Mind), deficits in executive functions (orienting, shifting attention, organization, reasoning), and lack of drive for central coherence (do not filter out details). On the other hand, these individuals may be very good at sustained attention and memory for details. Some individuals experience sensory impairments including over- or under-sensitivities, and possibly both at the same time.

Raising a child with autism is stressful. For example, the child may be hyperactive, self-injurious, wandering, or may not sleep well. In addition, parents may be socially ostracized by friends and strangers and may experience frustration and delays before receiving help. Co-occurring symptoms include hyperactivity, learning disabilities, anxieties/fears, mood problems, sleep difficulties, and self-injurious behavior. Epilepsy is also a common co-occurring medical condition.

ASD occurs from birth or early in childhood, although deficits are often not noticed until around age two when the lack of language and other skills become especially evident. At 12–18 months, children with ASD may show a lack of pointing, showing, orienting to their spoken name, and looking at the face of another person. Often, there are gradual improvements with age, though they are likely to continue to experience many difficulties. Hyperactivity, self-injury, and compulsions appear to worsen in about a one-third of adolescents with ASD. Typically, this is a chronic and lifelong condition; however, variability in outcome depends on language abilities and IQ.

There is no known cause for ASD. Sometimes, problems have been noted during pregnancy or birth, such as premature birth, bleeding in pregnancy, toxemia, and viral infections. Family and twin studies suggest that the heritability of an underlying liability to autism is above 90%, and studies of family members suggest that there may be a Broader Autism Phenotype in which less severe symptoms are inherited. Neurobiological studies have implicated the frontal lobes, cerebellum, medial temporal lobe, and limbic system structures, which can reflect a brain system specialized for social cognition. The amygdala, in particular, may be implicated in deficits of orienting to social stimuli, motor imitation, empathy, and joint attention.

There are currently no empirically validated treatments for ASD, though there is a great deal of empirical support for early intensive behavioral interventions. These comprehensive treatment programs are recommended to begin before 5 years of age, occur in the home or preschool, actively involve family members and peers, and involve one-to-one work with the child for 15–40 h per week. The interventions use behavioral principles to address the core deficits and excesses in behavior that are commonly seen in ASD. Some evidence supports cognitive-behavioral treatments for children with Asperger's disorder and higher functioning autism. These treatments teach children that thoughts and knowledge can affect feelings and behavior. They often use a skill-building approach to teach social skills, affective education, and management of comorbid disorders like depression or anxiety.

Rett's Disorder and CDD

Other PDDs in the DSM-IV include Rett's disorder and CDD. Rett's disorder is a severe neurobiological disorder characterized by deceleration of head growth between 5 and 48 months

of age, loss of previously acquired hand skills and subsequent development of stereotyped hand movements (e.g., hand-wringing), loss of social engagement that may reappear later, appearance of poorly coordinated gait or trunk movements, severely impaired language development, and psychomotor retardation. It is a disorder that occurs primarily in females and is thought to be caused by a specific X-linked gene mutation. The prevalence rate is ~1–4 per 10 000 females. The long-term prognosis is poor. Rett's disorders is associated with mental retardation, epileptic seizures, motor handicaps, and difficulties with communication. Some studies have indicated that the brain sizes of children with Rett's syndrome are about 12–34% smaller than the brains of other children. The inclusion of Rett's syndrome in the PDD category has been questioned and this disorder may be removed entirely in future editions of the DSM. The primary rationale for removal of the disorder is that these children often have PDD symptoms for only a brief period during early childhood, and social interactions often reemerge later in childhood, so inclusion in the autism spectrum may not be appropriate for most individuals. Moreover, since Rett's disorder has a specific etiology, it can be specified as a known medical or genetic condition associated with PDD, rather than its own category as a mental disorder.

CDD is characterized by a significant loss of previously acquired language, social skills, and adaptive behavior prior to age 10, following a period of apparently normal development in at least the first 2 years of life. Recent estimates suggest that CDD is rare, occurring in about 2 per 100 000 children. This diagnosis was included in the DSM-IV primarily to encourage research on the disorder, though little research still exists. It has been recommended that CDD be subsumed under the autism diagnosis in future editions of the DSM because there is no evidence that this disorder is different from Autism with a regressive course. Also, some case studies indicate that lost skills reemerged following treatment, suggesting the possibility that the symptoms were instead due to some treatable neurological condition.

Chunking

A L Gilchrist and N Cowan, University of Missouri, Columbia, MO, USA

© 2012 Elsevier Inc. All rights reserved.

Glossary

Adopted chunk method A method of measuring the number of chunks adopted by participants in free recall by examining whether the order of recalled information matches its initial presentation order; each series recalled in order is considered a chunk adopted by the participant.

Chunk A unit of storage in memory containing multiple items that are grouped or bound together to form a unified whole.

Chunk access measure An estimate of the number of chunks in working memory; based on the assumption that if at least one item from a presented group is recalled, working memory has accessed a unit corresponding to that group.

Chunk completion measure An estimate of the integrity of a presented group of items or interassociation between the items; based on the assumption that if the group was stored

as a well-integrated chunk and the chunk was accessed (i.e., at least one item recalled from it), then recall of the group should be nearly complete, including most or all of the items presented in that group.

Chunking A process or strategy that increases the amount of information that can be stored in memory by meaningfully grouping information together.

Immediate memory Portion of memory that is currently in our conscious awareness and is easily reportable; also known as *short-term memory*.

Transitional error probabilities (TEPs) method A method of measuring number and size of chunks in serial recall by examining the probability in making an error during recall of items; the proportion of errors in transition from one item to the next in recall, or TEP, should be smaller within a chunk and larger between chunks.

Introduction

Chunking is a strategy or process by which one can efficiently increase the amount of information that can be stored in short-term memory by reorganizing information in a meaningful way, or by finding patterns within a set of items to be remembered. Chunking may also involve grouping stimuli together on the basis of perceptual principles such as the similarity or proximity of certain items to be remembered. However, this form of chunking does not typically involve strategic effort in forming chunks. For present purposes, the more strategic method of chunking, in which long-term knowledge must be accessed or constructed to form larger groups of items, will be of particular interest. For a simple demonstration of chunking, consider the following scenario. You are presented with a string of letters, MAIBIFBCL. Most likely, you will not remember all nine letters. If the string is rearranged to FBICIAIBM, you will probably remember all of the letters. Why? The letters can be grouped into three familiar acronyms; the number of separate items to be recalled is now much smaller. As a result of this grouping, the amount of information that can be stored has effectively been increased. This is a very simple illustration of one way in which people can use chunking to remember more items than they would (or could) otherwise.

Chunking is arguably one of the most powerful ways to increase the amount of information that can be stored in memory. In this article, we will discuss what is currently known about chunking. First, we will review a seminal work on chunking and capacity limits in memory, George Miller's 'The Magical Number Seven, Plus or Minus Two.' Following this we discuss the purpose of chunking and its role in the capacity-limited immediate memory (which is sometimes also known as working memory or short-term memory), as well as a theoretical model of how chunking operates. We then raise

the issue of measuring chunks, discussing several different ways to do so. Finally, we will close the article with questions about chunking that are worth examining in future research.

What Is Chunking?

Published in 1956, George Miller's article "*The magical number seven, plus or minus two: Some limits on our capacity for processing information*" has fundamentally shaped our understanding of capacity limits in immediate memory and how these limitations may be circumvented through the use of chunking. In this review, Miller noted that seemingly unrelated tasks had a puzzling commonality: an upper limit in the number of items (approximately between 5 and 9) that could be processed or stored at any given time.

Miller reviewed capacity limits for tasks that tested immediate recall of stimuli. In these tasks, participants are presented with a list of items (e.g., words, letters); following the presentation of the list, participants are to recall as many items from the list as possible. Across various types of immediate recall tasks, it was found that memory span was consistently between five and nine items, regardless of stimulus type. Similar capacity limits can be found for tasks that examine the absolute judgment of stimuli that vary in more than one dimension, such as lines that differ in length and angular orientation. Though these tasks differ somewhat in terms of methodology, in both cases, stimuli in these tasks involve multiple features that are bound together to form a single, unified item. Because of these similarities, the limits on how many multifeature objects can be held in mind theoretically could be the same, regardless of task type.

Although the consistency of capacity limits across various immediate memory tasks was the primary emphasis of the

review, Miller closed his paper with a discussion of recoding (by which he meant the same thing that was later termed chunking) and its implications for immediate memory performance. Recoding was defined by Miller as a process of grouping or organizing input information into meaningful units, or chunks. Because information in immediate memory is limited to approximately seven items, grouping items together in a way that allows them to be more easily remembered can effectively increase the amount of information that can be stored and, eventually, recalled.

To illustrate the phenomenon of chunking, Miller reviewed a prior study where participants were to immediately recall sequences of binary (e.g., 101000100) and octal digits. In general, persons can correctly recall approximately nine of these digits when presented with one of these sequences. It was possible, however, that the number of binary or octal digits that were correctly recalled from memory could be increased by recoding the digit information in a more meaningful way. For example, consider the binary sequence of nine digits that was presented above. Miller suggested that more digits from the list could be recalled if the digits within the sequence were reorganized into a series of groups (e.g., 101, 000, and 100). These items might be even better recalled, however, if one knows how to convert binary digits into digits with a different base (e.g., decimal digits, which are based on a base of 10). If one groups the binary digit list in the manner above, 101 equals 5, 000 equals 0, and 100 equals 4 – grouping digits into larger chunks reduces demand on memory, as does converting the digits into a more meaningful form. Initially, participants only recalled about nine binary digits and seven octal digits; however, once they learned the recoding schemes similar to the one described above, span for these digits increased.

This illustration of recoding and chunking of items that is described above has little ecological validity outside of a laboratory setting; persons are rarely required to convert digits from one base to another in their everyday lives. However, Miller himself noted that using chunking or some means of recoding as a strategy to increase the amount of information that could be stored in memory was quite possible in an everyday setting. In particular, Miller suggested that the most common uses of these sorts of strategies were for the translation or grouping of verbal materials, though chunking is advantageous in memorizing nonverbal stimuli as well.

For example, much of what we know about chunking of nonverbal stimuli originates from studies that have examined immediate memory for various positions in chess. In a series of experiments, William Chase and Herbert Simon presented both chess masters and novice players with different configurations of chess pieces on a playing board. Participants were shown these configurations for 5 s, which were later covered up so that participants could not see them. In a critical manipulation, these configurations were either possible chess positions or were entirely random. Once the configuration was hidden from view, participants were to recreate the configuration from memory. When configurations were actually permissible within the context of a chess match, masters were more likely than novices to remember the configurations accurately. However, for random configurations, the memory performance of masters was no greater than performance for novices. When

Chase and Simon examined how various chess pieces were chunked, they found that masters were more likely to group chess pieces based on prior knowledge about chess – for example, they might classify a subset of pieces as an attacking or defensive position. This is starkly contrasted to the grouping strategy of novices, who were more likely to group subsets of pieces based on more shallow aspects (e.g., noting that a group of pieces form a candlestick). The findings from this study clearly demonstrated the role that prior knowledge can have in terms of what is retrieved from memory and how chunks are organized.

The Purpose of Chunking

One of the most important conclusions in Miller's seminal paper was that immediate memory, where we are able to hold information in mind briefly, is capacity-limited. It may be unclear to some why Miller closed his paper with a discussion of chunking; however, we forward the idea that chunking cannot be understood without a discussion of capacity limits in memory. Chunking is a way to circumvent capacity limits in memory to an extent. To illustrate this point, it is important to discuss any potential limitations on the amount of information that can be attended at any given point in time. As chunking can only be understood in the context of memory capacity limits, we discuss evidence supporting a four-item limit in immediate memory below; we follow this with a discussion of the implications of capacity limits upon chunking.

Evidence for a Four-Item Limit in Immediate Memory

Why is there a great deal of evidence for a memory capacity of four items when Miller initially proposed that immediate memory was limited to approximately seven items? It is possible that in these prior studies that Miller reviewed, small chunks could have been formed during item presentation, allowing participants to recall a higher number of items. Interestingly, when items are either too numerous or are presented too quickly for chunking to occur, participants typically recall no more than 3–4 items. This even occurs for items with which we are very familiar. For example, in a 1975 paper Donald Broadbent described a study where participants were asked to recall familiar lists of seven items, such as the Seven Wonders of the World or the names of the Seven Dwarves from 'Snow White.' Participants were typically able to recall all of the items; however, Broadbent noted that long pauses during retrieval of items tended to occur between the third and fourth items being recalled; these pauses suggested that additional retrieval of remaining items had occurred. Here, seven digits could not be grouped together to form a single chunk. Instead of memory being capacity-limited to no more than seven items, our immediate memory may only be able to maintain up to four items before our memory performance declines and retrieving items takes increasingly greater time.

Early cognitive research that examined capacity limits and chunking in immediate memory corroborated Broadbent's view. Many of these early studies involved the presentation and later recall of phonological or linguistic materials. In many of these studies, materials that were presented to

participants in these studies varied in terms of how meaningful they were. For an example, consider a study by Glanzer and Razel that examined immediate recall and chunking, where participants were presented with various types of verbal stimuli, including words, sentences, and familiar proverbs. As one moves from words, to multiword sentences, to proverbs that can incorporate multiple familiar sentences, it is clear that the intraitem associations become increasingly stronger as the presented information becomes more meaningful. It becomes considerably easier to group words together when they form a sentence; likewise, it becomes easier to group sentences together when they form a very familiar passage. Regardless of how meaningful stimuli were in the context of these various prior studies, researchers consistently found capacity limits of approximately 3–4 chunks for each verbal stimulus type. Herbert Simon, in a similar discussion regarding the role of meaning in the formation of chunks, obtained similar results. Though a greater number of words might be recalled from a familiar nursery rhyme than a novel prose passage, one typically does not recall more than four chunks across various linguistic stimuli. This is not to say, however, that increasing the meaningfulness of verbal stimuli in the manner described above has no effect upon chunking. As we will discuss in a later section, the amount of information that is contained within a single chunk (i.e., chunk size), though not the number of chunks maintained in memory, may vary as presented stimuli become increasingly (or decreasingly) meaningful.

More recent research has examined memory capacity limits when higher-order strategies are precluded. In a 2009 study, participants were initially presented with various lists of words that were learned to a 100% criterion. These lists were composed of either word pairs or singletons. In addition to varying the size of chunks, the number of pairs or singletons within a list was varied. By varying both of these factors, the influence of item limits or length limits upon recall could be examined. Consider an example of three trials in which a participant might see a list of four singletons, a list of four learned word pairs, and a list of eight singletons. Assuming that each learned word pair is grouped into a single two-word chunk, the list of four word pairs is comparable to the list of four singletons in terms of the number of chunks that are present within a list; however, the list of pairs has a longer overall length (i.e., a larger number of total words) than a list of four singletons. In contrast, when overall length is considered, the list of four word pairs is equivalent to the list of eight singletons; however, the list of pairs contains a smaller number of chunks. If a chunk capacity limit is the sole reason why recall is limited, the prediction is that individuals should recall the same number of chunks regardless of the list length, and regardless of whether the chunks are singletons or learned pairs.

Following this training phase, participants were presented with lists of word pairs that were to be immediately recalled in correct serial order. To preclude any additional rehearsal of items, participants were to engage in articulatory suppression by repeatedly voicing the word *the* during list presentation. Ordinarily in serial recall, the list length matters a lot. Under these suppression conditions, though, when the order of responses was ignored, a remarkably precise, core capacity limit of approximately three chunks was consistently observed across all list types and lengths. For example, in lists with as few

as 4 singletons or as many as 12 singletons, about 3 singletons were recalled from the list on average; and in lists with 4 or 6 learned pairs, about 3 of the pairs were recalled on average. This constant number of chunks recalled across many conditions provides strong support for fixed capacity limits in immediate memory. The results of other conditions also suggest, though, that using strategies like chunking or additional rehearsal can supplement memory performance a great deal beyond this core limit.

Chunking Overcomes Capacity Limits

As we have shown above, the number of items that can be stored in immediate memory is greatly limited; typically, no more than four items or chunks can be attended simultaneously. Because this number is so small, one might expect that this places a severe limit on the information that we can attend at any point. This is probably true for many instances in our everyday lives, as retaining every piece of information that entered our awareness would cost us the ability to process information quickly and efficiently. Luckily, our attention is able to rapidly shift to adapt to new information that enters our environment, if doing so is needed. However, there are certainly times when we need to maintain more information than our limited memory capacity will permit, such as when one receives a long, verbal list of groceries to buy at the store. In these cases, chunking is an easy, powerful way to ensure that as much information as possible is stored. For example, if one is able to group grocery list items together by their respective grocery departments (e.g., tomatoes, cucumbers, and grapes belong in produce; bread, cookies, and apple pie can be found in the bakery), more information can be stored beyond the 3–4 items one would recall if no chunking took place.

Various findings from research support the notion that chunking helps us to exceed severe capacity limits in immediate memory. The role of chunking is especially exemplified when linguistic materials are manipulated in some way. Consider, for example, when sentences vary in terms of their coherence (i.e., whether they make sense or are completely nonsensical). This is known as order of approximation, which corresponds to how many words in a row make sense. A sentence that has a low order of approximation (e.g., first-order) typically makes little sense, often sounding like a list of random words: *telephone call over easy cheese and then he*. Sentences that have higher-orders of approximation (e.g., fifth-order) sound increasingly like grammatically correct text: *when we saw the cat attacked by using claws*. If you read both of these sentences out loud and tried to recall each of them immediately, you probably will find that you recall a greater number of words from the sentence with a higher order of approximation. In coherent language, there are numerous semantic and syntactic associations that exist between words; as one moves from nonsensical language to a more coherent form, the various associations between words increase and a more coherent whole can be apprehended. The more that words are associated with each other, the easier chunking words together becomes. As a result, sentences with a higher order of approximation, like the example above, are more likely to be encoded as a single chunk. Thus, we see more words recalled from these sentences than from nonsensical sentences where interword associations are considerably fewer.

The notion that increasing associations will lead to a greater amount of recalled information is also apparent when standard, grammatical sentences are considered. In cases where the order of approximation for two sentences is equivalent, more information will generally be recalled from the sentence that makes greater use of interword associations. Thus, a greater number of words will be recalled from a sentence that is a compound of two smaller sentences (e.g., *Grandmother warmed the oven and she baked a fudge cake*) than would be recalled from two unrelated sentences.

Dramatic cases of chunking overcoming capacity limits are found in research that examines effects of deliberate practice and expert performance. You might be familiar with the digit span task, an immediate memory test that was mentioned above. Here, participants are presented with a list of digits that they are to recall immediately after presentation of the list, in the presented order. The length of the digit list increases until a participant makes an error or fails to recall a digit for several lists in a row. As Miller noted, the average person can accurately recall between five and nine digits in this task. This is typically considered a measure of one's basic memory capacity; however, as we argued above, a small amount of chunking is still possible in this task.

What would happen to one's digit span if a participant practiced this task for a few hours each day over the period of a year? Given findings from a previous study that did just that, it is very likely that your digit span could be over 80 digits! In this study, a single participant repeatedly practiced the digit span task for several months; by the end of the training period, he was able to report back up to 82 digits in the span task, well beyond the 5–9 digits that the average person recalls. The ability to chunk various digits together played a considerable role in the participant's remarkable span increase. Specifically, the participant himself noted that he used prior long-term knowledge of long-distance running times to group digits together to form multidigit chunks. For example, the digits 4, 5, and 2 could be grouped together to form 4.52, a very fast time to finish a mile run. This sort of recoding, where meaningless stimuli are grouped in a way that connects to one's long-term knowledge, is reported by many expert mnemonists to be a typical way that they encode stimuli that exceed capacity limits. The role of chunking should not be downplayed in this case, as it is unlikely that such a high number of digits could be recalled without some sort of organizational strategy developing over time.

We should note that chunking only circumvents the capacity limits in memory in the sense that more information can be recalled. In the grocery example we mentioned above, chunking allows us to remember a greater number of items on our shopping list. Although chunking increases the amount of information that is able to be stored, the chunks that are formed are still subject to the four-item capacity limit. A greater amount of information is being stored within a single chunk (i.e., the size of the chunk becomes larger). The number of chunks that can be stored in immediate memory, however, never exceeds four. This result has been found even in cases where the number of items that can be stored or recalled is exceptionally large, including the participant who recalled 82 random digits in the digit span task. As we noted above, the amount of digits that were accurately recalled is far beyond what would normally be recalled in an

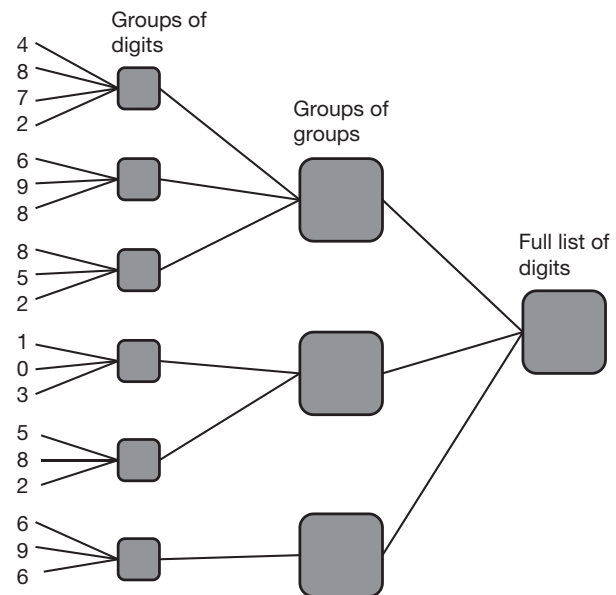

Figure 1 A hierarchical structure exemplifying the type of performance observed by Ericsson, et al. (1980) in a participant who learned to use athletic records and other memorized groups of digits to form multidigit chunks. The recalled list of digits was chunked into groups of 3–5 items (seen on the left), which were in turn spatially organized to form even larger groups, as shown on the right side of the figure. Although the total digit recall in the figure would greatly exceed what is considered the limit of immediate memory capacity if each digit were retained as a separate chunk, the number of larger groups on the right of the figure fall within this capacity (i.e., 3–5 chunks).

immediate memory task. However, it was found that he had chunked these digits into a hierarchical structure of four large supergroups (which were made up of various, smaller groups of digits), as is shown in [Figure 1](#).

It might be theorized that attention can ‘zoom’ up and down to different levels in the structure shown in the figure. When the mnemonist was thinking at the level of a single chunk that was just created, the number of digits in the chunk would be limited to about four. When the mnemonist zooms up to think on the superchunk level, however, he is limited to about four chunks per superchunk and at the list level, there should be only about four superchunks. In this way, the presumption is that the basic capacity limit does not change in an expert, but the way in which it can be used improves dramatically with expertise and practice.

Clearly, chunking does not entirely overcome the capacity limits inherent in the immediate memory system. Despite this, we suggest that chunking allows one to remember a greater amount of information than would be possible if no strategy were used at all. It is for this reason that chunking is regarded as such a powerful mnemonic strategy.

How Chunking Works

Chunking can help us increase the amount of information that can be stored and later recalled. This ability is important, as it can help us exceed a severely-limited immediate memory

capacity. If we understand the definition of chunking, as well as its necessity for the immediate memory system, a question that follows is how the process of chunking works. Above, we have suggested that items or chunks in immediate memory are stored in a capacity-limited region, where no more than four items may be consciously attended at any given time. Based on what we have previously learned about this region, we proceed with a discussion of how chunking may work in the context of this theory.

For chunking to occur, some degree of selective attention is often necessary. This is because items held in immediate memory receive attention; likewise, forming chunks from these attended items will also require attention and presence in conscious awareness. As an example of how this process might work, consider an instance where a person is provided with a seven-digit telephone number, 6847083. Assuming that there are no potential aides to record this number, one will have to store the series of digits in immediate memory. How might this proceed? Suppose that the first four digits of the phone number, 6847, enter into the capacity-limited region of immediate memory through selective attention. Because four items are currently being stored within this region, no other items receive attention or any form of processing. At this point, if more digits are to be stored, chunking must occur. Specifically, items within the capacity-limited region can easily be

chunked or associated with each other, as all of them are available and accessible in memory. As illustrated in [Figure 2](#), one could bind the digits 6, 8, and 4 into a single chunk – doing so reduces the number of items stored in immediate memory from 4 to 2. This allows room for two more digits (e.g., 0 and 8) to receive attention, and thus, enter the limited-capacity region. Further chunking can occur (e.g., 70 are formed into a single chunk); this again will reduce the number of chunks occupying the limited-capacity region, allowing the final digit to receive attention and storage. Through this process, the phone number is eventually memorized. The process of forming chunks in the capacity-limited region can be as recursive as needed – chunks can be grouped into even larger chunks, which is certainly beneficial for stimuli that are more complex or numerous than the example listed here.

In general, research supports the idea that chunking can occur through at least three possible ways. First, we can chunk or group items together by forming associations between items that are located in the capacity-limited region of immediate memory, in the manner described above. Second, in a similar vein to the first method, we can take advantage of perceptual cues present within a given set of stimuli (e.g., pauses in auditory lists, items in close spatial proximity) to form groups once items enter the capacity-limited region. Unlike the first case, where groups can be formed in any sort of fashion, the cues provide clear chunk boundaries. For example, a pause in between the third and fourth digit in a phone number (e.g., 684 7083) allows us to form two chunks – one containing the first three digits, and another containing the final four digits. Finally, we can also form an association between items that are in the capacity-limited region with prior knowledge that is stored in long-term memory. In general, long-term knowledge cannot be in conscious awareness unless it has been activated and brought into the capacity-limited region. Once long-term knowledge receives selective attention, forming a chunk or an association between this knowledge and other items in this region proceeds similarly to the first chunking process we described above.

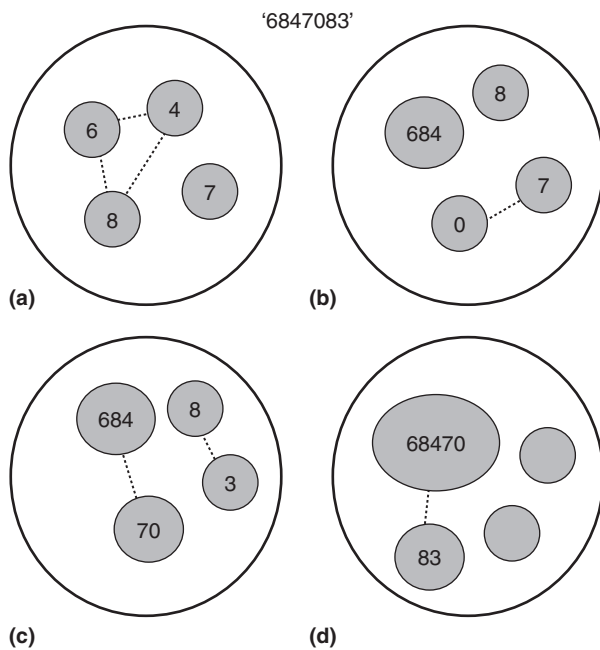

Figure 2 A model of how chunking may occur in the capacity-limited region of immediate memory. Digits in a phone number enter the region and form associations (indicated by dashed lines) to create larger chunks. Note, however, that the number of chunks that can be stored never changes. Encoding the phone number occurs in phases, as in this example: (a) Digits 6, 8, and 4 are first bound into a single chunk; (b) then 7 and 0 are bound into a chunk, and the second 8 enters the capacity-limited region; (c) chunks 684 and 70 are bound into a larger chunk, and 8 is chunked with 3, which has just entered the region; and (d) The two chunks that comprise the number are chunked, which will allow the entire phone number to occupy a single chunk and will free up several other chunks that can be used to accomplish something else (such as keying in the number or holding a conversation).

How Chunks Are Measured

Above, we discussed the notion of the boundaries of chunks, places where individuated chunks end and begin. In some cases, such as when stimuli contain perceptual cues that encourage chunk formation, the boundaries are relatively clear; we can tell how many chunks there are (the number of chunks), as well as how large each chunk is (chunk size). In a majority of cases, however, stimuli are considerably more complex (e.g., prose passages), and it may be unclear where these boundaries occur. This is particularly so when encoding of information is considered, as internal cognitive processes are occurring. How can we measure both the number and size of chunks in these cases?

One of the earliest ways proposed to examine chunk boundaries was done by measuring adopted chunks. Initially theorized by Endel Tulving and Jeanette Patkau, an adopted chunk is defined as recalled items that match the manner in which the stimuli were actually presented (i.e., order information must be preserved in recall). For example, a participant

is presented with the sentence “The quick brown fox jumped over the lazy dog.” If the participant recalls “The quick brown fox lazy dog,” two adopted chunks have been recalled. This is because the participant has recalled two phrases in correct order, but the whole sentence was not recalled verbatim (if this were the case, one adopted chunk would have been formed). Many early studies that measured adopted chunks in recall of unstructured materials found that across stimulus types that varied in terms of subjective meaningfulness; in the case of Tulving and Patkau, participants were presented with sentences that varied in terms of order of approximation to text, which was discussed previously. Findings from these various studies show that the number of adopted chunks that are recalled is constant, regardless of how meaningful the stimulus is. However, as we mentioned above, the size of these adopted chunks increases as stimuli become more meaningful. These studies concluded that there is a constant limit in terms of the number of chunks that can be maintained in memory; however, a greater amount of information (e.g., words within a sentence) can be grouped into a single chunk as stimuli become more meaningful and familiar to us.

Another way to measure chunks capitalizes on an important assumed property of chunks: the association between items contained within a single chunk should be considerably stronger than the association between items from two different chunks. Theoretically, this means that if one item that is part of a given chunk is recalled, other items within that chunk will likely be recalled as well (i.e., a positive relationship). In contrast, there is practically no relationship between recall of items that come from separate chunks; recall of one does not lead to recall of the other. In fact, as items from separate chunks are not bound to each other, we might expect that errors in recall will increase as one traverses a boundary between chunks. One way to measure chunk boundaries using these assumptions is to calculate the transitional error probability of recalled items. Using a mathematical formula, the probability of erroneously recalling a presented stimulus is calculated, conditional on the recall of the item presented immediately prior. In general, researchers have proposed that items within the same chunk will have low transitional error probabilities; when a boundary between two separate chunks occurs, the error probability should increase considerably.

A third means has similar assumptions to those of transitional error probabilities. As was stated above, items that are part of the same multi-item chunk are strongly bound together; in contrast, items separated by a chunk boundary (i.e., the items belong to two separate chunks) are not as strongly bound. It follows, then, that recalling items that are bound together within the same chunk should be faster than when items from two different chunks are recalled. This is because, in the latter case, two separate chunks which have little to no association to each other must both be retrieved. For example, Chase and Simon used this logic to measure chunk boundaries in their series of chess studies that was mentioned previously. In a chess board reproduction task, chess masters and novice players viewed a configuration of pieces, and were asked to copy the configuration onto a blank board; Chase and Simon were interested in how long it took participants to place successive pieces on the reconstruction board. When response times were examined, both for the immediate memory task

and the reconstruction task, it was found that a chunk boundary was defined at 2 s. If successive pieces were placed on the board in less than 2 s, those pieces belonged to the same chunk; if the placing down of two pieces had an interval of more than 2 s between them, the pieces belonged to different chunks. In general, it has been found in this and other studies that training increases the size of chunks; regardless of training level, the number of chunks that recalled remains the same.

A final method to measure chunks involves a posteriori assumption regarding how many chunks (and the size of those chunks) are stored in the capacity-limited region of immediate memory. Researchers have used two types of measures to examine chunk boundaries: chunk access and chunk completion. Chunk access is typically taken as a measure of the number of independent groups or units that are successfully retrieved at the time of recall. This is based on the assumption that items recalled from the same presented group (e.g., word pair, sentence) are part of the same chunk in immediate memory. For an example of how this might work, suppose that a participant were presented with the following word pairs in an experiment: pop-cube, apple-light, key-fish, and shoe-pill. The participant recalls the following items: pop, cube, apple, pill. Here, three separate chunks have been accessed, assuming that a pair functions as a single chunk – pop-cube, apple-light, and shoe-pill. The second measure, chunk completion, is taken as a measure of chunk size. This can be measured as the proportion of words recalled from the same chunk, provided that it has been accessed. Completion measures allow us to examine the coherence of chunks in immediate memory. Using the example above, the participant’s average completion for the list of pairs is 0.67 (0.5 for apple-light, 0.5 for shoe-pill, and 1 for pop-cube). Here, we see that chunking of the pairs is not perfect (there are instances where the entire pair is not recalled), but the size of chunks suggests that chunking of items is occurring somewhat.

Unresolved Issues

Throughout this article, we have described the phenomenon of chunking to the best of our ability, given what has been found in previous studies. That said, there is still much to learn about chunking. Below, we list some questions that, as of now, remain unresolved; by working to answer these questions, cognitive researchers will gain a better understanding of how chunks are formed and processed in immediate memory.

How Many Chunks Can Be Kept in Mind at Once?

Above, we proposed that chunking is necessary to overcome limitations in the capacity-limited region residing in immediate memory. In particular, we noted that this region can hold no more than four items or multi-item chunks at any given point in time; these items receive selective attention, and are in our conscious awareness at that time. There are, however, other views that report slightly different capacity limits. For example, recent studies by Klaus Oberauer and colleagues suggest that the capacity-limited region in immediate memory can only hold a single item at a time. Furthermore, if multiple items are present in conscious awareness, this is because they are

bound into a single chunk. Further research that examines chunk capacity limits is necessary to determine if any resolution between these conflicting views is possible.

Are Chunks Simple or Complex in Their Structure?

As chunking is often an internally generated process, it can be difficult for researchers to determine how chunks are organized in memory. A critical question worth examining in future research pertains to the organization of chunks in memory: when chunks are formed, are they separately stored and undifferentiated from each other, or are chunks connected to each other through some organizational structure? We argue, based on prior findings, that chunks in immediate memory may be organized by a hierarchical retrieval structure. For example, consider the study where a participant spent over a year practicing the digit span task to the point of accurately recalling 82 digits in the task. Based on retrospective reports, near the end of the training period, the participant was not only using his previously-reported strategy of encoding in terms of running time, but was also using other ways to give digits meaning. Furthermore, he reported deliberately organizing digit groups spatially, allowing larger groups (termed supergroups) to be formed; this nested organizational structure allowed digits to function as retrieval cues for remaining digits in a group or supergroup.

Similar organizational structures are presumed to operate in the comprehension of discourse or text, where the amount of information to be stored in memory typically exceeds immediate memory capacity limits. In a text retrieval structure, a linguistic representation contains several different organizational levels, allowing surface, semantic, and syntactic features to coexist in parallel and be chunked together. In general, only elements that have recently occurred or are central to passage comprehension are accessible in immediate memory. These various representations can serve as retrieval cues for what has previously been read, as recall of what has occurred earlier in a text passage is necessary for good comprehension.

From these examples, it is clear that chunks in immediate memory are most likely part of a larger, more complex organizational structure. People often need to know not only which elements belong together, but also the order in which they occur (as in a telephone number) or the way in which the elements are related to one another (as in the understanding of the slightly different chess configurations that are about equally good, and those that are not good at all). However, many studies that have examined organizational structures of chunks in memory focus upon exceptional domain-specific performance; even language comprehension can be considered a type of expertise. It is uncertain how chunks are organized in cases where expert performance is not required, or where task performance does not involve long periods of training.

Is Chunking Based on All-or-None Associative Strength, or Can Associations Be Continuous?

In our discussion of chunk access and chunk completion above, we noted in our example that word pairs were not perfectly chunked. Specifically, in the word pair example that we discussed above, completion rates were 0.67 overall.

Although items were presented in word pair form, there were instances where only one word in the pair was recalled. This potentially suggests that the associative strength between items within the pair was not sufficient to form two-item chunk. However, a thorny issue regarding completion rates as a measure of chunk size involves how we are to interpret associative strength between items. If two-thirds of the word pairs that are presented are successfully completed, as they were in our example, is it because one is only able to recall two-thirds of all of the pairs, with all pairs perfectly chunked together (i.e., associative strength equaling 1)? Or, alternatively, is it because one actually had some information about all of the pairs that were presented, but some pairs were so weakly associated or chunked that participants were unable to recall them accurately on every trial? Unfortunately, completion is not able to measure associative strength between items that make up larger chunks, and it is unclear whether associative strength is dichotomous (i.e., items are either chunked or are not) or is subject to a continuum of potential values. Future measures of chunking should be sensitive enough to be able to measure the strength of associations between items.

How Does Chunking Change with Age?

When immediate memory performance across the lifespan is examined, both children and older adults have worse performance than young adults. Two different views have tried to account for these differences. First, older adults and children may have a reduced memory capacity, meaning that they hold a smaller number of chunks in mind. Second, older adults and children may form smaller chunks. In two recent studies by Gilchrist and colleagues, participants ranging in age from the early elementary school years to young adults and older adults heard lists of unrelated English sentences. Each list of sentences varied in terms of how many sentences were present, as well as the length of each sentence. Chunk boundaries were measured by adapting chunk access and completion measures, discussed above, to sentence stimuli. The results suggested that both young children and older adults hold fewer chunks in mind than did young adults, but that chunk size did not change across the lifespan. Specifically, for these materials the completion rate for simple sentences remained at about 0.80 in all age groups, but the number of sentences accessed was smaller in children or older adults than in young adults.

Additionally, there is the question of how well young children and older adults are able to take advantage of chunking as an encoding strategy. Although completion rates for simple sentences were comparable across age groups, the ability to combine simple clauses to form compound sentences was not quite as good in the children and older adults. Previous research suggests that spontaneous use of strategies develops in later childhood, and then declines with adult aging. More research is needed to determine how the quality of chunking changes with age, and why these changes occur.

Concluding Remarks

Chunking is a process that allows us to meaningfully group items together to increase the amount of information we can

store and later recall. This process underlies much of how we learn information. Furthermore, chunking allows us to circumvent the capacity limits inherent in the immediate memory system; though chunks are still subject to capacity limits, we are able to store more information than if chunking were not possible, by fitting more information into each of a severely limited number of chunks that one can hold in mind concurrently. In this article, we have discussed chunking in depth, noting its purpose and a theorized view of how the process of chunking occurs. Chunking is one of the most powerful strategies to increase the information we hold in mind, yet there are many unresolved debates that should be examined in future research.

Glossary

Acquisition and extinction With a number of pairings of a conditioned stimulus (CS) and unconditioned stimulus (US), conditioning will occur (i.e., acquisition of an association). Conditioning is evidenced if the CS elicits a conditioned response (CR) that it did not elicit before the CS–US pairings. (The US elicits an unconditioned response, UR, regardless of conditioning.) If, after acquisition has occurred, the CS is then presented without the US, the CS loses its power to elicit a CR. This phenomenon is referred to as extinction. Extinction is not simply undoing or forgetting an acquired association but it is better conceptualized as learning something new, that is, learning that the CS is not a predictor of the US anymore as it was before extinction.

Compensatory conditioned response and learned drug tolerance The compensatory CR is a special form of a CR, especially in classical conditioning with pharmacological USs. Its effect is opposite to the effect of the UR. It is thought that this is a learned response, dependent on the CS's predictive strength that is activated in anticipation of a disturbance of an animal's (including humans') homeostasis. For example, if a CS predicts a US such as morphine, which lowers the heart and respiration rate, the compensatory CR elicited by the CS is an increase in heart and respiration rate. This compensatory CR is thought to be the basis for learned drug tolerance because the compensatory CR counteracts the UR, thus making the drug less effective.

Conditioned stimulus (CS), unconditioned stimulus (US), conditioned response (CR), and unconditioned response (UR) An unconditioned stimulus (US) elicits a response without any previous learning. This response (in the absence of learning) is known as an unconditioned response (UR). A conditioned stimulus (CS) elicits a response only if learning has occurred after the CS has been paired with a US. Without previous learning, the stimulus to serve as the CS is neutral and elicits no response. The response elicited by a CS is known as a conditioned response (CR). Pavlov discovered that when, for example, a sound (CS) was followed reliably by food (US), a dog would salivate in response to the sound (CR) just as it had salivated in response to the food (UR), even though the sound did not elicit any reaction prior to conditioning (i.e., CS–US pairing).

Contingency and contiguity Contingency refers to an if-then relationship. For example, *if* the CS occurs, *then* it will be followed by the US with a certain probability. Contiguity

refers to the separation between two events. For example, the US may follow the CS immediately or after a few seconds (high contiguity) or after a few hours (low contiguity). In contrast to Pavlov's original thinking, contiguity is neither necessary nor sufficient for conditioning to occur. For example, in taste aversion learning where the US reliably follows the CS but perhaps only after hours, there is a strong contingency with low contiguity, yet conditioning is likely to occur.

Excitatory and inhibitory conditioning A CS that predicts the *occurrence* of a US is an *excitatory* CS (CS+). A CS that predicts the *omission* of a US is an *inhibitory* CS (CS−). Note that the plus or minus designations do not correspond to 'good' or 'bad' outcomes. A CS+ can predict the occurrence of an aversive or unpleasant US (which would make the CS+ undesirable). A CS− can predict the omission of an aversive or unpleasant US (which would make the CS− desirable).

Little Albert and John B. Watson's attempt to develop a behavioral therapy for phobias John B. Watson was driven by a laudable desire to develop a behavioral therapy to help people to get rid of their phobias (intense, irrational fear); he was successful in laying the groundwork for this. In order to study the elimination of fear scientifically, he sought to create a fear response in a person such that he would know its etiology and be able to develop a therapy based on learning principles. Thus, he exposed Little Albert to a rat (CS) and then immediately followed this experience by a loud, fear-inducing noise (US). After a few of such trials, Little Albert showed a fear response (CR) when just seeing the rat, similar to the response (UR) he exhibited when initially hearing the noise without the rat. Watson has been maligned often because of his work. According to modern standards, he clearly violated ethical conduct in research, however, contrary to popular belief, there is no evidence that Little Albert was permanently or severely traumatized. Many young children experience aversive events such as loud noises in their lives, yet they will not be marred for life.

The Rescorla–Wagner model of classical conditioning The Rescorla–Wagner model is a mathematical model that attempts to describe phenomena underlying classical conditioning. Learning is predicted to be a function of the discrepancy between the maximum amount that can be learned and the amount that has been learned thus far. The rate of closing this discrepancy is determined by the salience ('noticeability') of the CS that is involved on a given conditioning trial.

Introduction

Classical conditioning is also known as respondent conditioning or Pavlovian conditioning. The latter name was given for obvious reasons, that is, to honor the man who discovered it,

Ivan Petrovich Pavlov. Pavlov was a physiologist, not a psychologist, who discovered this natural phenomenon of reflexive learning serendipitously while investigating the digestive system. Thus, he became one of the most influential figures in psychology. Pavlov studied the digestive system using dogs as

subjects (which also conveniently served as producers of gastric juices, sold as a digestive aid for people to supplement Pavlov's underfunded laboratory). The story goes that one day it struck him that, just before they were fed, his dogs salivated to the sound of the caretakers' footsteps. Initially, Pavlov labeled this form of salivation *psychic secretion* because it was not obvious how the dogs were capable of anticipating a stimulus (food) before it actually made contact with the dog's tongue or palate. Sometimes Pavlov is credited with having invented classical conditioning, which is simply an incorrect assertion. Classical conditioning can be assumed to have existed ever since the evolution of animals capable of learning about their environment, long before Pavlov. It is also an incorrect assumption that classical conditioning is a somewhat primitive form of learning. Classical conditioning operates in a wide variety of situations (examples below), including complex human behavior such as emotions, language, and cognition. It is also critically involved in many other forms of learning and conditioning.

Pavlov's great contribution to psychology was to *discover* the existence of classical conditioning, and to develop (and in this case truly invent) scientific methods amenable to its systematic investigation. Thus, he introduced experimental control (i.e., exclusion of confounding variables and ability to produce classical conditioning on demand), which allowed him to manipulate factors such as stimulus duration, intensity, modality, timing, and degree of relationship between two or more stimuli in order to establish causality (the overarching goal of all sciences) as related to behavior (the realm of scientific psychology). By doing so, he contributed tremendously to the application of the natural sciences to psychology – a discipline that was thought of as not being easily amenable to scientific investigations because of its assumed mental nature. Pavlov's contributions to the sciences can still be appreciated when considering that in 2000, Eric Kandel was awarded the Nobel Prize in Physiology/Medicine for having identified in the giant sea slug, *aplysia*, the neural circuitry underlying classical conditioning, which plays a critical role in the physiological mechanisms of memory. (Ironically, Pavlov received the Nobel Prize in Physiology/Medicine in 1904 for his investigations of the digestive system, but not for his discovery of classical conditioning.)

Generally, classical conditioning can explain learning about situations where events occur in a typical sequence, regardless of what the specific events are and what a person (or animal) does. This way, a prior event in the sequence becomes a predictor for the subsequent event.

Terminology

Classical conditioning can be conceptualized as follows (Figure 1): on the first trial, a conditioned stimulus (CS; red), which at this point has no power to elicit a relevant response, is followed by an unconditioned stimulus (US; blue), which – without prior learning – has the power to elicit an unconditioned response (UR; tics on the UR trace). After several such pairings or trials, the CS acquires the power to elicit a conditioned response (CR; tics on the CR trace).

In one of Pavlov's first experiments, the sound of a metronome served as the CS, meat powder placed in the dog's mouth

Figure 1 Schematic representation of classical conditioning involving conditioned stimulus (CS), unconditioned stimulus (US), conditioned response (CR), and unconditioned response (UR). Note that CRs only occur after several conditioning trials.

served as the US, and the salivation response (reflex) constituted the CR and UR. As can be seen in Figure 1, the metronome (CS) initially does not elicit any salivation (no tics depicted at the time when the CS is presented first), but the meat powder (US) does. After several trials (the sufficient number depends on several factors such as type of CS and US, their timing, salience, and relationship to each other), CRs (tics on the CR trace) can be observed when the CS is presented before the US. The US continues to elicit salivation (UR).

Apparently, the terms conditioned/unconditioned were an unfortunate inaccuracy when Pavlov's initial work was translated into English. Perhaps a better choice would have been the terms conditional and unconditional, because these indicate the different conditions under which a response does or does not occur. An unconditional response, for example, is a response that occurs unconditionally, that is, regardless of what was learned before, and a conditional response only occurs if certain conditions were previously met. The controversy regarding terminology, however, is by no means settled as there is an ongoing debate in the field of animal learning whether Pavlov, regardless of the issue of proper translation, indeed referred to conditionality (-al terminology) or to conditioning (-ed terminology) – the latter reflecting the notion that through conditioning a stimulus and response are changed (i.e., conditioned). For consistency in the literature, most writers nowadays have settled for the -ed, not -al, terminology.

Forms of Classical Conditioning

Delayed, Trace, Backward, and Temporal Conditioning

Figure 1 depicts what has become known as delayed conditioning. In delayed conditioning, the CS onset precedes the US onset, but there is no temporal gap between the CS offset and US onset. The CS and US may even overlap. The stimulus-stimulus interval, that is, the time between CS onset and US onset can be relatively short (i.e., seconds, short-delay conditioning) or long (i.e., hours, long-delay conditioning). This form of conditioning is considered quite effective because, as will be elaborated below, this arrangement makes the CS a clear predictor of the US.

Other forms of conditioning include trace conditioning, which is similar to delayed conditioning in that the CS onset

precedes the US onset. However, the CS offset occurs before the US onset such that there is a temporal gap between CS and US, when neither stimulus is present. This form of conditioning has been considered less effective than delayed conditioning, probably because of the weakened predictive power of the CS (depending on the temporal gap between CS and US). However, more recent research has shown that this does not have to be so. Whether or not one observes conditioning with the trace procedure depends critically on which CR is selected for observation. For example, when a pigeon is presented with a keylight (CS) followed by response-independent food (US) with a period of a dark key between the CS and US (i.e., trace conditioning), very few if any pecks at the lit key will be observed, implying that the procedure is ineffective and that little conditioning has taken place. However, if the pigeon's proximity to food is recorded, the pigeon's position with respect to the location of food delivery is an orderly function of how much time has elapsed during the trace. In other words, positioning becomes a learned response, and with this behavior in mind, the trace conditioning procedure is very effective in bringing about conditioning.

A third form of conditioning is backward conditioning. In this procedure, the US precedes the CS, and therefore the CS cannot predict the occurrence of the US. Unsurprisingly, little if any excitatory conditioning of the CS will occur. However, careful analysis reveals that the CS becomes a predictor for the US-free period to follow, because the CS explicitly indicates that there will be no US immediately after the CS. The CS becomes a so-called inhibitory stimulus (CS-; see below). As in trace conditioning, judgment of the effectiveness of the procedure depends critically on what response is being measured as the CR.

Finally, there is temporal conditioning – a procedure in which a US is presented repeatedly after a fixed-time interval has elapsed, without explicit CS. The sensation of passing time presumably serves as the CS.

Autoshaping: A Special Form of Classical Conditioning?

If a hungry pigeon is exposed to a situation where a keylight is followed by food regardless of the pigeon's behavior (defining the autoshaping procedure), the pigeon is likely to peck at the key after a few trials. Furthermore, if one keylight is followed by food and another keylight by water, the pigeon pecks at each of the two keylights reminiscent of the way it would peck during actual consumption of food or water: for food, one observes distinct peck movements toward the key, with beak open, whereas for water, one observes small, rapid beak movements, while the pigeon keeps its head close to the key. The keylight functions as the CS and food/water as the US; the peck at the keylight is the CR and actually eating or drinking (consummatory response) is the UR. One human example may be when people standing in an elevator stare at the floor indicator. Just as in classical conditioning, this behavior has no bearing on the outcome (e.g., whether people are staring or not, the elevator does not move faster or in a different direction). Autoshaping is of interest because it serves as a convenient model of classical conditioning with relevance to nonhumans and humans. For example, it can be shown that the ratio of the interval between trials (intertrial interval, ITI)

and duration of the CS is critical for learning rates. In general, under classical conditioning, the larger the ITI:CS ratio, the faster acquisition will occur.

Human Examples

The Case of Little Albert

One of the most famous case studies in psychology is the case of Little Albert. John B. Watson had designed a method to condition a child to be fearful, so he could develop, in a controlled manner, an effective treatment to subsequently eliminate fear. To accomplish this, he presented a pet such as a rat, rabbit, or other animal (CS) to Albert. Immediately after Albert saw the animal, a metal bar was struck to produce a loud noise (US). First, Albert did not cry when he saw the pet animal, but after repeatedly experiencing CS_{Pet}–US_{Noise} pairings, he began to cry (CR) as soon as he would see the pet, just as he would cry (UR) in reaction to the loud noise. The claims of Watson's putative cruelty and unethical conduct are probably vastly exaggerated. First, as sketched out in his book, *Behaviorism*, first published in 1924, Watson was driven by a genuine and admirable desire to develop an effective treatment of irrational fear (phobias) in people, regardless of how misguided and insensitive his approach may have been. Second, many babies or young children hear loud noises such as popping balloons at a children's party or suffer pain from falling, for example, and then cry because of it. They may even become afraid of balloons and stairs, which is actually a healthy and adaptive response. Yet one generally does not worry about these children being traumatized for the rest of their lives.

Language and Verbal Behavior

One of the most uniquely human behaviors is language, and classical conditioning (in linguistics sometimes referred to as statistical learning) is involved in language learning, as B.F. Skinner already recognized in the 1950s. Classical conditioning is particularly important for children to become effective listeners. Consider the following situation: A mother might say "Here's some milk!" or "Have a cookie!" The probability of occurrence of the actual items, milk and cookie, is much higher after the vocalizations 'milk' and 'cookie', respectively, than after the vocalizations of 'juice' and 'sandwich' for example. Since the sound of 'milk' (CS) often precedes the actual item milk (US), the CS becomes a predictor for the US. (In colloquial terms, the 'meaning' of the utterances 'milk' and 'cookie' is thus established.) Another example of verbal behavior is memorizing text (e.g., the word 'pledge' precedes the word 'allegiance').

'Cognitive Maps' and Memory

The learning of so-called cognitive maps is based in part on classical conditioning as well. Imagine that each day, on your way to work riding the bus, you drive by the convenience store with its bright-green awning immediately before arriving at the north-east corner of main street where the bus turns right. To be able to picture your way to work in your mind when, for example, giving directions to a friend ("Turn right immediately

after the convenience store with the green awning!'), you do not have to be actively driving to work. It is sufficient to be passively driven and to observe a series of landmarks in order to learn about specific localities. One landmark becomes the predictor for the next.

Classical conditioning is critical for some forms of memory (e.g., implicit memory, which is learning and remembering past events without explicit awareness). In order for a CS to remain a CS for a while after conditioning has occurred, memory – presumably encoded in altered neural connectivity – is essential. In the example above, learning about landmarks is only possible if stimulus-stimulus pairs are being remembered.

Embarrassment

Imagine a man finding himself attracted to a woman who rides the same bus he takes to work every morning. One day, he musters up all his courage to approach the woman and ask her if she might like to join him for a cup of coffee. The woman reacts by saying loudly (so everyone on the bus can hear it) 'You creep! Get lost!' The man blushes and feels embarrassed. The next day, as soon as the man sees the woman, he blushes and feels embarrassed all over again. In the framework of classical conditioning, the sight of the woman serves as the CS, the woman's initial verbal and embarrassing reaction as the US. Blushing and the feeling of embarrassment are the CR (when triggered by the mere sight or thought of the woman) or UR (when triggered by the woman's original reproach). This example illustrates that the association was established in one trial (initial situation) between two stimuli, that is, the sight of the woman (CS) and the embarrassing words (US).

Acquired Taste Aversion

Joe went to a restaurant where he shared a novelty pizza (duck meat and feta cheese topping) with his friends. In the middle of the night, he got violently ill with stomach cramps and nausea caused by a stomach virus. The next day, after talking to his friends who did not get sick, he realized that his illness was not caused by food poisoning. From this day on, even though he realized that his experience had nothing to do with the pizza itself, he immediately felt ill just smelling feta cheese or duck. In the framework of classical conditioning, the smell and taste of feta cheese and duck represent the CS, the toxin produced by the virus represents the US, feeling queasy in response to the smell of feta cheese and duck represents the CR, and feeling ill in response to the virus's toxin represents the UR. This example illustrates several additional aspects of classical conditioning. First, classical conditioning can occur with just one CS-US pairing. Pavlov's original demonstration required multiple CS-US pairings. Second, the temporal separation (referred to as contiguity) between CS and US can be quite long. Pavlov's original demonstration required rather close contiguity between metronome and meat powder. (If the metronome were presented hours before the meat powder, the dogs would not salivate to the sound of the metronome.) Third, classical conditioning occurred without awareness and contrary to what Joe deduced from his talk to his friends. Joe realized that the nausea after his restaurant visit had nothing to do with feta cheese and duck meat, yet these specific foods

continue to produce aversive reactions. Fourth, conditioning is more likely when novel stimuli with no or little prior history are involved. Joe had never experienced the combination of feta cheese and duck before. If it had been a standard pizza with tomato sauce and mozzarella, which he had eaten many times before in his life, it would have been unlikely that he develop an aversion to tomatoes and mozzarella cheese. This point will be elaborated in a subsequent section in the discussion of the so-called Rescorla-Wagner model (RWM) of classical conditioning, which in this article will serve as an example of one of several competing theories of classical conditioning. Fifth, some CS-US associations occur more easily than others, depending on what species is being considered. This phenomenon is referred to as species-specificity and underscores biological constraints on learning. Specifically, in humans, an association between a smell/taste CS and a nausea-inducing US occurs easily, but not an association between a visual CS and a nausea-inducing US. (The relationship might be opposite for another species, e.g., quail.) Note that Joe did not develop an aversion to the sight of the restaurant or of his bedroom even though these provided stimuli that were more contiguous than the smell/taste stimuli provided by the food in the restaurant. This point will be elaborated in the next example.

Fear-Conditioning

Here is another example of fear conditioning (compare with the case of Little Albert above) that involves pain without an experimenter's responsibility. Jane went to a restaurant where she shared the infamous novelty pizza (duck meat and feta cheese topping) with Joe and her other friends. After they finished and left the restaurant, she got hit by a car and experienced excruciating pain. After recovery, she got invited by her friends to go out for dinner again. She still liked novelty pizzas but to her own surprise, when she approached the restaurant, she broke out in cold sweat, her heart started racing, and she felt very fearful about being in another accident. In this example, the sight of the restaurant serves as a CS, the pain inflicted by the accident serves as a US, feeling fearful, breaking out in cold sweat, and her heart racing in reaction to the sight of the location where the accident had occurred represents the CR, and experiencing pain, fear, and dread because of the injuries she suffered from the accident when it happened represent the URs. This example, again, illustrates the species-specificity and biological constraints in classical conditioning (Jane developed an emotional response to the place where she ate, not to the food; the US was pain, not nausea). The mechanisms just described probably represent at least a partial explanation of the posttraumatic stress syndrome, where cues that have become associated with stress, pain, and injury can elicit extreme fear-responses even many years after the original situation that first established the association between the cues and the actual event. A second point is of importance: The CR and UR are not identical. Even though Pavlov hypothesized what he called stimulus substitution (i.e., the CS takes the place of the US) and thus tried to explain the similarities between CR and UR (both salivation), he recognized that the CR and UR were not identical (the saliva differed in chemical composition). The following example illustrates a situation where the CR and UR can even be opposite in their effect.

Learned Drug Tolerance

Bob and Serena had been using heroin for years, which they originally used recreationally under very specific circumstances, with their own routine and ritual. Because they had become increasingly more concerned about their health, they decided to quit and clean up. They stayed clean for 18 months, proudly overcoming the battle with initial physical withdrawal. They had not even been thinking of their past habit anymore, when one day they were invited to a party where old friends were shooting up heroin. As soon as Bob and Serena saw the familiar paraphernalia of syringe, spoon, lighter, and tourniquet, both experienced sensations that they immediately recognized as withdrawal symptoms. Whereas they always felt warm, happy, and relaxed when using heroin, they now, after months of abstinence, felt cold, irritated, and tense. This experience caught them completely by surprise because they had not used heroin for months and thought they had completely overcome withdrawal from heroin. An analysis of this situation within the framework of classical conditioning, somewhat simplified, is as follows: The paraphernalia function as CSs (cues that predict the imminent injection of heroin), the injected heroin functions as US, and the sensations and physical reactions resulting directly from the injected heroin are the URs. (A proper analysis is somewhat complicated by the fact that physical reactions themselves provide so-called proprioceptive stimuli.) What are the CRs? The analysis is in terms of so-called compensatory CRs. Considering that biological systems typically strive for homeostasis, CSs are assumed to be cues to allow the body to prepare and compensate for the impending physiological disturbances caused by heroin (US). With initial heroin use, these CRs are assumed to be nonexistent or weak but with repeated use, the CSs become increasingly strong as predictors (i.e., classical conditioning has occurred), and accordingly the elicited CRs become stronger as well. With drug use, the CSs are always followed by the US, but the URs are counteracted with increasing force by the CRs. The net effect of the drug thus becomes diminished. The user counteracts this in turn by increasing the dose of heroin to increase the net drug effect. The strength of the CR increases in turn, and thus the cycle continues. So, when Bob and Serena encountered the familiar CSs (paraphernalia) at the party, compensatory CRs were elicited (and experienced as withdrawal) that were not attenuated by the primary effects of heroin (because they were not using any). These unexpected withdrawal symptoms can contribute to relapse. Similar analyses can be applied to tolerance and withdrawal involving nicotine, caffeine, and alcohol, but also to less obvious situations involving the diminishing effects of thrill-seeking behavior (e.g., bungee jumping and skydiving), changing romantic attachment in short- and long-term relationships, and depressive reactions to retirement after a long work life.

In the example of learned tolerance, the effect of the CR and UR are in opposite directions. For example, if the UR is a decrease in heart rate, respiratory rate, pain sensitivity, and muscle tension, the CR is an increase in these measures. Note that this form of classical conditioning describes a phenomenon sometimes called psychological dependence. It occurs independently of systemic changes in opioid receptors or drug residuals, as can be logically verified as follows: After months of abstinence, putative opioid-receptor sensitivity

and drug residuals are identical moments before and after encountering the CSs, yet withdrawal occurs immediately upon encountering the CSs (environmental cues). Based on this analysis, a very effective therapy for drug dependence has been developed as will be presented in a subsequent section.

The Acquisition of Associative Strength in Classical Conditioning

Predictiveness: Contingencies and the RWM

The CS can be conceptualized as a signal that allows a person's (or animal's) physiology to prepare for events that happen with a certain probability: In the above examples, the metronome served as a cue for Pavlov's dogs' palates to be wet before the anticipated arrival of dry food; the mother's utterance 'cookie' was a signal that a cookie was on its way; the sight or thought of the person who inflicted embarrassment was a cue for more embarrassment; the smell of feta cheese was indicative of food that was likely to cause sickness (regardless of whether the food was the actual cause or not); the rat was a warning signal for Little Albert that a loud noise was about to happen; and the syringe for the heroin user was a cue for imminent disruption of physiological homeostasis. The critical point is that in these examples the CS becomes an effective predictor (more precisely an excitatory CS or CS+) for the occurrence of the US, if it signals a greater probability of the US in its presence than in its absence: $p(\text{US}|\text{CS}) > p(\text{US}|\text{no-CS})$. It is also possible that the CS becomes a predictor for the absence of the US. For example, a person might walk in a badly lit alley and worry about getting mugged. But as soon as the person sees a police station, the person might feel relief. The police station, CS, functions as a signal for the decreased likelihood of getting mugged and injured (US) because $p(\text{US}|\text{CS}) < p(\text{US}|\text{no-CS})$. In this case, the CS is inhibitory or CS-.

Perhaps it is helpful to think about how different types of CSs (CS+ and CS-) may elicit a range of human emotions with respect to different types of USs (desirable and aversive). Here are four examples: a person playing a slot machine who sees three cherries lined up (CS+ predicting the occurrence of a desirable US, money) probably feels happiness and excitement. A smoker who sees the 'No Smoking' sign (CS- predicting the omission of a desirable US, nicotine) probably feels unhappy and disappointed (perhaps even experiences withdrawal). A pilot seeing the warning light of engine failure (CS+ predicting the occurrence of an aversive US, danger) probably experiences fear. And finally, the Homeland Security Department's Code Green (Low Risk of Attacks; a CS- predicting the absence of the US, danger) probably elicits a feeling of relief and safety in people. It is important to realize that the signs in CS+ and CS- are not notations of the desirability of the CS or US. Instead, the sign signifies the type of contingency, a positive or negative contingency, which refers to 'if CS, then US' (positive contingency) and 'if CS, then no US' (negative contingency) – simply the degree of dependency between the CS and US. The desirability of the CS depends on the contingency and the type of US. Thus, a CS+ with respect to the occurrence of danger elicits the unpleasant emotion fear, whereas a CS- with respect to the omission of danger elicits the pleasant feeling of relief.

Several models of classical conditioning that see the CS as a signal for presentation or omission of a US have been proposed. One of them, the RWM, will be introduced as the most representative of these models, even though it has been shown that it cannot account accurately for all phenomena in classical conditioning. The RWM is also an example of an early model that proposed a mathematical equation that successfully predicted human behavior (even though it has been tested primarily in nonhumans). Here is a simplified version of this model: $\Delta V = s(A - V_{\text{sum}})$ where ΔV is the change in associative strength of a given CS (i.e., how much more or less conditioning has taken place after an additional CS-US pairing), s is the salience or noticeability of a CS (its value ranging from 0 to 1.0), A is an asymptote denoting the maximum amount of conditioning that a given US can support (sometimes conveniently expressed as percentage; it can be a desirable or undesirable US), and V_{sum} is the total of associative strengths of all stimuli that are involved in all previous conditioning trials. For example, if for a metronome $s = 0.50$, for a morsel of food $A = 100$ drops of saliva, and for all stimuli (metronome only, for simplicity) $V_{\text{sum}} = 0$ (before the first trial, before any conditioning has taken place), then $\Delta V = 0.50 (100 - 0) = 50$ after completion of the first trial. Thus, by completion of Trial 1, the metronome is predicted to have gained associative strength and can elicit 50 drops of saliva. After the second CS-US pairing, $\Delta V = 0.50 (100 - 50) = 25$; after the third and fourth pairing, $\Delta V = 12.5$ and $\Delta V = 6.25$, respectively. The cumulative associative strengths of the CS (V_{sum}) after Trials 1, 2, 3, and 4 are 50, 75, 87.5, and 93.75, respectively. Figure 2 depicts the acquisition curve of a CS over ten trials. ΔV in Trial 1 is added to V_{sum} in Trial 1 (amount learned prior to Trial 1) to produce a new sum (amount learned after Trial 1). This new V_{sum} is then inserted into the formula to determine ΔV for Trial 2, and so on. ($A - V_{\text{sum}}$) represents the amount of associative strength that still can be acquired after a given

Figure 2 Hypothetical example of an acquisition curve (in red) as conceptualized by the Rescorla-Wagner model. Refer to text for explanation.

trial (i.e., the difference between the maximum of learning and how much has been learned already). How much of this difference will actually be added by the next conditioning trial is proportional to the salience of the CS and the number of previous CS-US pairings. It should be clear that the equation describes an increasing, monotonic function of diminishing returns with an asymptote at A , which is a classic learning curve similar to the one that Hermann Ebbinghaus described over 100 years ago in his memory research. (Each opportunity to study a list of nonsense syllables constitutes one trial, and each trial results in learning additional words, but the length of the list sets the asymptote because one cannot recall more words than are on the list.) In the beginning, much can be learned on one trial; after many trials, very little can be learned on an additional trial even though performance is ever improving.

The RWM can also account for the phenomenon of extinction by assuming that $A = 0$. Extinction refers to a situation where after several CS-US pairings, the CS is presented by itself, that is, not being followed by the US anymore. This results in a decline of associative strength. The resulting curve looks like a forgetting curve (a horizontal mirror image of the learning curve in Figure 2.) However, the notion that extinction is similar to forgetting has not been substantiated. Extinction is better conceptualized as learning a new contingency involving the same CS. (Evidence against forgetting as an explanation comes from so-called re-acquisition tests, for example, in which after complete extinction, the original CS-US pairings are reintroduced. Reacquisition is typically faster than the original acquisition, despite the fact that both start at levels where the CS appears to have zero associative strength.)

The RWM is a powerful model that has been tested empirically many times. For example, one can change the value of A (e.g., increase or decrease US magnitude or introduce extinction with $A = 0$) and change the salience (e.g., make the CS, a light, brighter, or dimmer). Decreasing US magnitude, for example, results in lowering the asymptote of the obtained learning curve. Increasing or decreasing the brightness of the CS results in a higher or lower rate of acquisition, respectively. Generally, these predictions have been validated empirically.

Contiguity

Contiguity in classical conditioning refers to the closeness of two stimuli (mostly temporal closeness of two CSs, or between a CS and US). This was one of Greek philosopher Aristotle's (384–322 BC) Principles of Association. For example, if one happens to observe a shooting star (CS) and then immediately thereafter hears a loud bang (US), many would be tempted to see a causal relationship between these two events (even if there is none). Pavlov also recognized this principle and empirically tested it by varying the time between the metronome (CS) and food (US). The more closely together the CS and US occurred (however, not simultaneously), the more quickly conditioning took place. When the temporal separation was too large, no conditioning occurred. (Even if there was a contingency between metronome and food, that is, US-food always followed CS-metronome, if there was only negligible contiguity – for example, presentation of the metronome was followed by food 8 h later – no conditioning would occur.)

Thus, it came as a surprise when acquired taste aversion was discovered (see example above). Here, a long gap (e.g., hours) between CS-taste and US-sickness was possible and still allowed for fast conditioning (sometimes even in just one trial). Thus, contiguity is not necessary for conditioning to occur. In fact, even in situations with contiguity but without contingency (i.e., the CS is not predictive; the US is equally likely to occur with or without being preceded by the CS), no conditioning occurs. (Robert A. Rescorla introduced this no-contingency test as the truly random control group.) Thus, contiguity is not sufficient for conditioning to occur.

Stimulus Overshadowing and Stimulus Blocking

The failure of conditioning despite contiguity is further illustrated by two phenomena, stimulus overshadowing and stimulus blocking. Stimulus overshadowing might occur when two CSs – one salient, the other not – are competing for associative strength. The outcome is that the more salient CS accrues most of the available associative strength whereas the less salient CS, despite equal contiguity, fails to accrue much associative strength. A human example is as follows: most elevators are equipped with a visual signal (up or down arrow) and an auditory signal (one or two chimes) for the vision impaired to be informed about the direction of the elevator. In general, for people visual stimuli are more salient than auditory stimuli. Therefore, we learn more about the direction of the arrows (CSs) as predictors for the actual movement of the elevator (US, to move in the intended direction) than about the signal value of one versus two chimes. When asked, most people cannot tell whether one chime indicates up or down movement of the elevator.

Stimulus blocking refers to a situation where one of two (or more) CSs has a prior predictive (or associative) history with respect to the US, and as a result blocks a second predictive CS that is added later. Thus, despite the fact that the second CS is contiguous with the US, its acquisition of associative strength is drastically reduced. (According to RWM, $A - V_{\text{sum}}$, the potential of subsequent learning, is small if one CS had already accrued most of the associative strength. Thus, little associative strength is left to be accrued by the added CS.) A real-life human example of blocking involving classical conditioning alone is difficult to identify. However, it can be argued that a discriminative stimulus, S^D , in operant conditioning acquires its value or cue function through classical conditioning (i.e., given an appropriate response, the S^D is followed by a reinforcing stimulus, S^R). This $S^D - S^R$ pairing is one of the three binary associations that has been experimentally identified in the so-called three-term contingency of operant conditioning, $S^D::R - S^R$ (if S^D , and if R , then S^R), and, for the current analysis, is equivalent to the CS-US association in classical conditioning. The blocking rationale may then apply to a variety of human situations.

What follows is an experimental demonstration of blocking in humans (even though similar paradigms have been used to study blocking in other species): initially, a light (CS_{Light}) is presented and followed by a puff of air (US) aimed at one of the participant's eyes. Conditioning has occurred when CS_{Light} elicits an eye-blink response (CR), similar to the eye-blink response (UR) elicited by the US. Then a tone (CS_{Tone}) is added to CS_{Light} ,

forming a $CS_{\text{Light}} + CS_{\text{Tone}}$ compound. Blocking is demonstrated when even after many presentations of the $CS_{\text{Light}} + CS_{\text{Tone}}$ compound CS_{Tone} alone fails to elicit a CR. It is said that CS_{Light} blocked CS_{Tone} in its acquisition of associative strength.

Novelty

One last point in this section deals with novelty of the stimuli involved. To follow through with the example of learned taste aversion, as mentioned above, consider that a person may have eaten regular tomato and mozzarella cheese pizza many times before. In effect, there were many $CS_{\text{Taste}} - US_{\text{Wellness}}$ pairings in the past. If it so happens that one day the person gets sick after having eaten a tomato-mozzarella pizza, not much learned taste aversion with respect to the taste of tomato and mozzarella cheese would occur because the CS_{Taste} would have accrued a lot of associative strength already. In other words, there were many CS-US pairings in the past that established the food as safe, so that one bad experience will not have a large impact on the firmly established CS. However, if the person gets sick the first time a novel CS_{Taste} is experienced, the one CS-US pairing will have a proportionally great impact. Recall that according to the RWM, early training trials with a new CS have a relatively large effect: much can be learned on the first few trials, whereas relatively little new information is learned on late trials.

Therapies Based on Classical Conditioning

The final section of this entry addresses the role of classical conditioning in a number of therapies for clinical disorders. Four examples will be offered as a representative selection of treatments based on classical conditioning.

Treatment of Phobias

A phobia is an irrational fear that is intense enough to render a person dysfunctional and distressed. As discussed above, the case of Little Albert was John Watson's attempt to develop a model of fear (with known history) in order to develop a treatment to take fear away from a person. His student Mary Cover Jones continued his work and developed one of the earliest behavioral therapies based on what she called unconditioning. The approach was to introduce the established fear stimulus (white rat or rabbit) gradually, while keeping the child relaxed and distracted by allowing him to eat a favorite food (and the loud noise was omitted). Years later, in 1958, Joseph Wolpe used this as the basis for his so-called systematic desensitization through reciprocal inhibition or counterconditioning. Research over the following years revealed that the clinically relevant component of unconditioning, systematic desensitization, or reciprocal inhibition was extinction (though changing the value of the CS from being a predictor of something unpleasant to a predictor of something pleasant may contribute to a successful treatment as well). In this and other treatments such as flooding and implosive therapy, based on extinction, the client is exposed to the fear CS without being exposed to the fear US (and without being allowed to avoid the CS by withdrawal, for example). As a result, the CS loses its fear-eliciting properties.

Treatment of Drug Tolerance

In the previous example of learned drug tolerance, the paraphernalia elicited withdrawal because of their association with heroin use. The experience of withdrawal is thought of being one of the reasons why former addicts relapse, even after months or years of abstinence because the former addict is very likely to reduce the unpleasant withdrawal by giving in and using the drug again. Thus, one aspect of treatment of drug dependence should focus on eliminating the experience of this type of withdrawal. In order to do so, the former addict is intentionally exposed to the drug-cues (CSs) but is not allowed to actually administer the actual drug (US). For example, an addict may be allowed to cook up saline solution (an inert substance) and inject it but is not allowed to do so with actual heroin. Initially, the addict will go through severe withdrawal all over again. Each presentation of the drug-cues without actually administering the drug, however, serves as an extinction trial. With extinction, once again, the association of the drug-cue-CS with the actual drug-US is changed such that the CSs lose their power to elicit the compensatory CRs, which decreases the experience of withdrawal.

Treatment of Alcoholism

Even though a similar extinction technique, as described above, can also be applied to alcoholism or any other form of dependence, so-called aversion therapy, based on classical conditioning, has also been used for the treatment of alcoholism. The idea is based on the principle of taste aversion learning. The alcoholic ingests a drug (e.g., Antabuse), which has no effect until alcohol is ingested. If alcohol is ingested while being treated with Antabuse, the person gets violently ill. The idea is that the taste of the alcoholic beverage serves as the CS, and that the nausea induced by antabuse+alcohol serves as the US. After a few CS-US pairings, the taste and smell of alcohol becomes aversive. This therapy by itself has not proved to be very successful for reasons that are beyond the scope of this article.

Treatment of Nocturnal Enuresis

Nocturnal enuresis refers to bedwetting in children who are considered to be too old developmentally for bedwetting. One treatment approach is based on classical conditioning, which is applied after organic or medical conditions have been excluded as a possible cause for enuresis. For this, a pad (constructed like a sandwich of two sheets of mesh wire, separated by a cotton sheet) is placed under the sleeping child. When the child urinates on the pad (and, urine being a good conductor, thus closing the electrical circuit), a battery-operated alarm goes off and wakes up the child. The sensation of a full bladder is thought to be the CS, the alarm the US, waking up to the alarm the UR, and waking up to the sensation of a full bladder the CR. (When the CR occurs, enuresis is eliminated.) Note that the sensation of a full bladder always precedes the sound

of the alarm. Thus, the sensation of a full bladder becomes an effective CS eliciting a waking up response. Note that no awareness of learning is required for classical conditioning to be effective (i.e., the conditioning can take place even though the child is sleeping). Note also that there is an alternative explanation in terms of operant conditioning, which is beyond the scope of this article.

Conclusion

The present article on classical conditioning was an attempt to give a flavor of the richness and complexity of this form of associative learning. There is a vast literature on the different models of classical conditioning; for the sake of brevity, only the RWM was introduced as one example of the many quite successful models. Other aspects of classical conditioning were given only a cursory treatment: the application of classical conditioning to neural networking and cognitive models, the complexity of recent findings relevant for extinction, and an appreciation of the fact that in most conditioning situations, many stimuli are involved, which compete and interact in their involvement with associations that are being formed. The interested reader is referred to the list of suggested readings.

The Clinical and Cognitive Psychology of Conflict

A Parker, Gothenburg University, Gothenburg, Sweden

© 2012 Elsevier Inc. All rights reserved.

Glossary

Cognitive factors Higher-order psychological factors relating to intellect, reasoning, belief, and construct systems which may have an influence on lower-order events such as learning, perception, and conflict resolution.

Cognitive unconscious Information presented at a speed too rapid for conscious recognition nevertheless establishes some kind of memory trace. This information is subsequently learned more quickly than nonpresented information. The designation 'cognitive' is added to emphasize that the effect is in the area of learning and perception and is more limited in its motivational or an emotional influence than alleged to occur with the Freudian or dynamic unconscious.

Conflict A perceptual state involving the executive function of the organism where the immediate choices in the organism's repertoire, together with the outcome of these choices, are seen to involve incompatible motives and needs.

Constructs A term promoted by the American psychologist George Kelly to describe the belief systems which individuals use to divide persons (and the world in general) into specific categories such as pleasant–unpleasant, attractive–repulsive, and honest–dishonest. Constructs are usually bipolar and characteristic of the individual.

Coping skills The skills, including those known as defense mechanisms, for dealing with the demands (especially those that are psychologically threatening) of the environment.

Defense mechanism The description of the various ways in which consciousness is said to defend itself against potential anxiety by distorting the perception of the situation to become a less or nonthreatening one. The usual defense mechanisms are denial, projection, displacement, sublimation, and rationalization.

Emotional unconscious The evoking of activity in the deeper structures of the brain (the limbic system) which border on the cortex of the brain and communicate with bodily organs. While these brain structures mediate potential emotional experience, the experiences themselves may take the form of gut feelings or more generally, so-called somatic markers. They may unconsciously influence decision making and may be a part of what is experienced as intuition.

Gestalt psychology Literally, the study of how the whole is greater than the sum of its parts. An approach within psychology, which emphasizes a basic principle in facilitating

learning, perception, and even psychotherapeutic change, is to create a whole and meaningful image from its components. Conflictual aspects are resolved by combining their inherent polarizations or promoting a dialog between them.

Mindfulness The focusing of attention on the *flow* of immediate experience in the here and now alongwith enabling the attitude of openness, acceptance, and curiosity as to the content of experience. It derives from the practice of Zen meditation.

Mindfulness-based cognitive therapy This is aimed at breaking habitual thought and reaction patterns and expanding awareness to include feelings and bodily reactions that would not otherwise be attended to: in short, access to otherwise nonconscious processes.

Positive psychology A movement rather than a school, which derives from humanistic psychology, which aims to be a counterbalance to psychiatry by providing psychology with a positive and scientific base in cognitive psychology. It places an emphasis on the expression of higher motives and positive emotions involved in the search for meaningfulness, wisdom, and happiness in life. It is associated with the works and concepts of Philip Zimbardo, Mihaly Csikszentmihalyi, Martin Seligman, and Albert Bandura.

Psychoneuroimmunology The study of the way psychological factors interact via neural and chemical messengers (hormones) with the body's immune system, thereby providing a pathway for psychological factors to have determining effects on illness.

Social identity theory Social identity is composed of several different identities corresponding to the social groups of which we are a member. The more positive the images of these groups, the more positive is our self-esteem, and we strive to increase the status of our group membership by creating a series of ingroups and outgroups. This becomes a basis for social prejudice and group conflict.

State-specific memory This concerns memory that is specific to a particular state of consciousness and is not retrievable or only partially retrievable in other states. For example, events which a person recalls in a drug-induced state may not be recalled in the normal waking state and vice versa.

Stroop effect A technique for studying the effect of perceptual bias on recognition time and learning by using words for colors written in colors which are incongruous with their meaning: the word *red*, for instance, written in blue.

Conflict is an integral part of all human behavior, and its attempted resolution can be seen as a major part of the effort toward mastery of the environment. Unresolved and chronic conflicts are probably the most central problems that clinical psychology deals with.

A conflict can be defined as a motivational and emotional state that challenges the cognitive resources of the organism and which can result in mental and bodily stress. The motivational aspect is due to the perceived nature of our goals to which we attribute polarized negative and positive loadings.

This often means that there is an increase in emotions such as anxiety associated with nearing the goals and their associated loadings or with the threat of loss of the reward associated with goal. Conflicts, when they are experienced consciously, also involve a cognitive and executive aspect in terms of applying experience and eliciting skills which can lead to their resolution.

Knowledge concerning conflicts and their effects can accordingly be organized under the aforementioned headings of motivational aspects and emotional aspects relating to their unconscious and dynamic significance, and the cognitive and executive aspects concerning how they are consciously conceptualized and resolved. Since conflicts inevitably produce bodily stress, this is also an important component.

Axiomatic to the understanding of conflict behavior is the view first put forward by the philosopher of science John Dewey: "the brain is primarily the organ of a certain type of behavior, not an organ of knowing the world." This is to acknowledge that with respect to evolutionary demands, the human psyche would seem to be best equipped for handling straight decision making in the face of practical conflicts and then carrying out these choices. The brain may not be designed to give any simple resolution of abstract philosophical and ontological problems such as the meaning of life. This apparent truism may explain not only why existential conflicts are the most intractable but also why behavioral conflicts appear to be the most readily amenable to psychological intervention.

In this vein, it is true that early psychologists chose to study simple paradigms of conflict situations, often attempting to determine the variables governing their resolution or persistence in the form of symptoms. The approach known as behavioral psychology emerged from this with its foundations in the study of how rat behavior is determined by simple laws relating to the contingency and frequency of noxious and rewarding reinforcers. In contrast, the early psychoanalytic approach focused on the dynamic forces and defenses governing emotional conflict. Historically (with the exception of Gestalt psychology and a few partisan approaches such as Jungian psychology), it was much later that therapies and theories developed to take into account the unique nature of the human species: man's ability to conceptualize the environment and enter into existential conflicts. Recent developments are, however, giving this aspect a central role in illness. Unresolved psychological conflict with its resulting long-term stress appears to be an important and sometimes a crucial determining factor not only in psychological disturbance but also in the genesis of a wide range of illnesses. However, rather than continuing to focus on diagnosis and disturbance, there is a contemporary focus, known as *positive psychology*, on the enormous human potential for change and on the importance of existential questions and conflicts.

The Motivational Aspects of Conflicts

It was because of its simplicity that the behavioral approach made rapid progress in the study of learning; whenever it was applied to the study of conflict, it had to adapt to a more holistic approach, that of Gestalt psychology. One of the most influential gestalt psychologists, Edward C. Tolman, introduced concepts such as expectancies, signs, and cognitions as so-called 'intervening variables' placed in the middle of the simple

stimulus-response analysis of behavioral psychology. For Tolman, even rats were cognizant of the salient features of their environment. Another gestalt psychologist, Kurt Lewin, proposed what is now regarded as the classic analysis of conflict in terms of conflicting goals. This was of the trilogy of approach-approach, approach-avoidance, and avoidance-avoidance goal conflict.

In *approach-approach conflict*, both goals are accredited equal positive values and a choice naturally entails loss of one. Analogies are easy to find in the human situation, for example, when one is faced with a choice between equally attractive job offers or equally attractive roles, such as in career fulfillment and in parenthood.

Approach-avoidance conflict involves by definition an aspect of punishment or loss in achieving the desired goal and evokes fear or anxiety. Challenges by their nature often entail fears and contemporary fears may not be only of physical harm but of psychological annihilation or humiliation, for instance as often experienced by the challenges and risks involved in the public performance of skills. Many life crises, from the first step the child makes to his or her first date, can be seen as conflicts of overcoming anxiety. Their attempted resolution creates the learning experience for future skills and confidence in dealing with the demands of the environment.

Avoidance-avoidance conflict is often regarded as the most deleterious of conflict paradigms, since behaviorally, the organism cannot avoid punishment. Some conflicts can be of relatively minor significance: hard work or the prospect of exam failure. Other conflicts of this type can, however, have serious effects: a monotonous yet stressful work situation against the demeaning prospect of being out of work. (The situation is not helped by accumulating evidence of a rising incidence of myocardial disorders with this type of job.) The conflict can be one between physical harm and psychological damage. Consider the anxiety evoked by and the consequences involved in the choice between risking death and physical harm in war or alternatively refusing to take arms in war and undergoing group rejection and imprisonment.

Nonresolution of all types of conflict in terms of an outcome in making behavioral choice (or at least some form of behavioral action) necessarily implies stress. Stress, independent of whether or not it is of a chronic nature, can produce a variety of behavioral and, as will be discussed later, physiological symptoms.

Whereas the aforementioned conflict analysis can be regarded as a contribution from Gestalt psychology, the behavioral approach using animals resulted in some exact lawful relationships. For instance, in observations of animal behavior, whether in the laboratory or in a natural setting, one may speak of conflict between two incompatible types of behavior if tendencies for these two behaviors are simultaneously present.

An approach-approach conflict involves two tendencies in conflict approaching two different objects some distance apart, which implies that the incompatibility is a physical one. Here, the animal may reach a point in between where there exists a balance between the tendencies to be drawn to each object. The position of this point will be unstable as the tendency to approach either goal increases with its proximity. Any departure from the point of balance toward one goal increases the

tendency to approach the other goal with a concomitant decreased tendency to approach the other.

In avoidance-avoidance conflict, an animal is confronted by two objects it attempts to avoid. The tendency to avoid either goal is likely to increase with its proximity. Therefore, any movement toward either object is then likely to result in a return to the point of balance.

While behavioral psychologists initially studied these situations in terms of animal behavior, they eagerly sought parallels in humans. The Russian psychologist I.P. Pavlov described the behavior of his dogs when they were unable to discriminate between competing but similar stimuli as a basis for choosing one of them. He coined the term *experimental neurosis* to describe how they yelped, bit aggressively, or lay down and gave up the task. Many years later, the American psychologist, Martin Seligman, focused on behavior in the avoidance-avoidance paradigm and described a condition he termed *learned helplessness*. Seligman's dogs, on successively receiving electric shocks at whatever end of the cage they chose to move to, finally gave up in their efforts to avoid the shocks and became passive and behaved as if they were resigned to their fate. This passivity continued even when the experimental paradigm changed and the active behavior of the animal would have removed it from the noxious stimulus. Theoretically, the learned helplessness condition assumes altered responding in at least three major categories of behavior: emotional, motivational, and cognitive. Seligman and his coworkers assume parallels here with the kind of reactive depression in humans that results from the carminative effects of negative life events. By this account, one develops the strategy of giving up in the face of apparently irresolvable conflict, becomes depressed, and loses the belief that own actions can change outcomes. This simple observation has become the cornerstone of a group of therapeutic approaches known as cognitive therapy. The underlying principle here is to teach the human patient alternative ways of viewing his environment, create new choice situations, and thereby encourage certain activities that may lead to positive reinforcement, either in purely behavioral or in conceptual (cognitive) terms.

Another motivational behavior concerns fear and anxiety as a learned drive or secondary drive in which the first stage is shock fear and the second concerns the signs of fear. Fear or avoidance behavior becomes an acquired drive in its own right. In a classic experiment by Dollard and Miller, rats learned to work hard at pedal pressing for the 'reward' of being released from a cage they associated with electric shocks. Dollard and Miller regarded the dependency effects of drugs such as barbiturates as due to their reinforcement of drug using behavior via fear reduction. The behavioral psychologist, Hans Eysenck, emphasized that the persistence of neurotic behavior is due to avoidance of the feared object – by always running away at the first possible opportunity. For Eysenck, it is the first physiological signs of anxiety – increased pulsation of the heart or increased rate of breathing – that induce this behavior rather than fear as a learned drive.

'Conscience' for behavioral psychologists can be, to some extent, explained in terms of conditioning which occurred according to the reinforcement and contingency laws of learning or else through imitation as a basic form of social

learning. In these terms, neurosis is seen then as an internal conflict between conscience and drives.

Motivation was until recent years studied either as a largely conscious process in terms of behavioral psychology or as largely unconscious process in terms of the psychodynamic psychology of Freud and his followers. However in recent years, there has been some rapprochement between these previously opposed views. Nowadays, cognitive behavioral psychology views defense mechanism as forms of copying (or noncopying) skills. Even the concept of *nonintentional motivated behavior* is used to describe motives that influence behavior but which cannot easily be consciously expressed or integrated into the self-concept or role. For instance, a person may deny what is seen by others as obvious flirtatious behavior by maintaining it was only innocent friendliness because this is not part of the person's self-concept.

The Unconscious and Emotional Aspects of Conflicts

Conflicts involve emotion, especially anxiety, which is disturbing to the psychological function and efficacy. There is little doubt that the major contribution of the psychoanalysis, and in particular that of Freud, is in having provided a rich catalog of the means of dealing with anxiety from conflicts between drives and the demands of reality and social learning (the superego). These are the classical *defense mechanisms* originated by the ego as strategies to defend it against the ensuing anxiety. Their common feature is that they result in an initial amelioration of the conflict by distorting the perception of reality to fit in with the needs of the individual. However, some defense mechanisms such as intellectualization can also be seen as adaptive *coping strategies*.

As such, defense mechanisms may be regarded as the strategies an individual learns to enable personality to function in the face of conflict from the environment. Regression, for instance, often operates in situations where efforts at problem solving or conflict resolution, based on current learning, are blocked and frustration results. The individual then regresses to a behavior repertoire, which may have earlier given successful solutions.

In the case of other defense mechanisms such as the denial of the conflict or its projection onto others, the price for their operation is a distortion of reality, and this is often in the long run rather maladaptive. An accurate perception of reality – and one which includes the individual's own motives and behavior – is important from the point of view of successful conflict resolution and ultimately for the harmonious functioning of personality.

Nevertheless, the primary function of defense mechanisms, as the term implies, is to protect the executive function of personality from threat and breakdown. Experimentally, there are techniques which demonstrate how defenses operate. Many years ago, the term *perceptual defense* was coined to describe the higher recognition threshold required for the identification of emotionally loaded words that were rapidly flashed (tachistoscopically presented) on a screen.

To demonstrate this convincingly, one needs techniques that circumvent the problem of response bias. It might be that individuals recognize the emotionally taboo words but

refuse to say them or even admit that they see them. One of the techniques that can demonstrate that genuine subliminal conflicts do occur makes use of the *Stroop effect*. In the Stroop effect, subjects are asked to read the names of various colors that are printed in colors that conflict with the meaning of the word, for instance, the word RED is printed in green. Normally, this interferes with the naming of the colors by delaying the naming response. The Stroop effect can be shown to operate even subliminally, that is below the threshold for conscious recognition. Subjects report they are unaware of when a clinically loaded word is being presented, but its interference on their performance can nevertheless be demonstrated if they were required to say the meaning of color words. Such experiments have led many authorities to reject the notion that perception is unitary and accept that degrees of perceptual processing or at least perceptual registration of events can occur without full conscious awareness.

While some aspects of this approach may be intuitively appealing, the notion of the dynamic manipulation of the contents of consciousness by an all-powerful Unconscious lurking beneath its surface has never been accepted by mainstream psychology. Nevertheless, a concept known as the *cognitive unconscious* has come into vogue on the basis of experimental findings from the study of memory and perception. This notion describes how perceptions and learning can occur without the individual being cognizant of the information involved but nevertheless showing evidence of its acquisition in his or her behavior. There appears to be some form of unconscious monitoring and correctional activity present in routine decision making. The originator of the term the cognitive unconscious, John Kihlstrom, is a coauthor of a recent paper where he has expressed his contemporary view that "the unconscious is not just an oxymoron" but that nonconscious vigilance occurs for nonconsciously occurring biases and automatic compensatory processes can be unconsciously activated. It is well known that the skepticism toward this area owes its origin to the ill-founded claims for the subliminal effects on coca cola selling. Nevertheless, a current review of the literature by Ran Hassin, James Uleman, and John Bargh concludes that the outright dismissal of the claims was unwarranted.

There appears now to be a consensus that information can be cognitively registered in this way as *subliminal perception*. It is often said that there is no evidence for subliminal perception effecting behavior or decision-making processes. Nevertheless, the rapid exposure (at nonrecognition threshold) of emotionally loaded words such as those relating to hostility, rudeness, or politeness and also of concepts relating to behavioral stereotypes such as 'professor' and 'secretary' or 'soccer hooligan' has been shown to have an effect on later behavior. When tested in staged ambiguous situations, it was found that, depending on the nature of the exposure, participants behave more politely or rudely, intelligently or aggressively, etc. than control groups.

Another contemporary reconceptualization of unconscious processes is found in the work of Antoni Damasio. Damasio downplays the role of conscious processes in decision making and maintains that emotions often steer what we believe are our logical decisions. An important concept here concerns *somatic markers*, which means that emotions arise through the influence of bodily processes and the limbic system or deep

structures in the brain and exert subtle effects on us without our knowledge.

Nowadays, the term *dynamic unconscious* is restricted to the older Freudian use, while the terms *cognitive* and the *emotional unconscious* are generally reserved for the contemporary use of the unconscious. Some authorities prefer the more limited term *learning without awareness*. Damasio's concept, often termed the *emotional unconscious*, is seen, at least in a limited sense, to be a neurobiological concession to Freud.

The Bodily Effects of Stressful Conflicts

As has been described earlier, defenses are not just a liability but can also serve, at least in a limited way, a positive function in enabling the individual to cope with conflicts that would otherwise be overwhelming. It is then not surprising that several styles of coping have been identified which show differing relationships to mental and physical health. What are the 'healthy' ways of coping with stress and conflict? There are findings suggesting that both a *goal-oriented* and an *emotionally reactive* way of dealing with threats may be effective strategies. Both these strategies of handling threat show a positive relationship to indices of a healthy immune system. A fourth means of handling conflict is described as *defensive hostility*, which involves projection outward of hostility, related only negatively to psychosomatic health. Indeed, it appears likely that this means of defense, involving as it does the projection of threat and hostility, can hardly be considered to be adaptive as its effect would be most likely self-reinforcing, thereby leading to only more stress and conflict.

The earlier-mentioned studies of the use of various defense mechanisms in handling threat and conflict indicate that stress is not just a mental and behavioral event but also has, in some cases, a profound and lasting physiological impact. Indeed, *stress* can be defined in terms of this threat (where the stimulus can be of an internal or external origin) to the psychophysiological integrity or well-being of the organism. Generally, chronic stress has profound deleterious effects on psychophysiology through increased release of corticosteroid hormones and catecholamines. Under normal conditions, the body is programmed to provide short-term muscular responses to stress situations. The short-term effect of the aforementioned hormones is vasoconstriction, and the increased mobilization of fat and protein provides energy to the tissues in order to meet the demands of conflict. However, these same mechanisms, through the action of the hormones, lead to hypertension and vascular disorders in the long term. In addition, a significant reduction in lymphocyte number and activity occurs, an effect which may explain the now well-established finding that chronic stress leads to increased susceptibility to a wide range of illnesses.

The immune system is almost certainly phylogenetically older than the central nervous system and therefore is accredited as having the primary role of defending the organism against, as well as adapting it to, the environment. Like the nervous system, the immune system is also capable of learning, so much so that the term *psychoneuroimmunology* is now used to describe the study of how various components of the immune system learn to respond to conditioned stimuli. Stimuli

that are consistently and associatively paired with those that previously induced a stress response come also to have a stress-inducing effect when presented alone. The significance of this can hardly be overstated since it implies a direct link between illness, hormones, and psychological factors. Already, two adaptive systems have been described. Allergic reactions can be seen as overreactions analogous to the nervous system's anxiety states, and autoimmune diseases can be regarded as an analogy with depressive states in that the response becomes internalized and self-destructive. To quote the actor-cum-director Woody Allen: "I don't get depressed, I develop a tumor."

The Cognitive and Executive Aspects of Conflict

A concept from cognitive psychology that has been frequently applied to the study of conflict is called *attribution*. The notion of attribution concerns the type of rationalizations that are given by individuals as explanatory hypotheses for their behavior. If the explanation for one's behavior is said to be attributed to environmental causes and therefore beyond the control of the individual, then it is said to be externally determined. This contrasts with the attribution of personal responsibility for behavior whence the individual is said to be internally determined. Research indicates that the type of attributions individuals make predicts behavior. The positive loading of the events that are being attributed are of course crucial. For instance, patients who externally attribute positive events to others (external attribution) and negative events to themselves (internal attribution) are reported to score higher on scales of depression and hopelessness. By contrast, those who persistently attribute positive events to themselves and negative ones to others and to external forces, are more likely to score high on paranoia.

The growth of attribution theory has been a major factor in leading to what is sometimes called the cognitive revolution. This is a mark of progress in psychology which to some extent stands in contrast to the other revolution taking place, that of reducing behavior to neurobiology. The pivotal question is of course 'is the individual a victim of his neurology' or can major changes in our concepts of ourselves and the world lead to changes in behavior and even in our neurological processes. Some leading authorities in the area of emotion, such as clinical psychologist Arne Öhman, are impressed by the findings that argue that the brain appears to respond about a half second before consciousness reports making the decision (SEE LIBET EFFECT) and conclude therefore that the role of consciousness is merely to tidy-up afterward by creating meaning out of what has in fact already been decided by the brain.

Yet, it cannot be denied that the recent history of psychology supports the cognitive revolution by the upsurge of interest in 'consciousness' as an object for scientific study. Max Velmans and Susan Schneider, the editors of a recent volume on *Consciousness Studies*, note how the field, during its 15 years of existence, has increased to 600 000 books and articles. *Consciousness Studies* gives organizing structures such as 'the self' and state of consciousness the individual is in, as having a determining influence on behavior.

The issue, which naturally arises here concerning so-called nonconscious roots of behavior, is the supposition that not

all the contents of experience and perception are represented in the self-concept. Perceptions, which are in conflict with how the person has been taught to view himself and behave, are either reinterpreted in accordance with this or denied and therefore not given verbal identification. They are nevertheless present in the form of so-called nonverbal feelings.

While the principles involved in this process appear similar to those postulated by the psychoanalytic and psychodynamic theories of Freud, the descriptive language is clearly different in terms of being a more humanistic and existential one. Defenses are thus seen as styles for handling perceptual data and arise in order to enable the self, as the organizing principle in consciousness, to cope with the demands of the environment. Defenses arise when the more biological side of personality (temperament) is in conflict with the 'conditions of worth,' that is the conditional demands from the environment governing the expression of love and care toward the individual. These demands lead naturally to the learning of self-concepts, social skills, and roles but, in doing so, lead also to the dissociation of the incongruous, nonaccepted self-experiences that are in conflict with the learned role.

How can this approach deal with the problem that has beset psychoanalysis: the dubious ontological status of the unconscious? If one follows the phenomenology-cum-functionalism of William James and Carl Rogers, the solution may be to simply accept that consciousness exists in many different forms. Some of these are dissociated from one and another, and the various forms may utilize different languages of symbolic representation for memories and ranges of experiences. Supporting this conceptualization are the now well-established findings relating to state-specific memories. The study of altered states of consciousness and dissociated states sometimes reveals that these memories are organized as distinct and conflictual self-representations.

According to this view, conflict and anxiety can then have a positive function since there is assumed to be a force for growth existing as a biological principle. This drive operates during the opportunity for change – in a crisis or in a therapeutic context – and strives after creating the reintegration of experiences and split-off parts of the self. Indeed, dissociated and altered states of consciousness have often been claimed to be associated with creative problem solving and therapeutic change.

For many years, a medicopsychiatric view dominated clinical psychology, and the findings from behavioral research had an explanatory input limited to anxiety and phobic states. Even psychoanalytic categorizations were based on an essentially nineteenth century Kraepelinian system of medical classification. During the 1980s, although retaining the spirit of the Kraepelinian system of category thinking, there has been an attempt to produce a theory-free system known as DSM-IV. While the scientific validity of DSM-IV has been severely criticized, it is nevertheless generally agreed that the system has incorporated a more sophisticated view of how predispositional and situational factors interact. The consensus view among psychologists appears to be that long-term conflicts in the form of stress-related events – so-called *life events* – interact with biological (predispositional) factors to produce a variety of psychotic and neurotic disorders.

In dealing with conflicts and ensuing stress, research has identified that there are some basic coping skills. Being

successful at skilled performance, however, means not only learning from one's own experience and gaining positive feedback from successes, but also being inspired and learning from others and then becoming fully involved in meeting the challenge. It is this combination of factors which Albert Bandura calls *self-efficacy beliefs* and enables people to overcome obstacles and reach goals. Bandura was one of the first to emphasize that the most effective source of learning in mammals and humans is not that of the classical conditioning but that of *imitation and observational learning*.

Positive Psychology

A refreshingly new approach which incorporates much of the aforementioned points has enabled clinical and health psychology to build an alternative model to the medical one for the study of mental disturbance. This is known as *positive psychology*. Positive psychology approach combines the behavioral work on cognitive functioning with approaches that were more phenomenological in using terms like self-concept and self-esteem. Some of the research findings challenge the traditional ways of seeing mental illness. For instance, those of the English psychologist Richard Bentall and his coworkers give us good reason to question the unity and homogeneity of such disorders as schizophrenia and neurotic disorders. Their findings provide an alternative way of viewing these disorders to that of illness, in terms of degrees of cognitive dysfunction arising from biological predispositions and life events. By having a knowledge of biological factors such as temperament and important life events from early attachment onward, one can then see how certain patterns of dysfunction in beliefs, thought processes, and emotional expression – what one sees as ‘symptoms’ – can come to develop.

Self-esteem and self-concepts are clearly part of the executive functioning of the organism and can be seen as closely connected to the process of attribution. As mentioned earlier, by using these concepts, it has been shown that patients with depressive ‘symptoms’ have excessive *internal attributions* in the form of being fixated on negative events relating to themselves and will tend to interpret events to conform to their preconceived self-concepts. In contrast, deluded and paranoid patients have been found to make excessive *external attributions* in the form of persecutory ideas, perhaps as a defense against impending depression and low self-esteem, by blaming others for negative events. Generally speaking, these types of attributions become the foundation for an optimistic versus a pessimistic lifestyle. A pessimistic lifestyle is an important predictor of later illness.

Positive psychology is, however, not so much about illness per se but about our higher and healthy motives: the need for meaningfulness, happiness, and wisdom. In looking at what seems to be a healthy functioning style, a series of such relationships has recently been found by Trevor Archer and his colleagues at Gothenburg University. They discovered that an optimistic lifestyle and so-called *intrinsic motivation* which is the enjoyment of activities for their own sake rather than for external reward, together with the expression of positive emotions, were all closely related and formed a personality pattern of healthy functioning.

The recent history of clinical psychology can be said to follow the career of one of its most esteemed leaders, Martin Seligman, who began his work as a behavioral psychologist contributing to the concept of learned helplessness. Seligman moved on to become one of the founders of cognitive psychology focusing on attributional styles and now finally is the major proponent of ‘positive psychology’ with its emphasis on existential problems and authentic happiness in life. This reflects how the old divisions between behavioral, psychoanalytic, and humanistic psychology have begun to fade away. Behavioral psychology used to have the dictum: change behavior and you change the way of seeing things. For psychoanalysis, it was first insight and then change. While the aphorism for today's cognitive psychology is change the person's constructs and you can change his behavior, it is probably true to say that in practice, most psychologists use all the three means where and when appropriate.

The research behind this change has led to tangible effects and the current interest in Europe in *cognitive behavior therapy (CBT)* is one outcome of this. Following the recent evaluation of antidepressive medication, showing this to be a costly and largely ineffective treatment, there is now government-empowered support for providing the public with cost-effective evidence-based treatment. CBT tends to be the most favored among the various therapies, although there is no decisive evidence for its superiority over the more personal and dynamic forms of therapy. Nevertheless according to leading psychologist and governmental advisor, David Clark, the UK government plans during the next 3 years to educate 3600 psychological therapists under the supervision of clinical psychologists with the aim of providing a treatment for the 900 000 citizens who are estimated to need it for the treatment of anxiety and depression.

The enormous interest in consciousness and its role in cognitive processes mentioned earlier may be the reason why there is now an otherwise unlikely allegiance between Zen Buddhism and behavioral psychology teaching ‘mindfulness’ meditation. *Mindfulness* is the focusing of attention on the flow of immediate experience in the here and now along with openness, acceptance, and curiosity to its content. *Mindfulness-Based Cognitive Therapy* is aimed at breaking habitual thought and reaction patterns and expanding awareness to include feelings and bodily reactions that would not otherwise be attended to: in short, access to otherwise nonconscious processes. Clearly, the current focus of psychology gives us reason to modify Dewey's axiom, which we began with, as being a simplification. Humans may not be very effective as achieving it, but they do seek meaningfulness.

Resolving Social Conflict

While it is a long way from the study of rat behavior and the psychoanalytic couch to the resolution of internal and group conflict, already during the 1960s psychologists were becoming interested in the application of theories about group identity to social behavior. This will be covered more fully in other articles, but some landmarks are worth noting.

Muzafer Sherif and his coworkers carried out what is now regarded as a classic experiment in the resolutions of group

conflict. Working with boys at a summer camp, the researchers followed the process of how group identity and rivalry arose. Different codes of behavior evolved and with it conflict and opposition. Open hostility developed between the groups. At this stage, various techniques for intervention and conflict resolution proved successful. One of these was the formation of superordinate goals that required the cooperation of both groups in order to resolve an externally imposed threat. Another was the introduction of methods to promote interaction and contact between the groups.

There are a few examples of psychological intervention in real group conflict. One well-known example, albeit almost on an anecdotal scale, was the successful involvement of Carl Rogers in facilitating openness and communication between members of a small group of Catholics and Protestants in Northern Ireland. Rogers relied on creating a therapeutic atmosphere of empathy, acceptance, and warmth.

For many years, practical solutions to racial and group conflict were influenced by Gordon Allport and his suggestions for reducing conflict by increasing contact between groups and focusing on similarities between individuals. However, with the recent development of the approach known as *Social Identity Theory*, the emphasis has now shifted away from the individual toward dealing with intergroup differences and promoting an understanding of the need to maintain these in the face of threat and discrimination.

Another major contribution came from social psychologist Irving Janis who described how group decisions often make systematic errors of judgment which he called *groupthink* and *mindguarding*. Groupthink refers to the pressures in the group to maintain an illusion of unanimity, and mindguarding refers to the efforts to maintain solidarity and protect the leader from stress and contradicting viewpoints. Irving recommended the use of a 'devil's advocate' as a counter to groupthink.

Other psychologists such as Max Bazerman have extended their expertise to the area of negotiations. Bazerman describes the common mistakes that negotiators make such as being locked in and committed to one perspective, seeing the others' gains as their losses, and being overconfident of success. Although a strong case can be made for the involvement of a psychologist in international conflict, this seems to rarely occur. However, one psychologist who has made an important contribution in the global context is Albert Bandura who was mentioned earlier in the context of self-efficacy and observational learning. Bandura now works with the film media in the entertainment-education area, producing films in order to encourage social change. These are films intended primarily for third-world countries addressing major issues such as overpopulation, genital mutilation, the education of women, and

literacy. Role models, in the form of highly admired actresses and actors, and plot-lines are used to debunk false beliefs and encourage people's beliefs about their own efficacy.

There is a classical quotation from the days of behaviorism by the well-known psychobiologist, Frank Beach: "Psychology is the study of the white rat and the college sophomore." Clearly, the aforementioned research shows that today's psychology has come a long way and now is a dynamic and reality-relevant subject.

Clinical Assessment

E Gambrill, University of California, Berkeley, CA, USA

© 2012 Elsevier Inc. All rights reserved.

Glossary

Antecedents Events that immediately precede behavior and influence its frequency.

Behavior Any measurable or observable act or response. Behavior is defined broadly in some perspectives to include cognitions, feelings, and physiological reactions which, although they are not directly observable, are defined so that they can be measured.

Behavioral Approaches to understanding and altering behavior in which learning histories and current environmental contingencies of reinforcement and behavior repertoires are considered. These approaches differ in the degree of attention devoted to thoughts (e.g., cognitive-behavioral compared to applied-behavior analysis).

Clinical inferences Assumptions about causes and remedies regarding problems.

Cognitions Beliefs, schemas, self-statements, attributions.

Cognitive approach Attention is devoted to thoughts.

Cognitive-behavioral approach Attention is devoted to thoughts as well as behavior.

Consequences Events that follow behavior and influence its frequency.

Contextual (ecological) assessment Attention is devoted to individual and environmental factors. This is an integrated appeal.

Contingencies Relationships between behaviors and the events that follow (consequences) and precede (antecedents) them.

Evidence-based practice A process and philosophy designed to forward effective integration of clinical, evidentiary and ethical concerns.

Interpersonal approach There is a focus on interpersonal relationships.

Psychodynamic Approaches to understanding behavior in which unconscious mental and emotional processes (e.g., motives, defenses, conflicts) related to past and current experiences are emphasized for example in discussing moral conflicts.

Reliability The extent to which a measure is stable over time (stability). There are other kinds of reliability such as interitem reliability.

Transdiagnostic approaches Approaches emphasizing similarities across 'disorders.'

Validity The extent to which a measure measures what it was designed to assess. There are different kinds of validity (e.g., predictive, content, concurrent, construct).

Clinical assessment involves the clarification of presenting concerns and related factors including identification of outcomes that will be focused on. It should offer guidelines for selection of intervention methods. Assessment lays the groundwork for selecting plans and should indicate how likely it is that hoped-for outcomes can be attained. The likelihood may be slim when needed resources are not available or when problem-related circumstances cannot be rearranged. Assessment should indicate what factors influence clients' options. It should suggest 'leverage points' for pursuing valued outcomes. Interrelated goals (sometimes referred to as case formulation or case conceptualization) include: identifying and clarifying presenting concerns, detecting characteristics of clients and their environments that influence those concerns, interpreting and integrating data collected, and, in collaboration with the client, selecting outcomes to focus on. Assessment should offer clients more helpful views of problems and a useful vocabulary for describing concerns and options. Decisions must be made about what data to collect, how to gather this, and how to organize it. This phase is an ongoing process in which assumptions are altered as needed in response to new information, such as degree of progress.

The assessment methods used differ because of differences in theoretical perspectives which influence the kind of data

collected, how it is gathered and the uses and functions of these data. Carrying out an assessment is like locating the pieces of the puzzle. Certain pieces of the puzzle are sought rather than others depending on the clinician's theoretical orientation and knowledge, and puzzle completion may be declared at diverse points. Related decisions and inferences differ in how closely they attend to related empirical findings. Issues of practicality may limit evidence available. Data are sought that are useful, reliable, and valid. Specialized knowledge may be required and critical thinking skills are needed to weigh the value of evidence and examine the soundness of assumptions. Although decisions must typically be made on the basis of incomplete data, without a sound assessment framework, opportunities to gather useful data may be lost and ineffective or harmful plans suggested. Collecting irrelevant data wastes time and money and increases the likelihood of incorrect decisions. Assessment methods can be harmful as well as helpful. Limitations of and related potential adverse consequences of assessment/diagnostic methods, such as anxiety and worry because of a high rate of false positives, are often *not* candidly acknowledged. Even when the decision to use a test is well argued, there may be risks which should be clearly described to clients. Hiding potential harm and inaccuracy of assessment methods are common in the helping professions.

There is general agreement that an individualized assessment which considers cultural differences should be conducted. This does not mean that this is indeed done and practice perspectives differ in what is focused on. Individualized assessment avoids the client uniformity myth in which clients (or families, or groups) are mistakenly assumed to be similar. Behavior consists of different response systems, which may or may not be related depending on each individual's unique history (1) overt behavior (e.g., avoidance of crowds) and verbal reports (verbal descriptions of anxiety); (2) cognitions (thoughts about crowds); (3) physiological reactions (e.g., increased heart rate when in crowds). Each person may have a different pattern of responses in a situation. Only through an individualized assessment can these unique patterns and related situations be discovered. Suicidal potential should be assessed as relevant. Recognizing the signs of pathology is important anytime. This would be helpful in understanding what can be accomplished and how it can be accomplished. A clear mutual agreement between clinicians and clients about the focus of helping increases the likelihood of client engagement.

Forming a conceptualization of concerns, one that is shared by both the clinician and the client that will be helpful in attaining hoped-for outcomes, is an integral aspect of assessment. The kind of conceptualization suggested will depend on the theoretical orientation of the clinician. It is important to arrive at a common view of hoped-for-outcomes and how to attain them. This common view is a motivating factor in that, if clients accept it and if it makes sense to them, there will be a greater willingness to try out interventions that flow from this account. Mutually agreed-on views are fostered in a variety of ways, including questions asked, assessment methods used, and rationales offered. Focused summaries help to put material together within a new conceptualization. Identifying similar themes among seemingly disparate events can be used to suggest new views. High levels of facilitating relationship skills are associated with success and thus vital to develop and use.

The Guiding Role of Practice Theories

How presenting concerns are structured is a key part of clinical decision-making. Assessment frameworks differ in what is focused on, the kinds of assessment methods used, and how closely assessment is tied to selection of intervention methods. Preferred practice theories influence what clinicians look for and what they notice as well as how they process and organize the data collected. Theories favored influence beliefs about what can be and is known about behavior and how related knowledge can be developed. Theories differ along the following dimensions:

- Unit of concern (individual, family, community, society).
- Goals pursued (e.g., explanation and interpretation alone or understanding based on prediction and influence).
- Clarity of goals pursued.
- Criteria used to evaluate the accuracy of explanations (e.g., consensus, authority, scientific).
- Range of problems addressed with success.

- Causal importance attributed to feelings, thoughts, and/or environmental factors.
- Range of environmental characteristics considered (family, community, society).
- Causal importance attributed to biochemical causes.
- Attention devoted to past experiences.
- Degree of optimism about how much change is possible.
- Degree to which a perspective lends itself to and encourages empirical inquiry (finding out whether it is accurate).
- Degree of empirical support (evidence for and against a theory).
- Attention given to documenting degree of progress.
- Ease with which practice guidelines can be developed.
- Degree of parsimony.

Frameworks differ in the attention given to observation of interactions in real-life settings, in whether significant others (those who interact with and influence clients) are involved, and how directive clinicians are. They differ in the degree of attention paid to cognitions (thoughts), feelings, environmental characteristics (such as reactions of significant others), and biomedical factors. Different frameworks are based on different beliefs about the causes of behavior. Beliefs about behavior, thoughts, and feelings, and how they are maintained and can be changed influence what data are gathered and how data are weighted and organized. Presenting concerns can be viewed from a perspective of deficiencies (e.g., psychiatric labels) or from a contextual view in which both personal and environmental factors are attended to. For example, a key point of feminist counseling is helping clients to understand the effects of the political on the personal, both past and present. Frameworks that focus on psychological characteristics of individuals are based on the view that behaviors are influenced mainly by such characteristics. There is a focus on interiors – on understanding private phenomena believed to cause overt behavior such as mental schemas and dispositions. In interactional perspectives, attention is given not only to the individual but to people with whom he or she interacts. Interactional views differ in how reciprocal the relationship between the individual and the environment is believed to be and in the range of environmental events considered.

In contextual, ecological perspectives, individual, family, community, and societal characteristics (political, social, and economic) are considered as they may relate to desired outcomes. A contextual framework decreases the likelihood of focusing on individual pathology (blaming the victim), and neglecting environmental causes and resources. Practice perspectives that focus on individual causes of personal problems may result in 'psychologizing' rather than helping clients. The *Diagnostic and Statistical Manual of Mental Disorders* (2000) (DSM) published by the American Psychiatric Association encourages a focus on individual pathology, listing hundreds of behaviors as potential indicators of mental disorders (illnesses). The fifth edition will include even more. Transdiagnostic approaches focus on what is common across a variety of disorders. Assessment frameworks differ in the extent to which they take advantage of empirical information about behavior including factors related to client concerns, and the accuracy of different sources of data.

Sign and Sample Approaches: Diagnosis and Assessment

In a sign approach to assessment, observed behaviors are viewed as indicators of more important underlying (and unobserved) personality dispositions (typically of a pathological nature) or traits. Traits can be defined as a general tendency to react in consistent and stable ways. Examples are 'aggression' and 'extraversion.' Inherent in sign approaches, is the assumption that observable behaviors are the outward signs of some underlying process which must be altered to bring about any lasting change. For example, a clinician may conclude that a child who has difficulty concentrating on his school work and sitting in his seat is hyperactive. A focus of change efforts on the behavior itself, according to this model, would not succeed, because no change has supposedly been brought about in underlying causes. The underlying hypothetical constructs are viewed as of major importance in understanding and predicting behavior. Such dispositional attributions shift attention away from observing what people *do* in specific situations to speculating about what they *have* or are. In the DSM, behaviors are assumed to equate with mental disorders. This classification system has come under increased criticism for example for ignoring contextual factors related to client concerns and pathologizing every day problems in living such as common (mis)behaviors on the part of children.

The interactions between wishes, anticipated threats if wishes are expressed, and the processes used to cope with or defend against conflictual situations, are of interest in psychodynamic frameworks. Important elements in such processes are believed to be beyond conscious recognition of the individual experiencing them even when they may be recognized or inferred by others. The concepts of developmental stages and 'mechanisms' (psychological processes such as defense mechanisms) are central concepts. There is a focus on interiors. Defensive aims, processes, and outcomes are of interest. Defense mechanisms include suppression, undoing, repression, role reversal, projection, and regression. The defenses are believed to be heightened under conditions of high emotion, stress, and conflict. Motives include the wish to avoid unpleasant, overwhelming, or out-of-control states. Some unconscious processes anticipate such outcomes. Other aspects of psychoanalytic approaches include an emphasis on verbal reports concerning early histories and efforts to alter inner processes by verbal means. Compared to behavioral assessment, less attention is devoted to environmental variables that may influence behavior because of the assumed core relevance and stability of underlying dispositions. There are different kinds of psychodynamic assessment frameworks. For example, there are variants of object relations theory, each of which may have a somewhat different approach to assessment. In object relations theory, the concepts of mirroring and self objects are key ones. Attention is given to internal mental representations of the self and significant others. The term 'object relations' refers to the interplay between the images of self and others. Ego psychology emphasizes identification and support of strengths and working within the 'defenses' rather than breaking them down. Proponents consider resistance to change natural and work with and support adaptive strengths.

Defense mechanisms, such as rationalization of actions and projection of feelings onto others are identified but not necessarily discussed.

Behavioral assessment involves a sample approach. In a sample approach, direct observation of behavior in real-life settings or, if this is not possible, in situations that resemble these, is valued. Labels are used as summarizing categories rather than as terms indicating some underlying mental disorder. Unlike in sign approaches where the cause of behavior is assumed to be underlying dispositions, the cause of behavior is assumed to lie largely in environmental contingencies. Behavioral frameworks differ in the attention devoted to thoughts and environmental contingencies. Differences in focus are so marked that they have resulted in the formation of different journals, societies, and names (e.g., 'cognitive,' 'cognitive-behavioral,' 'applied behavior analysis'). Differences in emphasis are related to the role attributed to thoughts in influencing behavior. This role varies from a causal to a mediating role. In the former, reflected in cognitive and cognitive-behavioral frameworks, thoughts are presumed to play a key role in creating feelings and behaviors. In the latter, reflected in applied behavior analysis, thoughts are assumed to influence feelings and behavior in a mediating (not causal) manner. It is assumed that one must look to past and present environmental contingencies to account for both thoughts and feelings. It is assumed that feelings and thoughts are (covert) behaviors which themselves require explanation.

In cognitive-behavioral methods, attention is devoted to thoughts as well as behaviors. Thoughts of interest include attributions for behavior, feelings, and outcomes, negative and positive self-statements, expectations, and cognitive distortions. Attention is devoted to identifying the particular kinds of thoughts that occur in problem-related situations including related 'schema.' Cognitive-behavioral approaches differ in their assumptions about the kinds of thoughts that underlie behavior. However, all share certain assumptions such as the belief that individuals respond to cognitive representations of environmental events rather than to the events per se. It is assumed that learning is cognitively mediated and that cognition mediates emotional and behavioral dysfunction. In applied behavior analysis, environmental contingencies are focused on. A contingency analysis requires identification of the environmental events and occasion that maintain behavior. There is an interest in describing the relationships between behavior and what happens right before and after as well as 'met contingencies' – the relationships between cultural practices and the outcomes of these practices. There is an emphasis on current contingencies. Attention is directed toward the change of 'deviant' environments rather than the change of 'deviant' client behaviors. There is an interest in identifying functional relationships. A behavioral analysis includes a description of behaviors of concern as well as evidence that specific antecedents and consequences influence these behaviors; it requires a functional as well as a descriptive analysis.

Although there are differences, all behavioral approaches share many characteristics that distinguish them from sign approaches. Assessment is an ongoing process in behavioral assessment. This contrasts with some traditional approaches in which assessment is used to 'diagnose' a client in order to

decide on treatment methods. What a person does is of interest in behavioral approaches rather than what she has. Behavior is of great interest, especially the behaviors of individuals in real-life contexts and those with whom they interact. Identifying variables that influence the frequency of behaviors of interest including positive alternatives to behaviors to be decreased is a key assessment goal. Behavior is assumed to vary in different contexts because of different learning histories and different current contingencies as well, for example, different levels of deprivation and fatigue.

The focus on behavior has a number of implications for assessment. One is the importance of observing people in real-life contexts whenever feasible, ethical, and necessary to acquire helpful data. A range of assessment methods is used including observation in real-life settings as well as role plays. Multiple assessment methods are also called for because of the lack of synchrony in overt behavior, physiological reactions, cognitions (thoughts), and feelings. Assessment and treatment are closely related in a behavioral model. It is assumed that assessment should have treatment utility. There is an emphasis on the use of valid assessment methods. The principles of behavior are relied on to guide assessment and intervention. There is a preference for limited inference and a focus on constructing repertoires (on helping clients to acquire additional knowledge and skills that will increase opportunities for reinforcement). Clients are viewed in terms of their assets rather than their deficiencies. The preference for enhancement of knowledge and skills requires a focus on behaviors that are effective in real-life contexts. In a task analysis, the specific behaviors that are required to achieve an outcome are identified. For each step, performance is clearly described as well as the conditions in which it is expected to occur.

Some Important Distinctions

The form of a behavior (its topography) does not necessarily indicate its function (why the behavior occurs). Identical forms of behavior may be maintained by very different contingencies. Just as the same behavior may have different functions, different behaviors may have identical functions. The distinction between motivational and behavioral deficits is also important. If a desired behavior does not occur, this may indicate either that the behavior exists but is not reinforced on an effective schedule or is punished (a motivational deficit) or that the behavior is not present in the client's repertoire (a behavior deficit). Motivational deficits are often mistaken for behavioral deficits. Motivational and behavioral deficits can be distinguished by arranging conditions for performance of a behavior. For example, clients could be requested to role play behaviors and asked whether similar or identical behaviors occur in other situations. Behavior surfeits are often related to behavior deficits. For example, aggression on the part of a child may be related to a lack of friendship skills. It is also important to distinguish response inhibitions from behavior deficits. Emotional reactions such as anxiety may interfere with desired behavior.

Past History

Although the past is viewed as important in influencing current behavior in just about all perspectives, assessment frameworks

differ in how much attention is devoted to the past and what is focused on. Past experiences are a major focus in psychodynamic frameworks. Knowledge about past circumstances may be of value when it is difficult to identify current maintaining factors. Information about a client's past may provide valuable information about unusual histories related to concerns. An understanding of how problems began can be useful in clarifying the origins of what seem to be puzzling reactions. New ways of viewing past events may be helpful to clients. Information about a client's past may help clients to understand the source of current reactions. Demographic indicators about a client's past behavior in certain contexts may be better predictors of future behavior than personality tests or clinical judgments.

Information about the past offers a view of current events in a more comprehensive context. Major areas include medical history, educational and work history, significant relationships, family history, and developmental history. Helpful coping skills may be discovered by finding out what clients have tried in the past to attain valued outcomes. Research concerning autobiographical memory suggests that memories change over time, making it difficult to know whether reports are accurate. From a psychodynamic perspective, accuracy would not be an issue. Rather, the client's memories of events, whether accurate or not, are the substance of import. It is assumed in fact that memories may be distorted by unconscious motives/conflicts and so on. Excessive attention to past troubles may create pessimism about the future and encourage rationalizations and excuses that interfere with change, especially if this is not fruitful in selecting effective intervention plans.

What About Labels?

The term *diagnosis* refers to accurately identifying the cause(s) of symptoms of an individual. The term *diagnosis* was borrowed from medicine, in which a physician makes a diagnosis of a patient's condition and then recommends a treatment based on this diagnosis. Diagnoses are used as a guide to selection of interventions. Evidence-based diagnosis can be defined as the use of certain symptoms and signs (feeling hot and having a fever as determined by a thermometer) to identify an underlying condition (a bacterial infection). Such a diagnosis is evidence-based in two senses (1) the signs and symptoms accurately indicate the underlying condition and (2) accurate identification of the underlying condition points to an effective remedy (e.g., antibiotics). Thus in medicine, we often have both signs (an X-ray) and symptoms (a cough). Is this true of psychological concerns such as depression and anxiety? The answer from psychiatry is yes. It is assumed that symptoms (e.g., anxiety in social situations) reflect an underlying disorder (or dysfunction). But what signs do they use? Here, signs are observed by the examiner. Diagnosis and assessment are not either/or endeavors. Providing a diagnosis for clients is a requirement for third-party payment. This does not mean that clinicians cannot or should not carry out an evidence-informed contextual assessment describing, for example, personal and environmental factors that create risks and contribute to resilience.

Labels are used in assessment in two main ways. One is as a shorthand term to refer to specific behaviors. The term unmanageable may refer to the fact that a student often gets

out of his seat and talks out of turn in class. A teacher may use the label 'hyperactive' as a summary term to refer to these behaviors. With psychiatric labels, the label connotes more than a cluster of (mis)behaviors. It involves additional assumptions about the person so labeled. The *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV) includes hundreds of labels. Methodological and conceptual problems connected with the use of psychiatric labels include lack of agreement about what label to assign clients and lack of association between a label and indications of etiology or what intervention will be effective. Indicators on which psychiatric labels are based are vague, say little about positive attributes, potential for change, and change that does occur. Both trait and diagnostic labels offer little detail about what people do in specific situations and what specific circumstances influence behavior. Some behaviors may appear 'trait-like' in that they are similar over time and situations because of similar contingencies of reinforcement. Degree of consistency should be empirically explored for particular clients and behavior rather than assumed.

Labels are classifications and are thus subject to all the ways in which classifications are wrong (e.g., under or over inclusion). The classification system may be faulty in not accurately distinguishing between different 'syndromes,' that is, there may be 'boundary' problems. Clients may be given an incorrect label (it does not really describe them) or a label that does accurately describe them may not be used and valuable services may be withheld. Labels can obscure important individual variations among people and thus encourage the 'patient uniformity myth.' Use of labels may overlook cultural differences and encourage 'the psychopathologist's fallacy – the belief that because a child has been brought in as a patient, there must be something wrong with him or her.' We may start to think of a person as the label he or she is given. We may think our work is over when we give a person a diagnostic label rather than realizing it is just beginning in relation to carrying out a contextual assessment. Having a label may result in seeking out characteristics that complement the label.

Acceptance of a psychiatric label may prematurely close off consideration of promising options. The tendency to use a binary classification system (people are labeled as either having or not having something, e.g., as being an alcoholic or not), obscures the varied individual patterns referred to by a term. Psychiatric labels have been applied to an ever-increasing variety of behaviors viewed as 'mental illnesses.' Critics of the DSM highlight the consensual nature of what is included (reliance on agreement rather than empirical criteria) and the role of political and economic influences in its creation. Some writers argue that psychiatric classification systems trivialize human problems in living and encourage blaming victims for their plights rather than examining and altering the social circumstances that are often responsible. For example, they argue that they direct attention away from political, social, and economic conditions related to expected gender roles and focus on individual deficiencies. Many scholars argue that labels, such as 'mental illness,' are used for social control purposes and often result in harming rather than helping people. The American Psychiatric Association claims that its classification system is based on scientific evidence. However critiques raise doubts about these claims and discuss the role of political and

economic considerations in the creation and 'selling' of the DSM and document reliability and validity problems with this system. These include the consensual nature of what is included (agreement among individuals is relied on rather than empirical criteria), lack of agreement about what label to assign clients (poor reliability) and lack of association between a diagnosis and indications of what plans will be effective.

Although they may sound sophisticated, too often labels offer few if any guidelines about what to do to resolve problems. In the introduction to the DSM, it states that diagnostic labels say nothing about etiology nor offer guidelines for selection of service. Neither trait nor diagnostic labels offer enough detail about what people do in specific situations and what personal and environmental events influence their behaviors to be of value in clarifying problems and related factors. The individual variability of behavior is overlooked, resulting in lost opportunities to discover unique relationships between a client's behavior and his or her environments. Dispositional attributions shift attention away from observing what people do in specific situations to speculating about what they might do or have done.

Labels that are instrumental (they point to effective interventions) are helpful. Failure to use labels that are informative may prevent clients from receiving appropriate intervention. Labels can normalize client concerns. Parents who have been struggling to understand why their child is developmentally slow may view themselves as failures. Recognition that their child has a specific kind of developmental disability that accounts for this can be a relief.

A Contextual Evidence-Informed Assessment

A contextual assessment includes a clear description of hoped-for-outcomes and related factors and description of what a person can do and cannot do, what he or she can learn to do, and what is expected of him or her, as well as environmental factors that influence problem-related behaviors and positive alternatives. It is assumed that only if complaints are clearly described can they be translated into specific changes that would result in their removal. The emphasis on behavior and the influence of environmental contingencies call for the translation of problems into observable behaviors and the discovery of ways in which the environment can be rearranged. Clients are encouraged to recognize and alter the role they play in maintaining problems. For example, teachers and parents often reinforce behaviors they complain about. Assessment is individualized; each person, group, family, organization or community is viewed as unique. Data about group differences do not offer precise information about what an individual does in specific situations and what cues and consequences influence their behavior.

Practice-related research regarding concerns and possible causes and ways to discover them are drawn on. This kind of assessment often reveals that environmental deficiencies contribute to problems such as a low frequency of positive social interactions, lack of recreational opportunities or day care, and low wages. A contextual assessment encourages the description of *processes* rather than the study of *conditions*.

The characteristics of contextual, evidence-based assessment include the following:

1. Individually tailored as needed.
2. Use of assessment frameworks and methods that have been critically tested and found to be of value.
3. A preference for testing inferences.
4. A focus on clients' assets rather than their deficiencies.
5. A focus on the present.
6. Attention to current contingencies in interrelated system levels.
7. A clear description of concerns and related hoped-for outcomes.
8. A preference for observation of important interactions (as ethical, practical) are needed.
9. A clear description of assessment methods.
10. A close relationship between assessment and intervention.
11. Offering high level relationships skills.

A contextual framework decreases the likelihood of errors, such as emphasizing people's deficiencies.

A contingency analysis involves describing the context in which problems occur (i.e., the relationships between behavior in *real-life settings* and what happens right before and after), including alternative behaviors that, if increased, would compete successfully with undesired behavior. Considerable advances have been made in some areas in identifying problem-related contingencies. For example, assessment protocols have been developed to identify the cues and consequences related to self-injurious behavior of children. A *descriptive analysis* involves identification of problem-related behaviors and associated setting, events, antecedents, and consequences. A functional analysis includes altering events identified in a descriptive analysis to determine their actual influence. Implications for assessment of a focus on contingencies include observing people in real-life contexts when feasible, ethical and necessary to clarify problems and their causes. A second is an emphasis on collecting information about individuals. A focus on vague problems may prevent the discovery of related factors. If hoped-for outcomes are not clearly described, it will be difficult to determine the frequency of behaviors of interest or to assess progress. The specific referents to which clients refer when using vague terms (such as *uncooperative*, *immature*, or *aggressive*) may differ.

Sources of Influence

Influences on behavior include other people's actions, the physical environment, tasks and materials, physiological changes, thoughts, genetic differences, and developmental factors. Material and community resources and related political, economic, and social conditions influence options. It is important to obtain an overview of the client's current life as this may relate to problems, including relationships with significant others, employment, physical health, recreational activities, and community and material resources available. Antecedents of behavior, like consequences, have a variety of sources. In addition to proximal antecedents (those that occur right before a behavior), distal antecedents may influence current behavior. Past or future events may be made current by thinking about these.

These thoughts may then influence what we do, feel, and think. *Setting events* are antecedents that are closely associated with a behavior but are not in the situation in which behaviors of concern occur. For example, an unpleasant exchange with a teacher may influence how a child responds to his parents at home. The earlier event alters the likelihood of given reactions in subsequent situations.

Preferred practice theories influence the attention given to various sources. Problems vary in the complexity of related factors. Problems may be complex because clients lack needed skills, have interfering beliefs, or are threatened by proposed changes. Distinguishing between problems and efforts to resolve these will avoid confusion between the results of attempted solutions and effects of the original concern. Expected role behaviors in a certain culture may limit options. Ongoing discrimination against a group may limit opportunities. Clients may lack needed information or skills. A behavior deficit may exist (the client may not know how to perform a given behavior).

Other People/The Nature of the Client's Social Relationships

The influence of significant others in the maintenance of a troubled or troubling behavior should be explored. Behavior occurs in a context. How significant others respond makes up an important part of our environment. Significant others are those who interact with clients and influence their behavior. Examples include family members and staff in residential settings. Significant others are often involved in assessment. For example, in family therapy, family members participate in assessment and understanding relationships among family members is a key part of assessment. Interactions between couples is closely examined in relationship counseling. It is important to assess the nature and quality of the client's social network and social support system. Clients may lack social support such as opportunities for intimacy and companionship or the opportunity to provide support to others. Social interactions may be a source of stress rather than of pleasure and joy.

The Physical Environment

The influence of the physical environment should also be examined. Physical arrangements in residential and day care settings influence behavior. Unwanted behaviors may be encouraged by available materials. For example, toys that are visible to children may distract them from educational tasks. Temperature changes affect behavior as do degree of crowding and noise level. Characteristics of the community in which clients live that may influence complaints and possible intervention options should be assessed. Neighborhood quality influences well-being. For example, children who live in lower quality environments (e.g., there is little play space, housing is in industrial neighborhoods, upkeep of streets is poor) are less satisfied with their lives, experience more negative emotions, and have more restricted and less positive friendship patterns. There is a relationship between the number of nonaccidental injuries to children and the physical conditions of the home which is related to socioeconomic status.

Tasks and Activities

The kind of task confronting an individual may influence the rate of problem behavior. Particular tasks or activities may be high-risk situations for unwanted behavior. Many studies have found a relationship between the kind of task and behavior such as self-injury. Problems may occur because a task is too tedious or difficult or because an individual is uncomfortable or bored, or is told to do something in an unpleasant manner. In these instances, altering antecedents may correct the problem.

Biophysiological Factors

Presenting problems may be related to neurological or biochemical factors. Such factors may place boundaries on how much change is possible. Malnutrition may contribute to behaviors complained of. Discovering biochemical abnormalities only establishes that they are present, not that they cause certain behaviors. Premature acceptance of biophysical explanations will interfere with discovering alternative explanations that yield knowledge about interventions. Biochemical changes may be a result of stress related to social conditions such as limited opportunities due to discrimination. Certain kinds of illness are associated with particular kinds of psychological changes. Drugs, whether prescribed or not, alcohol, environmental pollutants, and nutritional deficiencies may influence health and behavior. Behavior changes may be due to brain tumors. Hormonal changes/imbances may result in mood changes which may be misattributed to psychological causes. On the other hand psychological changes may be misattributed to hormonal changes. People differ in return of diffuse physiological arousal (DPA) to baseline levels. Whenever physiological factors may be related to a problem as, for example, with seizures, depression, fatigue, or headaches, a physical examination should be required. Overlooking physical causes including nutritional deficiencies and coffee, alcohol, or drug intake may result in incorrect inferences. Reviewing use of prescribed medication is ever more important in our overmedicated society.

Cognitive-Intellectual Characteristics

People differ in their intellectual abilities which may influence problems and potential for attaining hoped-for outcomes. Genetic differences have been found in intelligence as well as in temperament and conditioning susceptibility. The importance of assessing what people say to themselves in relevant situations is emphasized in many assessment frameworks. For example, in cognitive-behavioral approaches, clients' internal dialogs (what they say to themselves) and the way this relates to complaints and desired outcomes is explored and altered as necessary. Certain thoughts may occur too much, too seldom, or at the wrong time. A depressed client may have a high frequency of negative self-statements and a low frequency of positive self-statements. In a radical behavioral perspective, thoughts are viewed as covert behaviors to be explained, not as explanations for other behaviors, although it is assumed they can serve a mediating function and influence both feelings and behaviors. The thoughts and feelings in a situation are assumed

to be a function of the contingencies experienced in a particular situation or in situations that are similar or associated in some way. A causal role may be misattributed to thoughts because the histories related to the development of thoughts is overlooked. The role of thoughts can be examined by varying certain thoughts and determining the effects on behavior.

Feelings

When feelings are presented as a problem or are related to a problem, associated personal and environmental factors should be identified. Assessment frameworks differ in the role attributed to feelings and in factors sought to account for them. Some emphasize the role of thoughts in creating feelings. Others emphasize the role of unconscious conflicts and motives related to early childhood experiences. Other frameworks focus on the role of environmental contingencies in influencing emotional reactions. For example, in a radical behavioral approach, feelings are viewed as by-products of the relationships between behavior and environmental events. Feelings can be used as clues to contingencies (relationships between behavior and environmental events). Changing feelings will not make up for a lack of required skills, or rearrange contingencies required to attain desired outcomes.

Cultural Differences

Cultural differences may affect both the concern that clients experience as well as the communication styles and assessment and intervention methods that will be successful. An individualized assessment requires attention to cultural differences that may be related to problems and potential resolutions. Culturally sensitive practice requires knowledge of the values of different groups and their historical experience and how these differences may influence behavior, motivation and view of the helping process. Different groups may prefer different problem-solving styles and have different beliefs about the causes of problems. The norms for behavior vary in different groups. It is important to be knowledgeable about cultural differences that may be mistakenly viewed as pathology. The degree of acculturation (the process of adaptation to a new or different culture) is important to assess. This may influence drop-out rate, level of stress, attitude toward clinicians, and the process and goals that are appropriate. Knowledge of challenges faced and preferred communication styles of people in different generations will be useful.

Developmental Considerations

Information about required behaviors at different ages and life transitions can be helpful in assessment. Knowledge of typical behavior at different times (developmental norms) can be useful in 'normalizing' behavior – helping clients to realize that reactions they view as unusual or 'abnormal' are in fact common. Knowledge about typical changes in different phases of life (e.g., adolescence, parenthood, retirement) allows preventative planning. The following kinds of information will be helpful (1) norms for behavior in specific contexts; (2) tasks associated with certain life situations such as parenthood and retirement; (3) the hierarchical nature of some developmental

tasks (some behaviors must be learned before others can be acquired). Different kinds of norms may be used in the selection of outcomes. Criterion referenced norms rely on what has been found to be required to attain a certain outcome through empirical analysis. Another kind of norm is what is usual in a situation. However, what is usual may not be what is desirable. For example, although it may be typical for teachers to offer low rates of positive feedback to students in their classroom, it is not optimal. The similarities of contingencies for many people at a given age in a society may lead one to assume incorrectly that biological development is responsible. The role of similar contingencies may be overlooked. Acceptance of a stage theory of development may get in the way of identifying environmental factors that can be rearranged.

Resources and Obstacles

Assessment involves identification of personal assets and environmental resources that can be used to help clients attain desired outcomes, as well as personal and environmental obstacles. Personal resources and/or obstacles include cognitive-intellectual abilities and deficiencies, physical abilities and handicaps, social skills and social-skill deficits, vocational and recreational skills, financial assets, and social support systems. Clients differ in their 'reinforcer profile' and in degree of motivation to alter problematic circumstances. Environments differ in opportunities for certain kinds of experiences (see section 'Physical Environment'). Resources such as money, housing, vocational education programs, medical care, or recreational facilities may be unavailable. Limited community resources (such as day care programs, high-quality educational programs, parent training programs) and limited influence over environmental circumstances may pose an obstacle. Child maltreatment is related to poverty. Unemployment is related to substance abuse and spouse violence. Agency policies and practices influence options. Lack of coordination of services may limit access to resources; clients may receive fragmentary, overlapping, or incompatible services.

Sources of Information

Sources of data include interviews, reports on standardized measures, data gathered by clients and significant others (self-monitoring), observation in the interview as well as in role play or in real-life settings, and physiological indicators. A variety of electromechanical aids are available for collecting data such as wrist counters, timers, biofeedback devices, and audio- and videotape recorders. Preferred theories influence selection of assessment methods. In approaches that focus on interiors (e.g., thoughts), self-report within the interview may be the main source of data used. The broader the scope of change efforts, for example school (or district)-wide positive behavior support systems, the wider the range of sources and kinds of assessment data needed.

In behavioral approaches, self-report is supplemented whenever possible by other sources of data such as observation in real-life settings, role play, and/or self-monitoring. (Clients keep track of some behaviors, thoughts, or feelings and surrounding circumstances and consequences in real life.) Some

sources, such as self-report in the interview, are easy to use and are flexible in the range of content provided. However, accuracy varies considerably. The question is: What methods will offer an accurate description of reactions or conditions of concern and related events? Individual differences will influence a client's willingness to participate in a given manner. Accuracy of decisions can be improved by using multiple methods, drawing especially on those most likely to offer accurate relevant data.

Self-report is the most widely used source of information. There are many different types of self-report including verbal reports during interviews and answers on written inventories. Interviews also provide an opportunity to observe clients. Advantages of self-report include ease of collecting material and flexibility in the range of material that may be gathered. Structured interviews have been developed for both children and adults in a number of areas. The accuracy of self-report depends on a number of factors including the situation in which data are collected and the kinds and sequence of questions asked. Helpful questions in assessing the accuracy of self-reports include the following (1) Does the situation encourage an honest answer? (2) Does the client have access to the information? (3) Can the client comprehend the question? (4) Does the client have the verbal skills required to answer questions? Special knowledge and skills may be required when interviewing children. Play materials and storytelling may be used to gather data about children's feelings and experiences.

Measures that have uniform procedures for administration and scoring and that are accompanied by certain kinds of information, such as norms for different groups, are referred to as *standardized measures*. Thousands of standardized questionnaires have been developed related to hundreds of different personal and/or environmental characteristics. Standardized measures are used for a variety of purposes including (1) describing populations or clients, (2) screening clients (e.g., making a decision about the need for further assessment or finding out if a client is eligible for or likely to require a service), (3) assessing clients (a more detailed review resulting in decisions about diagnosis or selection of intervention methods), (4) monitoring (evaluating progress), and (5) making predictions about the likely futures of clients (e.g., in relation to use of a particular intervention method). As always, a key concern is validity. Does a measure assess what it is presumed to assess? Reliability should also be considered. How stable are responses on a measure given a lack of real change? Unstable measures are not likely to be valid. How sensitive will a measure be to change?

Personality tests may be used to collect assessment data. *Objective tests* include specific questions, statements, or concepts. Clients respond with direct answers, choices, or ratings. *Projective tests* such as the Thematic Apperception Test, incomplete sentences test, and the Rorschach Inkblot Test are purposefully vague and ambiguous. It is assumed that each person will impose on this unstructured stimulus presentation unique meanings that reflect his or her perceptions of the world and responses to it. Psychoanalytic concepts underlie the use of most projective tests. These tests focus on assessing general personality characteristics and uncovering unconscious processes. Tests are used not as samples of the content domain (as in behavioral approaches), but as signs of important

underlying constructs. Whereas content validity is of great concern in a behavioral perspective, this is not so within a traditional approach. In fact, items may be made deliberately obscure and vague.

Valuable information can be obtained from data clients collect (self-monitoring). As with any other source of data, not all clients will be able or willing to participate. Observation of relevant interactions in real-life settings offers a valuable source of information. This is routinely used in applied behavior analysis. If observation in real-life settings is not possible, observation in role plays may provide a useful alternative. Physiological measures have been used with a broad array of presenting problems. Measures include heart rate, blood pressure, respiration rate, skin conductance, muscle tension, and urine analysis. Physiological measures are useful when verbal reports may be inaccurate. Certain kinds of desynchronies between verbal reports of fear and physiological measures may provide useful assessment data. Whenever presenting problems may be related to physical causes, a physical examination should be obtained. Failure to do so may result in overlooking physical causes.

Assessing the Value of Data

Assessment methods differ in their accuracy. For example, self-report of clients or significant others may not accurately reflect what occurs in real life. Observers may be biased and offer inaccurate data. General predictions about a person based on tiny samples of behavior in one context are not likely to be accurate, especially when behaviors of interest occur in quite different situations. Measurement inevitably involves error. One cause of systematic error is social desirability; people present themselves in a good light. Important criteria to consider in judging the value of data include (1) reliability, (2) validity, (3) sensitivity, (4) utility, (5) feasibility, and (6) relevance. *Reliability* refers to the consistency of results (in the absence of real change) provided by the same person at different times (time-based reliability), by two different raters of the same events as in interrater reliability, or by parallel forms or split-halves of a measure (item-bound reliability). Reliability places an upward boundary on validity. For example, if responses on a questionnaire vary from time to time (in the absence of real change), it will not be possible to use results of a measure to predict what a person will do in the future.

Validity concerns the question: Does the measure reflect the characteristic it is supposed to measure? For example, does behavior in a role play correspond to what a client does in similar real-life situations? Assessment is more likely to be informative if valid methods are used (methods that have been found to offer accurate information). *Direct* (e.g., observing teacher student interaction) in contrast to *indirect* measures (e.g., asking a student to complete a questionnaire assumed to offer information about classroom behavior) are typically more valid. Validity (accuracy) is a concern in all assessment frameworks; however, the nature of the concern is different in sign and sample approaches. In a sign approach, behavior is used as a sign of some entity (such as a personality trait) that is at a different level. The concern is with *vertical validity*. Is the

sign an accurate indicator of the underlying trait? *Horizontal validity* is of concern in a sample approach. Different levels (e.g., behavior and personality dispositions) are not involved. Examples include (1) Does self-report provide an accurate account of behavior and related circumstances? (2) Does behavior in role play reflect what occurs in real life? Different responses (overt, cognitive, and physiological) may or may not be related to an event. For example, clients may report anxiety but show no physiological signs of anxiety. This does not mean that their reports are not accurate. For those individuals, the experience of anxiety may be cognitive rather than physical.

The *sensitivity* of measures is important to consider; will a measure reflect changes that occur? The *utility* of a measure is determined by its cost (time, effort, expense) balanced against information provided. *Feasibility* is related to utility. Some measures are not feasible to gather. Utility may be compromised by the absence of empirically derived norms for a measure. *Norms* offer information about the typical (or average) performance of a group of individuals and allow comparison of data obtained from a client with similar clients. The more representative the sample is to the client, the greater the utility of a measure in relation to a client. *Relevance* should also be considered. Is a measure relevant to presenting problems and related outcomes? Do clients and significant others perceive it as relevant?

The Social Context of Assessment

Clinical assessment takes place in the context of a helper–client relationship. The nature of this relationship (the alliance) is considered important in all practice frameworks, including providing new conceptualizations and support that decreases demoralization and avoiding negative reactions that damage this relationship, such as excessive negativity (e.g., criticism). Influence of the clinician on the client has been found even in very nondirective approaches. The interpersonal skills of the clinician are viewed as essential for facilitating a collaborative working relationship, validating and supporting the client, and encouraging clients to participate in intervention programs. Great attention is given to the diagnostic value of transference and counter transference effects in psychodynamic therapies and the relationship itself is viewed as the primary vehicle of change. Traditionally, transference has been viewed as a reenactment between the client and the counselor of the client's relationship with significant others in the past, especially parents. Counter transference effects refer to feelings on the part of helpers toward their clients. Transferences are distinguished from therapeutic or working alliances within psychodynamic perspectives.

There is a continuing need throughout assessment to explain the roles and requirements of the client and the counselor, the process that will occur, and the rationale for this. Introductory explanations include an overview of mutual responsibilities and of the framework that will be employed. Because different client behaviors may be required during different phases of assessment and intervention, this 'socialization' is an ongoing task. Behavioral clinicians tend to be more directive than psychoanalytically oriented clinicians. They more frequently give instructions, provide information, and

direct conversation. Clinicians may err by being too directive or too nondirective. Overly directive clinicians may not recognize the need to help clients to explore and to understand their behavior. In contrast, nondirective counselors may err by assuming that self-understanding is sufficient to achieve desired outcomes (when it is not).

Common Assessment Errors and Their Sources

Errors in clinical reasoning account for many errors in clinical practice. Errors may occur in any phase of assessment: (1) detection of characteristics of the client and his or her life situation that are related to problems and desired outcomes; (2) integration and interpretation of data gathered; and (3) selection of outcomes to pursue in order to remove complaints. Errors made in the first two steps will result in errors in the third step. Examples of common errors are noted below. They result in incomplete or misleading assessment. Unexamined speculation may result in misleading accounts. Indoctrination into a certain culture of helping (e.g., biomedical) may contribute to failure to search for well-argued alternative accounts and over reliance on one form of data collection. Not keeping up to date with research regarding options and controversies maintains questionable beliefs. Some errors involve or result in inappropriate speculation – assuming that what is – can be discovered simply by thinking about the topic. Failure to keep up to date with research describing the evidentiary status of different kinds and sources of data as well as factors related to different presenting concerns is a key source of error in clinical assessment (see prior discussion of evidence-informed assessment). Here are examples of common errors:

- Selecting vague outcomes.
- Premature closure – Hasty assumptions about causes (failure to search for alternative accounts).
- Speculating when data collection is called for.
- Searching only for data that confirms a preferred view (confirmation biases).
- Confusing the form and function of behavior.
- Illusory correlation (confusing correlation and causation).
- Using misleading and/or uninformative labels (confusing naming and explaining).
- Confusing motivational and behavior deficits.
- Ignoring base rate data.
- Focusing on pathology and overlooking assets.
- Misuse of resemblance criteria.
- Collecting irrelevant material.
- Relying on inaccurate sources (e.g., anecdotal experience).
- Being misled by superficial resemblances of a client to other clients in the past or to a stereotype.
- The fundamental attribution error (attributing behavior to personality characteristics of individuals and overlooking environmental causes).

Errors in detection of relevant events include an overly narrow focus (e.g., confining attention to the client's thoughts), overly narrow use of data collection methods (e.g., reliance on the interview alone), and errors during data collection (e.g., observer bias). Inaccurate or incomplete accounts of client concerns and related factors often occur because

attention is narrowly focused on one source of informant (e.g., thoughts or feelings). There may be no contextual assessment in which environmental factors related to desired outcomes are identified. Sources of error in integrating and interpreting data include focusing on consistency rather than informativeness of data, hasty generalization based on limited samples, and inadequate conceptualization of problems due to theoretical biases (e.g., focus only on environmental factors) or inaccurate or superficial knowledge of a practice framework. Another source of error at this stage is the use of vague language and psychological jargon that is not informative. Errors in selection of outcomes focused on may occur because of errors in the first two phases. Client ethnicity, race, and characteristics (such as obesity) influence helper's views of concerns.

Studies of clinical decision-making indicate that decisions are made on the basis of quite limited data. Even though a great deal of data are gathered, only a small subset is used. Clinicians tend to gather more data than are needed and, as the amount of data gathered increases, so does confidence in its usefulness, even though accuracy may not increase. Clinicians have a tendency to confuse consistency of data with informative value. Irrelevant as well as relevant data may be influential. Clinicians, like other individuals, are affected by limited information-processing capacities and motivational factors. As a consequence, they do not see all there is to see. Because of preconceptions and biases, things that are not actually present may be reported and events that do occur may be overlooked. Confirmation biases are common. That is, data are sought that are consistent with preferred theories and preconceptions, and contradictory data tend to be disregarded.

Many factors that are not correlated with the true frequency of an event influence estimates of its frequency and how important it seems (such as how visible it is, and how vivid it is). It is easy to recall bizarre behavior and pay excessive attention to this, ignoring less vivid appropriate behavior. The frequency of data that are available is overestimated. Clinicians in a given settings are exposed to particular kinds of clients, which may predispose them to make certain assumptions. For example, a psychologist who sees many severely depressed individuals may be primed to attend to signs of depression. Base rate data that are abstract tend to be ignored, which increases the probability of inaccurate inferences. A lack of concern for sample size and sample bias can lead to incorrect judgments. General predictions about a person that are based on tiny samples of behavior in one context are not likely to be accurate, especially when behaviors of interest occur in quite different situations. Not distinguishing between description and inference may result in incorrect assumptions. Use of multiple sources of data within a contextual practice framework provides the greatest opportunity for sound clinical assessment.

Ethical Issues and Future Directions

Evidence-informed assessment encourages use of frameworks and methods that have survived critical appraisal in relation to their accuracy. Taking advantage of the steps involved in evidence-based practice, for example, consulting practice-related research, should contribute to making well-informed decisions regarding questions that arise. Lack of up-to-date

knowledge and related skills regarding valid assessment methods may result in the selection of ineffective and/or harmful interventions. It is thus incumbent on clinicians to draw on empirically sound methods that are useful in discovering the potential to attain valued outcomes and in selecting effective plans. Helpers and clients have preferred views about behavior and how it develops, is maintained, and can be altered. These views differ in the extent to which they have been critically appraised regarding their accuracy and usefulness in providing guidelines about how to attain valued outcomes or if they can be attained.

There are great stakes in how problems are framed and considerable resources are devoted to influencing how people think about personal and social problems. Many problems once viewed as sins were then seen as crimes and are now considered to be 'mental illnesses.' Beliefs about the causes of behavior influence how people are viewed. In past years, pathology was often attributed to housewives who wanted to work. Knowledge about social, political, and economic factors that influence the very definition of personal and social problems (their social construction) is vital so that clinicians consider concerns in their social context. This also decreases the likelihood of pathologizing clients (medicalizing problems in living). Honoring ethical obligations to clients requires selection of assessment frameworks and related methods that are compatible with empirical data regarding behavior. Accurate descriptions of different assessment perspectives increases the

likelihood that points of convergence and differences among varied views are correctly identified. Continuing research efforts are needed to identify valid methods and indicate assessment frameworks that are most likely to help clients achieve hoped-for outcomes. Increased interest in clinical reasoning and related errors and how to avoid them bodes well for enhanced quality of clinical decisions regarding assessment.

Clinical Psychology: An Information Processing Approach

P Fisher, University of Liverpool, Liverpool, UK

© 2012 Elsevier Inc. All rights reserved.

Glossary

Attentional bias Differential allocation of attention to self-relevant threatening stimuli relative to neutral stimuli.

Automatic processing Although no absolute consensus exists on the meaning of automatic processing, it generally refers to a cognitive process that operates unintentionally, without conscious awareness, is effortless, and requires no resources.

Cognitive architecture The organization of mental subsystems involved in the performance of information processing tasks.

Metacognition Cognition about cognition; any knowledge or cognitive process that is involved in guiding, monitoring, controlling, or appraising cognition.

Strategic processing In contrast to automatic processing, strategic or controlled processing is a conscious, effortful, volitional process which requires cognitive resources.

Introduction

Over a century ago, Lightner Witmer established the first psychological clinic and formally proposed and outlined a structure of clinical psychology. Subsequently, clinical psychology has blossomed as a discipline and undergone many paradigmatic transitions; but all have deigned to improve our understanding of human behavior and to improve the efficacy of psychological interventions. The information processing (IP) approach has become one of preeminent frameworks in clinical psychology, particularly in the United Kingdom and the United States, in the twenty-first century. The IP approach has been extensively utilized in an attempt to account for the core features of a broad range of clinical disorders in all subdivisions of clinical psychology. More importantly, IP models have moved beyond descriptive phenomenology and are illustrating how particular types of attentional, interpretative, and memory biases are involved in the etiology and maintenance of psychological disorders, ranging from anxiety disorders in children and adults to IP models of autism. This development has raised the usefulness of the IP approach to a new level, namely that theoretical expositions are translated into psychological interventions, either in an additive fashion to existing treatments or as innovative and novel approaches.

This article begins with a brief overview of the nature and development of the IP paradigm within cognitive psychology. It should be noted that within the rubric of cognitive psychology, IP can be considered from many perspectives, which accounts for the continued enthusiastic exploration of the IP approach from both theoretical and practical positions. IP can be studied from multiple perspectives including neurobiological and neuropsychological perspective. For example, understanding how lesions in specific brain regions map onto difficulties in learning or how specific neuropsychological deficits are associated with theory of mind difficulties in autism highlights the wide applicability of the approach. In this article, we will focus on how IP approach applies to emotional disorders. Following the overview of the IP paradigm, the value of the IP paradigm to clinical psychology is then presented, coupled with a discussion of the factors leading to the paradigmatic shift from behaviorism to cognitivism. The next section

discusses some of the experimental methods, research findings, and clinical developments within the IP paradigm using attentional biases in anxiety as the main exemplar. The final section of this article focuses on two innovative clinical developments for anxiety disorders: cognitive bias modification procedures and metacognitive therapy. Both are grounded within the IP framework, but theoretically are very distinct.

Overview of the Information Processing Paradigm

Empirical investigation within cognitive psychology includes, but is not limited to, the study of memory, attention, language, perception, higher level thought, reasoning consciousness, and cognitive development. The IP approach was developed as a framework within cognitive psychology to explain human behavior by reference to a cognitive system that mediates between incoming stimuli and behavior. The most familiar metaphor to explain the IP approach is the individual as a computer, and indeed the development of the IP approach is partially attributable to developments in computer technology during and following World War II. Specific guiding principles of the IP approach in cognitive psychology were outlined in the late 1970s. The first assumption was that people are autonomous individuals who intentionally engage with the other people and the environment. Next was the idea that the cognitive processor is a general-purpose, symbol-processing system involving both process, such as the allocation of attention, and content, such as an image in memory. Of central importance to the IP paradigm is the assumption that the cognitive system has a limited capacity. This proposition is crucial as it means there will be competition for resources leading to selective attention. For example, every day we are bombarded with stimuli and only a finite proportion can be selected and processed; how does this occur? Selective attention has engaged cognitive psychologists for over three decades and debate has centered on the extent to which selective attention is an automatic or strategic process. Although, a general agreement now exists that attentional bias is a combination of automatic and controlled processing, considerable theoretical disagreement continues as to the relative importance of each component in

psychopathology. More importantly, the adopted theoretical positions on automaticity have had a profound influence on research directions and clinical practice. This issue will be discussed in more detail later.

A further fundamental assumption of the IP paradigm is that IP takes time and that the time taken for a particular IP task can be specified. This allows predictions and testable hypotheses to be derived. For, example, attentional bias is inferred from differential response times to competing stimuli in a range of experimental tasks. The IP paradigm also specifies that cognitive processes are dependent upon, and constrained by, neuroanatomy and neurochemistry. Exploration of the interface between neuroscience and IP is an emerging field, which is providing valuable insights for the practice of clinical psychology. For example, neuroimaging assessment before and after psychological interventions is generating important data on the neurobiological mediators of change.

Evolution of the IP Paradigm Within Clinical Psychology

Clinical psychologists working in adult mental health embraced the IP paradigm during the 1970s for two main reasons. First, there was growing dissatisfaction with the prevailing clinical paradigm of behaviorism. Although behavioral therapy was, and continues to be, an effective treatment for many clinical problems, the underpinning theory had insufficient explanatory power. Classical and operant conditioning processes were unable to explain fundamental aspects of specific disorders or the psychological mechanisms effecting clinical change. Interestingly, contemporary theories of the mechanisms of change in behavior therapy explicitly focus on cognitive constructs and processes, rather than on the two-factor model that had dominated theorizing from the 1950s to the 1970s.

The second key influence was the development of schema theory proposed by Aaron Beck. This clinical theory placed schemas at the heart of emotional disorders. The construct of schemas was appropriated from work conducted on early research on memory processes. Schemas were defined as relatively stable and enduring cognitive structures that influence how an individual perceives and interprets information. The content of the schemata is thought to be of paramount importance and differentiates between anxiety and depressive disorders. Specifically, depression or anxiety will occur when a matching life event activates congruent knowledge stored in the long-term memory. Typically, depressogenic schemas incorporate negative beliefs about the world, the future, and themselves as being inadequate or worthless. In anxiety disorders, the content of schemas concerns personal vulnerability, uncertainty, and danger. It is hypothesized that schema activation results in biased IP, most readily seen by an increased presence of negative automatic thoughts and interpretative biases, more commonly referred to as cognitive distortions. Examples of cognitive distortions include selectively attending to one component of an event and ignoring other relevant aspects, or thinking in all or nothing terms.

The original exposition of schema theory was not explicitly developed within the IP paradigm; the theory clearly implicates many cognitive processes including memory, attention, and perception. Furthermore, the theory states that schemas

guide processing of incoming stimuli and influence perception and understanding, which in turn is translated in how people behave. However, neither the original exposition nor subsequent IP accounts of schema theory have provided a cogent model of how schemas guide IP and result in persistent emotional distress. It remains to be explained why a declarative belief such as 'the world is a threatening place' should result in heightened levels of anxiety and persistent worry. Schema theory remains a hugely influential and useful clinical theory, but has a number of conceptual limitations when considered from an explicit IP perspective. Notwithstanding this issue, the undoubted success of cognitive therapy continues to stimulate considerable research interest in the cognitive processes involved in the etiology and maintenance of clinical disorders. Cognitive behavior therapy (CBT) has become the predominant psychological treatment approach of the twenty-first century, having been extensively evaluated in over 400 randomized controlled trials and the breadth of application continues to grow. It is widely recognized that improvement in the efficacy of CBT approaches for specific disorders, such as social phobia, is a direct result of integrating schema and IP theories. Therefore, the IP paradigm will continue to flourish as it is assumed that further unraveling of cognitive processes, such as attentional biases in anxiety disorders, will enable increasingly effective interventions to be developed.

Significance of the IP Paradigm to Clinical Psychology

The value of any paradigm resides in its ability to generate theories and well-specified models; the IP paradigm has excelled in this regard. There are a multitude of theories and associated models derived from the core assumptions of the IP paradigm across all subspecialties of clinical psychology. Within adult mental health, a multitude of generic and disorder-specific models exist, some drawing very specifically on the IP paradigm and others integrating components drawn from the IP paradigm with other schools of thought. Once models have been developed and empirically evaluated, the next step is to translate the models into effective psychological interventions and again work conducted under the IP paradigm has been extremely successful and has produced many highly differentiated treatments. Both of these core strengths of the IP paradigm can be illustrated with reference to post-traumatic stress disorder (PTSD). The central premise of many models of PTSD is that memory processes operate differently to normal memories as a consequence of the traumatic conditions in which the memories were encoded. For example, the dual representation theory proposes that different components of trauma memories are stored in different memory systems. Specifically, features of the traumatic experiences that are attended to consciously are stored in the verbally accessible memory (VAM) system and can be recalled easily. The nature of the beliefs in this system is hypothesized to be dysfunctional and represents common beliefs expressed by trauma patients, such as 'I am to blame, it was my fault.' In contrast, there are other aspects of the traumatic experience which were not consciously attended to, but were encoded in a situationally accessible memory (SAM). These memories are only recalled when triggered by a trauma cue and result in increased

physiological reactivity, and reexperiencing symptoms. The model proposes that psychological treatment must correct information stored in both memory systems; therefore, cognitive restructuring methods are used to correct maladaptive beliefs, whereas exposure strategies are required to modify the physiological components of PTSD.

In contrast to the models of PTSD, which specify a critical role for memory disorganization, the metacognitive model of PTSD proposes that metacognitive beliefs and processes are more important in maintaining PTSD than specific aspects of memory such as encoding and retrieval. Indeed, the metacognitive model argues that maintaining factors in PTSD relates to a particular processing style called the cognitive attentional syndrome (CAS). The CAS consists of high levels of perseverative thinking, threat monitoring, and coping behaviors that are guided by metacognitive beliefs and proceduralized knowledge that become active following the trauma experience and subsequent symptoms. Patients engage in high levels of worry because they hold positive metacognitive beliefs about the usefulness of worry as a coping strategy and also because they have negative metacognitive beliefs about the uncontrollable nature of worry. In relation to memory, an example of positive metacognitive belief would be 'I must be remember all aspects of the trauma in order to move on,' whereas negative metacognitive beliefs focus on the dangers and consequences of not being able to recall every aspect of the event. These two categories of metacognitive belief combine to keep the person focused on the threat and engage in continued processing of the trauma experience.

Treatment would focus on the modification of positive and negative metacognitive beliefs about the CAS and would not involve cognitive restructuring of beliefs in the cognitive domain or use exposure exercises. These two examples illustrate the development and diversity of disorder-specific models that have been developed under the broad framework of the IP paradigm. Moreover, the two models highlight that the resultant treatments are distinct in how individuals with PTSD are assessed, conceptualized, and treated.

The development of models within an IP framework has directly influenced diagnostic classificatory systems such as the International Classification of Disease (ICD) and Diagnostic and Statistical Manual (DSM). Since generalized anxiety disorder (GAD) entered the diagnostic taxonomy in 1980, it has undergone substantive changes. Originally, GAD was conceptualized primarily as a disorder of anxiety but with very limited reference to cognitive processes. In the latest incarnation of the Diagnostic and Statistical Manual (DSM-IV), the cardinal diagnostic feature of GAD is a cognitive process, namely excessive worry, which a person finds difficult to control. Such diagnostic changes are very significant as they provide both an impetus and direction for research. In the case of GAD, research is ever more focused on understanding the psychological processes which underpin worry. Panic disorder represents another clear illustration of how diagnoses for anxiety disorders have been shaped by research conducted under the IP rubric. Panic disorder is defined according to the psychological mechanisms responsible for the maintenance of the disorder. Patients with panic disorder catastrophically misinterpret symptoms of anxiety which is both the primary target for intervention and the cardinal feature of the disorder.

Evidently, clinical psychology has benefited from research conducted within the IP paradigm in many ways. In addition to the taxonomic, treatment, and model development, the IP framework continues to broaden its horizons as it is being applied to an increasing number of clinical problems. Furthermore, the IP approach is contributing to our understanding of vulnerability to relapse following treatment or indeed the genesis of clinical disorders as can be seen in the child psychopathology literature where research is providing illuminating data on potential pathways to emotional difficulties. Finally, evidence is steadily being accumulated that models and treatments located within an IP paradigm are producing increasingly more effective and time-efficient psychological treatments.

Emotional Disorders and Information Processing Biases

A wealth of studies using a range of experimental tasks have demonstrated that people with elevated levels of anxiety demonstrate an attentional bias toward threatening stimuli compared to neutral stimuli. Such results are in accord with clinical accounts in which patients describe focusing their attention on signs of threats, for example internal sources such as unwanted thoughts and feelings or external signs of possible threat, typified by hypervigilance for signs of danger in PTSD patients. However, there may be both qualitative and quantitative difference in attentional allocation in the natural environment compared to laboratory experiments; this conundrum remains to be resolved. Nevertheless, research into biased IP in emotional disorders has made substantial advances over the past two decades. Early work in this area took a rather dichotomized approach to explain the IP biases observed in emotional disorders. For example, the majority of research found that anxiety disorders were characterized by selective attention toward threatening stimuli whereas affective disorders did not show this bias. Alternatively, depression and not anxiety was characterized by explicit memory biases toward self-relevant negative information. However, as the experimental paradigms and theorizing increased in sophistication, it has become evident that both anxiety and depression are characterized by a range of IP biases. Recent studies on depressed adolescents and on adults experiencing suicidal ideation have shown preferential attentional bias for self-relevant stimuli. A general finding is that the degree to which threatening stimuli are perceived as self-relevant is correlated with the magnitude of attentional bias. In PTSD, the interference effect observed on the emotional Stroop task is greater when the stimuli are most self-relevant; so, in combat veterans with PTSD, the interference effect will be greater for military stimuli than general trauma stimuli. A similar picture is seen in obsessive compulsive disorder, whereby biases are only observed when the stimuli are relevant to the individual specific obsessional concerns.

Components of Attentional Bias

Attentional bias in anxiety comprise at least three components, which change according to the stage of IP. The first stage is facilitated attention, in which threatening stimuli are detected

more rapidly than neutral or less threatening stimuli. The next stage is difficulty in disengaging from threat; in other words, anxious people find it difficult to shift their attention away from threatening stimuli; and the final stage is attentional avoidance, where people allocate their attention away from threatening stimuli. A broad range of experimental tasks (described below) have repeatedly demonstrated attentional bias at each stage of processing; however, the mediating mechanism(s) underpinning each component remains a source of controversy. Understanding the mechanisms responsible for attentional bias would facilitate the development of theoretically cogent and defined interventions.

Experimental Paradigms

The emotional Stroop was the first task used extensively to measure attentional bias in anxiety. In this task, participants are presented with a series of threatening and neutral words printed in different colors and the objective is to name the color that each word is printed in as quickly as possible whilst ignoring the semantic content of the word. Response times are measured and differences in latencies of color-naming between threat words and neutral words are indicative of attentional bias. Across a range of anxiety disorders, studies using the emotional Stroop have found increased latencies of color-naming of threat words. The most frequent conclusion is that slower color naming is attributable to an automatic processing bias in anxiety which directs attention toward threatening material. However, the emotional Stroop has been the center of considerable debate for many years as numerous authors have argued that the mediating mechanism underpinning is not rapid orientation or engagement with threatening stimuli but instead primarily reflects a later stage of processing, namely difficulty engaging with threatening material. Researchers have also suggested that attempts by participants to suspend further processing of the threat cues slow color-naming. Other explanations for the interference effect on the emotional Stroop relate to the other cognitive and emotional processes involved in undertaking the task as it is not a pure measure of attention. It may be that participants process neutral and emotional stimuli to the same extent; however, the negative stimuli produce an increase in emotion which inhibits reaction time performance. This brief account of the emotional Stroop highlights that interpretation of the observed interference effect is highly problematic. Overall, evidence suggests that the interference effect is not attributable to just one component of attentional bias, and that the component which explains most of the effect appears to be difficulty disengaging from threat, rather than facilitated attention.

An alternative task that has also been widely employed in assessing attentional bias toward threat and overcomes some of the limitations of the emotional Stroop is the dot probe task. This task is also thought to have greater ecological validity as it does not rely on words as stimuli and tends to use pictures that have personal meaning for the particular problem being investigated. For example, if a spider phobic was completing this task, then the neutral stimuli might be a range of everyday objects or animals that do not provoke distress, whereas the threatening picture would be relevant to the phobia. In this task, two pictures are presented simultaneously on a computer

screen. The pictures then disappear and a probe replaces one of the pictures. Participants are asked to indicate as rapidly as possible (by a button press) which stimulus has been replaced by the probe. Attentional bias is inferred through faster responses to the probes that replace threatening stimuli relative to the neutral stimuli. A major advantage of the dot probe task is that the interval between stimulus presentation and the probe can be varied, enabling assessment of the time course of the attentional bias. Studies which have examined the effects of facilitated attention and difficulties in disengagement overwhelmingly find that the attentional bias effect is accounted for by delayed disengagement. This does not mean that a fast automatic orienting bias does not occur, but it does imply that the rapid orienting response is not contributing as significantly to the maintenance of anxiety disorders as early research indicated.

Two other experimental tasks are frequently used to measure attentional biases. The visual search task allows assessment of spatial allocation of attention and speed of responding. Participants are asked to search for the target word amongst distractor words (as in a word search puzzle). A single threat word might be embedded in a matrix of neutral words and the reverse condition would ask participants to search for the neutral word amongst a set of self-relevant emotional words. Attentional bias is inferred from faster detection of threat words embedded in neutral words relative to detecting a neutral word embedded amongst other neutral words. The alternative condition is where participants are slower to detect neutral words in a matrix of threat words compared to detection of a neutral target word in a matrix of neutral stimuli. The final task that has been used frequently in attentional bias research is the spatial cueing task. In this task, the participant is asked to rapidly identify a target stimulus but they are cued (either by a neutral or threatening cue) to a spatial location on the computer screen before the target appears. The cue may be valid, in that the target appears in the same spatial location as the cue; alternatively, it may be invalid, in which case the target stimulus appears in a different spatial location to the cue. Attentional bias is inferred by faster response times for threatening cues in the correct spatial location or by slower response times on invalid trials. Both the visual search task and the spatial cueing task have produced robust results demonstrating attentional bias for threatening stimuli in a range of anxiety disorders, accounted for by difficulties in disengaging from threat.

As experimental tasks have increased in sophistication and ability to measure the different components of attentional bias, the most robust finding is that people with elevated levels of anxiety have difficulty in disengaging from threatening stimuli. In other words, anxiety disorders are characterized by a lack of flexibility of allocation of attention. In the next section, the issue of whether attention is primarily an automatic or controlled process is discussed in more detail.

Automatic and Controlled Processing

One of the most enduring theoretical disputes within IP accounts of emotional disorders and particularly in relation to attentional biases in anxiety is whether the observed bias is attributable to automatic or controlled processing. Automatic

processing has been defined as uncontrollable, unintentional, unconscious, capacity free, and effortless, whereas controlled or strategic processing is an intentional, volitional process, which requires conscious awareness, effort and is constrained by capacity limitations. As IP accounts of anxiety were proposed during the course of the 1980s and 1990s, the distinction between controlled and automatic processing became highly significant because it determined how psychological treatments for anxiety were developed. If attentional and interpretative biases are automatic processes, then this implies that psychological therapies should focus on enabling patients to cope and manage with anxiety or possibly through extended retraining, attentional biases could be alleviated. The alternative view that attentional bias is primarily a product of controlled processing will result in a very different psychological intervention, as the focus would be on modifying processing configurations, guided by beliefs/knowledge which is stored in long-term memory structures.

Examination of the automaticity of attentional biases in anxiety has moved away from a simple all-or-nothing dichotomy to exploring whether the different stages of processing are related primarily to automatic or controlled processing. The predominant view was, and continues to be, that facilitated attention represents an automatic process whereas the later stages of attentional bias (delayed disengagement and avoidance of threat) come increasingly under strategic control. However, research thus far has not unequivocally demonstrated that any stage of processing is either completely strategic or completely automatic. This is despite many studies concluding that attentional bias is an automatic process but this conclusion is unwarranted as these studies have generalized from an experimental task that has only manipulated one component of automaticity. For example, studies using the emotional Stroop have tried to determine whether the interference effect is attributable to an automatic process by using masked presentations. This task involves very brief presentation of the stimuli (<20 ms) and then the stimulus is masked for up to 480 ms before the next stimulus is presented. The idea behind this is that such rapid presentation prevents conscious awareness and therefore the observed interference effect reflects an automatic process. However, only degree of awareness has been manipulated and there is a question mark over the extent to which subliminal presentations with backward masking actually preclude conscious awareness. Therefore at best, studies have demonstrated that attentional biases are partially automatic, as no studies have successfully manipulated all facets of automaticity. This raises an important question, which is whether research focusing on differentiating automatic from controlled processing is meaningful or clinically useful as the majority of cognitive processes appear to be a combination of automatic and controlled processing. The more clinically useful question is determining whether strategic processing can exert an influence over the more automatic components of attentional bias.

Theories differ in the importance placed on each stage of processing. Some theories emphasize that anxious people exhibit an enhanced automatic bias for threat during the early stages of processing and avoidance of threat in the later stages of processing, often labeled as the vigilance-avoidance model. Others have argued that the early stages of processing

and the automatic or rapid orienting response have little impact on anxiety, instead arguing that anxiety is maintained by a difficulty in disengaging from threat. As reviewed earlier in the article, the evidence from various analyses of experimental tasks would indicate that early components of attention are less important than later stage of processing in the maintenance of anxiety disorders.

Clinical Applicability of Information Processing Models and Treatments

The ultimate test of the value of the IP approach is whether it has resulted in improved treatment efficacy as a result of translating theoretical advances into clinical treatments. The answer to this question depends on the treatment and disorder being investigated. Cognitive therapy for depression remains virtually unchanged in terms of treatment delivery and treatment efficacy over the past 30 years. Findings from empirical work on memory biases and attentional processes in depression have not been incorporated into cognitive therapy. The opposite is true for psychological treatments of anxiety disorders, where there are clear developments in the focus and nature of interventions for almost all anxiety disorders.

Cognitive Bias Modification

Following on from research demonstrating that individuals with anxiety disorders show a preferential attention for threatening stimuli, it was argued that attentional bias was an integral component of anxiety disorders. Prospective studies found that facilitated attention bias was predictive of greater emotional reactivity to a stressful event. Furthermore, that when nonanxious people were trained to either direct their attention toward or away from threat, those individuals who were trained to orient toward threat showed significantly higher emotional responses to a stressor task. As a result of such studies, it was hypothesized that people suffering from an anxiety disorder could be trained to reduce their attentional bias toward threat. Therefore, cognitive bias modification (CBM) procedures, designed to decrease attentional bias in anxiety disorders, have been developed. It has been argued that CBM procedures may have an important role in the treatment of anxiety disorders, especially as the current level of efficacy of psychological treatments for many anxiety disorders is somewhat limited. CBM procedures typically involve a modification of the dot probe task and train people to orient rapidly away from threatening stimuli. Recent applications of CBM procedures in clinical samples have shown promising results including significant reductions in anxiety and depression in a GAD sample, after a 4-week training program. However, a number of issues require resolution. First, these procedures are predicated on the assumption that the early stage of attentional bias, facilitated attention toward threat, is being modified. However, it appears that the CBM procedures are operating at the later stages of attentive processing of threat, namely avoidance of threat. In other words, CBM techniques are modifying strategic rather than automatic processing. A related issue is that if people are being trained to look away from threat, then this has important clinical

implications. Patients use avoidance to modulate anxiety, but with an important consequence, they do not learn more effective methods of responding to threat. A further issue with the CBM results is that although GAD patients showed reductions in overall levels of anxiety and depression, the cardinal feature of GAD, namely worry, remained comparatively unchanged. Studies such as these highlight that modifying attentional processes may result in reductions of anxiety, but anxiety disorders are not only characterized by attentional biases and other important aspects of the disorder remain unchanged. Further research is required to delineate the mechanism of action, especially as it is possible that these training procedures are actually counterproductive in the long run. Despite the need to clarify these issues, the recent studies on CBM raise a number of fascinating possibilities including whether the strategies can be successfully incorporated in existing CBT protocols with a resultant increase in treatment efficacy.

The Self-Regulatory Model of Executive Dysfunction in Emotional Disorders

One model that has been developed within an IP framework to explain the persistence of emotional disorders is the Self-Regulatory Executive Function model (S-REF). This model was proposed by Adrian Wells and Gerald Matthews as a transdiagnostic understanding of the factors involved in the maintenance of psychological disorder. The model attempted to overcome some of the limitations of schema theory and develop a model of psychopathology that was explicitly developed within the IP framework. The model specifies that psychological disorders should be conceptualized as predominantly top-down or conscious processes, with a set of self-regulatory strategies. According to the model, a particular style of thinking and coping with negative thoughts and feelings results in the exacerbation and maintenance of emotional distress. This particular style of thinking has been termed the CAS and consists of perseverative thinking, threat monitoring, and counterproductive coping strategies. In developing the model, the authors returned to earlier work on attention, which specified that there were different levels of control in the form of automatic and controlled processing. The S-REF model proposes that emotional distress is linked primarily to biases in the selection and execution of controlled processes for appraising and coping with intrusive cognitive and emotional events. More specifically, an individual's strategy for thinking and self-regulation in response to unwanted thoughts and feelings can either intensify and maintain negative emotions or result in brief emotional reactions. Emotional disorders such as anxiety and depression occur when the style of thinking and coping inadvertently leads to persistence and strengthening of emotional responses. The CAS is guided by metacognitive beliefs concerning (a) the benefits of engaging in each aspect of the CAS, for example 'worry helps me cope' and (b) the uncontrollable nature of the CAS, for example 'my worry is out of my control, I cannot stop myself from worrying.' In MCT, the CAS and the supporting metacognitive beliefs are the psychological processes that are targeted in therapy.

In contrast to cognitive therapy and CBM approaches, metacognitive theory does not link psychological problems to automatic processing biases or the content of schemas. Instead, metacognitive theory specifies that psychological problems are attributable to conscious and volitional strategies. In relation to the experimental paradigms used to assess attentional bias earlier in the article, metacognitive theory does not link the observed effects to activation of schemas or automatic processing but attributes them to strategy selection. In anxiety disorders, patients have a strategy of maintaining attention on sources of threat and engaging in worry-based processing as a means of coping.

The S-REF model is based on three basic levels of cognition: a level of reflexive and automatic processes that run with minimal or no conscious involvement. These processes may generate intrusions into consciousness that capture attention. The next level is an online form of processing which is conscious and capacity-limited, responsible for regulating and implementing appraisal and action. The final level is stored knowledge in long-term memory. The immediate activities of the online processing require access to stored knowledge in order to run. Online processing is guided by knowledge or beliefs that are metacognitive in nature. In line with one of the core values of the IP approach, the S-REF theory has generated many disorder-specific models, including models of depression, GAD, PTSD, social phobia, and obsessive compulsive disorder. Current research is evaluating the applicability of the S-REF model in an even broader range of issues such as alcoholism, psychosis, and persistent distress in survivors of cancer and myocardial infarctions. Evaluation of treatment efficacy of metacognitive therapy is in the early stages, but it is producing very high recovery rates across a range of clinical disorders.

Conclusions

IP models proliferate in clinical psychology, but the disparate nature of the underpinning theories leads to very different treatment approaches. This is a strength of the IP approach as it provides clinical psychology with a rich theoretical basis, from which further advancements can be achieved. The generation of novel interventions in the form of CBM strategies and metacognitive approaches are exciting innovations that hold considerable promise for the continually evolving practice of clinical psychology. In summary, the IP paradigm has resulted in a wealth of research and clinical developments that ultimately result in significant therapeutic benefits.

Glossary

Attentional resources A general-purpose reservoir of 'energy' or 'fuel' for processing that may be flexibly allocated to support effective attention.

Cognitive patterning A detailed description of the tasks or cognitive functions that are facilitated or impaired by a personality trait or stressor.

Executive functioning A set of control operations used to regulate attention and memory.

Extraversion A personality trait associated with sociability, assertiveness, and positive affect.

Idiographic approach The assumption that all aspects of personality are fundamentally unique and idiosyncratic to each individual.

Neuroticism A personality trait associated with a predisposition to experience negative affect.

Nomothetic approach The assumption that personality may be understood using universal concepts and principles that apply to all people.

Self-regulation The motivational and cognitive processes controlling goal-directed personal adaptation to the external environment.

Self-schema A structured set of beliefs about the self (which may not be fully accessible to consciousness).

Trait A personal disposition or characteristic showing long-term stability and influencing behavior in a range of situations.

Working memory A memory system used for information processing including both a central executive and short-term storage components.

Introduction and Historical Context

The essence of the cognitive psychological perspective on personality is that individuals differ in their understanding of the outside world and their own place in it. Thus, theories of individual differences in cognitive processes and structures should be central to the psychology of personality. Historically, the route to a cognitive understanding of personality has been surprisingly circuitous. In psychoanalysis, for example, the rationality of the ego often appears subservient to the basic drives of the id. Later theorists including George Kelly and Carl Rogers placed cognitive processes at the center of personality research, through emphasizing the person's active efforts at making sense of the world and of the self. However, these clinically oriented approaches lacked the benefits of the formal models of information processing provided by cognitive psychology.

At the dawn of the 'cognitive revolution' in the 1960s, we could discern three trends that continue to shape models of personality. The first comes from H.J. Eysenck's biological personality theory. Eysenck followed the behaviorist tradition of seeing cognition as secondary to more basic neural processes, but he pioneered the use of performance tasks as a means for testing personality theory. Tasks requiring memory and attention were used as a means of testing predictions from the arousal theory of personality traits. The failure of these attempts encouraged attempts to use cognitive psychological models as a basis for predicting personality effects.

The second trend was the development of social learning theories of personality by Walter Mischel and Albert Bandura. Such theories emphasized that social learning builds internalized cognitive structures, such as representations of self-efficacy, that provide both a coherent style of behavioral interaction with others, and a coherent sense of self. By contrast with trait

theory, social learning theories focus on the cognitive representations of the individual.

A third trend was for clinical psychologists to link emotional disturbance to broad individual differences in cognitive functioning, an approach more compatible with the notions of general personality traits. A.T. Beck's landmark schema theory elaborated the role of cognitive knowledge structures as a basis for personality, in relation to dysfunctional negative self-beliefs and styles of reasoning that are associated with clinical depression.

Contemporary personality research remains infused with a variety of cognitive constructs. However, personality researchers have adopted cognitive psychological methods and concepts in order to pursue rather different, although complementary, research aims. Next, three research directions are distinguished, relating to experimental studies of performance, the contents of self-representations in the 'cognitive self,' and long-term personality development.

Individual Differences in Performance

Personality traits relate to individual differences in performance of a variety of tasks. The conceptual model is that the trait is seen as a fixed quality of the person, which is associated with a range of biases that feed forward into observed behavior. Studies of human performance seek to relate personality to information-processing models that specify individual differences in components of memory, attention, decision making, and so forth. An important area of this research concerns cognitive bias in processing emotional stimuli, which has been related to anxiety and other traits linked to emotionality. Theory is then concerned with specifying the cognitive processes that mediate the behavioral expressions of the trait. For example, recent anxiety research has explored how anxiety

effects may be mediated by individual differences in executive processes. Because information processing can typically be related to neural systems, work of this kind also lends itself to cognitive neuroscience theory. Research of this kind is closest to 'standard' cognitive psychology in using experimental methods to investigate information-processing mechanisms in detail.

Experimental studies have also been used to investigate effects of personality on mood and emotion. It is commonplace (although perhaps simplistic) to identify neuroticism and extraversion traits with negative and positive emotionality, respectively. Although the dominant theoretical approach has been to relate these traits to brain systems for emotion and motivation, researchers are increasingly studying cognitive processes that may influence emotion, including biases in appraisal and styles of emotion regulation.

The Cognitive Self

In the classic experimental paradigm, the personality trait is a 'given' that influences cognitive processes and behavior over a short time interval. However, cognitive theory can also be applied to understanding the underlying nature of traits, given that the stability of personality implies that personal characteristics are represented in long-term memory (LTM). Variation in traits may correspond to variation in stable cognitive structures. Building on A.T. Beck's (1967) schema theory, researchers have explored how traits correspond to stable representations of self-knowledge, which in turn shape individual differences in social behavior. Traits may also correspond to 'implicit' procedural knowledge, such as well-learned scripts for interpersonal interaction, as well as to 'explicit' declarative knowledge.

Research on the cognitive self divides sharply into two separate camps. Following Mischel and Bandura, one line of research is concerned with 'idiographic' personality coherence at the individual level, and the role of the individual's cognitive-affective structures in producing consistency of behavior within specific situations. The alternative perspective assumes that features of the self such as dysfunctional negative beliefs may be assessed nomothetically, that is, as an attribute of all individuals, contributing to general traits. Typical methods include experimental studies, such as investigating speed of processing self-referent information, but may also employ other techniques, including subjective reports of self-beliefs. Recent research has increasingly focused on 'implicit' aspects of the self, for example, using techniques based on A.G. Greenwald's Implicit Association Test. For example, someone whose implicit self-esteem was low might respond more slowly if required to respond on the basis of an association between the self and positive qualities.

Personality Development

Temperamental qualities such as emotionality and self-control are expressed in early childhood, and form the precursors to adult personality. While temperament is often seen as essentially biologically based, there is increasing interest in how brain maturation and self-development are interrelated. For example, attachment theory is concerned with how the

innate neural programs for managing social interaction are shaped by experience to regulate the child's attachment to the caregiver. The development of (cognitive) working models of self and others plays a critical role in intimate relationships into adulthood. Research on personality and individual differences in cognitive development uses a variety of methods, including experimental studies and self-report. Studies of younger children obtain reports of behavior from parents or trained observers. Longitudinal studies that may run from infancy to adulthood are also important.

The developmental perspective helps us to understand how the cognitive self is acquired, as the child internalizes an increasingly sophisticated set of self-beliefs and strategies for self-regulation. Again, traditional social learning theory has often emphasized self-development as a process best understood at the level of the individual. However, normative traits may relate to consistent developmental trajectories and styles of person-environment interaction. For example, aggressiveness may relate to beliefs in the hostility of others, the acquisition of confrontive interpersonal strategies for self-defense, and willingness to engage with environments in which confrontation is likely.

Structure of this Article

The introductory overview of research on personality and cognition indicates the scope and diversity of this work. The remainder of this article is organized as three major sections. The first is concerned with work that is closest to the central goal of cognitive psychology, that is, to construct and test detailed models of the information processing that supports major psychological functions such as attention and memory. In personality research, the aim is to specify how personality traits correspond to individual differences in the parameters of information-processing models. The next section reviews integrative theoretical accounts of empirical findings, focusing on attentional resources, control processes, and the adaptive functions of cognition. The third section reviews applications of cognitive psychological research to other research topics which are concerned not only with individual differences in cognition, but also affective, motivational, and social functioning. These topics are self-regulation and emotion, the cognitive self and social functioning, and abnormal personality and clinical disorder.

Personality is itself a diffuse field of study, and some comment on its treatment in this article is needed. The research covered is primarily concerned with nomothetic trait models, which assume that the major features of personality can be described in relation to a psychometrically defined standard set of traits that are meaningful for all individuals. Coverage of idiographic personality models that emphasize the uniqueness of the individual will be brief.

The five factor model (FFM) is the dominant trait model at the present time. It includes extraversion-introversion, neuroticism (or emotional instability), conscientiousness, agreeableness, and openness as major traits. Traditionally, most cognitive research has been directed toward extraversion and neuroticism, and related traits such as anxiety. Work on the personality 'superfactors' is supplemented by studies of more narrowly defined traits, sometimes described as primary or

midlevel traits. Studies of clinical disorder have referred to the roles of both traits considered normal, such as neuroticism, and traits labeled as abnormal, such as schizoid and schizotypal personalities which may be associated with clinical schizophrenia. Recent work suggests that both types of trait may be treated as continuous dimensions, rather than discrete categories. That is, rather than an individual being rigidly categorized as either schizophrenic or nonschizophrenic, people vary in a continuous, graded fashion on the traits that capture core qualities of schizophrenia, such as experiencing delusions. In fact, there is quite good convergence between dimensional models for normal and abnormal domains. This article will focus primarily on constructs within the normal domain, but make some reference to abnormal traits.

Personality Traits, Information Processing, and Performance

The historical impetus for performance studies came from H.J. Eysenck's (1967) attempts to validate the arousal theory of personality from studies of various performance tasks. Interactions between extraversion and various stressful agents might be explained on the basis that extraverts were vulnerable to under-arousal whereas introverts were prone to over-arousal. Similarly, neurotic and anxious individuals were seen as liable to become over-aroused in emotive or stressful circumstances.

This research was valuable in showing that the impact of traits on performance is frequently moderated by environmental factors. However, it has failed to provide an adequate account of the performance data, for several reasons. First, evidence suggests that extraversion and neuroticism effects on personality may be found even with arousal controlled. Personality effects are not always (or even frequently) mediated by arousal. Second, the anxiety research of Charles Spielberger and Irwin Sarason highlighted the primacy of cognitive mechanisms over emotional physiological arousal in determining anxiety effects. Anxiety is harmful to performance because it is accompanied by worries that interfere with attentional processes. This perspective has been especially influential in studies of test anxiety. Third, personality effects vary substantially with the information-processing demands of the task. Performance is not a unitary construct, and traits are differentially related to different types of task. Fourth, the emerging cognitive neuroscience of personality, further discussed below, points toward brain mechanisms more specific than general cortical arousal as critical to personality.

Cognitive psychologists faced similar issues in seeking to understand effects of stressors such as noise and heat on performance. An influential critique set out by G.R.J. Hockey offered an alternative to arousal theory. He argued that the diversity of stressor effects across different tasks suggested a *cognitive patterning* of effects. The typical stressor appears to impair only certain components of information processing, while leaving others intact, or even improving processing. Hockey also pointed out that stressors may affect strategy as well as basic processing efficiency. Individuals under stress may appraise tasks and the priorities for applying effort differently.

The cognitive patterning approach provides a means for better understanding personality effects on performance. The assumption is that traits typically correspond to multiple, often small, biases in information processing. (Typically, cognitive ability is a stronger influence on processing and performance). There remains a need for a systematic investigation of the processing correlates of traits, but published studies allow at least an outline of the multiple influences of major traits, especially extraversion and anxiety/neuroticism.

Cognitive Patterning: Extraversion–Introversion

Table 1 shows an outline patterning for extraversion–introversion. Discussion of the individual entries in the table is beyond the scope of this article, but two general themes may be identified. First, the temporal characteristics of tasks may be critical. Extraverts appear to have the advantage over introverts where speed is emphasized, as evidenced by more risky speed–accuracy tradeoff in reaction time tasks, and faster motor response execution. Extraverts also tend to do somewhat better on short-term memory (STM) tasks, whereas LTM may favor introverts. Tasks in which stimuli are presented infrequently, including vigilance and reflective problem solving, tend to be better performed by introverts. Second, the coding or representation of task stimuli may be critical. Although extraversion is largely unrelated to verbal ability, extraverts show greater verbal facility in tasks including fluent speech production and retrieval from semantic memory. Indeed,

Table 1 Outline cognitive patterning for extraversion–introversion

<i>Cognitive function</i>	<i>Sample task</i>	<i>Result</i>
<i>Extravert superiority</i>		
Divided attention	Memory search for single or multiple targets	Extraverts faster in dual-task versions conditions
Short-term memory	Free recall of word lists	Extraverts better at immediate recall
Speed of motor response	Choice reaction time	Extraverts show faster response execution
Speech production	Conversation in a second language	Extraverts more fluent in speech production
<i>Introvert superiority</i>		
Visual vigilance	Detecting line signal	Introverts show higher detection rate
Long-term memory	Paired-associate learning	Introverts better at long-term recall
Problem-solving	Problem-solving tasks requiring insight	Introverts faster and more accurate: extraverts finish impulsively
<i>Qualitative performance differences</i>		
Vigilance	Detection of brighter target stimulus	Extraverts adopt a lower response criterion
Response to stress and arousal	Serial choice reaction time	Extraverts are faster when high in arousal; introverts are faster when low in arousal (also depends on time of day)

studies of divided attention suggest that extraverts may have an advantage in processing multiple symbolic (alphanumeric) stimuli. Note also that several of these effects are moderated by the arousal or stress level of the experimental setting. For example, extraverts may find it especially hard to sustain attention and vigilance when the surrounding environment is unstimulating and deactivating.

Cognitive Patterning: Anxiety and Neuroticism

A cognitive patterning for anxiety (or neuroticism) is shown in Table 2. Again, some general themes are evident. Individuals high in trait anxiety are vulnerable to overload, especially on tasks making high demands on attention and/or working memory. Neuroticism is also associated with difficulties in managing transitions in workload. Second, anxiety may also be related to compensatory effort as the person tries to cope with the distraction associated with their own worries. Indeed, anxiety may sometimes relate to enhanced performance on easy tasks. Third, anxiety relates to enhanced sensitivity to threat stimuli, as shown most directly in studies of selective attention. The emotional Stroop test requires participants to name the ink colors of threatening or other emotive words. A. Mathews and C. MacLeod pioneered research showing that

anxious individuals tend to respond relatively slowly on this task, especially when the threat words match their current concerns, implying a cognitive bias.

Other traits have been studied less extensively, so that no detailed cognitive patterning may be presented, but there are several promising research areas. Within the FFM, there is accumulating evidence, often from an organizational perspective, suggesting that *conscientiousness* tends to relate to enhanced performance of a variety of tasks. The information-processing basis for these findings is unclear, but conscientiousness has been linked to effort and goal setting. *Openness* relates modestly to cognitive ability, especially crystallized ability, and other tests with some intellectual content, including creativity tests. These relationships may be mediated by motivational factors, including 'typical intelligence engagement'; that is, more open individuals have a greater interest in intellectual activities, supporting skill acquisition.

Cognitive Neuroscience Perspectives

The psychobiological roots of research on personality and performance ensured that the introduction of cognitive models to the field was accompanied by continued interest in psychophysiological correlates of information processing. One of the more productive lines of research relates to evoked potential (EP) responses derived from the electroencephalogram (EEG). Differences between extraverts and introverts have been found in the amplitude of the P3 (or P300) wave that may reflect updating of working memory. These differences may be associated with performance differences on working memory task.

In recent years, the cognitive neuroscience of personality has been boosted by studies of brain imaging, using techniques including functional magnetic resonance imaging (fMRI). Such studies may indicate the individual differences in neurological functioning that correspond to performance variation. There are several promising lines of research. As already described, traits including extraversion and anxiety relate to attentional functioning. The cortical brain circuits that control different attentional processes are increasingly well-understood, and evidence from fMRI may be integrated with behavioral studies in order to elucidate the nature of personality effects.

Traditional biological theories of personality situated traits in subcortical systems such as arousal circuits and reward and punishment systems. In contemporary cognitive neuroscience, such circuits are relevant because their activity may modulate the cortical systems that more directly control information processing. For example, dopaminergic afferents may influence the areas of prefrontal cortex that support executive processing in attention and working memory. Extraversion may be related to reward areas of the brain and increased dopaminergic activity. Research is exploring whether this hypothesis explains the greater efficiency of working memory in extraverts, relative to introverts (in some task paradigms).

Similarly, structures including amygdala and anterior cingulate cortex may relate to individual differences in processing emotional information. Circuits including these structures may mediate effects of traits on cognitive bias in attending to emotional stimuli, shown by studies of the emotional Stroop test. Finally, research is also addressing the molecular genetics of

Table 2 Outline cognitive patterning for anxiety/neuroticism

<i>Cognitive function</i>	<i>Sample task</i>	<i>Result</i>
<i>Processing efficiency effects</i>		
Divided attention	Concurrent math and verbal memory	Anxiety leads to impairment in dual-task performance (especially on secondary tasks)
Working memory	Mental transformation of letter sequences	Anxiety-related impairment increases with memory load
Resisting distraction	Comprehending text with background speech	Anxiety relates to distraction by irrelevant speech
<i>Cognitive bias effects</i>		
Selective attention (single channel)	Emotional Stroop	Anxiety subjects are slow to name ink colors of threat words
Selective attention (multiple channel)	'Dot-probe' visual attention task	Anxious subjects respond more quickly to probe presented at location of threat
Semantic processing	Interpreting spoken homophones: for example, 'die' versus 'dye'	Anxious subjects biased toward selecting threatening interpretation
<i>Qualitative performance differences</i>		
Response to evaluative stress	Performance with evaluative instructions	Anxiety relates to performance impairment when evaluated
Memory strategies	Free recall of word lists	Anxiety relates to reduced strategic reorganization of words

the relevant neurotransmitters; future studies may identify polymorphisms that correspond to individual differences in cognitive functioning and performance.

Toward Cognitive Theories of Personality Effects

The delineation of the cognitive patterning of a trait is essentially a descriptive exercise, which provides the fine-grained account of trait effects necessary for subsequent theory building. Typically, cognitive psychological theories of trait effects reflect a progression of increasing specificity in relating traits to information-processing mechanisms. Early studies suggest an association with some broad cognitive function such as 'attention' or 'short-term memory,' without isolating any specific information-processing mechanism. Further work differentiates possible mechanisms and seeks to isolate those that are responsible for trait effects. For example, the cognitive bias associated with anxiety might be produced by either an early 'preattentive' bias in threat encoding, or by later strategic processes. Ideally, the end-point of theory development should be a computational model that identifies traits with quantitative model parameters. Extant research has rarely attained this goal, although promising work has been done from a connectionist perspective, especially in modeling the effects of traits linked to negative affect.

The cognitive patterning approach emphasizes that trait effects are *distributed* across multiple component processes. By contrast with traditional biological theories of personality, there is no single key process for trait action. Thus, we may arrive at a series of 'cognitive mini-theories' that describe the effect of a given trait on a given class of tasks (e.g., effects of extraversion on vigilance), but do not provide any general synthesis of the relationship between the trait and information processing.

Some researchers have attempted to provide general accounts of personality effects, which will be reviewed next. These theories relate to processing resources as a key mediating construct to the role of executive control functions in mediating anxiety effects and to the adaptive functions of cognitive biases associated with personality.

A Processing Resource Model

Processing resources are metaphorical reservoirs of energy that may be required for processing that remains under voluntary control. The concept has been influential especially in research on divided and sustained attention. There has been debate over whether resources are unitary, or whether multiple resource pools energize qualitatively different types of processing.

M.S. Humphreys and W. Revelle proposed that variation in resource availability may mediate the effects of both transient arousal states and a range of personality and motivational traits. Their multiple resource model incorporates resources for 'sustained information transfer' (SIT), required for a variety of demanding attentional tasks, and resources for STM. High arousal tends to increase the availability of SIT resources, consistent with evidence that stimulant drugs tend to enhance vigilance and other attentional tasks. Arousal also reduces

STM resources. The theory distinguishes on-task effort from arousal as an energetic construct. On-task effort increases functional availability of both types of resources.

The theory has inspired work in a variety of areas. The authors' own research focused primarily on effects of extraversion and impulsivity and their interaction with arousal manipulations including time of day and caffeine. They investigated tasks including cognitive ability tests and more basic information-processing tasks. They were able to show that interactions between personality and caffeine were consistent with the theory. A key assumption derived from the model was that complex tasks, requiring both SIT and STM resources, showed the inverted-U curve relating arousal to performance assumed by traditional arousal theory. A criticism of the model was that tasks most sensitive to interactive effects of extraversion and arousal appear to require routine, somewhat automatic stimulus encoding, and may not be highly resource-limited. Researchers are continuing to elaborate the theory.

The resource model has also been applied to understanding individual differences in vigilance. The state factor of task engagement (combining energy, motivation, and concentration) reliably predicts performance of a range of demanding vigilance and visual search tasks. The association between high engagement and attention is reliable only under high levels of task demand, as resource theory predicts, assuming task engagement can be identified with arousal. The hypothesis that arousal impairs STM has been less successful. Indeed, high task engagement may facilitate working memory. The multiple resource model also links STM deficits to reduced on-task effort, a hypothesis that is compatible with other cognitive models of anxiety.

Attentional Control Theory

Attentional control theory, developed by M.W. Eysenck and his colleagues, aims to explain anxiety effects on a range of tasks requiring attention and working memory in terms of specific executive control processes. It integrates several themes of existing anxiety research within the understanding of executive function provided by contemporary cognitive neuroscience. The first theme is the generally detrimental effects of anxiety and worry on various cognitive tasks. The initial cognitive mechanisms to which these effects were attributed were broadly described in terms such as cognitive interference and working memory impairment. However, attention and working memory may be regulated via multiple executive control processes, as shown by recent psychometric work in the area. Inhibition of conflicting responses, shifting between mental operations, and updating working memory are three separate control processes. Evidence reviewed by Eysenck and colleagues suggests anxiety reliably disrupts inhibition and possibly shifting, but not updating.

A second theme is that anxiety relates to selective attentional bias, in the form of enhanced attention to threatening stimuli. The bias effect can be demonstrated with 'subliminal' stimuli that are masked to the point where they cannot be consciously recognized, implying that anxiety influences early, preattentive processes. Attentional control theory assumes that attention is both stimulus-driven and goal-driven. Anxiety relates to enhanced sensitivity of the stimulus-driven system

to threat. A third theme is that attentional bias is controlled by expectancy and strategy choice as well as unconscious preattentive processes. Attentional control theory proposes that weakness of executive control, especially in relation to inhibition, accentuates the tendency of anxious individuals to be distracted by the threat stimuli prioritized by stimulus-driven attention. A fourth theme, articulated in M.W. Eysenck's earlier work, is that anxious individuals may compensate for disruption of attention via increased effort; an assumption that is also incorporated into the theory. It successfully integrates much existing anxiety research, although it has been developed too recently to be tested explicitly, other than in the ongoing work of Eysenck and his colleagues. These authors – consistent with a cognitive patterning perspective – also point out that the theory is directed specifically toward the effects of anxiety on attention and working memory. Other performance correlates of anxiety, such as effects on retrieval from LTM, are beyond its scope.

Cognitive-Adaptive Theory

Cognitive-adaptive theory, developed by G. Matthews, is an attempt to interrelate the multiple cognitive correlates of traits such as extraversion and neuroticism. It asks how the cognitive correlates of the trait support adaption to the individual's life circumstances. A key assumption is that there is a correspondence between personality traits and environments. A high level of a given trait equips the person to thrive in certain environments (with corresponding disadvantages in others). The cognitive correlates of a trait typically have an indirect rather than a direct effect on adaptation by facilitating the development of acquired skills congruent with the trait.

Extraversion-introversion effects illustrate this perspective. Extraverts are adapted to function well in cognitively demanding social environments. Cognitive correlates of extraversion (see [Table 1](#)) such as good verbal STM, and fluent speech production support acquisition of the relevant social skills. Neurologically based attributes of extraversion such as tolerance of high arousal and stimulation, and reward-sensitivity, facilitate adaptation in parallel with cognitive skills. Conversely, introverts are adapted to solitary environments in which task stimuli and positive reinforcement may be infrequent. The cognitive-adaptive perspective on anxiety and neuroticism suggests that anxious individuals are adapted to environments in which threats are disguised or ambiguous, requiring high threat sensitivity and subsequent threat avoidance. Individuals low in anxiety are more geared to direct confrontation of threat after it becomes salient.

Cognitive-adaptive theory explains the distributed nature of the cognitive correlates of traits. It is also compatible with theories that specify information-processing mechanisms in detail. The theory also goes farther than standard cognitive accounts in describing the dynamic nature of interaction between personality and cognition. The 'adaptive triangle' refers to the interplay between (1) the stable cognitive structures and biases that provide the basis for personality effects, (2) self-regulative processes that evaluate performance competence and coping potential, and (3) outcomes of behavior that may provide feedback both to influence further skill acquisition, and the person's beliefs about his or her own competence.

Further Research Directions

The research topics reviewed thus far are those that address the relationship between personality and cognition most directly, by collecting objective data on individual differences in performance from controlled experiments. However, the relationship between personality and cognition has also been explored using other methodologies such as analysis of self-reports of cognitive processes and clinical observations. This section briefly surveys the contribution of cognitive research to three further major areas of personality research: self-regulation and emotion, social behavior, and clinical disorder.

Self-Regulation and Emotion

There are many theories of emotion, but one influential approach is to see emotion as a concomitant of self-regulation. C.S. Carver and M.F. Scheier have suggested that avoidance and approach behaviors are controlled by feedback loops that aim to reduce discrepancy with some standard value. Personal and social standards may be represented as part of the self. Discrepancy generates negative emotion, whereas an acceptable rate of progress toward meeting the standard produces positive affect. The later work of these authors also describes discrepancy-enlarging feedback loops in which the system operates to increase distance from a reference value (e.g., avoiding ridicule). They also discuss the role of nonlinear dynamics. Personality may impinge on several features of feedback control systems, including the individual's personal standards, the availability of corrective actions, and dynamic properties of the system such as speed of response to feedback. Recent personality research has sometimes equated extraversion and positive emotionality with approach tendencies, and neuroticism and negative emotionality with avoidance.

Self-regulation models complement traditional neurological models of personality. At a more fine-grained level, research has identified several potential mediating processes. Traits may bias cognitive appraisal of stimuli and events. Neurotic individuals are more likely to appraise events as threatening, whereas extraversion relates to challenge, elevating negative and positive affect, respectively. In addition, as the transactional theory of stress and emotion describes, individuals manage demanding events dynamically, by implementing coping strategies, and processing feedback on outcomes of coping. Traits may influence how these cognitive regulatory processes operate. Neuroticism has been linked to emotion-focused coping, whereas extraversion is associated with greater use of task- or problem-focused coping. These associations may be demonstrated in both controlled laboratory settings and in real-life contexts.

Personality also relates to style of mood regulation. Individuals high in neuroticism and other traits linked to negative emotion tend to ruminate perseveratively on negative events and thoughts, perpetuating negative affect and worry. Conversely, extraverts may be better than introverts at repairing a bad mood or maintaining positive affect. Emotions may also be regulated through choice of activities and exposure to situations that are mood-uplifting or depressing. High neuroticism

individuals are more prone to become involved in disagreements with others that may elicit negative emotion, whereas extraversion is linked to mood-enhancing social participation.

A new perspective on personality, self-regulation, and emotion derives from research on the new construct of emotional intelligence (EI). Although conceptualization and assessment of EI remains controversial, emotionally intelligent individuals may possess personality characteristics that support more effective mood regulation. Attention to emotion, clarity of emotions, and mood repair are aspects of trait EI that may support mood regulation. Individuals high in EI may be better able to use and express their emotions constructively, even in difficult, potentially stressful circumstance.

Personality and Social Behavior

As previously indicated, traits may relate to the content of self-knowledge. For example, self-esteem may relate low neuroticism and high extraversion. Because of the social nature of the self, much of this knowledge refers to social relationships, such as the extent to which the self is generally liked or disliked by others. The person's typical social behaviors may be influenced by this knowledge. In addition, traits may relate to specific self-regulative processes such as self-verification (seeking confirmation for self-beliefs) and self-enhancement.

These principles have informed experimental studies of agreeableness. The trait relates to self-reported attributes including empathy, cooperativeness, and liking for others. There is indeed evidence that agreeableness relates to higher quality of social interaction, more satisfying close relationships and fewer conflicts with others. Controlled observational studies confirm that agreeableness relates to behaviors that may promote interpersonal relationships such as greater visual attention and more 'open' body positions. The effects of agreeableness may be controlled by cognitive processes including more positive perceptions of others and greater attention to prosocial stimuli. Agreeableness also relates to the social motivations that may be represented within the cognitive self, including motives to accommodate to the needs of others, and to resolve conflicts through collaboration. Conversely, aggressiveness as a personality trait relates to distorted perceptions of others that lead to false attributions of hostility, and to motives to cope with hostility via confrontation and aggressive behaviors. At the extreme, such cognitive distortions may contribute to externalizing disorders and antisocial personality.

Vulnerability to Clinical Disorders

Although causal relationships between traits and episodes of acute mental disorder may be bidirectional, it is accepted that certain traits may elevate vulnerability to disorder. Vulnerability may relate to cognitive as well as to biological factors. A.T. Beck's identification of the encoding of dysfunctional negative self-beliefs in the self-schema as a risk factor for depression has already been indicated. Abnormality in information processing as well as in the content of self-knowledge may also be important. For example, a bias toward attending to threat may lead to a chronic overestimation of the prevalence and severity of threat. Indeed, recent experimental studies

conducted by C. MacLeod and colleagues show that training participants to respond to positive or negative stimuli may influence anxiety congruently. Memory biases also contribute to the initiation and maintenance of disorder.

The self-referent executive function (S-REF) theory of A. Wells and G. Matthews aims to provide a comprehensive account of the various cognitive factors that may shape vulnerability to anxiety and mood disorders and their perpetuation. A key assumption is that multiple cognitive processes contribute to vulnerability. Cognitive content, information-processing, and dynamic person-situation interaction are all important. Critical to the symptoms of emotional disorder are cycles of perseverative worry or rumination that reflect misdirected executive processing. Several cognitive factors increase the likelihood of such self-referent processing including dysfunctional declarative and procedural self-knowledge, and excessive attention to threat and to the self. Metacognitions that worry is effective for problem-solving are also harmful. Emotion-regulation strategies intended to reduce awareness of disturbing thoughts and images may, paradoxically, strengthen dysfunctional self-knowledge. Avoidance of feared situations may produce a similar, harmful outcome, by preventing opportunities for disconfirming irrational negative self-beliefs. Both neuroticism and more narrowly defined personality traits related to metacognitive style may tend to enhance these maladaptive styles of interaction with the external environment. These insights have supported cognitive-behavioral therapies directed toward the person's style of attention and metacognition.

Abnormal personality traits may relate to attentional impairments that contribute to additional mental disorders. The strongest body of research surrounds the schizotypy trait. Schizotypy refers to traits such as unusual and disorganized patterns of thinking, together with interpersonal difficulties, that may raise vulnerability to schizophrenia. Several studies show that schizotypy is associated with impairments in selective attention, associated with weaknesses in inhibition of task-irrelevant stimuli. P. Venables proposed that the selective attention deficit tended to flood the person's consciousness with confusing and sometimes bizarre ideas and images, similar to the positive symptoms of schizophrenia. Additional traits that have been linked to maladaptive attention include sensation-seeking, impulsivity, and tendencies to cognitive failures.

An Integrative Perspective on Personality and Cognition

One of the difficulties of cognitive personality research is that of seeing the forest for the trees. Personality appears to be associated with often small-magnitude biases in a wide variety of cognitive processes. G. Matthews has suggested that it is useful to place cognitive expressions of personality within the trilevel explanatory framework for cognitive psychology advanced by Z. Pylyshyn. Personality effects on behavior may variously be attributed to individual differences in

- (1) parameters of the physical, neural architecture for information processing (biological level),

- (2) parameters of the virtual processing architecture associated with constructs such as attentional resources and working memory (symbol-processing level), and
- (3) self-knowledge, personal goals, and beliefs about strategies for goal attainment (semantic level).

Thus, different problems in personality call for different types of cognitive explanation. Cognitive-adaptive theory is an attempt to show how the information-processing correlates of personality traits may cohere around individual differences in adaptation. At the most basic level, traits may represent different styles of adaptation to human social environments, adaptations that call for different cognitive strengths.

Glossary

Behavioral experiments Planned experimental activities based on experimentation or observation, which are undertaken between patients between therapy sessions. The primary purpose is to help patients to test the validity of their maladaptive beliefs, in order to obtain new information about themselves and the world.

Cognitive restructuring A technique used in cognitive-behavioral therapy to identify and correct negative thinking patterns, by replacing them with more rational beliefs.

Exposure A technique used in cognitive-behavioral therapy which involves presenting a patient with anxiety-provoking stimuli for a long enough time to decrease the intensity of his or her emotional reaction.

Metacognitions The knowledge you have of your own thoughts and the factors that influence your thinking.

Mindfulness A kind of nonelaborative, nonjudgmental, present-centered awareness in which each thought, feeling, or sensation that arises in the mind is acknowledged and accepted as it is.

Introduction

The development of cognitive behavior therapy could be divided into three generations. Behavior therapy (BT) could be considered as the first wave, where behavioral principles developed in the laboratory were used in a clinical setting in treating psychological problems (e.g., phobias). The second wave was cognitive therapy (CT) developed by A.T. Beck in the early 1970s, which initially was developed to treat depression, but later expanded to the treatment of other psychiatric disorders as, for example, anxiety and personality disorders. From the late 1980s to early 1990s, we could notice a synthesis between behavior therapy and cognitive therapy, into cognitive behavior therapy, which today has a large evidence base related to its treatment efficacy. During the two last decades, a number of new treatments have evolved from the cognitive therapy foundation, which many have classified as the 'third wave' of cognitive behavior therapy. This article describes the theory behind and therapeutic techniques used in traditional cognitive behavioral therapy (CBT) and newer developments in the third wave of cognitive therapy. In addition to treatment principles and cognitive theory, the efficacy of cognitive behavioral therapy is also discussed.

What Is CBT?

CBT has rapidly grown as a therapy approach in the last 20 years. It acknowledges that the processes between cognitions, emotions, and behaviors are influenced by complex interactions between biological processes and environmental and interpersonal influences. The relation between cognitions, emotions, and behavior is accentuated in this approach and particularly how change in cognitions could influence alterations in emotions and behavior. Departing from psychoanalytic concepts, several post-Freudian theorists like Adler, Sullivan, and Horney have influenced the development of CBT. Core beliefs and self-schemas from Kelly's personal construct, and the rational-emotive therapy from Ellis contributed to the theory and methods used in CBT. Beck and others extended

CBT to a wide array of conditions like depression, anxiety disorders, eating disorders, schizophrenia, bipolar disorder, chronic pain, personality disorder, and substance abuse. More than 300 controlled studies of CBT have been completed for a variety of psychiatric disorders.

CBT integrates two originally separate theoretical understandings and treatment approaches, namely, the behavioral and the cognitive approach. The most stringent behavioral approach exclusively focuses on observable and measurable behavior and does not take into account the mental processes. The cognitive approach, according to Beck, asserts that emotional disorders are maintained by a 'thinking disorder' where cognitions are viewed as antecedents and determinants of feelings and behaviors. Negative automatic thoughts are essential in CBT and manifest themselves as rapid content-specific thoughts. For example, in depression, these thoughts have a content that reflects negative ideas about the self, the world, and the future, while for anxiety, they usually reflect the theme of danger and an underestimation of coping. The cognitive theory further states that negative automatic thoughts are rooted in early negative experiences that may facilitate the formation of more permanent negative beliefs (core beliefs). Particular situations relevant to a negative belief may activate it. Once the negative belief has been activated, negative automatic thoughts will occur in the stream of consciousness. Beck therefore proposed a cognitively based therapy aiming to reverse dysfunctional cognitions and related behaviors. Panic disorder is one particular example where cognitive and behavior theories come together. According to Clark's cognitive model of panic disorder, patients suffering from panic attacks typically have cognitive symptoms like catastrophic fears of physical calamities or loss of control combined with behavioral impulse to escape or avoid. Altering dysfunctional cognitions and encouraging the reversal of maladaptive behavioral coping like avoidance would therefore be a focus in CBT.

The principal element of CBT is that cognitive processing is given a prominent role, because humans continually appraise the significance of the events they observe and take part in. Depending on the appraisal, emotional and physical reactions often form the basis for behavioral responses. According to the

Heimberg's cognitive model of social phobia, patients with this disorder may have the following thoughts related to an invitation to a social event: "I don't know what to say . . . Everyone can see that I am nervous . . . Others will think I'm stupid . . . It is best if I don't go at all . . ." These thoughts that are typical in social phobia could give emotional and physiological responses like severe anxiety, physical tension, and autonomic arousal like dry mouth, increased heart rate, and increased sweating. Avoidance of a feared situation strengthens the relation between negative thinking and avoidance, primarily because the avoidance gives an immediate reduction of stressful emotional and physical reactions. However, the avoidance also limits or eliminates alternative learning experiences because an individual avoids situations that may contribute to new information, and therefore strengthens his or her dysfunctional assumptions.

Basic concepts

In CBT, it is not the event in itself that affects our behavior and emotion, but it is how the event is appraised that influences our responses. CBT has identified three levels of cognitive processing, namely (1) conscious processing, (2) automatic thoughts, and (3) schemas (core beliefs). The first process allows us to monitor and assess our interaction with the environment, integrate past memories with present experiences, and plan and control the future. The two latter concepts are parts of automatic information processing and thus not part of a controlled and voluntary information process. In this article, the concept of automatic thoughts and schemas will be described.

Automatic thoughts

Automatic thoughts are cognitions that flow rapidly through our minds while we are remembering a situation or are in the midst of one. These thoughts are typically subliminal and not subjected to careful rational analysis, but they do influence how we evaluate the significance of particular events. All humans have automatic thoughts, but it is only when the situation triggers negative automatic thoughts that these thoughts form the basis for psychological disorders. Research has shown that individuals with psychological disorders often experience a flood of maladaptive automatic thoughts that contribute to generate stressful emotional reactions and dysfunctional behaviors. For depression, the negative automatic thoughts often spin around themes like failure, hopelessness, and low self-esteem. For anxiety disorders, such thoughts often focus on the prediction of danger, harm, uncontrollability, and inability to manage threats. In CBT, increased awareness of primarily negative automatic thoughts and subsequently the emotions and behaviors they contribute to create is among the initial steps of the treatment.

Cognitive errors

Initially, in CBT, it was theorized that there would be characteristic errors of logic in the automatic thoughts typical for individuals with emotional disorders. Research has later confirmed that there are pathological styles of information processing where characteristic cognitive errors are typical. Beck and colleagues have identified six main categories of cognitive

errors: arbitrary inferences, selective abstraction, dichotomous or all-or-nothing thinking, magnification and minimization, overgeneralization, and personalization. The CBT therapist typically educates the patients about these cognitive errors which thereby increase the patients' ability to identify when they make such cognitive errors, and make new evaluations less influenced by them.

Schemas and core beliefs

In CBT theory, schemas are core beliefs that underlie or govern information processing, and underlie the more superficial layer of automatic thoughts. These core beliefs are enduring principles of thinking that are typically shaped in early childhood. A multitude of life experiences influence the development of these schemas, like parental modeling and teaching, educational activities along with peer experiences and traumas. It is theorized that these schemas develop in order to facilitate the processing of the multitude of information that individuals face in their everyday life. It is thought that they serve as a screening, filtering, or coding function in assigning meaning to information for the individual. Some researchers differentiate between nuances of the levels of schemas; however, it has been found that most patients benefit from recognizing the general concepts of maladaptive schemas and that these have a strong influence on self-esteem and behaviors. The goal in CBT is to identify and develop adaptive schemas and simultaneously modify and reduce the influence of the maladaptive schemas.

Overview of CBT Therapy Approach

There are some fundamental principles for administering CBT treatment. The cognitive processes involved in appraisal of information described earlier are equally relevant for clinical and nonclinical individuals and as such relevant for all humans. The CBT is at present, problem- and content-oriented. In addition to a thorough diagnostics, it is very important to develop an individualized case formulation at the beginning of therapy, as this will serve as a guideline throughout the therapy and direct therapist interventions. An early identification of a shared goal of therapy is important and can facilitate the therapeutic alliance. The CBT sessions follow a particular pattern for each session, starting with establishing an agenda, establishing the main themes of therapy are discussed, designing content appropriate homework tasks, and at the end of the session, letting clients summarize the session and learning points.

The general approach is founded on scientific principles, and the therapist aims to view the client's assumptions, automatic thoughts, and schemas as testable scientific hypothesis that ideally can generate behavioral experiments in order to check out the validity of the patient's thoughts. This is often labeled collaborative-empirical therapeutic relationship. One particular often used technique called Socratic questioning involves formulating questions in order to stimulate curiosity and inquisitiveness and aiming to get the patient involved in a learning process. This technique has been shown to facilitate guided discovery, where the therapist leads the patient to discover the dysfunctional patterns and behaviors and thereby generate alternative cognitions or operationalize their assumptions to make them testable in behavioral experiments. Psychoeducation is also an important part of CBT in

normalization of symptoms, also in addition to deepening the understanding of the relation between cognition, emotion, and behavior.

Particular techniques

Identifying negative automatic thoughts and subsequently the underlying core beliefs is a primary objective of CBT. Once the content of the negative automatic thoughts and schemas is identified, these assumptions are later challenged. This is often labeled cognitive restructuring, which basically involves identifying cognitive errors, examining the evidence (pro-con analyses), reattribution, exploring alternative explanations or ways of understanding situations, and listing rational alternatives and cognitive rehearsal and behavioral experiments to test hypothesis based on either negative automatic thoughts or schemas. One example of a particular technique in CBT is the ABC technique. Listing Antecedents (situations), Beliefs, and (emotional) Consequences, in three columns, familiarizes the clients with how particular situations may activate different automatic beliefs, which again elicits emotional reactions. Proposing and exploring alternative beliefs may alter the emotional reaction.

Behavioral techniques are primarily designed to help clients break patterns of avoidance and helplessness, gradually face feared situations, build adaptive coping skills, and reduce maladaptive emotional and autonomic arousal. A behavioral experiment is designed to explore the validity of the patient's existing beliefs about themselves, others, and the world, and to construct and test new more adaptive beliefs. Behavioral experiments take a scientific approach and tests whether a particular automatic thought or a core belief could predict what happens in the real world. It is therefore important to generate one or more precisely operationalized predictions based on the theory the client and therapist want to test. If the theory of a patient suffering from social phobia is 'I blush when I talk in social situation and therefore others think I am stupid,' then it should be possible to observe the blushing on a video, and further we should check if others really think someone is stupid for blushing. Behavioral consequences of particular sets of cognitive errors may lead to behavioral avoidance and safety-seeking behaviors, which in itself contributes to maintain the psychological disorder. Following each behavioral test, it is important to evaluate the outcome, and explore if the predictions were true and if there is reason to maintain or abandon previous behavior and negative automatic thoughts and schemas.

Efficacy of CBT

CBT has played a very important role in establishing the evidence-based approach within psychotherapy, by using meticulous scientific methods to explore the validity of theory and therapy. Initially a treatment for depression, CBT has become a treatment approach to very many different psychiatric disorders. With time, many studies have evaluated the efficacy of CBT, so meta-studies are rather common. One such study undertaken in 2006 by Butler and colleagues summarized 16 methodologically rigorous meta-analyses. Large effect sizes were found for CBT for unipolar depression, generalized anxiety disorder, panic disorder with and without agoraphobia, social

phobia, posttraumatic stress disorder, and childhood depressive and anxiety disorders. Moderate effect sizes were found for marital distress, anger, childhood somatic disorder, and chronic pain. CBT and behavioral therapy was equally effective for adult depression and obsessive-compulsive disorder. For bulimia nervosa and schizophrenia, there were found large uncontrolled effect sizes. Another meta-analysis of 108 treatment trials across anxiety disorders in 2007 by Norton and colleagues found that treatment was superior to no treatment and expectancy control treatments.

In summary, there are many randomized controlled treatment trials for CBT with large numbers of participants that collectively support the efficacy of CBT across a wide variety of diagnoses. Collectively, these studies suggest that CBT could be considered the treatment of choice for anxiety and depressive disorders. Despite extensive evidence, the scientific and hypotheses-driven approach of CBT has resulted in the development of newer cognitive treatment approaches, which we describe next.

The Third Wave of Cognitive Behavior Therapy

The third wave represents a new approach to CBT, and examples of such so-called third wave CBT therapies include Acceptance and Commitment Therapy (ACT), Dialectical Behavior Therapy (DBT), Metacognitive Therapy (MCT), Mindfulness-Based Cognitive Therapy (MBST), Cognitive Behavioral Analysis System of Psychotherapy (CBASP), Functional Analytic Psychotherapy (FAP), and Integrative Behavioral Couple Therapy (IBCT).

Compared to traditional CBT, the aforementioned types of third wave cognitive behavior therapies have important differences between them and some shared features. While traditional CBT is primarily engaged in working with the content of thoughts (disputing, change and restructuring content of the person's thoughts), these new forms of cognitive behavioral therapies try to work to change the relationship between the person and his or her thoughts and feelings. The therapeutic methods used for change have also a more experiential character than the didactic approach which is well known in traditional cognitive behavior therapy. In many of the third wave therapies developing mindfulness and acceptance of your thoughts play a leading role, while disputing the content in the thoughts is emphasized in traditional CBT. It would be impossible to give a full description of all the third wave cognitive behavioral therapies in this article. As ACT, DBT, and MCT are treatment approaches developed to treat a broad variety of psychological problems and also have been tested out empirically, these treatments are described in some detail in relation to their theoretical basis, treatment principles, and treatment efficacy.

Acceptance and Commitment Therapy

ACT described their theoretical basis for understanding psychopathology, and their model for psychological treatment is embedded in what is called Relational Frame Theory (RFT). The details of RFT go beyond the scope of this article, so just a very short version of the theory is given here. From a RFT

perspective, psychopathology develops mainly because individuals have problems in separating the process of thinking from the products of thinking. This cognitive fusion between the process and products of thinking leads to an excessive or improper regulation of behavior by verbal processes. The behaviors of individuals will then be guided more by their inflexible verbal networks than by contingencies of reinforcement in their environment. The process of cognitive fusion leads to other processes in developing psychopathology. As individuals have problems in separating the content of thoughts from the process of thinking (thinking the thought), many people start to fear and avoid their own thoughts, feelings, and bodily sensations as a way to cope with and regulate their negative emotions. This process of escaping thoughts and emotions is destructive, because it leads to what is called 'experiential avoidance.' It will trigger people to think that certain emotions, thoughts, and bodily sensations are dangerous to experience and therefore must be avoided. All in all, these psychological processes will cause people to miss out of their experiences of their present moment. They will disappear in what Stephen Hayes describes as "a cacophony of human thinking and its reasons, explanations and justifications for behavior." In accordance with RFT, it would therefore be of importance to down-regulate these negative processes so that people could start clarifying their personal values and goals and let them guide their behavior instead.

In ACT, psychological suffering is seen as being caused by experiential avoidance and cognitive fusion. This would result in psychological inflexibility that leads to a failure in taking the needed behavioral steps into acting according to a person's core values of life. If people's actions are directed by their personal values, it would bring more vitality and meaning into their lives. Making people clarify their values and act according to these goals would increase their psychological flexibility and make them less vulnerable to psychological problems.

ACT's principles of treatment is focused around six core treatment principles, where all of them are aimed at helping the client to develop an increased psychological flexibility, making the client experience the present moment more fully, and trying to let the clients' behavior be guided by their personal values and goals. A short description of these six treatment processes in ACT is given in the following paragraphs.

- *Cognitive defusion*: Cognitive defusion techniques try to make the client to change the way one interacts with or relates to one's thoughts. Instead of trying to alter the form of the thoughts and their frequency, the client is taught to perceive thoughts and emotions as they are, not as what they appear to be.
- *Acceptance*: Acceptance of the thoughts and emotions is taught as an alternative to experiential avoidance. Instead of trying to avoid specific thoughts and emotions, the client is taught to allow emotions and thoughts to come and go, without struggling to suppress and avoid them.
- *Contact with the present moment*: ACT tries to increase the client's skill of having a nonjudgmental contact with his or her private events and events in the environment as they occur. In order to make this happen, the client is trained in developing skills to develop a better awareness of the 'here

and now.' If the experience of the 'here and now' is guided by interest and openness instead of an experiential avoidance, it would increase psychological flexibility in the individual.

- *Observing the self*: Since human language leads to a sense of self as a locus of perspective, the self cannot be contacted consciously since it is at the core of consciousness itself. It is therefore essential that the client gets access to his or her transcendent sense of the self. A transcendent sense of the self instead of having a picture of the self as a fixed entity, would help the client to experience his or her thoughts and feelings as ideas of themselves, instead of permanent and predetermined characteristics.
- *Values*: Early in treatment, the client is asked to list values in different life domains, in order to make them discover what is important to oneself and life. When the client chooses directions in life which are based on their personal values instead of choices based on avoidance or cognitive fusion, it could help the client to develop a more vital and meaningful life.
- *Committed action*: While personal values never really can be fully achieved, committed actions involving these values must be broken down to make concrete short- and long-term goals. Based on these goals, committed actions to achieve their values are carried out by clients.

These core treatment processes in ACT are overlapping and interrelated, and could be chunked into two groups of interventions according to ACT. Mindfulness and acceptance processes involve acceptance and cognitive defusion which will result in a better contact with the present moment, and the development of the client's ability to see their personal self in a context. The processes of commitment and behavior change involve contact with the present moment, where the clients could see themselves in a context, and make their values explicit and committed actions in accordance with these values. All of these treatment processes use different exercises, homework, and metaphors in order to work and change the client's psychological problems.

There are a substantial number of controlled trials investigating the efficacy of ACT on a diversity of psychiatric disorders. A meta-analysis by Öst done in 2008 showed that ACT compared to waiting list conditions reported a large effect size both at treatment and follow-up. Powers followed up with a new meta-analysis in 2009 where further new ACT studies were included. The meta-analysis from Powers showed that ACT outperformed control conditions as waiting list, treatment as usual (TAU), and psychological placebo both at posttreatment and follow-up with a medium effect size. However, when ACT was compared to established active treatments as for example CBT, ACT showed no distinct advantage over these treatments.

Dialectical Behavior Therapy

DBT is a psychotherapeutic intervention originally developed to treat persons with borderline personality disorder (BPD). Although it was originally developed for chronically suicidal individuals with BPD, DBT has since then been adapted for other psychiatric disorders characterized by emotional dysregulation problems. These disorders include substance

dependence, binge-eating disorders, and depression in elderly and suicidal adolescents.

DBT came into being mostly because traditional cognitive behavior treatment showed important shortcomings in the treatment of BPD, and combines the basic strategies for behavior therapy with eastern mindfulness practices. DBT tries to integrate both the concepts of acceptance and change in their treatment philosophy. The therapist is focused on accepting and validating people's feelings, thoughts, and behaviors as reactions of patients' suffering and problems, but at the same time trying to educate patients that some of these feelings and behaviors are maladaptive and in need of change. The DBT treatment could be broken down in phases where in the first phase self-injurious and suicidal behavior takes the main concern and needs to be taken under control, which is then followed by a focus on therapy-interfering behaviors. The next phase is directed on how to enhance the quality of life and make the clients feel better, to resolve problems in living and residual disorders, and finally to find joy and meaning in their lives. Acceptance procedures in DBT include mindfulness and a variety of other validation and acceptance-based strategies. Change strategies in DBT include behavioral analysis of maladaptive behaviors and the introduction of new problem-solving techniques, including skills training, contingency management, cognitive modification, and exposure-based strategies. The goal of the treatment is to help the patient to engage in functional life-enhancing behavior even when intense emotions are present. The therapy could be split into several components. Among the components is the use of highly structured individual or group skill training, individual psychotherapy, and telephone contact between the patient and the individual therapist. In both group and individual therapy, learning and improvement of skills is emphasized. These specific skills are divided into four modules: mindfulness skills, interpersonal skills, emotional regulation skills, and distress tolerance skills. In addition to all these aforementioned techniques, a team regularly meets the therapists to keep them motivated and supervise them in order to provide effective treatment for their patients. For a further in-depth description on the treatment principles of BPD, the books listed in the Further Reading section is recommended.

Since DBT is developed for the treatment of BPD, it is understandable that most of the studies done on the efficacy of DBT are focused on BPD, although there are a few studies related to the use of DBT in treating eating disorders and on depression. The original DBT treatment lasts for 1 year, but studies with shorter treatment duration have been published. Öst's meta-analysis from 2008, showed an overall effect-size of a mean of 0.58 the DBT studies included in this meta-analysis. In line with the results of ACT, DBT showed large effect sizes compared to a waiting list condition, but in comparison to treatment as usual and other active treatment, the effect size was moderate.

Metacognitive Therapy

Metacognition refers to the cognition applied to cognition and may be defined as any knowledge or cognitive processes that is involved in the appraisal, control, and monitoring of thinking. According to metacognitive theory, there is a distinction

between metacognitive knowledge, which is information that individuals have about their own thinking and about the strategies that affect it, and metacognitive regulation, which comprises the strategies used to change the status of thinking. As many people experience negative thoughts but do not develop psychological disorders, MCT proposes that thought content is not so important as suggested in CBT, but it is the reactions to the thoughts which play a prominent role in the development and maintenance of psychological disorders. MCT is focused on the core question: Why do people have problems regulating their preservative and fixative style of thinking?

The theoretical grounding of MCT is the Self-Regulatory Executive Function (S-REF) model, which emphasizes the similarities in maladaptive cognitive processing across psychological disorders. The S-REF model postulates a thinking style called the Cognitive Attentional Syndrome (CAS). The CAS is a universal feature of psychiatric disorder and is responsible for prolonging and intensifying distressing emotions within the individual. The CAS consists of inflexible self-focused attention, preservative thinking style in the form of worry and rumination, and threat monitoring and coping behaviors that backfire and fail to modify erroneous beliefs about your thinking and the world around you. The CAS is considered to be a problem for psychological well-being because it focuses appraisal on threat, it fails to provide information that can modify erroneous appraisals and beliefs, it drains attentional resources for more adaptive responses, it also biases perception and automatic processing in a negative and skewed manner, and consequently it maintains the psychological problems. Threat monitoring is a particular process of the CAS where a person focuses his or her attention to external and internal threats as a way to cope. This way of coping causes the individual to become hypervigilant and aware of potential internal and external threats. Such a focus often leads to negative thoughts, worry, and rumination, causing the person to become depressed and anxious. Avoidance and thought suppression is the last template of the CAS. Such cognitive processes block new information processing and thus preserve erroneous beliefs about themselves, others, the world, the past, and the future. There is a large evidence-base to prove that the CAS is associated with the vulnerability and serves as preserving factor of emotional disorders.

The CAS is driven by metacognitive beliefs and knowledge stored in long-term memory, and exists as programs for guiding cognitive information processing and coping behaviors. MCT implies that all disorders could be linked to a higher level of metacognitive beliefs about thinking and that these fall into either positive or negative categories. Positive metabeliefs concern the advantages of worrying, ruminating, threat monitoring, and controlling of cognition. An example of such positive metabeliefs could be 'Worrying about the future helps me to be prepared for forthcoming negative events.' Negative metabeliefs are linked to the uncontrollability of worries and rumination or the dangerous consequences of such thinking processes. An example of such negative metabeliefs could be 'Worrying too much could make me lose control, and make me go mad.' MCT suggests that positive metabeliefs make a person vulnerable to develop emotional disorders and that negative metabeliefs serve as a maintaining factor for distress. The problem is that the metabeliefs lock the individual into a

processing style filled with worry and rumination which prolongs anxiety and depressive symptoms, because the person focuses on metabeliefs and cognitive processes that strengthen dysfunctional patterns. CAS occurs in response to initial negative thoughts or intrusions and the persons use worry and rumination as a way to cope with these thoughts.

A metacognitive therapy normally starts on building a case conceptualization that is grounded in a disorder-specific model. When doing metacognitive therapy, the therapist needs to work at the metacognitive level. In order to do this, the MCT therapist focuses on detecting and modifying the aspects of the CAS; preservative thinking, maladaptive attentional strategies, and unhelpful coping strategies. Clients are helped to see that problems are not the occurrence of negative thoughts, but that their problems lie in how they react to the thoughts themselves. It is essential that the client shifts from a content focus to a metacognitive way of processing. This will facilitate the development of a new awareness to their cognitive processes.

Techniques from the standard CBT, such as Socratic questioning and behavioral experiments, could be used, but in MCT, these techniques are aimed at the metacognitive level rather than at the cognitive level. Metacognitive beliefs are restructured through experiencing new types of relationships with cognitions, so the CAS could be modified. The MCT therapist incorporates techniques such as detached mindfulness, attentional training, and situational attentional refocusing in order to manipulate and change metacognitive beliefs and the CAS. It is essential for the client to develop new plans for processing by challenging the patient's negative and positive metabeliefs. Such changes are typically changed through new corrective experiences of their thoughts and thinking, with very little focus on the actual content of thoughts.

There is a large evidence base supporting the role of the CAS and the importance of metacognitions in psychological disorders. Some studies on the effectiveness of MCT have been completed, and other studies are ongoing. Several open trials indicate that MCT is an effective treatment for generalized anxiety disorders, social phobia, posttraumatic disorder, obsessive compulsive disorder, and major depressive disorders. However, there is a lack of large randomized controlled trials comparing MCT to established evidence-based treatments, which implicates a need for such studies before conclusions regarding the efficacy of metacognitive therapy could be drawn.

Conclusions

This article has described what characterizes different forms of cognitive behavioral therapies. While traditional CBT is primarily engaged in working with the content of thoughts, the third wave of cognitive behavioral therapies tries to work to change the relationship between people and their thoughts and feelings, and with less focus on the content of thoughts. In the last four decades, CBT has shown that it is an effective

psychotherapeutic treatment approach for mostly all of the psychiatric disorders listed in the diagnostic manuals. Although the results from clinical trials are promising, third wave cognitive behavioral therapies need to be compared to already evidence-based treatment for different psychiatric disorders in larger controlled trials, to prove if this is a more effective treatment than traditional CBT. Although there are few clinical studies related to the effect of these new cognitive behavioral approaches, it is important to acknowledge that the results are promising based on the fact that these types of therapeutic interventions are rather new.

Cognitive Bias

A Wilke, Clarkson University, Potsdam, NY, USA

R Mata, University of Basel, Basel, Switzerland

© 2012 Elsevier Inc. All rights reserved.

Glossary

Bounded rationality The principle that organisms have limited resources, such as time, information, and cognitive capacity, with which to find solutions to the problems they face.

Cognitive bias Systematic error in judgment and decision-making common to all human beings which can be due to cognitive limitations, motivational factors, and/or adaptations to natural environments.

Ecological rationality The principle that there is a match between the structure of information in the environment and the judgment and decision-making strategies of humans and other organisms.

Heuristic Judgment or decision-making mechanism or cognitive shortcut that relies on little information and modest cognitive resources.

Heuristics and Biases: A Short History of Cognitive Bias

In the early 1970s, Amos Tversky and Daniel Kahneman introduced the term ‘cognitive bias’ to describe people’s systematic but purportedly flawed patterns of responses to judgment and decision problems. A term search for ‘cognitive bias’ in the Social Sciences Database of ISI Web of Knowledge reveals close to 4000 hits covering the past 35-year period and an exponential increase in the usage over time, suggesting that the term ‘cognitive bias’ has since gained significant influence in the psychological and social science literatures.

Tversky and Kahneman’s research program – the heuristics and biases program – addressed the question of how people make decisions given their limited resources. The program was inspired by Herbert Simon’s principle of bounded rationality. In the late 1950s, Simon attempted to oppose the idea of classical rationality, which was concerned mostly with the formalization of normative solutions to judgment and decision-making problems through probability theory and statistics, with the idea of bounded rationality, which addressed the specific constraints faced by agents in their environments. For example, humans have only limited time, information, and cognitive capacity to decide which mate to choose, food to eat, or house to buy, and so may have to rely on simple decision strategies or heuristics to make their decisions. The heuristics and biases program followed the bounded rationality principle by attempting to identify the specific constraints or biases associated with human judgment and decision-making.

The heuristics and biases program was inspired by research on perceptual biases, and proposed that the human cognitive system like the perceptual system was designed to make inferences about the external world based on imperfect cues that could lead to errors in some situations. The program thus generated a straightforward and productive research paradigm, which can be described as follows. First, participants were presented with a reasoning problem to which corresponded a normative answer from probability theory or statistics. Next, participants’ responses were compared with the solution entailed by these norms, and the systematic deviations (biases) found between the responses and the normative solutions were

listed. Finally, the biases were explained as the consequence of the use of heuristics or simple cognitive principles. Using this strategy, researchers in the heuristics and biases program have produced an extensive catalog of norm violations. We present a partial list in [Table 1](#) that spans the judgment and decision-making, social, and memory research domains. Naturally, the goal was to provide explanations of these violations due to reliance on a small set of cognitive principles, the most popular judgment and decision mechanisms proposed being *representativeness* (a judgment is based on how much the hypothesis resembles available data), *availability* (a judgment is based on how easily an example can be brought to mind), and *anchoring-and-adjustment* (a judgment is based on a specific value or anchor and then adjusted to account for other factors).

The heuristics and biases program represents the most influential psychological research program to emerge in the last 40 years, and its merit lies in showing the shortcomings of classical economic approaches and the value of a bounded rationality perspective on understanding human judgment. The heuristics and biases program has, however, been criticized. First, researchers have argued that there are no unequivocal norms for defining rational judgments and decisions. For example, there are different concepts of probability espoused by statisticians and philosophers that imply different norms, which makes deviations from one hard to interpret as error or bias. Second, the program has been criticized for presenting only vague models of human reasoning. For example, the representativeness, availability, and anchoring-and-adjustment heuristics proposed by Tversky and Kahneman do not provide quantitative predictions of people’s judgments and it is often unclear which heuristic is applied under which condition. Third, the heuristics and biases program has been criticized for focusing on people’s initial responses to judgment problems rather than providing opportunity for learning from experience. For example, some anomalies to classical decision theory are eliminated if people have substantial experience with a decision problem. Similarly, many classic paradigms in this tradition involve participants’ responses to situations described in word vignettes, which are not ecologically valid and thus may offer inadequate insights about everyday decision-making.

Table 1 Examples of common cognitive biases

<i>Cognitive bias</i>	<i>Short description</i>
Confirmation bias	The tendency to selectively search for or interpret information in a way that confirms one's preconceptions or hypotheses
Conjunction fallacy	The tendency to assume that specific conditions are more probable than a single general one
Endowment effect	The tendency that people often demand more to give up on an object than they would be willing to pay to acquire it
Fundamental attribution error	The tendency to overemphasize personal factors and underestimate situational factors when explaining other people's behavior
Gambler's fallacy	The tendency to think that future probabilities are changed by past events, when in reality they are unchanged (e.g., series of roulette wheel spins)
Halo effect	The tendency for a person's positive or negative traits to extend from one area of their personality to another in others' perceptions of them
Hindsight bias*	A memory distortion phenomenon by which with the benefit of feedback about the outcome of an event, people's recalled judgments of the likelihood of that event are typically closer to the actual outcome than their original judgments were
Hot-hand fallacy*	The expectation of streaks in sequences of hits and misses whose probabilities are, in fact, independent (e.g., coin tosses, basketball shots)
Illusory correlation	The tendency to identify a correlation between a certain type of action and effect when no such correlation exists
In-group bias	The tendency for people to give preferential treatment to others they perceive to be members of their own group
Mere exposure effect	The tendency by which people develop a preference for things merely because they are familiar with them

Asterisks refer to examples that are discussed in the main text.

This view echoes well Egon Brunswik's argument for the study of the mind by relying on the informational cues present in natural environments.

Ecological Rationality: Putting Cognitive Biases in an Environmental Context

One fundamental criticism of the heuristics and biases program is that it has severely neglected the ecology of judgment and decision processes. The principle of bounded rationality is deeply associated with the idea that cognitive systems are fundamentally adapted to their environments – either through individual learning or by design through natural selection. Simon illustrated this with a metaphor: mind and environment as blades of a pair of scissors. Similar thoughts have been espoused by a number of other theorists. For example, Roger Shepard saw human vision as reflecting regularities of the physical world. John Anderson advanced the idea that memory is structured so as to mimic the probability of information occurring in the world and thus being needed by the organism.

In the late 1990s, Gerd Gigerenzer, Peter Todd, and the ABC Research Group presented a research program – the fast and frugal heuristics program – that extended the principle of bounded rationality and gave new breadth to the idea of cognitive bias. The fast and frugal heuristics program emphasized the principle of ecological rationality, that is, how the success of reasoning strategies depends on the structure of the environment. A good example of this principle is demonstrated by the United Parcel Service (UPS) Right Turn Policy: UPS, an international shipping company, delivers millions of packages every year in numerous delivery trucks. The right turn policy involves carefully mapping out routes for all deliveries to reduce the number of left-hand turns each truck makes, which helps reduce accidents as well as save fuel, thus maximizing overall profits. Naturally, this strategy works well in the United States and other countries where traffic keeps to the right. One would predict, however, that the right turn policy

would have the opposite results in countries, such as England, India, or Hong Kong, where people drive on the left.

The fast and frugal heuristics program has proposed an alternative research paradigm to the heuristics and biases' one. The program starts by analyzing the statistical structure of a specific task environment people face and then – based on the analysis – derives attributes of the cognitive models of reasoning that perform well in that environment. In sum, this program holds that exploring the characteristics of the environment will contribute to our understanding of what reasoning processes people follow and when and why these processes work well.

According to the fast and frugal heuristics program, a cognitive bias is the tendency to solve problems using a particular cognitive tool or heuristic. Crucially, it sees the selection of a particular heuristic not necessarily as the product of cognitive limitations but rather as a bet on the part of the organism about the structure of the environment in which it finds itself. One metaphor that guides the fast and frugal heuristics program is that of the mind as an adaptive toolbox of simple decision mechanisms, a repertoire of strategies, with each strategy tuned to a particular environment. A model of mind based on an adaptive toolbox is, therefore, boundedly rational in the sense of relying on few cognitive resources, and ecologically rational in the sense of being tuned to characteristics of natural environments.

Some have suggested that the differences between the Heuristics and Biases and the Fast and Frugal Heuristics programs are not substantive, boiling down to a disagreement between those that stress that the human mind is fallible and those who claim that it is often accurate. One clear contribution of the Fast and Frugal Heuristics program has been, however, to emphasize the role of environment and specify the statistical properties of environments that make particular cognitive biases or heuristics successful. In addition, the focus on ecological rationality has spurred new approaches that emphasize the role of environment and sampling in determining adaptive behavior. Specifically, recent approaches are devoted to understanding the role of sampling in generating

bias with less focus on the cognitive apparatus and more on environmental stimuli. For example, people's risk judgments of low probability events are often inflated. One possibility is that such bias is due to selective memory retrieval. However, an unbiased memory may also produce inflated judgments of risk due to biased media coverage of natural catastrophes and accidents. Current and future work on cognitive bias is concerned with the role of biased sampling in both the external environment and the internal cognitive apparatus.

Evolutionary Rationality: Understanding Why Cognitive Biases Occur

The concept of ecological rationality describes the match between structure and representation of information in the environment on one side, and the simple decision-making algorithms such as heuristics on the other. Whenever this match exists, heuristics can perform well. Evolutionary rationality holds, however, that it is important to consider the match between mind and the *past* environments in which the mind evolved. In other words, evolutionary rationality attempts to sketch the evolutionary origins of cognitive bias.

Some evolutionary scientists have followed the Heuristics and Biases program approach of using errors to study cognitive bias. The underlying principle behind such research strategy is that while people can make rapid adaptive decisions using simple and reliable cues, they are still at risk of making errors. However, these researchers have tried to introduce the role of costs to theories of cognitive biases. The argument goes that eliminating errors altogether is rare, if ever possible, but the costs associated with certain errors may lead organisms to systematically commit one type of error over another. This principle is at the heart of error management theory – a theory that applies evolutionary logic to signal detection theory. Imagine the problem of reliably identifying a recurrent danger in the environment such as poisonous snakes. For any given relevant percept (e.g., a long slender object on the ground), one must make a decision: snake present or snake absent. Because of the dire consequences of being bitten by a venomous snake, it is better to have a low evidentiary threshold for inferring that long slithering objects are snakes so as to identify every snake you encounter, than to require too much evidence and occasionally incur a costly surprise. Because both types of errors cannot be minimized at the same time, asymmetries in the costs of two types of errors (false positives and false negatives) should lead systems to be biased in the direction of the least costly error.

Examples of such biases can be found in auditory perception. For example, listeners perceive tones with rising intensity to change faster than equivalent tones falling in intensity – an effect termed auditory looming. Auditory looming has also been found to occur in nonhuman primates and is well explained in an error management theory framework. The enhanced saliency of rising intensities associated with approaching objects causes listeners to reliably underestimate object arrival time. The bias occurs with tones but not broadband noise showing some specificity for sound that provides reliable single-source information and made almost exclusively by biological organisms. Of course, any time a bias affects

perception of the physical environment, there are risks of misapplying it to irrelevant objects that could lead to any variety of costly errors. The degree to which this is true will largely determine how advantageous the bias will be, and thus its impact over evolutionary time. In the case of auditory looming, the costs of false alarms (e.g., wasting time by being ready too early) are relatively low compared to the costs of misses (i.e., not being prepared for an approaching object). The difference in these costs allows for the selection of a bias that causes people to systematically overestimate a reliable auditory cue of movement toward a listener.

Examples of Research on Cognitive Biases

In this section, we introduce two examples of research on cognitive bias. The first example focuses on search in the external world and how people's perceptions of events or their co-occurrence may be biased toward frequent, natural distributions. In this example, cognitive bias arises from experimenters observing an organism's behavior or judgments in environments that are very atypical compared to those experienced across phylogenetic and/or ontogenetic time. The second example focuses on biases in internal search from memory and emphasizes that cognitive bias may occur both due to cognitive limitations and motivational factors. For example, an individual's inaccurate recall of poor past performance may be due to poor memory and/or a motivation to preserve a positive view of the self.

Foraging, Hot Hands, and the Structure of the Environment

The work of Andreas Wilke and colleagues on human foraging behavior in patchy environments, illustrates that an awareness of ancestral conditions can be key to understanding human decision-making strategies. When resources are distributed in patches (i.e., areas with a high density of the resource surrounded by areas with low density), animals are required not only to make decisions on where to forage, but also on how long they should forage in a particular patch as resources diminish. Biologists have studied simple decision mechanisms that solve this problem of patch time allocation and identified resource environments where these mechanisms work well. Different patch-leaving strategies are necessary because resource environments differ in how resources are distributed across patches. The number of resource items within a patch can either be similar (evenly dispersed distributions), completely random (Poisson distributions), or some patches may only contain a few items while others will be very resource rich (aggregated distributions). Wilke and colleagues tested how well humans can adapt their patch-leaving behavior when faced with such resource distributions in a computerized foraging game. The results showed that participants applied patch-leaving rules that were particularly appropriate for aggregated environments also in other types of environments (e.g., those with evenly dispersed and Poisson distributions). Were research participants ecologically *irrational*?

This finding is less puzzling once one considers that aggregation in space and time, rather than dispersion, is likely to have been the norm for most of the natural resources humans

encountered over evolutionary time. Species of plants and animals rarely, if ever, distribute themselves in a purely random manner in their natural environment, because individual organisms are not independent of one another: Whereas mutual attraction leads to aggregation for some species, mutual repulsion leads to regularity (dispersed environments) in others. Most often, these deviations from randomness are in the direction of aggregation, because aggregation offers considerable benefits such as a common habitat, mating and parenting, or the benefits of group foraging. Since humans have been hunters and gatherers for a very long part of their history, it could well be that our evolved psychology is adapted to assume such aggregated resource distributions as the default. Thus, participants in the foraging experiment might have behaved *evolutionarily rationally*.

The idea that humans expect aggregation in space and time also helps to explain why apparent misconceptions of probability, such as the hot-hand fallacy, may not reflect fundamental shortcomings of the human mind but rather adaptation to the statistical structure of natural environments. The hot-hand fallacy occurs when research subjects expect lucky streaks in hits and misses in everything from basketball to coin tosses when in fact the probabilities of events are independent. When a basketball player hits many shots in a row, for instance, the natural expectation is that he has a 'hot hand' and will shoot another successfully. People are often surprised to discover that this strong intuition does not square with the reality that the success of the next shot is determined independently from the shot before it.

The foraging example presented above hints at an explanation for the hot-hand phenomenon based on limited experience with evolutionarily novel events like coin tosses, and gambling that involve random events. Instead, one can ask about the structure of objects and events surrounding important adaptive problems faced by our ancestors, and what kinds of adaptations might have been shaped by selection. Evolutionary behavioral scientists would argue that many of these – plants, animals, human settlements, and even weather – would have been organized in an aggregated, clumpy fashion – not perfectly at random (independent) like those in Las Vegas. Thus, the default human expectation is aggregation, clumpiness, and nonindependence. To explore this hypothesis, Wilke devised additional computer tasks in which the subject could forage for fruits, coin tosses, and several other kinds of resources, and present them to American undergraduates and a South American indigenous population of hunter-horticulturalists (the Shuar). In each population, subjects exhibited the hot-hand phenomenon for all resource types, despite the fact that the resources were distributed randomly by the computer. The one exception found was for coin tosses for the American students only for which the hot-hand expectation was reduced though not altogether eliminated. This suggests that the expectation of aggregation in space and time may be the psychological default that is overcome only through extensive experience with truly independent random phenomena like coin tosses. This runs in contrast to the original explanation offered for the hot-hand phenomenon – that it is attributable to biased sampling by the mind – and instead suggests it is a consequence of the minds' adaptation to the distribution of resources in the natural environment.

Memory Biases: Cognitive and Motivational Determinants

Would humans be better off if we had been blessed with superior cognitive abilities, such as unfailing memories? One view on the rather limited cognitive capacities of the human mind is that limitations, such as forgetting, have functional significance. Some researchers, like John Anderson, have suggested that the function of memory is not simply to store information, but rather provide relevant information in specific situations. According to this view, the human memory system is organized such that it facilitates the retrieval of information that is recent, frequent, and relevant to the current context. In other words, memory is designed to provide the information we are most likely to need. Many man-made information systems are built in such way. For example, computer applications usually incorporate a timesaving feature as follows: When a user tries to open a document file, the applications presents a 'file buffer,' a list of recently opened files from which the user can select. Whenever the desired file is included on the list, the user is spared the effort of searching through the file hierarchy. For this device to work efficiently, the application must provide the user with the desired file. It does so by 'forgetting' files that are considered unlikely to be needed on the basis of the assumption that the time since a file was last opened is negatively correlated with its likelihood of being needed now. In other words, such a system has a bias toward information that is likely to be needed.

Although memory systems are very often efficient, they can sometimes fail because forgetting and sensitivity to contextual knowledge may lead to systematic error. The hindsight bias is one of the most frequently cited and researched cognitive biases in the psychological literature. Hindsight bias is a type of memory distortion in which, with the benefit of feedback about the outcome of an event, people's recalled judgments are typically closer to the outcome of the event than their original judgments were. Research on hindsight bias is particularly important because it is a ubiquitous phenomenon and one with potentially detrimental consequences in applied settings, such as law and medicine.

In the 1970s, Baruch Fischhoff was concerned with professionals such as clinicians' or politicians exaggerated feeling of having known all along how patients' recovery or elections were going to turn out. To study this issue empirically, Fischhoff asked participants to assess the probabilities of various possible outcomes concerning upcoming events, for example, President Nixon's historic trips to China and the Soviet Union (e.g., Pres. Nixon will meet Chairman Mao; Pres. Nixon will announce that the trip was a success). After the trips, participants were asked to recall their predictions. Results showed that participants tended to exaggerate what they had known in foresight.

There are two common experimental designs that have been used in the psychological literature. In the *memory* design, participants first make judgments concerning some stimuli, then receive feedback on some or all of the items, and are finally asked to recall the original judgments. In the *hypothetical* design, participants first receive feedback concerning some or all of the items and are then asked to say what they would have estimated had they not been given feedback. Empirical results using either design have shown that recalled or hypothetical estimates are commonly biased toward the feedback information.

At present, there is no single theory that can explain all patterns of data and moderator variables that have been studied in laboratory or real-world settings (e.g., expertise, experimental materials). One potential reason for this is that multiple processes are involved in producing the effect. In fact, there is largely consensus that the bias is multiply determined, and involves both cognitive and motivational factors.

Regarding cognitive factors, the prevalent idea is that both processes of retrieval and reconstruction play a role. For example, when reporting the original judgment participants are likely to both try to retrieve the specific memory of the event as well as reconstruct the original judgment process. Accordingly, the hindsight bias effect can occur by new information (feedback) biasing (1) the retrieval cues used to query memory for the original judgment, (2) the reconstruction of the judgment process, (3) or both. This view also suggests a prominent role for inhibition processes. Accordingly, research shows that individuals with strong inhibitory deficits have more difficulties inhibiting feedback about the outcome of an event from entering working memory and thus show increased hindsight bias. As expected, this is particularly the case when the correct response is either in sight or accessible in working memory at the time of the attempt to recall one's original response.

In addition, there is evidence that hindsight bias may serve motivational goals. For example, people seem to change the perceived probabilities of events so that negative events appear inevitable as a way to mitigate disappointment and personal blame. However, this seems to occur mostly in situations people can control and in situations that are unexpected, suggesting that such phenomena should be interpreted in the light of people's attempts at preparing for future events. In other words, these forms of hindsight bias can be seen as arising from the use of a sense-making process, whereby people integrate all they know about a topic into a coherent mental model. In this light, human memory is not so much designed

to accurately reconstruct the past as it is to make sense of it to better deal with the future.

Cognitive Disorders

M E Berryhill, D Peterson, K Jones, and R Tanoue, University of Nevada, Reno, NV, USA

© 2012 Elsevier Inc. All rights reserved.

Glossary

Cognitive disorders Illnesses in which the primary symptoms are related to thought, attention, and perception.

Consciousness Awareness of surroundings.

Disorder Root cause of a syndrome.

Disoriented person Someone who is unable to report where he or she is, why he or she is there, and/or what time it is.

Syndrome Cluster of commonly co-occurring symptoms.

What Are Cognitive Disorders?

Although we never fully know someone else's experience, in general, people agree on many aspects of the world around us. In other words, where you are, what day it is, who you are, and so on are questions that participants in a conversation can typically agree on. In contrast, when consciousness and thought processes themselves – problem solving, attention, perception, and language – are disrupted, patients are said to have cognitive disorders. Patients with these disorders may be disoriented, inattentive, have memory and language disturbances, and sensory irregularities including hallucinations. The cognitive disorders, delirium, amnesia, and dementia, are some of the most devastating diagnoses for at least two reasons. First, these disorders separate patients from his or her normal conscious states. This makes communication very challenging and it can make it difficult for caregivers to know if the patient's symptoms have been alleviated. Second, diagnoses such as dementia are progressive and unrelenting indicating that the patient will not return to his or her former state. In the paragraphs below, we detail aspects of each of the primary cognitive disorders, delirium, amnesic disorders, and dementia. These descriptions delineate the criteria set forth in the diagnostic and statistical manual (DSM-IV-TR), which mental health clinicians use to assess psychiatric illness.

How Do We Recognize and Treat Delirium?

Delirium

Delirium is a group of conditions characterized by disturbances of consciousness and changes in cognition that occur over short periods of time, on the order of hours or days. Delirium can have a rapid-onset and resolve itself so that the person returns to normal rather quickly. However, because delirium is secondary to an underlying cause it requires immediate medical attention. To more precisely distinguish between delirium brought on by different causes, there are several different classifications: delirium due to a general medical condition (disease basis such as inflammation, fever, or infection, malnutrition, dehydration, major stress), substance-induced delirium (drug withdrawal), delirium due to multiple etiologies (disease and substance basis), or delirium not otherwise specified (where the underlying cause cannot be determined). In delirium, these subclassifications are important in determining the appropriate course of treatment.

Symptoms

There is no laboratory test for delirium. This makes diagnosis challenging and attention to the symptomology is critical. The classic symptoms of delirium include a disturbance of consciousness accompanied by a change in cognition. In other words, the patient may be confused, and unable to respond to simple questions. These symptoms develop over a short period of time, usually hours to days. Delirium symptoms may fluctuate during the course of the day. If medical attention is quickly sought, delirium is a temporary condition that will last up to a few weeks in duration. Patients with delirium must be monitored for noncompliance with medical directives, such as removing intravenous tubing. During the delirious episode, a patient may have moments of lucidity, in which he or she is aware of what is happening around him or her. Disorientation is often the first symptom to appear in cases of mild delirium, and is exhibited by an individual being unable to report time or place. For example, the patient may not know the day, the month, or even the year. In addition, attention, and particularly sustained attention, is abnormal in delirium patients. Irrelevant objects easily distract individuals with delirium. For example, they may stare at the flowers in the room rather than look at the person speaking to them. Cognition also changes in delirium. In particular, new memory formation is impaired. A simple test for memory impairment is to ask the individual to remember several unrelated objects (e.g., apple, clock, turtle) and then to ask him or her to report the objects after several minutes of conversation. Communication through speech and language may be disrupted for a variety of reasons. An individual may have a difficulty articulating words (dysarthria), a deficit in naming objects (dysnomia), an impaired ability to write (dysgraphia), or even language production or comprehension deficits (aphasia). Symptoms affecting attention, memory, and orientation may be compounded by sensory abnormalities including hallucinations. For example, delirium patients may perceive imaginary people in the room with them. Hallucinations may be in any sensory domain.

Delirium is also associated with disturbances in the sleep-wake cycle. Sleep-wake cycle disturbances mean that the regular pattern of daytime alertness and nighttime rest is abnormal. Symptoms may include daytime sleepiness, nighttime agitation, and difficulty in falling asleep. Patients may sleep during much of the day and be awake or agitated during the night to the point where a complete reversal of the night-day sleep-wake cycle occurs. Patients often report experiencing nightmares.

Psychomotor abnormalities are often associated with delirium such that diagnosed individuals are hyperactive or hypoactive. It is more common to observe hyperactivity in delirium patients but decreased activity including sluggishness and lethargy associated with hypoactivity may also be witnessed. In the same individual, psychomotor activity may even shift from one extreme to the other over the course of a day. The hyperactive state is more likely to prompt symptoms such as hallucinations. Finally, emotional states may be disturbed in delirious states. Individuals diagnosed with delirium may display intense emotional disturbances associated with anxiety or fear. Other emotional states include depression, irritability, anger, euphoria, and apathy. There can be rapid and unpredictable shifts from one emotional state to another. Threatening hallucinations or paranoid delusions often induce a strong fearful response in the patient and such individuals may attack those who are falsely perceived as threatening. Alterations of emotional state are most common at night or in the dark because of the lack of other environmental cues.

When delirium is suspected, electroencephalogram (EEG) may be used as a confirmatory tool. The EEG signal in delirium patients reveals slowed processing to sensory inputs (e.g., lights, sounds). EEG can also be used to follow recovery over time. As the patient improves, the EEG signal should return to normal.

Prevalence

As with all of the cognitive disorders, the prevalence of delirium is not consistent across the population. Indeed, the prevalence of delirium in the general population is normally very low, less than 1% of young adults over 18 years of age and rising slightly in those over the age of 55. Although rare, certain populations including the elderly and hospitalized individuals have a much higher incidence of delirium. In hospitalized individuals the prevalence of delirium ranges from 10% to 40%, with the elderly being the most likely to be affected. Disease can also increase the likelihood of delirium. In hospitalized cancer patients, as many as one-quarter may be affected. The numbers are even higher for those with AIDS (30–40%). Populations with the highest prevalence of delirium are residents of nursing homes (60%) and individuals diagnosed with a terminal illness (up to 80%). It is important to note that the prevalence of delirium depends on many aspects of their overall health.

Time Course

Delirium usually develops quickly over hours to days. The disorder usually presents with symptoms such as restlessness, anxiety, irritability, disorientation, and disturbed sleep. An individual's delirium may resolve in a few hours to days, or symptoms may persist for weeks. Elderly individuals who also are diagnosed with dementia are especially susceptible to longer lasting delirium and they are less likely to fully recover. However, treatment is important and failure to treat the underlying cause of the delirium (e.g., withdrawal, nutritional problems, or disease) may lead to more severe conditions including coma, seizures, and even death. Delirium can also prompt additional medical complications in elderly

individuals. Complications due to delirium may include pneumonia and bedsores. These types of complications can lengthen hospital stays. Patients who develop delirium during a hospitalization also have a high mortality rate in the months following discharge.

Treatment

Most individuals diagnosed with delirium achieve a full recovery. However, successful treatment ultimately depends on the appropriate diagnosis and amelioration of the underlying cause. Treatment most often involves pharmacological treatment in conjunction with appropriate interventions to relieve symptoms. Neuroleptics (antipsychotic medications) are the most common medication used to treat delirium when the patient is agitated and possibly aggressive. Benzodiazepines (sleep-inducing, antianxiety medications) are used to combat withdrawal symptoms. In addition to medications, supportive therapy involves environmental modifications such as ensuring balanced nutrition, hydration, and creating a controlled and supportive environment for the patient. Finally, support from health care professionals and family members are necessary in achieving treatment goals and ensuring patient health.

Current Research Directions

Current research in delirium treatment focuses on two fronts: the prevalence and consequences of delirium in hospitalized patients, and new treatments. Recently, a multicenter investigation including over one hundred intensive care units revealed that delirium was associated with increased mortality rates and longer hospital stays. The large scale of this study provided an important step toward assessing the widespread effects of delirium. Future research focused on delirium as an independent risk factor may provide health care professionals with additional diagnosis criteria and will also substantiate delirium as a critical health concern.

Progress is being made in therapeutic treatments to improve outcomes following delirium. The use of cognitively stimulating activities (e.g., reading, writing, word games, puzzles, etc.) in the attempt to reduce delirium severity, duration, and functional loss was studied in postacute care settings. Their promising results suggest that cognitive stimulation may promote faster recovery and improve physical function and mental status. This type of research will help improve our understanding of a disorder whose cause and long-term effects are not yet fully understood.

How Do We Recognize and Treat Amnesic Disorders?

Symptoms

A second group of cognitive disorders are called amnesic disorders. These disorders are all associated with impaired memory processes. Symptoms of amnesic disorders include specific types of memory impairment, which can be serious enough to dramatically impair a person's quality of life. Specifically, certain amnesic disorders prevent patients from explicitly learning any new information. This symptom is referred to as anterograde amnesia. Other patients may have trouble

remembering information from their own past. This deficit is called retrograde amnesia. Additionally, both types of amnesic impairments may occur simultaneously. In some instances, people will spontaneously create stories to fill in missing details from their memory. This process of adding supporting details, which never occurred, to memory is known as confabulation. The person does not intend to mislead; he or she is genuinely not aware that the information is not true. Serious cases of these disorders can involve impairments in maintaining knowledge of time and space. People suffering from these disorders may forget where they are or exhibit confusion of time. In amnesic disorders, however, confusion of time extends beyond momentary lapses of memory for matters like the current day of the week to more severe impairments such as failing to know the current calendar year. Other characteristics of the amnesic disorders may include an apparent lack of caring about anything, limited emotion when communicating with others, and general confusion.

Furthermore, in order to be categorized as an amnesic disorder, social or work-related problems must occur alongside memory deficits. The manner of measuring the impact these disorders have on a person's life involves comparing their current state with their functioning prior to onset of the amnesic disorder. Another important requirement for reaching a diagnosis of amnesic disorder exists. The amnesic symptoms must continue beyond a single episode. This distinguishes the disorder from delirium. The amnesic disorders do not include disruptions of other cognitive functions, which are related to dementia. It is also important to note that cultural differences that place emphasis on memories for certain types of events should be taken into account. Types of information that a person ought to know in one culture may have little meaning for people from a different culture. As such, lack of memories for culture-specific information outside an individual's cultural background should not be taken as an indication of the presence of an amnesic disorder. Finally, in spite of the serious memory deficits in these patients, other cognitive processes remain intact. In other words, symptoms are restricted to the mnemonic realm.

Causes

As with delirium, there are multiple underlying causes of amnesic disorders, but all causes result in permanent brain damage. Specifically, amnesic disorders can result from a variety of physical events affecting the integrity of the brain itself. Physical causes typically result from three types of circumstances. The first of these is related to medical conditions often resulting from, but not limited to, physical trauma to the brain. For example, the person may have been involved in an accident that caused damage to specific parts of the brain. Vascular problems can also cause brain damage. An example is stroke, which is caused by insults to blood vessels in the brain. A second cause of amnesic disorder is due to metabolic damage to the brain. In these cases, severe vitamin deficiency can lead to brain damage. This phenomenon is associated with substance-induced amnesic disorders (see below). A third cause is disease. Medical conditions causing amnesic disorders include temporary lack of oxygen (hypoxia), virus (herpes simplex encephalitis), or bacterial infection (bacterial meningitis).

The characteristics of the amnesic disorder depend on the parts of the brain that are affected and how severely they are damaged. One of the best known cases of an amnesic disorder is that of the neuropsychological patient H.M. This patient suffered from a seizure disorder presumably brought on by a head injury. To minimize the detrimental effects of this condition on the brain, the portions thought to be triggering seizures were surgically removed. The excised structures were located in regions on the lower left and right sides of the brain known as the medial temporal lobes. The medial temporal lobes and related structures include the hippocampi, parahippocampal gyrus, entorhinal cortex, mammillary bodies, and fornix. Some of these structures, particularly the hippocampi, are necessary for the formation of long-term memories. On removal of portions of the medial temporal lobe, H.M. experienced dramatic, but specific memory deficits. He could no longer form new long-term memories, although short-term and procedural memory remained intact. In other words, he could remember his childhood, he could remember the question you just asked him, and he could remember how to do things like riding a bicycle, but he could not remember what happened that morning or a few moments ago. The case of H.M. established that damage to the medial temporal lobe and surrounding regions can cause an amnesic disorder as he lost the ability to form new long-term memories.

Substance-Induced Amnesic Disorders

As noted, amnesic disorders can be caused by substance abuse and either recreational or prescription medications. Excessive consumption of alcohol over many years can cause permanent brain damage. One well-known example is Korsakoff's syndrome, in which severe thiamine deficiency develops because the patient's calories come primarily from alcohol. Alcohol does not contain necessary vitamins. This chronic thiamine deficiency leads to cell death in the mammillary bodies, and results in permanent memory deficits. People with Korsakoff's syndrome will confabulate their personal histories in part because they are unable to remember the past and they cannot form new memories. These patients have both anterograde and retrograde amnesia.

Some other substances such as medications (e.g., anticonvulsants) may produce side effects that can create amnesic deficits. Additionally, exposure to environmental toxins such as industrial solvents, lead, mercury, and carbon monoxide may alter the typical functioning of the brain in a manner consistent with amnesic symptoms. In substance-related types of amnesic disorder, it is essential to prevent reexposure to the substances.

Time Course

Depending on the cause of the amnesic disorder, the time course of symptom onset can vary. If the cause is a traumatic head injury, for example a car accident, the onset of amnesic symptoms may be instantaneous. In these cases, symptoms observed after the acute stage immediately after trauma are generally permanent. In some cases, some symptoms may subside. On the other hand, the time course of amnesic disorders caused by substances is more variable. In some cases,

the memory symptoms may be temporary, although if the brain has been permanently damaged, the amnesic disorder is also permanent. In the case of Korsakoff's syndrome, it may take many years to develop and only with prolonged alcohol abuse. Disease processes such as meningitis and encephalitis can progress very rapidly – over the course of hours and days, and with early intervention they can be treated with some success. If treatment is sought early, greater chance of recovery is possible. If treatment is delayed, these rapidly developing diseases may quickly lead to permanent amnesic symptoms.

Treatment

Prevention is the best treatment for amnesic disorders. Traumatic injuries can be prevented by use of helmets and taking extra safety precautions. Brain damage due to substance exposure can be entirely avoided. Once a person has experienced brain damage, the prognosis is very poor for alleviating amnesic disorders. If the amnesia is caused by a substance (e.g., alcohol or drug), it is important to prevent continued exposure. In some cases, treatment in the form of teaching people suffering from amnesic disorders memory strategies for improving their day to day functioning may help. Essentially, this type of treatment is designed to establish coping strategies to maintain function and independence in these individuals. These may include making lists and altering their environment to provide external memory cues. For example, labels placed around the house may help remind the patient where commonly used objects are found and how to use them. Additionally, counseling may help people diagnosed with amnesic disorders to regain a sense of purpose and focus on existing positive aspects of their life. Substance-induced amnesics may benefit from drug treatments typically used to reduce irritability or confusion associated with memory deficits.

Current Research Directions

While no effective treatment currently exists to cure amnesic disorders, recent research has examined various prospective treatments. A series of recent endeavors have used animal models, mainly mice, to investigate the efficacy of newly identified chemical compounds. Some of these compounds lead to improved memory performance in animals including methylene blue (a diaminophenothiazine drug) and others that are found in nature, including neferine (from *Nelumbo nucifera* seeds), Marapuama extract (from a type of wood in the Amazon), *Ficus religiosa* Linn (from a fig tree), *Murraya koenigii* leaves, *Asparagus recemosus*, and *Bacopa monniera* (a perennial herb). These compounds now require extensive testing before any drugs will be appropriate for humans with amnesic disorders.

There are advances in improving the independence of those with amnesic disorders as well. Recent approaches include the use of technology and external cues to improve memory function. The SenseCam[®] (Microsoft) automatically takes digital pictures after designated intervals (e.g., every 2 min). The amnesic user can therefore review the sequence of images as a reminder of recent events. Similarly, the implementation of SmartPhone technology allows people with amnesic symptoms support for managing everyday tasks. These tasks can be

accomplished by creating reminders of frequent upcoming events (via alert messages) and memo options available within most SmartPhone technologies. For example, a person with amnesia could enable an auditory alert system on his or her phone signaling him or her to take a dosage of an important medicine or of an upcoming appointment such as a visit to the doctor. Another external cue approach involves the Memory Support System, a calendar and organizational system shown to help people with memory impairments to be more self-sufficient.

How Do We Recognize and Treat Dementia?

The third member in the cognitive disorder grouping is dementia. Dementia consists of memory impairments accompanied by at least one additional cognitive problem. The second cognitive deficit may include dysfunction of language (aphasia), the loss of motor planning (apraxia), or loss of the ability to recognize certain objects (agnosia). The cognitive deficits resulting from dementia must be severe enough to cause impairment in social or occupational ability. Dementia is generally a progressive condition, but it may also be static and rarely in remittance. Dementia also disrupts cognitive and social functioning in patients.

Prevalence

The overall prevalence of dementia in the adult population increases with age. The estimates are in the range of <2% for adults 65–69 years of age. The incidence of dementia increases rapidly after the age of 85 to somewhere between 16 and 25%. A diagnosis of dementia in children is rare and difficult because multiple cognitive deficits must demonstrate documented deterioration.

Time Course

The DSM-IV criterion for a diagnosis of dementia is on the basis of a pattern of cognitive deficits beginning with absentmindedness that becomes more notable over time. As previously discussed, dementia can be progressive, static, or in remittance. The degree of disability may depend largely on the amount of social support available to the patient. This support allows the patient greater independence for longer periods of time. An additional factor is the type of cognitive deficits observed in the patient. Finally, in demented individuals, severe infections and accidents can be fatal. Dementia is typically associated with progressive incapacitation, which requires fulltime monitoring. Individuals with advanced dementia are typically in residential nursing homes.

Differential Diagnosis

To some extent, dementia treatment depends on the appropriate diagnosis of the underlying cause of symptoms. However, as there is no cure for dementia, knowledge of the cause provides for better management of symptoms. The minimal state exam (MMSE) is a commonly used neuropsychological test that can be used at the patient's bedside to quickly identify the possibility of dementia. The MMSE asks common

knowledge questions everyone should be able to answer easily. For example, 'Where are you?' Individuals are scored on a 30-point scale; scores of 25 or higher are considered to be in the normal range and lower scores are strongly correlated with dementia. The most important aspect of diagnosis is to ensure that the patient is actually demented and not suffering from another cognitive disorder with similar symptoms.

Dementia Arising from Alzheimer's Disease

The difficulty in diagnosing dementia in patients with Alzheimer's disease (AD) arises from the gradual onset and continual cognitive decline characteristic of AD. AD is assumed if no other cause can be found, and when it is clear that the patient is not suffering from delirium. Other causes such as central nervous system conditions (e.g., Parkinson's and Huntington's disease), systemic conditions (e.g., HIV), and other causes such as head trauma must be ruled out first to receive this diagnosis. Thus, the majority of dementia cases are of the AD type. AD patients have great difficulty with explicit memory tasks, for example repeating a story or remembering a picture. Visuomotor skills are less affected. The course of AD is progressive; those with the diagnosis generally lose 3–4 points (out of 30-points) on the MMSE per year. The prevalence of AD increases substantially after the age of 65. The rates increase rapidly after the age of 65, from ~11%, to more than 26% by the age of 85. There are also genetic factors related to AD. Relatives of AD patients are more likely to develop AD than the general population. In postmortem analysis, AD patients have neurofibrillary tangles (tangled protein masses) and senile plaques (protein and cell deposits). These signs of AD are found throughout the brain, especially in the hippocampus. In addition, neuronal cell loss is particularly noted in the temporal and parietal lobes of the brain. Patients with AD are likely to die within ten years of diagnosis.

Dementia Due to Frontal Lobe Dementia

In frontal lobe dementia, the frontal lobes show atrophy and cell loss within portions of the brain as in AD. Instead of dominant memory symptoms, these patients present with symptoms typical of frontal lobe dysfunction such as problem solving and planning. Frontal lobe dementia is thought to have many causes and several variants, including Pick's disease. Pick's disease is a degenerative disease that affects the frontal and temporal lobes. Difficulties with memory, motor function, and other features of dementia materialize later in the course of the disease. Pick's disease typically begins with personality changes before memory loss. Individuals may become more distractible, socially inappropriate, and impulsive. At autopsy, Pick's disease is confirmed by the presence of Pick bodies (characteristic protein bundles found inside neurons). Frontal lobe dementias account for an estimated 10% of disease-based dementia cases. Patients are diagnosed at an earlier age, generally in the mid-50s and people live for ~10 years following diagnosis.

Vascular Dementia

Vascular dementia is the second most common form of dementia after AD. Vascular dementia results from interrupted blood flow to the brain. Commonly, vascular dementia occurs

after a stroke. Strokes that cause a blockage in arteries within the brain are called infarctions. Multi-infarct dementia (MID) is caused by a large number of small strokes, which often go unnoticed. MID develops gradually because of the cumulative effects of multiple mini-strokes. A major stroke can lead to rapid-onset vascular dementia. When vascular dementia is diagnosed in conjunction with AD, it is referred to as mixed dementia. Symptoms of delirium and depressed mood can occur simultaneously in vascular dementia.

Dementia from Other Medical Conditions

A wide range of other conditions can cause dementia. Dementia can result from medical conditions such as HIV, Parkinson's disease, Huntington's disease, Pick's disease, Creutzfeldt-Jakob disease (colloquially known as 'mad cow disease'), traumatic brain injuries, hypothyroidism, brain tumors, or vitamin B12 deficiency. For example, in HIV-related dementia, the virus destroys the myelinated white matter pathways throughout the brain. Myelinated white matter tracts enable faster connectivity between regions of the brain and damage to these tracts disrupts proper intercortical communication. Behavioral changes resulting from HIV-related dementia include apathy, social withdrawal, delirium, delusions, forgetfulness, imbalance, slowness, poor concentration, and difficulties with problem solving. Within AIDS patient populations, more than a third develop HIV-related dementia by the time of their death. In these patients, the cerebral cortex is generally intact but deeper brain structures including the basal ganglia and white matter tracts show damage.

Dementia commonly follows from Parkinson's disease. Parkinson's related dementia is characterized by reduced cognitive abilities, executive dysfunction, and impaired memory. Parkinson's disease is a result of a progressive deterioration of certain cells in the nervous system as dopamine producing cells in the substantia nigra die. Additionally, dementia can result from the genetic disorder Huntington's disease. Creutzfeldt-Jakob disease is caused by a viral infection that causes the misfolding of proteins. These patients typically develop symptoms of dementia as well as involuntary movements. The virus is transmissible, and can be exchanged between people and even humans and animals.

Finally, head trauma is a growing public health concern. The severity of head trauma is correlated with the severity of the subsequent dementia. Generally speaking, in traumatic brain injuries there is memory loss. Dementia resulting from a single head injury is usually not progressive; instead, after the acute stages of treatment, the dementia symptoms remain constant. Dementia resulting from multiple head traumas (e.g., in the sports of boxing or football) leads to more notable progressive dementias. Repeated traumatic brain injury has cumulative detrimental effects on the brain and often causes memory loss and depression.

Treatment

Dementia cannot be reversed as it results from tissue damage in the brain. The primary treatment is to improve the quality of life of patients by making life more simple and comfortable. Medical treatments are aimed at improving symptoms

Table 1 Comparison between the cognitive disorders: delirium, amnestic disorders, and dementia

	<i>Delirium</i>	<i>Amnestic disorders</i>	<i>Dementia</i>
Symptoms	<ul style="list-style-type: none"> ● Disturbed consciousness ● Disorientation ● Speech and language disturbances ● Memory impairment for recent events 	<ul style="list-style-type: none"> ● Impaired memory ● Failure to remember old or new information 	<ul style="list-style-type: none"> ● Memory impairments and other symptoms ● Agnosia ● Apraxia ● Aphasia
Age of onset	<ul style="list-style-type: none"> ● All ages 	<ul style="list-style-type: none"> ● Trauma: all ages ● Substance abuse: older middle age 	<ul style="list-style-type: none"> ● Elderly, especially over 85 years old
Time course	<ul style="list-style-type: none"> ● Rapid-onset ● Resolution after hours or days 	<ul style="list-style-type: none"> ● Following head trauma ● Prolonged onset when due to substance abuse ● Permanent 	<ul style="list-style-type: none"> ● Progressive over decades ● Permanent
Causes	<ul style="list-style-type: none"> ● Medical condition ● Substance induced (e.g., toxin exposure) 	<ul style="list-style-type: none"> ● Physiological general medical condition (e.g., head trauma) ● Substance induced (e.g., toxin exposure) 	<ul style="list-style-type: none"> ● Disease process ● Reduced blood flow ● Vitamin B12 deficiency ● Hypothyroidism
Treatment	<ul style="list-style-type: none"> ● Supportive therapy ● Pharmacological 	<ul style="list-style-type: none"> ● Technology (e.g., smartphones, SenseCam[®]) ● Memory strategies ● Pharmacological 	<ul style="list-style-type: none"> ● Treat symptoms ● Supportive therapy

in dementia patients. Recently, several cholinesterase inhibitor drugs have been approved for AD treatment and are used in other dementia populations. This class of drugs prevents the decomposition of the neurotransmitter acetylcholine and shows evidence of slowing the memory decline in AD. In vascular dementia, prevention of further vascular problems is a priority. Treatment targets conditions such as high blood pressure, diabetes, and high cholesterol. Antidepressants are often prescribed for those who also have depressive episodes; sedatives are prescribed to treat agitation. Education of family members or caregivers toward strategies that make life more comfortable for those with dementia is beneficial.

Current Research Directions

Dementia is a topic of considerable research, in particular because as our population ages, the number of individuals diagnosed with dementia will also increase. Currently, five approved drugs inhibit acetylcholinesterase to elevate the level of acetylcholine in the synapse. However, a recent review of these drugs reveals that the effectiveness of these drugs is questionable. Patients on these drugs improve only marginally. Selegiline, a drug that is used to treat Parkinson's, is often used as a treatment for dementia although studies have found no long-term benefit. Several new compounds, including soybean-derived phosphatidylserine, show some improvement in those with mild cognitive impairments. The improvements were seen mostly in tests of delayed verbal recall, which may be effective at improving the quality of life of elderly dementia patients. Recent findings suggest that alternative treatments may also be beneficial in treating dementia. In one study, elderly patients suffering from dementia were incorporated in everyday Montessori classes with preschool-aged children. Dementia patients were involved in teaching the normal lessons and playing along with the children. Taking part in the activities was positively correlated with positive engagement. Music therapy seems to

help treat some symptoms of dementia, although statistically significant approaches have not yet been confirmed.

Differential Diagnoses of Cognitive Disorders

It can often be difficult to distinguish between the cognitive disorders (see Table 1). All of them include disorientation and confusion. Yet, proper diagnosis is essential for appropriate treatment. There are important guidelines that can improve diagnostic accuracy. For example, if the patient does not have disturbed consciousness, the patient does not have delirium. The diagnosis of delirium follows when a patient has a rapid-onset and episodes of disturbed consciousness and fluctuating cognitive symptoms. Although symptoms of delirium fluctuate regularly, symptoms of dementia and amnestic disorder are more stable. If the patient is conscious, and only has memory problems, the diagnosis is amnestic disorder. Amnestic disorder involves severe memory impairment, which can be seen in dementia but does not involve cognitive deficits such as apraxia, agnosia, aphasia, or other executive function deficits. Finally, if the patient is conscious, shows evidence of memory problems, and has other cognitive disruptions, the diagnosis is dementia. Symptoms of dementia may persist for months unlike those seen in delirium. Unfortunately, there are no magic cures for the cognitive disorders. Future research is needed to treat these burgeoning public health problems and to improve the quality of life for patients and their families.

Cognitive Dissonance Theory

E Harmon-Jones, Texas A&M University, College Station, TX, USA

© 2012 Elsevier Inc. All rights reserved.

Glossary

Action-based model A theoretical reinterpretation of the original theory of cognitive dissonance that posits that the cognitions most likely to cause dissonance are those cognitions with opposing action implications. Inconsistent cognitions that have no likelihood of influencing the individual's behavior should not arouse dissonance.

Effort justification According to dissonance theory, individuals should experience dissonance whenever they engage in an effortful activity to obtain an outcome. Dissonance occurs because the cognition that the activity is unpleasantly effortful is inconsistent with engaging in the activity. Dissonance can be reduced by exaggerating the desirability of the outcome, which would add consonant cognitions.

Induced compliance paradigm Experimental paradigm used by psychological researchers interested in studying cognitive dissonance processes. This paradigm has been used to test the hypothesis that dissonance should be aroused when a person acts in a way that is contrary to his or her attitudes. The amount of dissonance experienced will be inversely related to the amount of external pressure or justification for behaving in that manner. For example, an individual who is forced by an authority figure to behave contrary to his/her attitude should experience less dissonance than an individual who was subtly coerced into behaving contrary to the attitude. If the external pressure is low, individuals may change their attitudes to be more consistent with the counter-attitudinal behavior.

Misattribution paradigm An experimental paradigm used by cognitive dissonance researchers to test whether dissonance-related attitude change was indeed motivated by negative emotional feelings, as the theory proposed. In this paradigm, dissonance is created in standard ways but some subjects are led to believe that their negative emotional

feelings created by dissonance are actually caused by another source, such as the bright lights in the room or a pill they had just consumed. When individuals believe that their dissonance-created negative feelings are caused by another source, they do not show the typical attitude change that occurs as a result of dissonance.

New look A theoretical reinterpretation of the original theory of cognitive dissonance that posited that cognitive inconsistency was not the cause of dissonance but that feeling personally responsible for producing a foreseeable negative consequence was the cause. This reinterpretation was applied primarily to the induced compliance paradigm, which is the main experimental paradigm used to test dissonance theory.

Self-affirmation A theoretical reinterpretation of the original theory of cognitive dissonance. This reinterpretation posits that dissonance is not the result of cognitive inconsistency or self-inconsistency, but is instead the result of a threat to one's self image.

Self-consistency A theoretical reinterpretation of the original theory of cognitive dissonance. Instead of positing that any type of cognition can be involved in creating dissonance, this reinterpretation posits that only cognitions involving the self-concept will arouse dissonance. According to this view, dissonance only occurs when one behaves contrary to his/her self-view.

Spreading of alternatives According to research derived from cognitive dissonance theory, after individuals make difficult decisions, they often perceive their chosen option as more positive and their rejected option as more negative than they perceived these options prior to the decision, when the options were perceived as similar in value. In other words, the individuals spread apart their attitudes toward the decision options from predecision to postdecision.

Cognitive dissonance theory and research dominated social psychology from the 1950s until the 1970s. The theory revolutionized thinking about psychological processes, particularly regarding how rewards influence attitudes and behavior, and how behavior and motivation influence perception and cognition. In the 1990s, research on the theory was revived and it has since been gaining in interest. In addition to the explicit, renewed interest in the dissonance theory itself, the theory has had implicit influence on much of contemporary theorizing.

The Original Version of the Theory

Leon Festinger formulated the original theory of cognitive dissonance in the mid-1950s, and the first formal and complete

presentation of the theory appeared in 1957. The theory was presented in abstract terms and, consequently, it has been used to understand a variety of phenomena, as is shown below. Festinger theorized that when an individual holds two or more elements of knowledge that are relevant to each other but inconsistent with one another, a state of discomfort is created.

He called this unpleasant state 'dissonance.' Festinger theorized that the degree of dissonance in relation to a cognition = $D/(D + C)$, where D is the sum of cognitions dissonant with a particular cognition and C is the sum of cognitions consonant with that same particular cognition, with each cognition weighted for importance. Several theorists have proposed that the dissonance between cognitions could be determined by assessing whether a person expects one event to follow from another.

Festinger theorized that persons are motivated by the unpleasant state of dissonance and that they may engage in 'psychological work' to reduce the inconsistency. This work will typically be oriented around supporting the cognition most resistant to change. To reduce the dissonance, individuals could add consonant cognitions, subtract dissonant cognitions, increase the importance of consonant cognitions, or decrease the importance of dissonant cognitions. One of the most often assessed ways of reducing dissonance is change in attitudes. Attitude change is expected to be in the direction of the cognition that is most resistant to change. In tests of the theory, it is often assumed that the knowledge about recent behavior is usually most resistant to change, because if a person behaved in a certain way, it is often very difficult to undo that behavior. Thus, attitude change would be consistent with the recent behavior.

Festinger presented dissonance theory during the heyday of cognitive consistency theories, and he discussed dissonance as a cognitive consistency theory. However, as several subsequent theorists noted, dissonance theory contained an important element not present in other consistency theories. That is, dissonant and consonant cognitions are defined in relation to a particular focal or generative cognition. Moreover, this focal cognition is usually related to a behavior, a point to which we return later.

Experimental Paradigms Used to Test the Theory

Free Choice

In 1956, Jack Brehm examined dissonance theory's predictions for postdecision processing. According to the theory, after a decision, all of the cognitions that favor the chosen alternative are consonant with the decision, whereas all the cognitions that favor the rejected alternative are dissonant. The greater the number and importance of dissonant cognitions and the lesser the number and importance of consonant cognitions, the greater is the degree of dissonance experienced by the individual. In a decision situation, dissonance is typically greater the closer the alternatives are in attractiveness, as long as each alternative has several distinguishing characteristics. Dissonance caused by a decision can be reduced by viewing the chosen alternative as more attractive and/or viewing the rejected alternative as less attractive; this particular pattern of attitude change has been referred to as spreading of alternatives.

Brehm conducted an experiment in which participants made either an easy or a difficult decision between two alternatives. The difficult decision was one in which the alternatives were close in attractiveness, whereas the easy decision was one in which one alternative was much more attractive than the other. Participants were asked to evaluate the decision options before and after the decision. Brehm found that, after persons made a difficult decision, they changed their attitudes to become more negative toward the rejected alternative (and slightly more positive toward the chosen alternative). After an easy decision, participants did not change their attitudes. Some scientists have questioned whether this paradigm actually provides support for a dissonance theory interpretation. However, research has dealt with these challenges and provided evidence that difficult decisions cause spreading of alternatives for the reasons outlined by dissonance theory.

Induced Compliance

In 1959, Leon Festinger and Merrill Carlsmith reported an experiment to test the hypothesis that dissonance should be aroused when a person acts in a way that is contrary to his or her attitudes. To test this prediction, they brought participants into the laboratory and asked them to perform a boring task. Then, participants were paid either \$1 or \$20 to tell 'another participant' that the task was interesting. According to dissonance theory, lying for a payment of \$20 should not arouse much dissonance, because \$20 provides sufficient justification for the counter-attitudinal behavior (i.e., it adds 20 cognitions consonant with the behavior). However, being paid \$1 for performing the same behavior should arouse much dissonance, because \$1 provides just enough justification for the behavior (i.e., it adds only one consonant cognition). As expected, participants in the \$1 (low-justification) condition changed their attitudes to be more positive toward the task, whereas participants in the \$20 (high-justification) condition did not change their attitudes.

Effort Justification

Dissonance is aroused whenever a person engages in an unpleasant activity to obtain some desirable outcome. From the cognition that the activity is unpleasant, it follows that one would not engage in the activity; the cognition that the activity is unpleasant is dissonant with engaging in the activity. Dissonance should be greater, the greater the unpleasant effort required to obtain the outcome. Dissonance can be reduced by exaggerating the desirability of the outcome, which would add consonant cognitions.

In the first experiment designed to test these ideas, in 1959, Aronson and Mills had women undergo a severe or mild 'initiation' to become a member of a group. In the severe initiation condition, the women engaged in an embarrassing activity to join the group, whereas in the mild initiation condition, the women engaged in an activity that was not very embarrassing to join the group. The group turned out to be dull and boring. The women in the severe initiation condition evaluated the group more favorably than the women in the mild initiation condition. This paradigm continues to be used fruitfully in research, and it has been usefully applied in psychotherapy.

Other experimental paradigms have been used to test the theory but they are used less frequently and because of space limitations are not described here.

Challenges to the Research and Original Theory

After these and other dissonance results appeared in the literature, some theorists began to question whether the results were due to motivation. Some theorists hypothesized that the effects were due to nonmotivational, cognitive processes or impression management concerns. However, subsequent research confirmed that dissonance is a motivated process. That is, research revealed that during the state of dissonance, individuals evidence heightened electrodermal activity (which is associated with activation of the sympathetic nervous system) and report increased negative affect. After discrepancy is

reduced (attitude change occurs), self-reported negative affect is reduced. However, electrodermal activity does not decrease at this point unless individuals are distracted from the cognitive discrepancy. It is possible that the arousal following attitude change is the result of a motivation to follow through with the commitment.

Moreover, research using the misattribution paradigm has revealed that discrepancy reduction is motivated by the need to reduce negative affect. In the misattribution paradigm, participants are provided a stimulus (e.g., a placebo) that is said to cause specific side effects. It is assumed, following Schachter and Singer's two-factor theory of emotion, that individuals may mistakenly attribute their dissonance arousal to this other source, but only when the expected side effects of the other source are similar to the state produced by dissonance. The nature of the internal state can then be inferred indirectly by determining the type of stimuli to which individuals misattribute the state aroused by dissonance. In this paradigm, participants are exposed to treatments that will or will not arouse dissonance, and then they are either provided or not provided a possible external cause for their experienced state. Research has indicated that participants in the dissonance arousing conditions will misattribute their arousal to stimuli that are said to cause negative affective side effects and that once this misattribution is made, dissonance reduction (attitude change) does not occur.

Beginning in the late 1960s, researchers began to propose motivational explanations for dissonance effects that differed from Festinger's originally proposed theory. Three revisions of dissonance theory have been proposed, and their originators have provided evidence to support these conceptions. These include Aronson's self-consistency theory, Steele's self-affirmation theory, and Cooper and Fazio's new look at dissonance.

Self-Consistency

In his self-consistency theory, Elliot Aronson proposed that dissonance is due not merely to an inconsistency between cognitions. Instead, he posited that dissonance occurs when a person acts in a way that violates his or her self-concept, that is, when a person performs a behavior inconsistent with his or her sense of self. Because most persons have a positive self-concept, dissonance is most often experienced when a person behaves negatively, behaving in an incompetent, irrational, or immoral manner. One of the primary predictions derived from this revision is that low and high self-esteem individuals should respond with less and more dissonance reduction (e.g., attitude change), respectively, because in dissonance experiments high self-esteem individuals are induced to act in ways that are more discrepant from their positive self-views. Experiments testing this prediction have produced mixed results. Also, Beauvois and Joule obtained results that are difficult to explain with this revision.

Self-Affirmation

Claude Steele proposed a different alternative to Festinger's dissonance theory. He proposed that persons possess a motive to maintain an overall self-image of moral and adaptive adequacy. He stated that dissonance-induced attitude change occurs because dissonance threatens this positive self-image.

Whereas Festinger's dissonance theory posited that individuals are motivated to reconcile inconsistent cognitions, Steele proposed that, instead, individuals are merely motivated to affirm the integrity of the self. In support of this idea, Steele presented experiments, where, following a dissonance induction, participants either were, or were not, presented with an opportunity to affirm an important value. When participants were allowed to affirm an important value, dissonance-related attitude change did not occur.

However, Simon, Greenberg, and Brehm presented evidence supporting an alternative explanation for Steele's findings that was in line with the original theory of dissonance. Festinger's original theory proposed that the degree of dissonance experienced depended upon the importance of the dissonant and consonant cognitions. Simon et al. hypothesized that making an important value salient could reduce dissonance by reducing the individual's perception of the importance of the dissonant act. They conducted an experiment in which participants who opposed a tuition increase were given a high choice to write essays in support of a tuition increase (a counter-attitudinal statement). After writing the essay, participants were either given an opportunity to affirm an important value (self-affirmation condition), or asked to write about a value that was not important to them personally but was of general importance (value salient condition, e.g., world hunger), or neither (control condition). Participants were then asked to rate the degree to which they supported a tuition increase. Participants in the control condition changed their attitudes to be more favorable toward a tuition increase, as expected. Participants in both the self-affirmation and value-salient conditions did not change their attitudes. They had trivialized, or reduced the importance of, the tuition increase issue by thinking about other important values, even when these values were not personally important and thus not self-affirming. Other evidence has been presented that is difficult to interpret in self-affirmation theory terms.

In more recent work testing his self-standards model of dissonance, Jeff Stone has found that individuals with low self-esteem show less attitude change following induced compliance if their personal self-standards were primed (by rating their personal ideal for themselves on untrustworthy, precise, and ethical traits) immediately after the writing of the counter-attitudinal essay. When normative standards (by rating what their peers thought they ought to be on untrustworthy, precise, and ethical traits) or no particular standards were primed, participants with low self-esteem showed the same amount of attitude change as participants with high self-esteem. Stone suggested that "for self-consistency to operate in dissonance, something in the context must make idiosyncratic self-knowledge accessible. Otherwise, dissonance processes are not necessarily moderated by individual differences in the structure and content of self-knowledge" (2003: 852). Stone suggested that these results cast doubt on both self-affirmation and self-consistency theories, and he proposed that both the self-affirmation and self-consistency models are correct, but under different conditions.

New Look

Joel Cooper and Russell Fazio proposed the idea that the discomfort experienced in dissonance experiments was not

due to an inconsistency between the individual's cognitions, but rather to feeling personally responsible for producing an aversive consequence. They stated, "Dissonance has precious little to do with the inconsistency among cognitions per se, but rather with the production of a consequence that is unwanted." In support of this idea, in 1970, Cooper and Worchel replicated and extended Festinger and Carlsmith's classic experiment. In addition to the conditions of the original experiment, Cooper and Worchel added conditions in which, when the participant tells the confederate that the boring task is interesting, the confederate is not convinced by the lie. They found that attitude change occurred only in the low-justification condition where the confederate believed the lie. This result and others have been interpreted as indicating that dissonance-related attitude change occurs only when individuals feel personally responsible for producing an aversive consequence. The new look, or aversive consequences, revision of cognitive dissonance theory was widely accepted.

However, the results obtained in paradigms other than the counter-attitudinal action paradigm are not consistent with the aversive consequences model. Dissonance research using a selective-exposure paradigm has demonstrated that persons are more willing to examine materials that confirm their beliefs than materials that dispute their beliefs. Research using a belief disconfirmation paradigm has shown that, when persons are exposed to information that challenges their beliefs, they often strengthen their original belief. Research using a hypocrisy paradigm has shown that persons change their behavior to be more in line with their beliefs when they are reminded of times when they did not live up to their beliefs. It is difficult to reconcile any of these lines of dissonance research with a conception of dissonance theory in which the production of an aversive consequence is the only motivator of dissonance-related attitude change.

According to the original theory of cognitive dissonance, the production of aversive consequences would be expected to increase the amount of dissonance produced because an aversive consequence may be an important dissonant cognition. However, the original theory would deny that an aversive consequence is necessary to produce dissonance. In the induced-compliance experiments testing the necessity of aversive consequences, attitude change may have occurred only when participants caused aversive consequences for a number of reasons. First, the lack of attitude change in the no-aversive consequences conditions is a null effect. Null effects are difficult to explain and subject to multiple alternatives. Second, attitude change may have been produced, but may have been too slight to be detected with the small sample size of these experiments. Third, not enough dissonance may have been aroused in these experiments to produce attitude change without the additional help of an aversive consequence. For example, too much justification for the counter-attitudinal behavior may have been provided. Fourth, in these experiments, dissonance may have been produced in the no-aversive consequences conditions, but may have been reduced by a route other than attitude change.

To examine whether attitude change could occur in an induced compliance setting in which aversive consequences were not produced, Harmon-Jones and colleagues conducted several experiments. Under the pretext of participating in an

experiment on memory, participants were exposed to an attitudinal object. They were assured of privacy and anonymity, and then given high or low choice to write a counter-attitudinal statement about the object (to manipulate justification). They were asked to discard the statement in the trash after writing it so that there was no chance of the statement causing an aversive consequence. This manipulation was on the basis of Cooper and Fazio's statement, "making a statement contrary to one's attitude while in solitude does not have the potential for bringing about an aversive event" (1984: 232). Other experiments revealed that dissonance produced in this experimental paradigm caused more nonspecific skin conductance responses and greater self-reported negative affect.

These results demonstrate that dissonance affect and dissonance-related attitude change can occur in situations in which a cognitive inconsistency is present but the production of aversive consequences is not present. They also demonstrate that the experience of cognitive dissonance evokes an unpleasant motivational state that motivates dissonance reduction. These experiments have supported the original conception of dissonance theory over the revisions. But why does dissonance evoke this negative motivational state? Why is inconsistency aversive? Festinger simply proposed that inconsistency was aversive but never thoroughly explained or tested why inconsistency was aversive.

Action-Based Model of Dissonance

To address these questions, Harmon-Jones proposed an action-based model of dissonance. The model concurs with other areas of psychological research in proposing that perceptions and cognitions can serve as action tendencies. The model further proposes that dissonance between 'cognitions' evokes an aversive state because it has the potential to interfere with effective and unconflicted action. Dissonance reduction, by bringing 'cognitions' into consonance, serves the function of facilitating the execution of effective and unconflicted action. The action-based model uses the term 'cognitions' to be consistent with the language of the original theory. However, for the model, the more accurate term for the psychological construct involved in dissonance is action tendency. That is, it is the inconsistency between important action tendencies that causes dissonance. This line of thinking is consistent with the thinking of past dissonance theorists who emphasized behavior as the focal or generative cognition. The action-based model extends these past views by suggesting that the other (nongenerative) cognitions most likely to arouse dissonance are those that have action tendencies inconsistent with the generative cognition.

The action-based model proposes that inconsistency between cognitions makes persons uncomfortable because inconsistency has the potential to interfere with effective action. From the viewpoint of the action-based model, cognitions are important because they guide the actions of an organism. When an individual holds two relatively important cognitions that are inconsistent, the potential to act in accord with them is undermined. To reduce the inconsistency and resulting negative affect, individuals engage in a variety of cognitive strategies.

For example, dissonance results when one 'freely chooses' to engage in behavior that is inconsistent with an attitude or

belief. The 'free choice' is subtly induced by the experimenter in experimental research. Experiments have shown that when individuals engage in such behavior, they often change their attitudes to be consistent with their recent behavior, as discussed previously. After making difficult decisions, individuals value the chosen alternative and devalue the rejected alternative more than they did prior to the decision. In both of these dissonance-evoking situations, dissonance occurs because there are cognitions that are inconsistent with a chosen course of action. That is, in the former situation, the past attitude is inconsistent with the current behavior. In the latter situation, the positive aspects of the rejected alternative and the negative aspects of the chosen alternative are inconsistent with the decision. The dissonance thus has the potential of interfering with the translation of the decision into effective action. According to the action-based model, attitude change produced by dissonance is the result of following through with the commitment to the behavior. The attitude change is posited to be one of a number of processes that would assist with the translation of the commitment into effective and unconflicted action. Thus, according to the action-based model, dissonance evokes a negative affective state that signals the organism that something is wrong and motivates the organism to engage in behavior to correct the problem. The correction of the problem often involves following through with the commitment to the behavior or decision. This view of dissonance is consistent with past as well as present theorizing on the function of dissonance and dissonance reduction.

Other scientists have advanced similar but not identical conceptions. For instance, in 1951, Lewin discussed the organism's capacity to 'freeze' upon an action tendency following a decision. In 1967, Jones and Gerard discussed the concept of an unequivocal behavior orientation that was described as an adaptive strategy that forced the individuals to bring their relevant cognitions into harmony with each other. Another perspective consistent with the present model is Julius Kuhl's theory of action control. He proposed that to insure that the intended action rather than a competing action tendency will be executed, the intended action tendency has to be selectively strengthened and protected against interference until the action is executed. The postdecisional spreading of decision alternatives may serve the function of putting the decision into action. When one considers that dissonance is primarily a theory about postdecisional processing, it is easy to see how these theories fit with the present conception of the function of the dissonance process.

Experimental Tests of the Action-Based Model

Action-Orientations

An action-oriented state is a state that often occurs following a decision. When a person is in an action-oriented state, implementation of decisions is enhanced. In 2002, Harmon-Jones and Harmon-Jones integrated these ideas with dissonance theory to propose that this action-oriented state that follows decision-making is equivalent to the state in which dissonance motivation operates and dissonance reduction occurs. They hypothesized that experimentally manipulating the degree of action-orientation experienced following a decision should affect the degree of dissonance reduction.

Harmon-Jones and Harmon-Jones conducted an experiment to test these ideas. Participants were asked to make either an easy decision or a difficult decision, choosing to perform one of two physical exercises that the participant rated attractive and unattractive or rated as very similar in attractiveness. Participants were asked to fill out a mindset questionnaire after the decision. The neutral mindset questionnaire asked participants to list seven things they did in a typical day, while the action-oriented mindset questionnaire asked participants to list seven things they could do to perform well on the exercise they had chosen. Participants were then asked to re-evaluate the exercises. Results indicated that participants in the high-choice, action-oriented condition changed their attitudes to prefer the chosen exercise more than participants in the other conditions.

In a second experiment testing the action-based model, Harmon-Jones and Harmon-Jones replicated the results of the first experiment using a different manipulation of action-orientation. In this experiment, action-orientation was induced by asking participants to think of an important decision that they had made and to list the steps they intended to use to successfully follow through with their decision. The participants in the action-orientation condition engaged in more attitude change following a difficult decision than did participants in the comparable conditions. This study replicated the results of the previous study, but provided stronger support for the model because it used an action-orientation induction unrelated to the decision at hand.

Neural Processes Involved in Dissonance

To assist in translating the behavioral commitment or intention into effective action, approach-motivational processes should be activated, as the individual works to successfully implement the new commitment. Thus, the increase in approach motivation should activate the left frontal cortex, as much past research has found this cortical region to be involved in approach-motivational processes.

Other research has suggested that activity in the anterior cingulate cortex is involved in monitoring the occurrence of errors or the presence of response conflict. Importantly, research has found increased anterior cingulate cortex activity, as measured by the event-related potential known as the error-related negativity, when behavior conflicts with the self-concept. This finding suggests that even higher level conflicts, the type with which dissonance theory has been most concerned, also activate the anterior cingulate cortex. More recently, Vincent van Veen and colleagues found increased anterior cingulate cortex activation in the induced compliance paradigm.

Based on this past research, dissonance (or potential response conflict) first activates the anterior cingulate cortex, and then activates the left dorsolateral prefrontal cortex, which assists in resolving the conflict. To test the prediction that dissonance is associated with increased left frontal cortical activity, university students who were opposed to a tuition increase participated in a study ostensibly concerned with attitudes and personality. They were randomly assigned to one of two choice conditions. In the low-choice condition, participants were told they were to write an essay supporting a 10% tuition increase at their university. In the high-choice

condition, participants were told that writing the essay in favor of the tuition increase was their choice and completely voluntary. However, the instructions subtly encouraged them to write such an essay. EEG was assessed for 1 min following the beginning of the writing of the counter-attitudinal essay, as past research has revealed that dissonance is greatest at this point in time. Moreover, the commitment alone (and not the complete essay writing) is sufficient to evoke dissonance. Then, participants completed an attitude measure. Replicating past research, results revealed that high-choice participants changed their attitudes more than low-choice participants. Supporting the primary prediction, results also revealed that high-choice participants evidenced greater relative left frontal activity than low-choice participants.

Another experiment extended the above research by testing the hypothesis that an action-oriented mindset would not only facilitate discrepancy reduction following a decision, but would also increase relative left frontal cortical activity. Replicating past results, the current experiment demonstrated that the action-oriented mindset caused greater spreading of alternatives than the neutral mindset condition. Moreover, the action-oriented mindset caused greater relative left frontal activation than the other condition. These results supported our predictions and suggest that the dissonance reduction involves activation of the left frontal cortex and approach-motivational processes.

In the previous experiment, the psychological process (action-orientation) was manipulated and the proposed physiological substrate was measured (left frontal cortical activation). Studies of this type are limited in the causal inferences that can be drawn. Because the measured physiological activation may be only one of a number of physiological activations that occur in response to the psychological manipulation, it is possible that one of the other unmeasured physiological activations is more responsible for the psychological process. To provide stronger causal inferences regarding the role of a particular neural structure's involvement in a particular psychological process, it is important to reverse the direction and manipulate the physiology and measure the psychology. Such measurement also provides stronger causal evidence than simply correlating the proposed mediator with the outcome. Thus, an experiment used neurofeedback to manipulate left frontal cortical activity. After neurofeedback training, participants were given a difficult decision and following the decision their attitudinal spreading of alternatives was measured. The manipulated decrease in relative left frontal activity led to a decrease in spreading of alternatives.

Individual and Cultural Differences

Research has suggested that individual and cultural differences may moderate dissonance processes. For instance, individuals with greater preferences for consistency show greater attitude change after being given high choice in an induced compliance situation, and individuals from Eastern cultures show greater dissonance-related attitude change as compared to individuals from Western cultures when interdependence is salient. As noted by Wicklund and Brehm, individual (or cultural) differences in dissonance-related attitude change could emerge because of differences in the initial perception of discrepant

cognitions, the awareness of dissonance, the tolerance of dissonance, and/or the mode of dissonance reduction. If attitude change is the only measure in a standard dissonance experiment examining individual differences, it is impossible to determine why a particular individual difference may be related to a pattern of attitude change. In order to determine why a particular individual, or cultural, difference relates to a pattern of attitude change, it would be necessary to measure the relationship of this difference to factors influencing dissonance.

Heine and Lehman found that North Americans and East Asians differ in their attitudinal responses to difficult decisions. While North Americans showed the typical spreading of alternatives following the difficult decision (regarding choice over popular compact disk music selections), East Asians did not. This observed effect was not consistent with earlier observations by Haruki Sakai and colleagues who had found dissonance-related attitude change following public but not private induced compliance.

However, Hoshino-Browne and colleagues noted this discrepancy between results and suggested that the experiments by Sakai and colleagues may have produced dissonance-related attitude change because participants were concerned about the interpersonal consequences of their actions. That is, the participants, who were typically motivated to be interdependent with others and avoidant of interpersonal conflict, experienced dissonance because they had acted inconsistently with those cultural ideals. To address these issues and others, Hoshino-Browne and colleagues conducted four studies in which European Canadians and Asian Canadians made difficult decisions for themselves or for a friend. Results indicated that whereas European Canadians spread alternatives more for self than friend decisions, Asian Canadians spread alternatives more for friend than self decisions. These results serve as a reminder that the importance of the cognitions was one of the factors affecting the magnitude of dissonance in Festinger's original theory. Cultural values would be expected to relate to the importance of cognitions, and thus, to the amount of dissonance these behaviors would evoke.

Conclusion

Several experiments have challenged the revisions of dissonance theory and have provided support for Festinger's original conception of dissonance. Clearly, dissonance has much to do with inconsistency and is not due to such limiting conditions as a self-threat or the production of an aversive consequence. As Aronson noted, a number of social psychological theories, such as self-affirmation theory, could be thought of as dissonance in other guises. In addition to the theories noted by Aronson, much research and theory concerned with guilt and self-regulation over prejudiced and other impulses may be understood from the perspective of dissonance. Incorporation of the key variables and past research of dissonance theory into these and other research enterprises will likely benefit those enterprises and lead to a more cumulative psychological theory.

Festinger did not propose why cognitive inconsistency produces discomfort and motivates perceptual, cognitive, and

behavioral changes. However, the action-based model of dissonance does propose an underlying motivation. Research on the action-based model suggests that dissonance reduction may serve the function of assisting in the successful execution of a commitment, which may facilitate effective and unconflicted action. Incorporation of these ideas derived from action control thinking may assist in stimulating new research on dissonance theory and assist in connecting the large body of dissonance theory evidence with other research literatures concerned with action orientation, behavioral regulation, emotion regulation, and the neural processes that underlie these important psychological processes.

As dissonance theory goes on to its sixth decade, it clearly has weathered many challenges but still provides much explanatory, integrative, and generative power.

Glossary

Adaptation A genetically controlled trait that has evolved by natural selection.

Analogous traits Similar traits that evolved independently in different species in response to similar environmental pressures.

Comparative psychology The study of mind and behavior in nonhuman animals.

Convergent evolution The process by which natural selection produces similar adaptations in different species that live in similar environments.

Homologous traits Similar traits possessed by different species as a result of inheritance from a common ancestor.

Phylogeny The evolutionary development and history of a species or higher taxonomic grouping of organisms.

Primates The discipline that studies nonhuman primates.

Trait A morphological, physiological, or behavioral characteristic of an organism.

Evolutionary Foundations of Comparative Primate Psychology

Psychology is the discipline that studies mind and behavior. Within psychology, there are many subfields including, among others, biological, clinical, cognitive, comparative, developmental, educational, evolutionary, industrial/organizational, personality and individual differences, and social psychology. Some of these subfields are often recognized as independent disciplines. Comparative psychology, which involves the study of mental processes and behavior in other animals, is also known as ethology or behavioral biology. Within comparative psychology, there are subfields specializing in the study of particular groups of animals. For example, the comparative psychology of nonhuman primates is sometimes called behavioral primatology, or simply primatology.

All of these multilevel disciplinary subdivisions have resulted from the growth of psychological research, its expansion in many different directions, and the increasing specialization of researchers addressing different types of questions about mind and behavior. Although specialization is both welcome and inevitable, the risk involved in these sub-fields turning into independent disciplines is that they may become conceptually disconnected from psychology and from each other. With regard to the study of mental and behavioral processes in non-human primates, it is important to discuss how this area of research is conceptually linked both to comparative psychology and to psychology in general.

A frequently used rationale for conducting comparative psychological research is the 'animal model' argument. This argument is that similarities in brain structure and function, or physiological processes, or learning abilities in animals and humans allow researchers to use animals as models for a specific aspect of human behavior, or cognitive process, or its underlying neurobiological or physiological regulation. For example, according to Gottlieb and Lickliter, the 'animal model' approach entails finding "nonhuman species with behavioral and psychological repertoires that are similar to humans so that the results of experiments with the model may throw light on seemingly

related behavior in human beings" (pp. 311–312). Evolutionary arguments do not figure prominently in comparative research conducted with the animal model approach. Particular organisms are selected mainly on the basis of practical criteria, such as they are small and cheap to maintain in the laboratory, they reproduce frequently, and it is easier to conduct experimental studies that may require highly invasive procedures. The most common organisms that fit these criteria and are used in comparative psychological research include fruit flies, cockroaches, some frogs and reptiles, pigeons and some other birds, and of course, rats, mice, and other rodents. Although comparative research with these 'model organisms' can make some beneficial contributions to psychology, there are risks involved in selecting organisms based solely on practical criteria. One of these risks is that the extrapolation of findings or conclusions from animal to human research may be inappropriate.

Comparative psychologists who use the 'animal model' argument as rationale for their research not only recognize the limitations of this approach but, surprisingly, also minimize the contributions comparative research can make to psychology. This position is exemplified by Gottlieb and Lickliter, who argued that "the certainty that animal models are faithfully mimicking their presumed human counterparts in the arena of psychological, social, and behavioral function is always open to even greater question" (p. 312). As a result, they conclude that the main contribution of comparative research to psychology is to provide food for thought, that is, hypotheses but not data, general principles but not facts.

In a critique of Gottlieb & Lickliter's article, I argued that a logical corollary of their position is that the rationale for doing comparative animal research in general is very weak. Computer simulations can be a good source of testable hypotheses about human behavior. Studying human behavior can be an excellent source of testable hypotheses about human behavior. Why bother with animals? Given the economic costs, the logistic difficulties, and the ethical issues associated with animal research, such research would no longer be warranted if its contribution were only to provide hypotheses or food for thought. Even animal studies with highly invasive

experimental procedures that are impossible in humans would be difficult to justify if their main contribution were only to provide hypotheses. I argued instead that animal studies provide much more than food for thought, and discussed many cases in which animal data have clear cross-species validity and direct extrapolability to the human condition. To give just one example, in his 1969 formulation of attachment theory, British psychoanalyst John Bowlby did not use information from nonhuman primate research just to develop the hypothesis that there they might be an attachment system in humans or some general principles about its functioning. He showed that there were 'formal similarities' in the infant response to separation, the development of fear of strangers, and the use of the mother as a secure base in monkeys and in humans. Based on these and other similarities, he argued that the development, regulation, and adaptive function of the attachment system are very similar in humans and some other primates, and that this similarity is probably due to common descent, that is, humans and closely related primates inherited the infant attachment system from their common ancestors. Thus, Bowlby provided a clear example of how data from nonhuman animals, and not just hypotheses or general principles, can be directly extrapolated to humans and how one can develop a theory of behavior that has a strong evolutionary foundation and cross-species validity.

Evolutionary biologist Theodosius Dobzhansky once said "Nothing in biology makes sense except in light of evolution." Many evolutionary and comparative psychologists believe that the same should be said about psychology as well. Comparative psychological research can be strongly justified on evolutionary grounds, and evolutionary arguments can also help select the best study organisms and the research questions that can be best addressed from a comparative perspective. One evolutionary rationale for conducting comparative research is that similarities in behavior between animals and humans are the result of common phylogenetic history. In this view, certain traits are similar in animals and humans because they were inherited from a common ancestor, that is, they are 'homologous.' Studying these traits in animals helps one elucidate the phylogenetic history of human behavior. In general, the probability that two species have homologous traits is higher the closer the phylogenetic relationship between the species. Thus, human behavior is more likely to be homologous to the behavior of other primates than to the behavior of nonprimate animals. This provides a strong evolutionary rationale for using nonhuman primates, especially primates that are closely related to humans, in comparative psychological research.

Another evolutionary rationale for conducting comparative research is that similarities in behavior between animals and humans may be the result of convergent evolution. This means that similar traits in animals and humans evolved by natural selection in response to similar pressures from the environment, but independently in different species. These traits are considered 'analogous' and studying them can help one understand how the environment has shaped human behavior through the action of natural selection. Similar adaptations to the environment can occur in species that are distantly related and, therefore, in theory, to investigate the adaptive aspects of human behavior from a comparative perspective,

honeybees can be as good as models as chimpanzees are. In reality, however, there are many constraints on the type of adaptations to the environment that organisms can evolve through natural selection. Therefore, similarities in genetic, anatomical, physiological, and cognitive constraints increase the probability that organisms will evolve similar adaptations to the environment. Thus, human behavior is generally more likely to be analogous to the behavior of other primates than to the behavior of nonprimate species. This provides another strong evolutionary rationale for using nonhuman primates in comparative psychological research.

Studying the mind and behavior of nonhuman primates that are closely related to man can potentially enhance the understanding of many human mental and behavioral processes for clear evolutionary reasons. Although primatology and psychology are sometimes considered different disciplines, there is no conceptual reason why this should be the case. In fact, the history of research on primate minds and behavior illustrates that, from the very beginning, studies of primate and human minds and behavior were closely interwoven.

History of Comparative Primate Psychology

The implications of primate behavior research for understanding human behavior were first explicitly recognized by Darwin, who in his 1872 book on *'The Expression of Emotions in Animals and Man'* drew several parallels between the facial expressions of nonhuman primates and those of human beings. However, it was psychologists rather than evolutionary biologists who began the systematic study of primate behavior and cognition at the beginning of the twentieth century.

One of the first psychologists to conduct systematic primate behavioral research was Wolfgang Köhler. As a Gestalt psychologist, Köhler was interested in cognitive processes other than learning and was curious to see if apes could use 'insight' to solve novel cognitive tasks. In a research station established at Tenerife on the Canary Islands, Köhler conducted many elegant experiments with chimpanzees during the period 1913–1917. Many of these experiments involved the manipulation of the environment to obtain food rewards and the use of previously familiar objects in novel and instrumental ways. Köhler's research questions and some of its procedures were very innovative and some of its findings are still highly cited in contemporary research. He can certainly be considered one of the founders of modern research on primate cognition.

In the United States, the systematic study of primate behavior was pioneered by Robert Yerkes, a Harvard-trained psychologist who established a primate research facility in Orange Park, Florida, with the goal of making primates available to many different kinds of scientific inquiry, most notably, psychological research. Yerkes felt that research on the behavior and cognitive abilities of primates, and in particular the great apes, would help answer some questions in psychology that had historically been very difficult to address. His contributions to primate behavior research were many and ranged from studies of spatial cognition and problem-solving to research on social and maternal behavior.

In addition to the pioneer efforts by Köhler and Yerkes, other early attempts to study primate behavior and cognition

were made in Russia, France, Cuba, and other parts of the world. The 1920s and 1930s also saw the beginning of attempts to teach language to chimpanzees. The first of such attempts was made in 1930 by Kellogg and Kellogg who raised a young chimpanzee named Gua along with their son Donald. The Kelloggs' experiment turned out to be a failure but it was followed by many others, using similar or different strategies.

Along with the growing recognition that primate behavior could be useful to understand human behavior, the years before World War II were characterized by increasing interest in studying primates in their natural habitat and understanding the basic principles regulating their social organization. With World War II, research on primate behavior was interrupted for almost a decade, but in the early 1950s and especially in the 1960s, there was renewed interest in studies of primate behavior all around the world. Japanese primatologists' intensive and long-term studies of social behavior led to the discovery of kinship systems and cultural traditions in macaque societies. Primate behavior research in Japan, however, was originally conducted within the tradition of anthropology, and it is only later that such research established a strong connection with psychological science. The 1950s also witnessed the resumption of research with rhesus macaques on the island of Cayo Santiago, in Puerto Rico, where an American zoologist, Clarence Ray Carpenter, had established a colony of these monkeys prior to the War. The availability of genealogical information on the animals and the long-term observations of their behavior contributed, along with the work of Japanese primatologists, to the identification of the matrilineal structure of macaque society and the mechanisms underlying the acquisition of dominance.

As more information on primate social behavior became available, Harvard anthropologist Sherwood Washburn developed the conviction that extant primate species could provide important information on human origins and social evolution. He and his graduate students pioneered field studies of primate behavior in Africa and Asia, placing particular emphasis on aggressive and maternal behavior. These two topics dominated much of primate behavior research through the 1960s and 1970s. Interest in anthropology and human origins also motivated paleontologist Robert Leakey to begin long-term studies of chimpanzees, gorillas, and orangutans, which were led by Jane Goodall, Diane Fossey, and Birute Galdikas, respectively.

Psychologists' interest in primate behavior rose dramatically with the resumption of research in captivity after World War II. Harry Harlow's research at the University of Wisconsin played a pivotal role in this process. After making important contributions to the study of primate learning, Harlow concentrated his efforts on elucidating the nature of infant attachment and social development in rhesus monkeys. Harlow's well-known experiments with surrogate mothers demonstrated that the mother's ability to provide contact comfort is a more important determinant of infant attachment than her ability to provide milk, thus providing a fatal blow to secondary-drive theories of attachment. Because Harlow's work touched upon many areas of research that were very important to psychologists at that time (e.g., learning and motivation, attachment, normal and abnormal social development, the social origin of affective disorders), and because Harlow's academic career took place within psychology, during the years in which most

of his work was conducted and published, primate behavior research was very well known among psychologists.

Although Harlow was very effective in promoting the importance of primate behavior research in the scientific community and the general public, the person who made the most systematic effort to conceptually integrate primatology and psychology was probably the British ethologist Robert Hinde. Hinde's interest in primate research was sparked by John Bowlby, who encouraged him to set up a colony of rhesus monkeys in Cambridge and investigate mother-infant attachment processes. From the study of social influences on the mother-infant relationship, the scope of Hinde's research was gradually broadened and elaborated into a conceptual framework for the study of social processes, which distinguished three main levels of complexity: interactions, relationships, and social structure. Hinde made important conceptual contributions to the science of social relationships, and for decades was one of the most articulate proponents of the conceptual integration between biological and psychological approaches to the study of behavior.

Thanks to the efforts of talented and charismatic scientists such as Harlow and Hinde and the success of field studies of primate behavior begun in the 1960s, primatology reached a peak in popularity in the 1960s and early 1970s. In the mid- to late 1960s, in particular, behavioral research in the United States thrived at the newly established Regional Primate Research Centers, and most research proposals to study primate behavior were readily funded by federal and private agencies. In the 1960s and 1970s, a large number of articles and books on primate behavior were published, and primate behavior research was probably well represented in all branches of scientific psychology, including developmental, social, cognitive, and clinical. The heyday of primatology, however, did not last long. In the early 1970s, that is, only ten years after the establishment of the NIH-funded Regional Primate Research Centers, there were already significant cuts to research funding.

The realization that evolutionary theory could be effectively applied to the study of social behavior in the 1960s and 1970s gave a great boost to primate research in the field. Although anthropology and psychology had been the disciplines dominating primate behavior research up to the 1970s, ecology and evolutionary biology acquired a leading role in most subsequent research. The fact that behavioral ecologists were mostly interested in questions of adaptive function whereas psychologists were mostly interested in questions of proximate causation or development of behavior was one of the several factors that contributed to the growing separation between primate behavior research and psychological science that occurred in the 1980s and early 1990s. Another important factor was the rapid progress of biological disciplines such as genetics, molecular biology, and neuroscience and the growing popularity of scientific reductionism. In particular, the success of neuroscience led to the optimistic view that many important questions about behavior would eventually be answered by studies of brain anatomy and function, thus rendering behavioral research unnecessary. One corollary of this view was the belief that comparative research with primates may not be as useful as research with other species, given the difficulty of conducting molecular work with primates.

Despite the current weakness of primatological research, in the last decade, some favorable conditions have emerged for renewed cross-fertilization between primatology and psychology. The cognitive revolution that occurred in psychology in the middle of the century was followed, a few decades later, by a similar cognitive revolution in the field of animal behavior, and primate behavior in particular. Thanks to the efforts of pioneers such as Donald Griffin and Gordon Gallup, once it became scientifically acceptable to ask whether animals have a sense of self and understand other individuals as having a mental life of their own, the field of primate cognition boomed. It became apparent that many of the questions traditionally addressed by cognitive psychologists could also be addressed, with similar or new experimental procedures, in primates as well. Therefore, research on primate cognition shifted from the study of learned behavior to the study of mental representations of the self and of the physical and social environment. Today, cognition is the branch of scientific psychology in which primate behavior research is best known and represented. Interestingly, and in line with the notion that comparative psychological research should have strong evolutionary foundations, a further impetus for research on primate cognition has been provided by the framing of cognitive investigations within ecology and evolutionary biology, which has led to a new understanding of primate cognitive adaptations, their ecological significance, and evolutionary origins.

Comparative Primate Cognition

Primate cognitive adaptations can be conceptualized as complex "behavioral adaptations in which perceptual and behavioral processes are (1) organized flexibly, with the individual organism making decisions among possible courses of action based on an assessment of the current situation in relation to its current goal; and (2) involve some kind of mental representation that goes beyond the information given to direct perception." Cognitive adaptations, and their underlying neural substrates, evolve by natural selection in response to recurrent problems posed by the physical, ecological, or social environment. Within this framework, the question can be raised as to whether the primate order as a whole exhibits cognitive adaptations that are different from those of other animals, and whether primates that are phylogenetically closest to humans show evidence of cognitive specializations similar to those of the human species.

The study of primate cognitive adaptations has involved many aspects of physical and social cognition. Primate research in the domain of *physical cognition* has addressed how monkeys and apes acquire information about the physical space in which they live and the inanimate objects in it, how information is mentally represented and processed, and how it is retrieved and used to make decisions. Free-ranging primates form spatial maps that represent the environment in which they live and use them to make travel decisions as they search for food within their home range. In the laboratory, primates exhibit knowledge of movements of objects through space and understanding of object permanence, that is, the notion that objects continue to exist and maintain their features and properties if they have been moved or hidden from view.

For example, primates search for hidden objects and can solve tasks that require mental rotation of object orientation. Though primates are proficient at these tasks, there is no evidence that primates have greater understanding of space and objects relative to other mammals, nor is there evidence of significant differences among primate species (e.g., between monkeys and apes).

Other research in the domain of physical cognition has involved object manipulation tasks, in which objects are used in relation to other objects, and which require an understanding of causality (e.g., the relation between the use of the tool and the goal to be accomplished with it). Many species of primates, and especially capuchin monkeys and the great apes, are proficient tool users and also show some evidence of understanding of causality. However, primates' tool using skills have been matched or even surpassed by those of some corvid birds. Discrimination learning studies have addressed whether primates learn to discriminate particular features of objects and assign these objects to categories on the basis of similarities and differences in these features. These studies have shown that primates can not only discriminate and categorize objects but also understand complex rules underlying categorization, for example, the notion that categories of objects can be formed on rules such as identity, oddity, sameness, or difference. Similar to birds and other mammals (e.g., laboratory rats), primates also possess the ability to make accurate estimates of small quantities of items as well as the ability to solve simple tasks involving quantity conservation or summation. The exact perceptual or conceptual mechanisms underlying these skills remain unclear.

Taken together, studies of primate physical cognition have shown that monkeys and apes possess the ability to form mental representations of their space and objects, including hidden ones, but show little evidence of greater learning skills or greater understanding of the physical world and its properties than other vertebrate animals do. The strongest evidence for a potentially unique primate cognitive specialization in the realm of physical cognition involves the use of tools and the understanding of relational properties of objects including causality. This is particularly strong in large-brained primate species that face strong ecological pressures for complex food processing such as capuchin monkeys, and for all species of great apes.

In the domain of *social cognition*, early studies of primates' ability to recognize themselves in a mirror were driven by the hypotheses that mirror self-recognition indicates self-awareness and that knowledge of the self forms the basis for theory of mind. On the mark test of self-recognition, primates as a whole perform better than other animals, and apes perform better than monkeys. However, the notion that learning how to use a mirror to inspect inaccessible aspects of one's body necessarily entails possessing a concept of self has been questioned. Experimental evidence for theory of mind skills including intentionality or attribution of knowledge or ignorance to others is scarce but stronger for chimpanzees and other apes than for monkeys. Theory of mind is clearly a unique primate cognitive specialization but could be limited to the human species, and possibly the great apes. Complex forms of social learning involving emulation, imitation, or teaching have also been documented mainly in great apes,

where they are believed to form the basis for the origin and spread of behavioral traditions that may approximate elementary forms of human culture. The question of whether or not culture can be considered a cognitive specialization unique to humans or shared by other primates rests on how culture is defined and what operational criteria are used for its identification across species.

While the question of whether nonhuman primates have the ability to think about other individuals' mental states remains unanswered, it is well recognized that they excel at the task of observing other individuals' behavior, remembering past interactions, and making predictions about the future. Primates form complex social relationships with others and have knowledge and memory not only of their own relationships, but also of relationships between other individuals. Studies investigating this aspect of social cognition have assessed primates' ability to recognize kinship, dominance rank relationships, or friendships between individuals that reside in their social group. Knowledge of social relationships is used in complex cooperative and competitive strategies involving exchange of favors, alliance formation, opportunistic exploitation of social situations, and manipulation of other individuals with deceitful tactics.

Complex social strategies in group-living monkeys and apes invariably entail the exchange of vocal or visual signals between individuals. *Communication* can therefore provide a window into the primate social mind. Specifically, many aspects of communication can provide insights into social cognition, including the role of social learning in the developmental acquisition of signal production, comprehension, and usage; the extent to which signals are under volitional control and can be used flexibly; the complexity in the structure of signals; the information content or meaning of signals; the extent to which signals are combined with other signals within the same modality or across different modalities to accomplish different functions; the extent to which combinations of signals exhibit properties of human languages such as grammar or syntax; and the extent to which the production of signals is modified in relation to the presence of particular individuals (audience effects), their attentional states or current behavior, and possibly also their mental states.

The search for cognitive complexity in primate communication has often focused on vocalizations, in part because of possible direct parallels between monkey vocalizations and human speech. For example, great emphasis has been placed on the finding that vervet monkeys and other primates possess different alarm calls for aerial and terrestrial predators, and are therefore capable of semantic communication. It is now recognized, however, that this ability is shared by a number of birds and other mammals. Food calls have also been given as examples of referential signals, as according to some researchers, they convey information about the type, quantity, and location of food to other conspecifics. It is unlikely, however, that primate vocalizations about predators or food require a higher degree of cognitive complexity than similar vocalizations used by other mammals, birds, and other animals. This is because the problems faced by most primates during foraging or escaping predators are simply no different in complexity from those faced by most other animal species. Therefore, it is difficult to argue that these activities posed a special pressure to evolve higher cognitive or communicative abilities in primates.

The agonistic screams of macaques appear to elicit different responses from other group members in relation to characteristics of opponents such as their dominance rank, and representational signaling in the context of recruitment of agonistic support is an ability that might have been strongly selected for in the social environment of group-living primates. Vocalizations that are emitted in order to coordinate the behavior of group members during travel or to facilitate affiliative and bonding interactions are an even more promising area of investigation because, unlike antipredator calls and recruitment screams, these signals are not obviously associated with states of high arousal. Contact vocalizations that facilitate coordination of group movements and close-range interactions are particularly well developed in arboreal species such as New World monkeys. The complexity of vocal structure and vocal sequences in New World monkeys, however, is likely to be the result of the pressures of arboreal life rather than those of social variables. Moreover, the referential nature of agonistic screams, grunts, or other short-range contact calls has been called into question even for the Old World monkeys and apes.

Regardless of how primate calls are interpreted, there is little or no evidence that primates as a whole show complex cognitive specializations in their vocal communication abilities relative to other animals. Moreover, there is no trend toward increasing complexity in the structure, function, and use of vocal signals from the prosimians to the New World monkeys, the Old World monkeys, and the great apes, suggesting that the evolutionary increase in brain size that occurred in the Cercopithecoids and the ape lineage was not associated with increasing complexity in vocal exchanges or their cognitive substrates. Such an evolutionary trend, however, is observable in the use of nonvocal signals. In the Old World monkeys and in the great apes, there is a clear increase in the role played by facial expressions (associated with the development of complex facial musculature) relative to vocalizations. Moreover, in the great apes, there is an involvement of the arms and hands in making social gestures to a degree that is not observed in other nonhuman primates or other animals.

Although there is no good evidence that manual gestures are socially learned from others, the flexibility with which great apes use gestures in different contexts likely requires considerable developmental learning and experience. If gestures develop through a process of ontogenetic ritualization, it would require many exposures to and opportunities to perform a particular action before it becomes a gesture. If the forms of gestures are largely innate, then a period of learning when different gestures are likely to be effective (e.g., visual only when visible) would be required. Thus, it is possible that primates, and especially great apes, have evolved cognitive specializations to attend to and learn to use social variables (such as identity, visual attention, and dominance) during communication, and particularly during gesture.

The importance of development in shaping primate communication has been investigated in only a limited number of studies, and almost all of them have focused on vocal communication. Additionally, little is known about the relationships between cognitive abilities such as understanding visual attention, gaze following, and individual recognition and the structure and use of communication systems in nonhuman primates. In humans, language develops alongside a whole

range of cognitive abilities – building upon some and providing the foundation for others. The relationship between the emergence of language and other cognitive abilities is well studied in humans: similar work is needed in nonhuman primates. Comparative developmental studies are needed to understand whether and how development of one ability (e.g., understanding social hierarchies) affects or is affected by the development of communicative behaviors (e.g., using different strategies when communicating with a dominant vs. a subordinate individual). Within this framework of research, developmental studies of gesture acquisition and experimental studies of gesture use have the potential to shed new light on the social-cognitive specializations of great apes and, more generally, provide a window into the nonhuman primate mind.

Glossary

Basal levels Baseline or resting state levels of hormones.

Behavioral economics A field of research interested in economic decision making with an emphasis on whether to cooperate for collective gain or defect for individual gain.

Cortisol A steroid hormone that is part of the physiological stress response that can also act as a behavioral inhibitor.

Dominance An aspect of personality characterized by a drive for attaining and maintaining high social status.

Moderator A variable that controls the nature of the effect that an independent variable has on a dependent variable.

Status An individual's position in a social hierarchy relative to other members of the hierarchy.

Testosterone A steroid hormone that has masculinizing effects on an individual that can also influence behavior.

Competition

Whether it is for a significant other, a promotion, or the admiration of peers, social competition dictates a large amount of human behavior. This article will provide a review of the scientific research on social competition in humans. We will discuss the social function of competition, dispositional dominance, and the underlying physiology that drives dominance behaviors, focusing on testosterone. To that end, we will discuss the dynamic relationship between testosterone, personality traits, situational forces, and cortisol. We will also discuss sex differences in competitive behaviors, and conclude with a discussion of the field of behavioral economics with an eye toward how this research has informed our understanding of competitive behaviors.

The Social Function of Competition

Across all species, individuals must compete for access to limited resources. Yet, rarely do individuals compete over every uneaten apple or available mate. Rather, competitions are used to establish a social hierarchy, and this hierarchy is the primary means by which limited resources are allocated throughout the group. High status, though risky to pursue, grants the individual increased access to limited group resources.

High status within the hierarchy gives an individual numerous benefits. For humans, high status grants the possessor the power to direct groups (i.e., leadership), control inner-group functioning, influence lower status group members, and gain privileged access to group resources. From an evolutionary perspective, competition exists to facilitate the perpetuation of those genetic lines that are most fit to reproduce. By competing for high status, the most able individuals are most likely to reproduce. By virtue of having high status, individuals who win social competitions are healthier, have better diets, less stress, are more likely to copulate, and their offspring are more likely to live to a reproductively viable age. In short, high status yields a life style that is generally more pleasant, healthier, and more productive, and thus is generally more desirable than a life of low status.

A large body of research has examined both human and nonhuman competition. Among many nonhuman species, competition takes the form of physical aggression between individuals or groups. This aggression is used to establish who is granted access to what resources, including food, territory, or mates. Even among humans, competition may take a violent and physically aggressive form. The establishment of territory, access to coveted resources, or religious conflict between countries and/or groups may lead to large scale conflict, such as war. Smaller scale interpersonal violence, such as physical beatings or homicides, may be born out of interpersonal competition over a highly coveted resource, for example two men fighting over the same woman. Across a number of species, including humans, males tend to be the primary perpetrators of aggressive competition. This may be due to patriarchal social structures, evolution disproportionately benefiting aggressive males, or the underlying biological mechanisms driving behavior. As discussed below, research suggests that it is a combination of all three.

Unlike nonhuman animal species in which physical aggression is the primary form of competition, human competitions do not always involve violence or physical aggression. Instead, humans have multiple routes to obtain resources and establish status. These alternate, nonaggressive routes include eminence (i.e., status given as a result of high levels of achievement), birthright, knowledge or ability, prosocial behaviors, and social manipulation or coercion. Some of the more explicitly competitive, but nonaggressive, means to pursue and obtain high status include academic achievement, work promotions, elections, or athletic competitions.

Research has shown that social competition develops at a young age, even during prepubescence. Children learn at an early age that there are both coercive and prosocial means for gaining status, and they learn to utilize both effectively. Even children who do not actively pursue high status clearly learn to recognize the behavioral strategies being utilized by their peers. Research shows that not only do children recognize different strategies, but they respond to them in different ways. Even amongst prepubescent children, coercive strategies tend to lead to less stable, more transient forms of high status, whereas

prosocial strategies tend to lead to more long lasting and stable forms of status. As an example, a bully may use coercion to establish his/her dominance, but that is very tenuous. A more friendly and prosocial strategy, alternatively, is more likely to yield higher numbers of friends, increased popularity among peers, and thus a stable coalition of social support.

Dominance and Competition

The drive to engage in social competition to move up the social hierarchy characterizes much interpersonal human behavior. 'Dominance' refers to this striving for attaining and maintaining high status. Within the realm of personality and social psychology, dominance is often conceptualized as a trait-like feature of a person's personality (i.e., it is an inherent, enduring, and relatively static aspect of an individual's social behavior). Dominance, as with other personality traits, varies between individuals, with some individuals exhibiting higher levels of dispositional dominance than others. Competition is a common behavioral outcome of a dispositionally dominant individual's striving for high status, and individuals high in dominance tend to succeed in achieving the high status positions they desire.

Dominance can be expressed interpersonally in a number of ways. Postural expansion, or carrying oneself to maximize one's perceived size, maintaining eye contact while speaking to another individual (whereas maintaining eye contact while listening to another individual is perceived to be nondominant), and lower rates of smiling among women (but not men) are some behavioral expressions of dominance. Dominant individuals also respond to perceived status threats with anger and aggression. High dominance has been characterized by actions such as spontaneously and eagerly engaging in interpersonal competition, establishing oneself as being in charge of a group, projecting competence regardless of actual ability, behaving assertive, and controlling the actions of others.

Dominance and Testosterone

A great deal of social endocrinology work has explored the role of hormones in human social behaviors, and no hormone has been given greater attention than testosterone. Testosterone is an androgen, meaning it is a steroid hormone derived from cholesterol that has masculinizing effects on an individual. Testosterone is produced in both men and women by the gonads, adrenal glands, and within the brain, though due to the fact that the testes produce testosterone in much larger quantities than any other source, men tend to have roughly seven times as much testosterone as women. Despite the great difference in testosterone levels between men and women, relative testosterone levels within sex can have similar influences on social behaviors in both sexes. For instance, a woman high in testosterone relative to other women will behave similarly to a man high in testosterone relative to other men, even though the high testosterone woman's testosterone levels will be much lower than the high testosterone man's. Although all hormone levels are subject to fluctuations caused by a number of factors, basal (i.e., resting or baseline) steroid hormone levels have been found to stay relatively static over extended

periods of time, leading many researchers to treat basal testosterone as a trait-like factor. It is worth noting that the majority of research on testosterone and competitive behaviors has focused on males. The findings and effects discussed below are based primarily on research on males, but sex differences and effects among females are discussed in section '[Sex Differences in Competition](#).'

In nonhuman animal species, testosterone has been associated with rank in the social hierarchy in a variety of species (e.g., baboons, deer, mandrills, chimpanzees, ducks, possums, mice, rats, grouse, finches), although only when the social hierarchy is unstable (justification for this is provided below in our discussion of the challenge hypothesis). Testosterone has also been found to be positively correlated with dominance-related behaviors, such as aggression. Just as with nonhuman animals, research on humans has established that there is a positive correlation between basal testosterone levels and dominance. Research shows that testosterone correlates positively with many behavioral aspects of dominance, such as high self-regard, scores on personality questionnaires, reactions to competitive outcomes, and social dominance. Basal testosterone also correlates with increased sensitivity to status-relevant information, even when that information is presented outside of conscious awareness, and reacts by rising or falling as a result of engaging in socially competitive behaviors.

The link between testosterone and aggression deserves special mention. Popularly, testosterone is believed to cause increases in aggressive behavior, but this is not entirely true. Research suggests that testosterone promotes dominance behaviors, which can be manifested behaviorally in a number of ways. In terms of aggression, though, dominance will only manifest itself as physical aggression in social groups in which physical force is an acceptable and efficient means by which to compete for status (e.g., prison populations). Social norms dictate that physical aggression in the pursuit of status is a potentially costly behavioral strategy, with the possibility of incurring punishment for violating those norms (e.g., arrests for violent crimes). Even in those instances when testosterone leads to aggressive behavior, research has found that the effect tends to be moderated by neurobiological mechanisms related to low levels of impulse control (e.g., low frontal lobe activity, low levels of serotonin).

Although the human literature supports the idea that testosterone is linked to dominance, it is not the case that testosterone influences behavior in every situation. The challenge hypothesis postulates that testosterone will influence behavior only during critical periods to facilitate behavior during moments of high competition, such as mating seasons or during times of hierarchy instability. Although originally developed to explain the mating behaviors of birds, the challenge hypothesis has since been expanded to explain a wide range of testosterone-behavior relationships in a variety of species. Researchers have confirmed that humans' physiology and psychology interact in ways that are consistent with the challenge hypothesis.

The critical role of the situation, according to the challenge hypothesis, is that testosterone will not have an effect on behavior if the situation does not contain a status threat or an opportunity to increase status. Put another way,

if testosterone is the underlying biological force driving dominance-related behaviors, testosterone will not influence behavior if there are no dominance-related gains to be had. If the social hierarchy is firmly established, there is nothing to be gained; then any influence testosterone might have on behavior will disappear. It is when the hierarchy is unstable, and thus high status positions are available, that testosterone's influence over behavior will become apparent. This is in contrast to the 'mouse model' which portends a direct cause and effect relationship between testosterone and behavior across all situations.

In summary, research has established that basal testosterone strongly influences dominance behaviors in humans. Further, both humans' and nonhuman animals' behavior will only be influenced by testosterone in social environments in which it is possible for an individual to increase his/her status. This means that competition is generally only engaged in when there is something to be gained from competing. It is also the case that testosterone and dominance strongly interact with the outcome of those social interactions in which status is gained or denied. The successful attainment or denial of high status and overt threats to one's status has been found to carry powerful psychological and physiological consequences.

Testosterone and Status Mismatches

The psychological motivations that drive an individual's desire for competition are deeply rooted in physiology, namely the testosterone circulating through their bloodstream. Given that this motivation is so deeply rooted, you would expect that successful attainment or the denial of high status would have dramatic consequences for a highly dominant individual. Research has found that success or failure when competing does elicit strong psychological and physiological reactions.

Researchers have found that when an individual engages in social competition, basal testosterone predicts a number of reactions to the successful attainment of high status or relegation to low status. If an individual is high in testosterone and experiences a victory, he/she will be content, indifferent to status-relevant information, report lower levels of negative emotional affect, and perform well on complex cognitive tasks. The opposite effect has been shown for high testosterone individuals who experience a loss. These high testosterone individuals show increased levels of negative affect, cognitive impairment, and an increased focus on status cues when relegated to low status positions.

Notably, this research has found opposite patterns of effects for those low in testosterone. Low testosterone individuals who experience a victory become unhappy, report high levels of distress, show cognitive impairment, and experience physiological arousal, such as increased heart rate. Those low testosterone individuals who lose a competition, though, report being quite content, perform very well on complex cognitive tasks, experience a drop in heart rate, and show a lack of interest in status-related information.

Termed the 'mismatch effect,' this illustrates the role of basal testosterone in social competition. Individuals high in basal testosterone have a strong desire for high status, whereas those with low basal testosterone levels actively avoid high status. When an individual is placed in a position of high or

low status that is incongruent with his/her desired status (i.e., a high testosterone individual in a low status position or a low testosterone individual in a high status position), they experience a number of negative consequences. A mismatch between actual status and desired status causes emotional distress, hypervigilance toward status-related information, physiological arousal, and a decline in complex cognitive processing. This mismatch effect also illustrates individual differences in dominance by demonstrating that not everyone is striving for positions of high status, that there are some who would prefer to avoid high status if at all possible. The adverse effects of status mismatches can also extend from the individual to the group level. If status mismatches exist among individuals within a given group, those mismatches are associated with greater pessimism among group members as to the likelihood of the group's success on a task. Also, as the correlation between individuals' testosterone and their status within a group becomes more negative (i.e., mismatches increase), the group as a whole functions more poorly.

It is clear that testosterone is intimately linked with dominance, and the successful attainment or denial of high status elicits strong reactions in dominant individuals. Winning or losing status competitions causes psychological and physiological reactions, and can lead to maladaptive behaviors. One strong reaction caused by the interaction of dominance and competitive outcomes is the short-term fluctuations in hormone levels that can further influence behavior.

Dynamic Testosterone Fluctuations in Competition

Although basal testosterone levels remain static over time and can be treated essentially as personality traits, testosterone levels are also subject to dynamic fluctuations in reaction to changes in the social environment. If basal testosterone is a biomarker of trait dominance, changes in testosterone levels are akin to a transient dominance mood state. A temporary rise in testosterone can lead to a temporary elevation in one's social competitive drive. Similarly, a temporary drop in testosterone can temporarily suppress one's natural competitive motivation. The reciprocal model of social endocrinology tackles the dynamic relationship between basal hormone levels, the environment, and transient hormone fluctuations. Specifically, hormones influence behavior, behavior influences the environment, changes in the environment cause temporary fluctuations in circulating hormone levels, and these temporary fluctuations in turn further influence behavior and the environment. Hormones, and certainly testosterone, act not only as partial causes of behavior, but also experience the effects of behavior.

Research on testosterone and competition has found that testosterone rises in response to competitive environments. Many athletes experience a rise in testosterone prior to engaging in athletic competition to facilitate dominance behaviors in the competitive environment. Athletes' testosterone rises significantly more before a competition played at home than away, presumably because more status is on the line when a team plays at home, and that the rise tends to be the strongest when a team is competing against a serious rival. This suggests that not only does testosterone rise in anticipation of a competitive event, but that the degree of status threat moderates the magnitude of testosterone increase.

A number of studies have also found that not only does testosterone increase in reaction to a competitive environment, but that it fluctuates in predictable ways in response to the outcome of a competition; specifically, testosterone increases following a victory and decreases following defeat. In fact, an individual does not even need to actually engage in competition to elicit these effects. An individual's testosterone follows this same pattern even when they experience a vicarious victory or defeat, such as an imagined victory, watching their political candidate win an election, or watching their sports team win a game.

These temporary fluctuations are an important signaling mechanism that prompts an appropriate behavioral response (i.e., rising levels prompting further engagement in competition, falling levels prompting withdrawal from competition). The temporary changes in testosterone following a loss influence how individuals choose to behaviorally react to that loss. They are either motivated to attempt to regain high status when testosterone increases or withdraw from the possible further loss of status when testosterone decreases.

Even though many researchers have found that testosterone levels change in reaction to the outcome of a competition, some research has failed to find this effect. Instead they found that testosterone changes following a competition were moderated by a number of psychological factors. For instance, in some group competitions, increases in testosterone are positively correlated with how much an individual contributes to his/her team's victory, such that the more a given individual was responsible for his/her team's victory, the more his/her testosterone will increase. It has also been found that changes in testosterone levels are negatively correlated among winners who attributed their victory to external factors (e.g., luck), and were positively correlated amongst losers who made the same external attributions. This suggests that simply engaging in competition is not enough, but that psychological factors, such as motivation and cognitive appraisals of the competitive situation, are what drive reactions to competitive outcomes.

Nonconscious motivational drives can also moderate the effect of competition on testosterone fluctuations. Namely, those who are high in implicit (i.e., nonconscious) power motivation show the expected hormonal reactions to winning or losing a contest. In this case, the competition–testosterone–change link is dependent on personality factors related to an unconscious desire for power and high status, not merely the experience of winning or losing. Some research has also found that some personality factors not even directly related to status and power can also influence the relationship between competition and testosterone change, such as social anxiety.

Even though previous research has clearly linked testosterone to status-seeking, there have been striking inconsistencies across studies. Although much of the research summarized above did indeed show effects of testosterone on behavior, other studies have found weak or null effects. One explanation is that testosterone's effect on behavior is moderated not only by psychological factors, but also by the hormone cortisol.

The Moderating Role of Cortisol

Cortisol, like testosterone, is a steroid hormone. Cortisol is known primarily for its role in the physiological stress response

via activation of the hypothalamic–pituitary–adrenal axis (HPA-axis). The HPA-axis consists of the series of communications between the hypothalamus and the pituitary and adrenal glands. When the hypothalamus receives information that there is a threat in the environment, it relays a signal via the pituitary gland to the adrenal gland, which releases cortisol, as well as other hormones such as epinephrine and norepinephrine. The resulting stress response causes physiological changes which include increased respiration, heart rate, blood pressure, and blood glucose levels. These changes are all intended to prime the organism to physically respond to the threat by facilitating fight or flight behaviors. Unlike the catecholamines (i.e., epinephrine and norepinephrine), cortisol is able to pass through the blood–brain barrier, making it the primary behavioral influence during active stress responses. As such, cortisol has been shown to have not only physiological effects, but psychological and behavioral effects as well.

Not only is cortisol linked to the experience of stress, but it has been linked to approach and avoidance behaviors as well. Approach motivation is conceptualized as a broad system motivating behavior toward desirable and rewarding outcomes. Avoidance motivation, on the other hand, is a parallel system that motivates an individual to behave in ways that facilitate moving away from undesirable outcomes. Essentially, high approach motivation is characterized by appetitive behaviors and sensitivity to reward, whereas avoidance motivation is characterized by avoidant behaviors and sensitivity to punishment. High levels of cortisol have been found to correspond to behavioral inhibition, shyness, and introverted behavior, all avoidance motivation behaviors. Low levels of cortisol, on the other hand, have been found to correspond to extraverted and disinhibited behaviors, more approach-motivated behaviors.

Cortisol has been shown to play a moderating role between testosterone and behavior. Namely, high cortisol levels can suppress the action of testosterone. Given what we know about the relationship between testosterone and dominance behaviors, combined with the moderating role of status-relevant situational cues, the impact of cortisol provides yet another important factor underlying the manifestation of social competition. Testosterone is the underlying force driving social competition, but certain psychological (e.g., need for power) and situational (e.g., status threat) conditions must be met for testosterone to be manifested behaviorally. In addition to these conditions, testosterone's behavioral manifestation also depends on low levels of basal cortisol.

For instance, research shows that basal cortisol and basal testosterone interact to significantly predict individual differences in overt aggression among adolescent males, such that testosterone and aggression are related only when the individual also has low levels of cortisol. When cortisol is high, testosterone and aggression are unrelated. Furthermore, the effects of testosterone on competition and leadership behaviors are also only expressed when basal cortisol is low. For instance, when cortisol is low, basal testosterone predicts whether or not an individual will continue competing or will withdraw from competition after having been defeated once. Specifically, high basal testosterone motivates an individual to re compete after a loss, while low basal testosterone motivates withdrawal to avoid further losses, but this effect is only observed if basal cortisol is low. When cortisol is high the

effects of testosterone following a defeat are suppressed. This cortisol–testosterone interaction effect can even be extended to other dominance-relevant situations, such as leadership. Once again, basal cortisol moderates the effect of testosterone on behavior, such that when cortisol is low, the higher an individual's basal testosterone, the more dominant their behavior will appear to others. This behavioral effect of testosterone completely disappears among those leaders who have high levels of basal cortisol.

This moderation suggests that the biological underpinnings of social competition are more complex than a univariate relationship between testosterone and competition. It is not enough to have a testosterone-fueled desire to attain and maintain high status, but one also needs to have an approach motivated social style to act on that desire. Or at the very least, to not have a socially fearful, avoidance motivated behavioral style.

Research on the physiological interaction of testosterone and cortisol suggests a number of possible mechanisms for how cortisol is able to moderate the relationship between testosterone and behavior. Just as cortisol is tied to the HPA-axis, testosterone is tied to the hypothalamic–pituitary–gonadal axis (HPG-axis). The HPG-axis cues the release of testosterone in preparation for reproductive behaviors. These two axes have an antagonistic relationship, that is, when one axis is activated, the other is suppressed. Thus, when the stress response is activated, reproductive behaviors will be suppressed until an organism's physiology has returned to baseline. Cortisol, as well as other glucocorticoids, can also have an impact on the expression of androgen receptors. High levels of glucocorticoids downregulate the expression of androgen receptors. Thus, high levels of cortisol might not affect testosterone levels, but rather affect the degree to which testosterone could influence behavior by regulating the number of available receptor sites for testosterone to bind to.

Sex Differences in Competition

As stated above, the majority of research on social competition has focused disproportionately on male behavior. There is a relative dearth of research on competitive behaviors among women, but the existing research does suggest that there are sex differences in how men and women engage with and react to competition. Some evolutionary psychologists have theorized that there should be clear sex differences in competitive behavior. Namely, men are more motivated by competition, both as individuals and as a group, whereas women are motivated by social needs. For instance, some behavioral research has found that women tend to cooperate more than men across situations, whereas men tend to cooperate with one another primarily as a means to compete as a group against another group. These theories suggest that, evolutionarily, women are more interested in protecting offspring and promoting social cohesion for the purposes of maintaining social stability and security. As is outlined below, there are mixed findings on how women's competitive tendencies match or differ from those of men.

A number of research studies have found that females (both women and young girls) tend to be less competitive than their

male counterparts. There are a number of possible explanations for why men and women differ in their competitive tendencies. As mentioned above, some evolutionary theorists have suggested that although it is beneficial for men to engage in competitions to establish status, women benefit more from prosocial engagement to establish social stability. Research on stress and threat response behaviors seems to support this view, by exploring the possibility that the traditional 'fight or flight' response may be specific to male behavior, and that females may respond to threat by engaging with friendly conspecifics to establish safety and security in numbers. These theories suggest an inherent behavioral tendency away from competition and toward friendly social engagements among females.

On the other hand, anthropological research suggests that these sex differences in competitive behavior may result from strong socializing forces. When comparing patriarchal societies to matrilineal societies, women raised in a matrilineal society tend to be more behaviorally competitive than the men in that society, whereas in patriarchal societies, men tend to be the more competitive sex. These findings are conceptually in line with evolutionary theories in a broad sense, namely that different behavioral orientations (i.e., competitive vs. cooperative) yield different social benefits. The clear difference between these views is whether these differences are innate or learned. It appears that it is some combination of both. Although research in anthropology has shown that socialization determines whether competitive behaviors are more prevalent among men or women, research in social endocrinology suggests that there are underlying physiological systems tied to sex differences in competitive behaviors.

As stated previously, women's levels of circulating testosterone are much lower than men's, due to differences in the sources of testosterone. The testes produce the vast majority of testosterone in men, whereas women's testosterone is produced primarily by the adrenal glands, and to a lesser extent the ovaries. Ultimately, women have roughly a seventh of the amount of circulating testosterone as men. It is worth noting that although women's testosterone levels are significantly lower than men's, their basal testosterone is equally stable over time.

Research examining the relationship between testosterone and dominance in women has yielded mixed results in terms of whether testosterone's effects are the same across sexes. Women's basal testosterone predicts aggression and dominance, social status, performance in individual versus group competitions, and cognitive impairments associated with status mismatches. In fact, the research on the effects of status mismatches has been conducted primarily with mixed-sex samples, and has found similar patterns of results for both men and women. Some research, though, do not replicate the testosterone effects found in men among a female sample. Research on the anticipatory changes in testosterone prior to an athletic competition has found that some female athletes do not experience an elevation in testosterone leading up to a competition, but other findings support this relationship. Other research has also found that some female athletes do not experience the postcompetition fluctuations in testosterone (i.e., a win or lose dependent increase or decrease in testosterone), but other findings have found this postcompetition fluctuation.

Although the replicability of testosterone–dominance findings among women is mixed, preliminary research has begun to examine the possibility of a female-specific endocrine-dependent form of dominance. Some researchers have found that certain hormones, for instance the estrogen estradiol, are better predictors of dominance behaviors in women than testosterone. This research suggests that women possess a similar endocrine–dominance relationship, simply one that is not necessarily testosterone specific. The research to date examining dominance in women indicates that further understanding of the potential sex differences in the physiological underpinnings of dominance behavior is an important and rich avenue for future research.

Although there appear to be sex differences in competitive behaviors, research is mixed as to what those differences are and what is underlying those differences. Behavioral research suggests that women are not as competitive as men, possibly due to socialization or due to the different evolutionary goals associated with competition versus cooperation. Social endocrinology research has also produced mixed results in terms of sex differences and dominance. Some research, such as reactions to status mismatches, show limited sex differences, yet other research, such as athletic competitions, show clear differences between men and women. These mixed results may be due to erroneously applying theories and approaches derived from male-specific research to females.

Competition and Behavioral Economics

A rich field of research that has looked at human competitive behaviors is the field of behavioral economics. The study of behavioral economics relies on the basic premise that in most instances there are limited resources available to a group, thus creating an inherent conflict between the interests of the group and any one individual within that group. For instance, by focusing solely on one's own interests, the individual may utilize more of a given resource than his or her equitable portion. This overuse of a resource creates shortages for the rest of the group, which in turn leads to increased and potentially costly competition within the group. Behavioral economics utilizes interpersonal economic 'games' that rely on pitting an individual's self-interest against that of a cohort. In most instances, an individual can obtain a modest gain by cooperating with his/her partner, but could potentially obtain a larger gain by defecting from his/her partner. High levels of dispositional competitiveness have been linked to an increased propensity to betray one's partner to obtain more resources, but a number of situational and social factors influence behavior as well.

Research shows that the behavior of an individual's partner exerts a powerful influence over how that individual will behave. If a partner is viewed as acting unfairly, the other individual will respond by rejecting any kind of cooperation, even if that rejection knowingly causes all of the resources to be lost for both players. This retaliatory behavior serves to reinforce social cooperation and maintain a certain level of parity within the dyad regarding the distribution of resources. Aggressive and competitive behavior on the part of one's partner increases the likelihood that an individual will respond with

an equally aggressive and competitive behavioral style. The opposite effect has also been found to be true. Individuals are more likely to behave cooperatively and noncompetitively if they are interacting with a cooperative partner.

Two important situational factors moderate this reciprocal effect. First, reciprocity is particularly pronounced if individuals are interacting repeatedly over a series of trials. Repeated cooperative interactions lead to developing a sense of trust. Because individual success is tied to the behavior of the individual's partner, individuals recognize that punishing an aggressive partner and trusting a cooperative partner is the best strategy for maximizing one's gains. Second, physical distance and anonymity both decrease reciprocal behaviors. If an individual is physically isolated from his/her partner and is able to behave anonymously, it increases the likelihood that that individual will behave aggressively and competitively, regardless of the partners' behaviors. Anonymity appears to nullify the social motivation to reciprocate.

The threat of retaliation is also affected by the magnitude of the resources at stake. When individuals are engaging with one another during an economic decision making game, the higher the stakes, the more likely individuals are to act fair and cooperate with one another. If there is relatively little to be gained or lost, individuals will act more competitively, because the potential to gain an extra amount is offset by the potential to lose an equally small amount. On the other hand, when the stakes are higher, not only is there a potentially larger gain to be had, but there is also the threat of potentially larger losses. Humans have a well established aversion to losses, so as the stakes increase, the threat of a large loss exerts a greater influence over behavior than the potential for a large gain, meaning that as the stakes increase, competitive behaviors decrease.

In addition to situational and social forces, individual differences also influence whether one acts aggressively or cooperatively toward his/her partner. Research has shown that dispositional dominance is a power factor in determining whether an individual tends toward a competitive or cooperative orientation. The effect of dominance is moderated by situational forces, in some instances driving an individual to treat their partner as a competitor and attempt to secure as many resources for him/herself as possible, and actually facilitate cooperative behavior between individuals in other instances.

In some interactions, an individual high in dispositional dominance may view cooperation as an acknowledgment that both individuals are equal, and may opt to act aggressively to establish his/her higher social status. Research has supported this theory, showing that high dominance individuals view these situations as moments of potential status instability. If the pair is even, at the outset, high dominance individuals will engage with their partner with a competitive motivation, attempting to acquire more resources than the partner in order to elevate their own status. If the pair is asymmetrical in some way (e.g., one individual has more resources than the other), high dominance individuals will respond to this asymmetry as a status challenge, and respond with aggression and/or retaliation in order to obtain or preserve their status. On the other hand, research has also shown that in certain circumstances high levels of dominance may actually increase the likelihood of cooperative behavior. Recall that there are a

number of strategies for obtaining high status, one of which is to behave prosocially toward one's peers. In the context of economic games, by acting prosocially toward one's partner, it minimizes the likelihood that the partner will retaliate or punish the individual, and increases the likelihood that the partner will reciprocate the cooperative behavior. It has been suggested that a key circumstantial factor in determining which behavioral strategy will be adopted is whether or not an individual feels a continued dependence on one's partner to succeed. Individuals dependent on their partners are more likely to adopt a prosocial strategy, thus maximizing their benefit in the long term.

Conclusions and Current Research Trends

Competition among social animals takes many forms, including physical aggression between individuals over a specific resource and social competition for high status positions within a hierarchy. High status positions offer a much more efficient and less costly means to distribute limited resources. Just as is the case among rats, mice, chimpanzees, baboons, and countless other social animals, it is also the case among humans.

The primary biological fuel driving social competition is testosterone, which manifests itself behaviorally as dominance. Dominance behaviors are meant to facilitate one's ascension up the social hierarchy by besting other individuals within the same hierarchy. The effect that testosterone has on dominance behaviors is moderated by two important factors. One is the hormone cortisol, which acts as a behavioral inhibitor, such that when cortisol is high, testosterone's influence on behavior is suppressed. The other important factor is the presence/absence of appropriate social circumstances; namely, conditions under which competition will yield actual social rewards.

Recent research has begun to explore more complex neurobiological and genetic factors that may be influencing competitive behaviors. Neuroscience research is examining the potential role of brain structures related to emotion regulation and impulse control on behaviors such as aggression and economic decision making. Behavioral genetics research has been studying how genetic variations on neurotransmitter and neurochemical promoter genes potentially influence complex social behaviors, such as how the underexpression of certain neurotransmitters may reduce impulse control or blunt threat responses. These approaches are being combined with continued research on situational, environmental, and cultural

influences over competitive behavior to further elucidate the dynamic and interactional relationship between the environment and biology that gives rise to complex social behaviors. Ultimately, the merging of multiple disciplines has led to a highly nuanced examination of the biological, social, and environmental forces influencing social competitive behaviors.

Glossary

Confabulation The emergence of memories of events and experiences which never took place.

Frontal-subcortical loops Anatomically defined, separate loops connecting specific parts of the prefrontal lobes with the striatum, globus pallidus, substantia nigra (reticular part), and the thalamic nucleus having connections with the loop's originating part of the prefrontal cortex.

H₂[15]O-PET Positron emission tomography using radioactively labeled water to study the distribution of metabolic activity in the brain.

Orbitofrontal cortex Area at the inferior aspect of the frontal lobes. Its posterior medial part has limbic connections and projects to the ventral striatum.

Substantia nigra Anatomical structure in the midbrain with two components: (1) the reticular part participates in the frontal-subcortical loops; (2) the pars compacta has the dopaminergic neurons, which have multiple functions. They are part of the brain's reward system; their degeneration contributes to the symptoms of Parkinson's disease.

Definition

Confabulation derives from the Latin word 'confabulari' whose original meaning was to gossip, to chat, or to discuss something with somebody. The word 'fabula,' contained in confabulation, primarily meant a chat, dialog or tattle with people, but it also meant the saga, fairy tale, and fiction.

Confabulation made its first appearance in the medical literature around 1900, when Carl Wernicke used the term in his textbook on psychiatry and defined it as 'the emergence of memories of events and experiences which never took place.' The term replaced the previous denominator, which Sergei Korsakoff had used in his writings on confabulation around 1890: pseudoreminiscences. Korsakoff had defined them as 'a situation in which a patient conceived of an event that he had not really experienced, but that had only come to his mind, as if it had really happened to him.'

Thus, since its first appearance in the medical literature, confabulation denoted a failure of memory, a mnestic phenomenon. Later authors introduced diverse refinements to the definition, claiming that confabulations had to be unintentional; that they might have fantastic features, or not; could only occur in organic brain damage, or also in psychiatric disease; only concerned autobiographical memory, or might extend to semantic memory, etc. None of these limitations is unequivocally accepted.

The term confabulation was eventually also used to describe false statements emanating from incorrect perceptions of bodily states or of the outer world. These confabulations may be classified as nonmnestic confabulations. For example, the term was used to describe the false idea of patients who have half of their body paralyzed but believe that they can move it normally, a situation called anosognosia. Likewise, patients with psychosis or organic brain damage may believe they are in another place than the real one (reduplicative paramnesia) or pretend to know unfamiliar people or not to know familiar people (Capgras syndrome; misidentification syndromes). These nonmnestic confabulations often occur independently of mnestic confabulations and normally have different anatomical bases. Their

association with mnestic confabulations will be discussed below. In the following, confabulation denotes mnestic confabulations unless otherwise stated.

Forms of Confabulation

From the beginning of the twentieth century, many authors distinguished different types of mnestic confabulations. The most common distinction proposed the following dichotomy:

1. Momentary confabulations (other terms: out-of-embarrassment, classic compensatory, or plausible confabulations): in most definitions, these confabulations were considered a consequence of memory loss resented by the patient who would invent answers to questions in order to avoid embarrassment.
2. Fantastic (or productive) confabulations: these would be produced spontaneously and resemble delirious, dreamlike states, as seen in psychosis.

Another distinction, initially used to separate different degrees of confabulation, is the following one:

1. Provoked confabulations: these confabulations occur in memory tests and may also occur in healthy subjects. They were also considered a normal response to a faulty memory.
2. Spontaneous confabulations: these were considered a pathological phenomenon, possibly reflecting an incoherent and context-free retrieval of memories. Another definition requires patients to act in agreement with the confabulations as the proof of their spontaneous generation.

The precise definitions proposed by different authors often seemed to be influenced by, and limited to, the precise types of brain damage that they had studied. Although the two classifications are widely accepted, the precise meaning of the terms varies considerably between studies. Numerous authors used these classifications to describe different degrees, rather than different forms, of confabulation. However, some

dissociations have been proven. For example, the tendency of patients to make intrusions in memory tests, that is, to produce words that were not originally in the test (provoked confabulations) doubly dissociates from the tendency to act according to spontaneously produced confabulations. Also, the severity of confabulations does not predict an association with behavior: patients producing the most intense fantastic confabulations, reported at times when antipsychotic medications were not available yet, showed no tendency to act on the basis of these confabulations.

Thus, the proposed classifications described above, which entail a dichotomy, do not account for the known dissociations between confabulations. I suggested the following classification that accounts for the currently known forms of confabulations:

1. Simple provoked confabulations encompassing intrusions or occasional distortions in memory tests. These confabulations may also occur in healthy subjects. Thus, when recalling the words from a previously learned word list, subjects may produce items that were not in the list.
2. Momentary confabulations, which consist of false verbal statements produced upon some form of incitement, be this questioning or the circumstances of a discussion. False statements can range from a slightly distorted response to a question – and then appear to be provoked – to elaborate, apparently spontaneous confabulations in a discussion. Momentary confabulations may occur in diverse brain diseases, may be present initially or appear in the course after brain damage, and are probably not a unitary disorder. For example, a hospitalized patient may falsely believe to have been at work in the morning (autobiographical confabulation), pretend to know what he ate for lunch on January 5th 2003 (autobiographical) or invent elements when recounting a fairy tale (semantic confabulation).
3. Fantastic confabulations, which have no basis in reality and are intrinsically nonsensical and illogical. These confabulations are very rare and may occur in severe psychosis, delirium or advanced dementia. For example, patients have been described who believed that they were the richest kings on earth, had been Adam in paradise or had already landed on Mars.
4. Behaviorally spontaneous confabulations in which patients recount invented recent experiences and describe plans for the future that are incompatible with their current situation. At least occasionally, they also act according to such false ideas. Mostly, they enact former habits: they think they have business meetings or that they are expected at home. This form is always accompanied by amnesia (as measured by free recall) and disorientation: the patients do not know the time, place or their current role. For example, a 58-year old mother, who had suffered rupture of an aneurysm of the anterior communicating artery, left the examination in the conviction that she had to feed her baby, who was 35 years old at the time.

Until now, only the dissociation between forms 1 and 4 has been proven. Patients may have a combination of momentary and behaviorally spontaneous confabulation, possibly also fantastic confabulations.

Simple provoked confabulations – according to the above definition – require focused memory testing and will then become evident as intrusions. The other forms are normally easily detected in a discussion, when patients talk about events or experiences that have not really taken place. Questionnaires containing questions that cannot normally be answered have been proposed to quantify momentary confabulations. Fantastic confabulations are often produced spontaneously by confused patients but may be spurred by questions. Behaviorally spontaneous confabulation normally requires clinical observation: while the confabulations come out in discussions, in which patients recount experiences and actions that have not truly taken place, the spontaneous behavior betraying the spontaneity of the false ideas may only be revealed by behavioral observation. The combination of amnesia with disorientation increases the likelihood that a patient has behaviorally spontaneous confabulation; the absence of disorientation makes the presence of behaviorally spontaneous confabulation unlikely.

Disorders Associated with Confabulation

Initial descriptions of confabulations emphasized their association with anterograde amnesia and disorientation. Later observations suggested an association with false recognition as well as behavioral particularities, namely, anosognosia and misidentification syndromes. The following paragraphs summarise the evidence.

Simple provoked confabulation will not be particularly considered in the following; as they also occur in healthy subjects, these associations are obviously not mandatory for provoked confabulations to occur. Overall, simple provoked confabulations (intrusions) are more common in brain damaged subjects, but their intensity correlates neither with the severity of amnesia nor of executive failures. Most notably, simple provoked confabulations are not associated with false recognition: among comparably severe amnesic subjects, the number of intrusions produced in a recall paradigm does not correlate with the number of items falsely recognized in a recognition paradigm.

In the other forms of confabulation, the associations are more complex.

Amnesia

Relevant momentary, fantastic, and behaviorally spontaneous confabulations are always associated with moderate-to-severe amnesia as measured with tests of delayed free recall, that is, when subjects have to reproduce information from memory with no external help. By contrast, if a memory task is relatively free of strategic demands and just requires recognition of previously presented material, amnesia is not always present. This may be tested, for example, with a continuous recognition task, in which subjects see a long list of items (typically pictures) and are requested to recognize item repetitions within the series. Under such conditions, occasional behaviorally spontaneous, and presumably also momentary and fantastic confabulators, may demonstrate intact learning and recognition. Thus, in

terms of simple information storage, confabulation and amnesia may dissociate; confabulation need not be associated with a gap in memory.

Disorientation

Disorientation describes the inability to correctly acknowledge the current time, place, one's role, and personal identity. These dimensions are called orientation to time, space, situation, and person, respectively. Personal orientation is rapidly restored after most types of brain damage. While fantastic confabulations, as described in the early literature, are often characterized by absurd misinterpretation of one's own identity, momentary and behaviorally spontaneous confabulation were mostly described in patients with intact personal orientation. Most patients with momentary confabulations, especially if they also have severe amnesia, are also disoriented. But the association is not mandatory. This is different with behaviorally spontaneous confabulation which is characterized by a confusion of reality that is practically always measurable as a disorder of orientation. Although disorientation can result from severe amnesia alone, most instances of disorientation have the same mechanism as behaviorally spontaneous confabulation, namely a failure of memory filtration and extinction capacity that will be described below.

False Recognition

False recognition describes the erroneous familiarity with items in memory tasks; test subjects believe they have encountered a piece of information in a specified previous context (e.g., a word in a previously presented word list) when, in fact, the information has not been presented. Although false recognition may occasionally be observed in memory impaired patients, there is no confirmed association with any form of confabulation; indeed, the two phenomena doubly dissociate.

Paramnesic Misidentification

Paramnesic misidentification describes erroneous interpretations regarding places, people, or the current situation. Some patients with behaviorally spontaneous confabulation, possibly also other confabulations, are convinced that they are not at a hospital but rather at a familiar place, typically their home or their work place. This false identification of one's current whereabouts is called reduplicative paramnesia. Similarly, patients may falsely recognize strangers as friends or colleagues, or deny familiarity with people they correctly perceive (Capgras syndrome). Although these misidentifications of places or people can sometimes be observed in behaviorally spontaneous confabulators, the association is not stable: many patients do not have such misidentification problems. Conversely, these misidentifications may occur without any other form of confabulation and are then not accompanied by corresponding acts. The same is true for another form of paramnesic misidentification: *déjà-vu*, the strange feeling that one has already lived the present situation in precisely the same way. *Déjà-vu* has no confirmed association with mnemonic confabulation.

Anosognosia

This term was originally introduced to describe the unawareness of unilateral hemiplegia, but is nowadays used to describe unawareness of disease in general. The false statements that the patients make about their paralysed side have been called confabulations (classified as nonmnestic confabulations in this article). Conversely, diverse authors suggested that anosognosia of memory failure was a common feature of and a prerequisite for the occurrence of confabulation. Whereas fantastic confabulators, as they have been described in the old literature, have mostly no sense for the absurdity of their thoughts, momentary confabulations may also be produced by patients who are fully aware of, and suffer from amnesia. In behaviorally spontaneous confabulation, the association is more complex: although patients are normally unaware of the falseness of their perceived reality, occasional patients may be aware of having a memory problem.

Normal False Memories

Normal false memory denotes false products emanating from normal memory processing by healthy subjects. Apart from occasional provoked confabulations, which may also occur in healthy subjects, the confabulations discussed in this article occur in the context of pathological brain dysfunction or damage and are, therefore, by definition distinct from normal false memory. Nonetheless, a brief review may be warranted, all the more so because some mechanisms hypothesized to explain confabulation were meant to cover normal false memories, too.

Memory storage and retrieval is thought to rely on associative processes that do not necessarily produce a precise record of an experience. Even personally very engaging memories – so-called flash-bulb memories – may undergo significant distortion over time, even if they are normally relatively resistant to alterations. The fact that the healthy brain processes the meaning, rather than just perceptual features of information renders memory vulnerable to associative errors. This weakness, resulting from the associative power of memory, is exploited in the DRM-paradigm (Deese-Roediger-McDermott-paradigm) in which subjects learn a list of words (e.g., door, glass, pane, shade, ledge, sill, house, open, curtain, frame, view, breeze, sash, scream, shutter) which together associatively encircle a target word not present in the list (e.g., window). When healthy subjects learn such a list and later recall it, they are likely to produce the target word, which is also falsely recognized as having been present in the list. Amnesia seems to have a protective effect against this type of susceptibility. In the standard DRM-paradigm, confabulating amnesics did not differ from nonconfabulating amnesics as regards susceptibility to the DRM-effect.

Errors of normal memory have had the most dramatic impact in eyewitness testimony. Indeed, innumerable studies have shown that the precision of memory storage and retrieval may be heavily influenced by cognitive and mood states at the time of an event (e.g., ethnical biases), information received after an event (e.g., confirmatory feedback) and the phrasing of questions. Manipulative procedures are most efficacious if

the memory of an event is relatively weak and manipulative information or questions are plausible. Under certain circumstances, it is possible to plant completely invented memories that may be held with similar conviction as true memories.

The relationship between normal false memories and confabulation has never been formally explored. However, it appears that normal false memories are created during the normal processing (retrieval, reconsolidation) of memories and may be augmented or induced by manipulation at storage or just before retrieval of information. There is no evidence that pathological confabulations have to be planted first or require suggestive questioning. They are very often composed of fragments of memories of real events experienced before the occurrence of brain damage. It is therefore likely that normal false memories and pathological confabulations have independent mechanisms effective at different stages of memory processing.

Etiologies and Anatomy of Confabulations

Not all confabulations require brain damage. Provoked confabulations can also be induced in healthy subjects, although their frequency markedly increases after brain damage. In the following, the causes and the anatomy of behaviorally more relevant confabulations will be reviewed: momentary, fantastic, and behaviorally spontaneous confabulation.

The distribution of brain diseases provoking confabulations has evolved over the last century. The sequels of malnutrition and alcohol can nowadays be limited with vitamin B1 supplementation; syphilis of the nervous system can be treated with antibiotics. Conversely, previously deadly diseases such as herpes encephalitis and aneurysm bleeding are nowadays more often survived; unfortunately, some survivors are left with severe cognitive deficits including confabulation.

Since the early descriptions, a multitude of causes of confabulations were recognized: paralytic dementia (syphilis), alcoholism and malnutrition, infections, hypoxia, traumatic brain injury, diverse types of poisoning, etc. With many of these causes, confabulations occurred during an acute confusional state (delirium), that is, a state of incoherent thinking, hallucinations, and fluctuating attention.

Momentary Confabulations

Momentary confabulations have been recognized in many brain diseases. In the early literature, malnutrition, especially in the context of chronic alcohol abuse, was the most frequently reported cause of confabulation, nowadays known to be caused by a deficit of thiamine (vitamin B1). The Wernicke-Korsakoff syndrome – according to the original descriptions – encompasses amnesia, a strong tendency to confabulation, disorientation, plus physical impairments: oculomotor disturbances and ataxia. The precise cause of the amnesia itself is still a matter of debate: destruction of the mamillary bodies or the dorsomedial thalamic nucleus, or frontal and medial temporal lobe dysfunction have been invoked. In what way confabulatory amnesia in this syndrome anatomically differs from nonconfabulatory amnesia, is unknown.

Nowadays, the most quoted cause of relevant momentary confabulation is rupture of an anterior communicating artery

aneurysm with destruction of the basal forebrain and orbitofrontal cortex. However, confabulatory amnesia is very rare with modern neurosurgical and neuroradiological treatment and may concern a maximum of 3–5% of affected people.

Many other causes of momentary confabulation are known, ranging from traumatic brain injury and tumors to ischemic stroke, encephalitis, or hydrocephalus. Many of these diseases do not induce circumscribed brain lesions and do, therefore, not contribute to the understanding of the anatomical basis of momentary confabulation. In those diseases that cause circumscribed brain lesion (tumors, stroke, etc.), confabulations appear to be more common when a lesion involves the anterior ventral part of the brain including the orbitofrontal cortex, basal forebrain, and hypothalamus. But the association is not strict: occasional patients with posterior lesions involving the medial temporal lobe or even the parietal lobe, who confabulated significantly, have been described.

Fantastic Confabulations

The most striking examples of fantastic confabulation, completely nonsensical and illogical, were described in the early literature in patients having advanced syphilis of the nervous system (paralytic dementia) or schizophrenia. Both diseases are nowadays causally or symptomatically treatable. Neither has a circumscribed anatomical basis. In the more recent literature, fantastic confabulations, typically less absurd than those following the above causes, were reported in the early phase after acute brain damage of diverse etiologies, including, for example, aneurysm rupture, encephalitis, or multiple sclerosis. In addition, they have been described in advanced dementia, which differs from a confusional state by more stable basic attention.

Behaviorally Spontaneous Confabulation

Behaviorally spontaneous confabulations share many causes with momentary confabulations: rupture of an anterior communicating artery aneurysm, traumatic brain injury, herpes encephalitis, etc. Indeed, behaviorally spontaneous confabulators sometimes go on to produce only momentary confabulations: they no longer act according to their confabulations and orientation improves. The anatomical basis of behaviorally spontaneous confabulation has become clearer over the last years. **Figure 1** shows an overlap of focal brain lesions of patients presenting behaviorally spontaneous confabulation (with disorientation) in comparison with nonconfabulating patients having similarly severe amnesia, as determined with measures of free recall. As **Figure 1** shows, the confabulating patients had a strong lesion overlap in the area of the posterior medial orbitofrontal cortex. Additional lesion sites have been described: a lesion of the knee of the right internal capsule; stroke of bilateral paramedian thalamus; amygdala damage on the right side combined with perirhinal damage on the left side; or lesions (sarcoidosis, tumor) of the anterior hypothalamus. In summary then, all hitherto reported cases presenting with behavioral spontaneous confabulation, which persisted beyond a confusional state (delirium), had lesions that involved the posterior medial orbitofrontal cortex, in particular area 13, or brain areas having a direct connection with it.

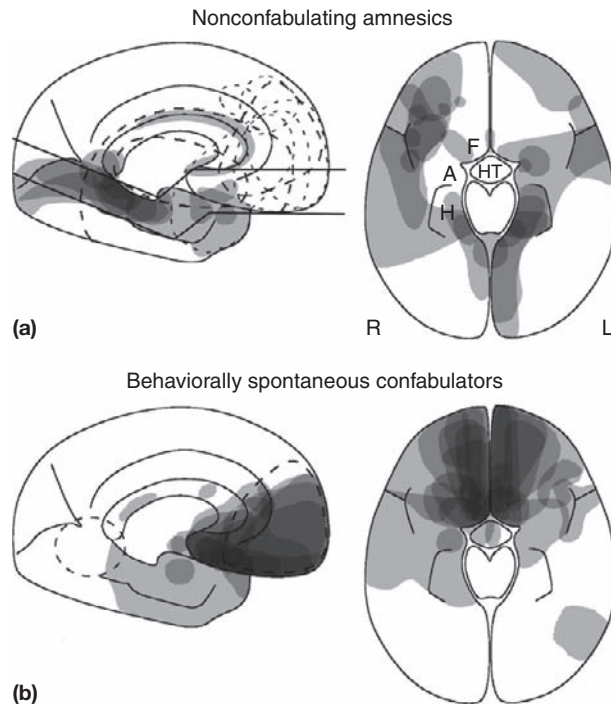

Figure 1 Anatomy of behaviorally spontaneous confabulation. (a) Lesion overlap of nonconfabulating amnesics. (b) Lesion overlap of behaviorally spontaneous confabulators. Shaded areas indicate lesions of the paramedian cortex (left template) or inferior surface (right template). Dashed lines are used to indicate lesion of the lateral convexity (left template). A, amygdala; F, basal forebrain; H, medial temporal lobe including hippocampus; HT, hypothalamus. Reproduced from Schnider A (2008) *The Confabulating Mind. How the Brain Creates Reality*. Oxford: Oxford University Press, with permission from Oxford University Press.

Area 13 was also activated – as measured with $H_2[15]O$ positron emission tomography – in healthy subjects, who successfully performed a task of memory selection on which behaviorally spontaneous confabulators had failed.

A continuing mystery is that only a small minority of patients having a type of brain damage that normally accounts for significant momentary or behaviorally spontaneous confabulation will actually confabulate beyond the confusional state. This is true for ruptured aneurysms, diencephalic tumors, traumatic brain injury, and alcoholic Korsakoff syndrome. Amazingly, only a few percent of these patients subsequently present with behaviorally spontaneous confabulation. Also, most patients with this syndrome eventually stop confabulating and regain a correct sense for reality. It seems that the structures essential for reality adaptation in thinking, whose failure accounts for behaviorally spontaneous confabulation, are redundantly organized.

Clinical Course

There are very few studies describing the clinical course of confabulation, and most of these are case reports. In degenerative

disorders, confabulatory tendency may increase over time, although no specific pattern has been described. If confabulation is due to acute brain damage, it normally decreases over time and transitions between different forms of confabulation may occur. Patients who produce fantastic confabulations in an acute confusional state (delirium) may subsequently cease to confabulate, produce momentary confabulations, or suffer the reality confusion characterizing behaviorally spontaneous confabulation. The latter transition has only been described in patients having damage to the posterior medial orbitofrontal area or structures directly connected with it. Patients having behaviorally spontaneous confabulation may simply stop to confuse reality and to confabulate; others may stop to produce inappropriate acts but still produce momentary confabulations in response to questions. Momentary confabulations may occur in the course of a memory disorder with no transition to other forms of confabulation. These observations indicate that the different forms of confabulation are at least partly independent disorders rather than different degrees of a common disorder. Confabulatory behavior of any kind often ceases despite continuing amnesia.

The course of behavioral spontaneous confabulation has been studied more specifically. Virtually all patients eventually stop to confuse reality. They stop confabulating and regain correct orientation about time, place, and their current role. The duration of the confabulatory phase seems to depend on the lesion site. If a patient has behaviorally spontaneous confabulation beyond termination of the initial confusional state and has a lesion that involves the posterior medial orbitofrontal area, the confabulatory phase may last many months. In a notable case, the transition from the state of reality confusion to appropriate behavior occurred within one week after 18 months. If the lesion does not directly involve the posterior medial orbitofrontal area, there is a high chance that the confabulatory phase lasts less than 3–6 months. Very rare cases with permanent reality confusion over several years have been described. Clinical improvement is not reliably associated with the recovery of amnesia or of executive dysfunction (although these functions, in groups of patients, tend to improve). The improvement is, however, associated with recovery of the capacity to distinguish between memories that pertain to ongoing reality and memories that do not. The evaluation of this capacity will be described below.

There is no specific treatment with proven efficacy for behaviorally spontaneous confabulation. Single patients were trained to use diaries and notebooks with the goal of teaching them to respect a schedule. Another goal was to have them take notes whose belated study would provide evidence to the patients that their thoughts were false. In severe reality confusion, this approach – while worth a trial – is not efficacious. Some patients may profit from neuroleptic treatment, whose effect can be estimated within a few days. In our experience, patients should not permanently be confronted with the fact that their ideas are false. It is more useful to provide an environment of protected freedom where patients can express their (false) ideas about reality and freely move around without putting themselves in danger, for example, by stepping into the street while they still have attentional deficits. Hospitalization in a specialized unit with the possibility to prevent the patients from leaving may be necessary.

Mechanisms of Confabulation

Since the early descriptions of confabulation, at the end of the nineteenth century, investigators have speculated about its mechanisms. Common themes have been that confabulators fill gaps in memory (gap-filling hypothesis), may do so to obtain satisfaction (motivational hypothesis), have the combination of amnesia with a mental control disorder (executive hypothesis), have a problem in the association of elements constituting a memory (reconstructive hypothesis), fail to verify whether a memory refers to a real event in the past or not (monitoring hypotheses), or confuse information from distinct periods (temporal order hypothesis). Most hypotheses were derived from observation alone; controlled evidence has remained extremely scarce. In addition, many theoreticians made no difference between the diverse forms of confabulation and suggested that their theory was valid not only for all forms of mnestic confabulations, but also for nonmnestic confabulations and false recognition. The following is a brief summary of the prevalent hypotheses and their empirical bases.

Gap-Filling

One of the earliest interpretations of confabulation, especially momentary confabulations, was that the patients fill gaps in memory to avoid embarrassment. Arnold Pick proposed a special version of the gap-filling account in which he interpreted gap-filling as a physiological process similar to the filling of the blind spot in vision. This process would serve the coherence of memories. Gap-filling is still proposed in present-day textbooks.

As far as empirical data exist, they do not support the gap-filling account. Diverse studies have shown that provoked confabulations, momentary confabulations, or behaviorally spontaneous confabulations do not correlate with the tendency to respond to questions about items that do not exist or which the patients cannot reasonably answer. Their tendency to respond to such questions does not differ from nonconfabulating amnesics. Thus, confabulators do not have an indiscriminate tendency to fill gaps in memory. In addition, as described above, even severe confabulators may not necessarily have a 'gap in memory' if their encoding and retrieval capacity is tested with a conceptually simple recognition task. Thus, while gap-filling may be a reasonable explanation for certain instances of confabulation, it is definitely not a generally valid account of any type of confabulation.

Motivational Hypothesis

An early variation of the gap-filling idea held that elaborate confabulations (intense momentary or fantastic confabulations) may provide satisfaction to the patient. The idea has also been applied to nonmnestic confabulations, in particular falsely favorable accounts of one's hemiplegia (anosognosia) or patients' beliefs that they were near their home rather than at hospital (reduplicative paramnesia). These nonmnestic confabulations were interpreted as embellishment of the true situation, motivated by the wish to be in a better state than the real one.

The motivational hypothesis has recently been revived. Indeed, patients with apparently elaborate momentary

confabulations after lesions in the orbitofrontal area tended to produce more positive accounts of their past and present than healthy subjects asked to invent responses to similar questions. The idea was again that the wish to embellish reality might be an inducer or modifier of confabulations. It is unclear whether the comparison with intentionally invented ideas by healthy subjects is valid. Also, the account does not explain why false memories come up in the first place. Finally, the positive emotional bias of confabulations may also depend on sociocultural circumstances: Korsakoff noted that confabulations in his patients mostly referred to deaths and funerals.

Executive Hypothesis

A very early observation was that confabulation was not explained by memory failure alone but required additional mental impairments, nowadays called executive dysfunctions. Single cases have been described in whom fantastic or momentary confabulations decreased with improvement of executive functions. Such findings are, of course, not specific. Diverse group studies showed that brain-damaged subjects who confabulated had overall worse executive functions than patients who did not confabulate. In the absence of an appropriate matching criterion, this observation just shows that more severe brain damage is likely to produce more severe deficits, without any specific conclusion about confabulation. Also, executive dysfunction is such a broad class of failure that the specificity of the account is unclear. Importantly, diverse studies showed that behaviorally spontaneous confabulators do not differ from nonconfabulating patients with similarly severe amnesia on a select series of executive functions. Thus, momentary and behaviorally spontaneous confabulations are not explained by general executive dysfunction. Fantastic confabulations have only been described in disease states characterized by severe and multifaceted executive dysfunction (delirium, severe dementia, severe schizophrenia), but the association has never been formally explored.

Provoked confabulations appear to require some form of cognitive flexibility: among similarly severe amnesics, the number of intrusions in memory tests was positively correlated with measures of mental drive and relatively better retrieval success in memory testing. It appears that provoked confabulations at least partly constitute the pay-off for a particularly broad search in an imperfect memory.

Monitoring Hypotheses

Korsakoff suspected that confabulations were based on some defect in the association of memories, a defect that would nowadays be called a disorder of reconstructive processes. Where precisely the defect lies, has never been specified. Many authors, including early ones, thought that confabulations resulted from an inability to verify whether an upcoming memory relates to a real event (reality monitoring) or to verify the memories' provenance (source memory). Although this interpretation is phenomenologically hardly contestable, empirical evidence is lacking. While confabulating patients who failed in reality and source monitoring have been described, nonconfabulating amnesics often appear to have the same difficulty. Thus, the knowledge about when and

from what source a memory was acquired in the past is not critical for the occurrence of confabulation. Hitherto, no experimental paradigm able to separate between patients having any form of confabulation and an appropriately matched nonconfabulating brain-damaged control group has been demonstrated. Nonetheless, as will be shown further down, behaviorally spontaneous confabulation can indeed be interpreted as a defect of preconscious filtering of upcoming memories, a defect that might be conceived as a failure of a preconscious, real time or on-line monitoring process.

A particularly elaborate version of a monitoring hypothesis is the strategic retrieval hypothesis by Moscovitch and coworkers. It describes a chain of processes, subserved by specific medial temporal and frontal structures, that leads up to correct, or incorrect, memory retrieval. A critical structure is the ventromedial prefrontal cortex, which together with the frontal pole would convey the feeling for the rightness of memories. The hypothesis was tested by comparing groups of confabulating and nonconfabulating patients who were asked to recall personal events upon a cue or to recount in detail fairy tales or bible parts. Confabulating patients indeed produced more erroneous recollections. Although the authors suggested that these findings explained behaviorally spontaneous confabulation, the limitation to a singular pathology (rupture of an anterior communicating artery aneurysm in one study) leaves open the possibility that the findings simply reflect the severity of cognitive failures in general. In an earlier study, confabulating patients had indeed had more severe executive dysfunction. More importantly, semantic memory need not be affected in behaviorally spontaneous confabulation. Thus, this hypothesis pertains particularly to momentary confabulation. It suggests that – at least in the explored etiologies – the severity of momentary confabulation is also measurable by the number of confabulations in semantic memory. However, it does not clarify the precise mechanism or stage of processing whose defect is responsible for confabulation. Of note, other authors used similar experimental evidence (errors in fairy tale recall) to support the temporal order hypothesis of confabulation, which will be discussed next.

Temporal Order Hypotheses

An observation already made by early clinicians was that confabulations very often consist of bits and pieces from real events in the patients' past, but assembled with incorrect temporal order. This element, by the way, relates to most instances of all forms of confabulation, possibly with the exception of intense fantastic confabulations that defy any concept of logic. An early suggestion was, therefore, that elaborate confabulations reflected a loss of the temporal order in memory. Single case observations supported this view. However, an inability to know in what temporal sequence information was previously seen also occurs in nonconfabulating amnesic patients and in patients having prefrontal lesion with otherwise intact memory. Thus, the simple knowledge about when in the past an event happened is not relevant for the occurrence of confabulation.

A more recent refined version of the temporal order hypothesis holds that confabulating patients have lost the temporal frame in consciousness – they have a pathological

awareness of personal temporality. Similar to the monitoring hypotheses, the temporal order hypothesis formulated this way can hardly be contested, but the authors did not limit the theory to any specific form of confabulation and provided no experimental paradigm to separate confabulating from nonconfabulating amnesics or to explore the mechanisms behind the shift in personal temporality.

Nonetheless, in conceptual agreement with monitoring and temporal order hypotheses, experimental evidence on behaviorally spontaneous confabulation has indeed shown an inability to refer memories to ongoing reality, and in that sense a defect of monitoring or loss of the temporal frame in thinking. The mechanism, which will be discussed in the next paragraph, is specific for behaviorally spontaneous confabulation; no evidence exists that it applies to other forms of confabulation.

Confabulation and Reality

Confabulations are – first of all – verbal descriptions of false memories about events and experiences which never took place. In most instances, these false verbal statements relate to past events and do not necessarily influence the way in which patients perceive ongoing reality. This is different with behaviorally spontaneous confabulations: the patients not only recount recent experiences which have not taken place in reality, but also falsely interpret ongoing reality. This confusion of reality is manifested by measurable disorientation about time, place, and current role, and in the fact that the patients act according to their falsely perceived reality. In most instances, they enact previous habits, such as, going to work. Thus, behaviorally spontaneous confabulation constitutes more than a false verbal account of recent experiences: it is a disorder of reality perception. Its study may help us understand how the brain recognizes that a memory refers to ongoing reality, or not. Given its anatomical specificity, it also represents a natural human lesion model for the orbitofrontal influence on reality perception.

Confabulation and Memory Suppression (Filtration)

We found that behaviorally spontaneous confabulators fail to suppress the interference of memories that do not pertain to the 'now.' We arrived at this conclusion using the following experimental task: patients performed repeated runs of a continuous recognition task in which they saw a long series of pictures among which they had to recognize repetitions. Most importantly, all runs were composed of exactly the same picture series. In this way, the first run demands learning and recognition of new information. From the second run on, subjects are familiar with the pictures; now, the task demands the ability to realize that a picture – although it appears familiar – comes up for the first or a repeated time within the ongoing run.

We found that the performance of healthy subjects and nonconfabulating amnesics remained constant over the different runs. Behaviorally spontaneous confabulators, in contrast, had a specific increase of false positive responses, that is, they indicated more and more frequently that they thought they had just seen a picture in the ongoing run, when indeed they

had seen it in a previous run, up to 45 min earlier. Thus, they failed to suppress the interference of their currently irrelevant memory of an item's appearance in a previous run. This failure also very highly correlated with the degree of orientation, measured with 20 questions about orientation to time, place, current situation, and personal information. In addition, this failure individually paralleled the clinical course of the reality perception of the patients, irrespective of the persistence of amnesia. Translated to normal thinking, the results meant that the ability to realize what day it is, where we are, and what our current role is, depends much more on the ability to filter out ideas that do not pertain to ongoing reality than on the ability to learn new information.

Normal Reality Filtration

The same experimental paradigm was used in adapted form to study reality filtration in healthy subjects. In agreement with the anatomical data in patients, who had lesions of the posterior medial orbitofrontal cortex or directly connected structures, we found that healthy subjects performing a similar task while their brain activation was monitored using $H_2[15]O$ -PET, activated the medial temporal lobe as they learned the new pictures in the first run. In subsequent runs, however, the posterior medial orbitofrontal cortex, in particular area 13, started to activate, reflecting the need to select, rather than acquire, currently relevant memories. A subsequent study using an even more difficult task showed that this selection process not only activated orbitofrontal area 13, but also subcortical structures involving the head of the caudate nucleus, the substantia nigra, and the medial thalamus. These structures participate in frontal-subcortical loops; some of them are part of the dopaminergic reward system. A study using evoked potentials showed that this selection or filtering process occurs at an early stage of processing, between 200 and 300 ms. Refined analysis suggested that filtering of memories that do not pertain to ongoing reality are possibly conveyed by transient inhibition of synchronization in temporo-parietal association cortex between 200 and 300 ms. In contrast to this early response, the distinction between new and repeated information in the first run, reflecting learning and recognition, was expressed in amplitude modulation at about 400–600 ms. These findings indicated that the filtering of memories according to their relation with ongoing reality (200–300 ms) occurs before the recognition, and presumably the re-encoding, of information, which occurs at 400–600 ms. In other words, before we even know what we think, the brain (orbitofrontal cortex) has already decided whether an upcoming memory relates to ongoing reality or constitutes a fantasy.

Reality and Extinction Capacity

What might be the mechanism behind this filtering capacity? The hypotheses on confabulation described in the last paragraph would probably suggest prefrontal high-level monitoring processes. This appeared unlikely to this author. Indeed, the 'invention' of memory in evolution would appear to be a dangerous step if an organism were not endowed at the same time with a mechanism allowing it to immediately sense whether a memory relates to ongoing reality, and might therefore guide behavior, or

whether it constitutes a mental association having no current behavioral relevance, a fantasy. We, therefore, suspected that the filtering of currently relevant memories depends on a phylogenetically ancient faculty. One striking characteristic of behaviorally spontaneous confabulation is the incorrigibility of inappropriate action plans. Although patients may be constantly at odds with the hospital environment which should normally convince them that they are not at a business meeting or at home, they continue to act according to their false reality. Thus, the patients continue to act on the basis of ideas (anticipations) which may have been valid in the past but which do not refer to current reality. This behavior is reminiscent of the behavior of animals that continue to act upon a previously reward-predicting cue although it has stopped to be followed by reward. In technical terms, we suspected that behaviorally spontaneous confabulation reflects deficient extinction capacity. Primate experiments showed that the only prefrontal area whose damage induces a specific deficit of extinction is orbitofrontal area 13. Single cell recordings showed that this area, which is constantly damaged or disconnected in our patients, contains a particularly high density of neurons that specifically fire in response to the nonoccurrence of expected reward.

In agreement with this interpretation, we recently found that disorientation and behaviorally spontaneous confabulation are very strongly associated with a deficit of extinction capacity, as measured by a simple, explicit anticipation task. A similar task performed by healthy subjects induced strong activation of the orbitofrontal cortex (pole and area 13) and induced specific electrocortical potential variations at 200–300 ms. These findings suggest that, rather than invoking high level monitoring processes, the brain uses an ancient biological faculty – extinction – to keep thinking and behavior in phase with reality.

Conclusion

Confabulation is not a unitary phenomenon. Both functional and anatomical dissociations can be recognized. At the current stage of knowledge, four forms of memory-related confabulations with distinct mechanisms can be distinguished:

Provoked confabulations, manifested as intrusions in memory tests, appear to reflect a normal response to a faulty memory. They are more frequent in brain-damaged subjects but also occur in healthy subjects. They have no specific anatomical basis.

Momentary confabulations evoked by the context of a discussion or by questions are the most common form of confabulation and may relate to autobiographical or semantic memory. No specific mechanism or anatomical basis has been described, although they seem to be more frequent after ventromedial prefrontal lesions, similar to behaviorally spontaneous confabulation. Momentary confabulations are probably a group of different disorders with different mechanisms and different clinical courses, but these subtypes have yet to be determined.

Fantastic confabulations are a rare phenomenon occurring in a delirium (confusional state), advanced dementia or psychosis. Their mechanism or mechanisms have never been specifically explored.

Behaviorally spontaneous confabulation constitutes a confusion of reality as reflected in inappropriate acts according to the confabulation and in disorientation. They seem to emanate from the defect of an orbitofrontal filtering mechanism, which probably relies on extinction capacity, that filters upcoming memories according to their relation with ongoing reality at an early stage of memory evocation, before the precise content is recognized.

Future studies should specify the type of confabulation under investigation and substantiate claims about mechanisms by controlled, empirical data.

Glossary

Aggressive conflict communication Conflict communication consisting of name calling, swearing, put downs, verbal threats, and menacing/controlling/painful physical behaviors.

Communication process Senders and receivers arrive at similar meanings through the exchange of messages (symbols and signs).

Conflict A difference or incompatibility between people, which becomes significant when it has adverse effects on their relationship and/or escalates to verbal abuse and physical violence.

Conflict communication behavior Conflict management; observable interaction that occurs when people are in a conflict situation.

Mediation Action in which a neutral third party intervenes in a dispute to facilitate communication between the conflicting parties.

Personal relationships Friends, colleagues, neighbors, romantic partners, spouses, and family members.

Strategy A cognition; a mental or psychological state; a disposition; a preference for a way of responding to other people during a conflict.

Conflict may be defined as a difference of opinion or incompatibility between people. However, it becomes significant when it has adverse effects on their relationship and/or escalates into aggressive conflict communication.

Conflict communication may be viewed as a process that includes antecedents and consequences. Antecedents occur at an early stage of *potential* conflict communication wherever a difference of opinion or incompatibility exists. Conflict communication becomes an *actuality* when one or more parties are aware of the existence of this difference or incompatibility or believe that the incompatibility exists. Consequences occur at the final stage of development when the conflict *threatens the relationship* because each of the partners perceives that significant, undesired sacrifices must be made to satisfy the other or the conflict communication escalates into verbal abuse and physical violence.

According to researchers, there are at least three ways in which conflicts may escalate and do harm to a relationship. First, the more excited and heated the conflict (in terms of physiological arousal, especially for men), the more likely the partners are to disengage from their relationship during the next few years. Second, some patterns of conflict are more disastrous to the relationship in the long run even if they appear more desirable at the beginning. Third, certain nonverbal behaviors during conflict (e.g., woman's disgust, man's miserable smile, etc.) predict relationship breakups later. The fact that certain communication behaviors and ways of dealing with conflict are associated with relationship dissatisfaction and breakups necessitate a better understanding of conflict communication.

A better understanding of the subject is achieved by placing relevant theory and research within a particular research perspective or tradition. This is no easy task for two reasons. First, when attempting to put together empirical findings on the subject of conflict communication, one discovers that the extensive research on conflict in personal relationships appears disorganized. Numerous empirical studies in several related disciplines, such as psychology, sociology, communication, and family, and published research reports appear to reflect

different orientations to doing research, use different types of measures, and reflect the jargon of their particular disciplines. The first step then is to identify the major perspectives on gathering data and to organize the relevant studies along the lines of these major research approaches.

A second problem is that more than one research perspective or approach appears to dominate the study of conflict in personal relationships. Scholars view the nature of conflict communication differently, depending on their particular research approach. Therefore, this article describes conflict communication and its role within the context of four different research approaches.

The System–Behavior–Interactionist Approach to the Study of Conflict Communication Behavior

According to the system–behavior–interactionist research approach, poorly managed conflicts increase in degree and complexity, and may go beyond differences regarding a specific problem, issue, or argument because of the emotional nature of many close relationships. In its most negative form, conflict is expressed as an emotionally charged communication behavior pattern that typically involves anger and hostility, escalates, and harms the personal relationship.

On the Nature of Conflict Communication

Conflict communication from this perspective may be viewed as verbal and nonverbal interactions between persons expressing opposing interests, concerns, or opinions. Partners' conflict communication is categorized as constructive or destructive according to whether it results in mutually satisfying outcomes, or escalates and harms the partners' emotional ties.

Research Question Asked in This Approach

Researchers who work within the system–behavior–interactionist paradigm have invested considerable time and effort, attempting

to answer the following question: How do partners resolve their differences without doing harm to their personal relationship?

Typical Case for Data Collection

Usually, researchers who adopt this approach to the study of conflict in personal relationships focus on dyadic interaction and typically recruit romantic partners, spouses, family members, or friends, create a conflict situation, audiotape or videotape their interaction, and compare the conflict communication patterns of those who are satisfied with their relationship with the patterns of those who are not. Recording the interactions between partners in conflict appears to be useful for subsequent examination of the interactions and for the identification of constructive and destructive dyadic communication patterns.

Relevant Theories and Key Concepts

Relevant theories view communication and conflict as *stochastic* processes in which the data for research take the form of a series of events that occur in a sequential pattern, preceding events constraining the probabilities of subsequent ones. Partners' conflict communication may be compared to a game in which the move of one partner constrains the alternatives available to the other, thereby reducing uncertainty in predicting subsequent moves or plays. Because of the interdependent nature of behaviors during conflict communication (where antecedent behaviors influence the probabilities of subsequent behaviors), the system-behavior-interactionist approach is particularly useful for examining communication behaviors that are linked to one another in an escalating process.

Sources of Dyadic Conflict

A partner's behavior is said to be problematic when it produces conflict communication. From the system-behavior-interactionist perspective, problematic behaviors are of interest because they fit the assumption that subsequent behaviors (i.e., conflict communication) are dependent on preceding behaviors (sources of conflict). Because one way to deal with conflict is to eliminate the behavior that leads to it, it is necessary to first identify the problematic behavior.

Efforts to identify problematic behaviors in personal relationships have produced lengthy lists. Moreover, the same behaviors are not always perceived as problems by both men and women, and different behaviors appear to be perceived as problems at different stages in the development of a relationship.

While some researchers describe a number of problematic behaviors that lead to conflict communication in personal relationships, others focus more on the escalation of conflict. Once the conflict is under way, behavioral interaction measures are useful for observing and recording the interrelated behaviors that occur during conflict and lead to escalation.

Measuring Instruments for Collecting Data in Dyads

A number of dyadic measures are available for observing the stochastic nature of conflict communication behavior. For example, the Couples' Interaction Scoring System (CISS)

developed by Gottman consists of eight verbal behaviors or content codes (disagreement, agreement, mind reading, communication talk, solution proposal, summarizing other, summarizing self, feeling, or problem information) and three nonverbal behaviors or affect codes (positive, negative, or neutral). Interestingly, with the exception of agreement, verbal behaviors (content codes) did not discriminate between dissatisfied and satisfied couples, although nonverbal behaviors (affect codes) did generally discriminate between the two types of couples.

By listing specific, concrete verbal, nonverbal, affect, dominance, and avoidance behaviors, measuring instruments like these provide a clear idea of what system-behavior-interactionists mean by conflict communication behavior and enable them to objectively observe the escalation of conflict in personal relationships.

Research Findings

Negative conflict communication is characterized by negative affect, coercive/controlling, escalating, rigid messages, and conflict avoidance.

Negative affect

When engaged in conflict, dissatisfied partners rely more on a type of communication called negative affect (or punishing, aversive) messages. The measuring instruments described earlier have revealed the following negative characteristics of conflict communication:

- Dissatisfied partners display higher rates of aversive behaviors, express more criticism/blame/accusations, are less responsive, and display fewer problem-solving behaviors and reinforcers than satisfied partners.
- Dissatisfied partners are more likely than satisfied partners to use cross-complaints and counter-complaints, and less likely to engage in validation sequences.
- Compared to satisfied partners, dissatisfied partners are more likely to begin a conflict by directly attacking each other with criticism and negatively loaded statements, followed by attempts by each to justify himself/herself and blame the other.

Coercive/controlling behaviors

Researchers have revealed that coercive and controlling behavior during conflict interaction (as well as at other times) is associated with dissatisfying marital relationships. However, there appear to be sex differences in the use of controlling messages. In conflict interactions that were behaviorally coded, men assumed a more coercive stance, while women took an affiliative or accommodating position.

Escalation: negative reciprocity

Once hostility is expressed by either partner, it is likely to escalate in frequency over the course of the interaction. In both dissatisfied and satisfied partners, negative communication behavior is more likely to be reciprocated than positive. Of course, dissatisfied partners demonstrate stronger negative reciprocity than happy ones.

Early research findings indicate that reciprocity of negative affect is symmetrical. However, researchers detail different types of negative affect messages and reveal that most of the husband's negative affect consists of anger and contempt, while only a little of the wife's negative affect is anger and contempt. Most of her negative affect is whining, sadness, and fear. While a husband may reciprocate his wife's anger, she does not reciprocate his. Instead, the wife responds with fear to her husband's anger, suggesting that their relationship is not symmetrical or fairly balanced.

According to Gottman, dissatisfied partners begin a conflict verbally with complaints and criticism follow nonverbally with hostile behavior and end without agreement on a solution.

Rigidity

Research shows that interactions between dissatisfied partners show a higher degree of structure and more predictability of one spouse's behaviors from those of the other than is found in the interactions between satisfied partners.

Conflict avoidance

One way of managing a conflict is the use of indirect methods such as teasing and humor for expressing unacceptable emotions on threatening or embarrassing topics. Because these methods serve to remind partners of their bonding, they can promote solidarity, reestablish intimacy, and excuse a slight. Not all jokes are equal, however. Benign humor consists of jokes about the self, about the relationship, or about the partner in a gentle manner. Hostile humor includes jokes about the partner in a negative way, particularly with sarcasm. Researchers report that more satisfied couples use humor not to resolve sources of conflict, but to bring a verbal disagreement to an end on a playful note.

Other avoidance behaviors include denial of conflict, change of topic, contradictory statements about the presence of conflict, statements that direct the focus of conversation away from the conflict issues, and abstract, noncommittal, and indirect statements. Researchers have observed a strong reciprocity tendency in partners' interaction in that avoidance behaviors were typically followed by other avoidance behaviors. They have also found that less satisfied couples engaged in fewer avoidance behaviors than more satisfied partners. At least one researcher reports that conflict avoidance in marriage is a complex topic in that different types of married couples use conflict avoidance to different degrees and in different ways, ranging from hostile to friendly.

There may be a difference in the way men and women engage in conflict avoidance behavior. According to Gottman, men show a larger autonomic nervous system (ANS) response to stress, respond more readily, and recover more slowly than do women. If extreme ANS response is viewed as harmful, unpleasant, and undesirable, then men might be more inclined than women to avoid situations that would be associated with repeated ANS activation. Thus, men may become more conciliatory and are likely to avoid conflict or terminate it by withdrawing.

Other researchers have observed that both husbands and wives are more likely to be demanding when arguing over a change one wants in the other, and as likely to be withdrawing

when arguing over a change their partner wants them to make. Although neither sex indicated that it would be more demanding than the other sex, data revealed that, overall, men withdraw more than women.

Conflict Training: Helping Couples Resolve Issues and Improve Their Intimate Relationships

Some behaviors lead to more positive outcomes than others, that is, some behaviors de-escalate emotional outbursts. For example, discussion that focuses on resolving a problem is less emotionally upsetting than name calling and partner blaming.

How can one learn or be taught de-escalation behavior in a conflict? Behavior modification may be used to reinforce positive behaviors but not negative behaviors. In addition to behavioral modification, training in conflict communication skills is directed toward enhancing emotional ties within the personal relationship. By observing their own concrete verbal and nonverbal behaviors on videotape, partners learn how they convey interest or disinterest, and warmth or coldness, as well as attraction or repulsion.

The system-behavior-interactionist approach accounts for many empirical research studies of conflict in personal relationships. In addition to its productiveness as a research paradigm, it has also generated many useful techniques for helping partners improve their personal relationship by encouraging positive, constructive, and integrative conflict communication.

The Rules-Interventionist Approach to Mediated Conflict Communication Rules

The notion of mediation as conflict communication may at first appear novel. Although opportunities for interaction seem limited by the presence of an outsider (a mediator), disputing partners may exchange information, influence one another, and develop mutual agreements. However, mediation may not be appropriate for every dispute. Where effective, mediation facilitates communication between partners, is future oriented, and often includes renegotiation of the personal relationship. Thus, mediation is a unique form of conflict communication in which partners may participate in a more formal conflict resolution process than they normally encounter in their everyday lives.

On the Nature of Conflict Communication

A dispute is defined as conflict communication when people are unable to resolve the issue by themselves, and normal relations are unlikely until the dispute is resolved. The rules-interventionist approach views conflict communication as mediation in which a neutral third party creates and enforces certain rules that enable partners to resolve their dispute. Mediators strive for the development of reasonable outcomes for all concerned. Mediation is normally seen as an alternative to adjudication, in which a judge imposes a decision upon the disputing parties.

Research Question Asked by Rules–Interventionists

The rules–interventionist approach to the study of mediated conflict has generated studies designed to answer the question: What role does a third party play in helping partners learn how to resolve issues? This research approach is useful for incorporating the actions of an impartial third party or mediator along with those of the conflicting partners to determine the effects of the role of the mediator and the partners on the outcome of the mediation process.

Typical Case for Data Collection

Understanding helps personal relationships and interaction over time. For one or both partners, however, understanding may no longer hold, resulting in a breakdown in communication between them. Researchers who take a rules–interventionist approach to the study of conflict communication call attention to the role of a third party in helping partners communicate, resolve disputes, and restore or redefine their relationship as the typical case involving partners in personal relationships. For example, mediators may help divorcing spouses legally dissolve the marriage, restructure the family, and create new relationships in which former spouses can cooperate with each other (on matters such as custody and visitation) long after the divorce.

Relevant Theories and Key Concepts

Because mediated conflict presents a context or type of relationship entirely different from that of dyadic conflict communication as discussed earlier, the study of mediation appears to need a different research approach. The rules–interventionist approach is particularly useful because it is designed for three interacting roles – two partners and a mediator – and the effect on the outcome of each person's role.

Unlike the system–behavior–interactionist approach, in which stochastic probability governs the outcome of interaction, in the rules–interventionist approach, the mediator intervenes to place interaction under the control of *rules* designed to limit emotional conflict, reduce uncertainty and surprises, and encourage open communication, cooperative problem solving, and equitable treatment.

Successful mediators begin mediation by announcing communication rules. These rules go beyond explanation of the process and legality of mediation, and place limits on the agenda and the tone of the discussion. Ruled out are common negative verbal tactics such as name calling, verbal abuse, and introduction of irrelevant issues and nonverbal tactics such as screaming, threatening gestures, standing up, or refusing to look at each other.

Mediation theorists view personal relationships as complex, private systems and as delicate entities that must be respected. They assume that partners are in the best position to decide mutually acceptable outcomes with minimal intervention by others. However, while partners determine issues and make decisions for themselves, the mediator enforces the communication rules.

Sources of Mediated Conflict

There is a difference between the sources of conflict that give rise to particular behavioral dyadic interaction patterns and those that give rise to mediation. Compared to private conflicts

that tend to occur in the privacy of the home or involve only the partners themselves, mediated conflict is seen more as a social or public event because of the presence of the third party as mediator. In the case of divorce mediation, the sources of conflict may be reduced to five types.

- *Control over resources*: money, property, space, children, and so forth that may be viewed as not sharable.
- *Preferences and nuisances*: activities of one person impinging on another's sensibilities, preferences, or sensitivities.
- *Values*: concerning what should be, for example, religious and ideological issues.
- *Beliefs*: concerning what is, for example, fact and reality.
- *The nature of the relationship*: repair and redefinition of personal relationships.

Mediation may be rated and evaluated by using triadic interaction measures to observe and record conflict communication. One such measure was created by Donohue.

Measuring Instruments for Collecting Data in Triads

Donohue and his colleagues developed a measure for coding partners' and mediators' verbal acts. They distinguished between two types of verbal acts: cues to subsequent utterances and responses to prior utterances. In addition, the partners' verbal acts were identified according to the following categories:

- *Attacking*: personal accusations; negative evaluations.
- *Defending*: presenting proposals, providing information, requesting information or clarification, or providing a rationale for one's position.
- *Integrating*: any utterance that agreed with the prior utterance, demonstrated support for a proposal or position.

Finally, Donohue and his colleagues added the following categories to code the mediator's interventions.

- *Structuring*: identifying and enforcing interaction rules.
- *Reframing*: helping to restructure disputants' own proposals; pointing out areas of agreement.
- *Expanding/requesting*: requesting proposals; requesting clarification of proposals; requesting reaction to proposals.

By applying both the coding schemes of Donohue to recorded mediation, one might better understand the role of the mediator and how her or his actions help to settle disputes.

Research Findings

Researchers have applied different interventionist measures to essentially overlapping data derived from 80 audiotapes of divorce mediation. Using these tapes for coding triadic interaction, researchers found that successful mediators were more likely than unsuccessful mediators to use more intense structuring and reframing interventions in response to attacks. The more successful mediators were also more likely to rephrase negative comments and turn them into more positive ones. Researchers have shown that successful mediators were more in control of the mediation, used more interventions to involve the divorcing partners in finding the information necessary for agreement, and distributed more of these interventions fairly and consistently between the disputants.

Other researchers report that the most important difference between cases that were settled successfully and those that were not was the amount of time disputants expected mediators to spend discussing the final settlement. In the successful cases, mediators not only felt obligated to spend more time discussing the terms of the final agreement, but were also expected to spend more time discussing possible solutions in general. They were not expected to spend much time explaining the mediation process to the spouses, requesting disclosure of feelings, and making statements about the parties' attitudes.

In all, researchers discovered that the following patterns of actions implied that rules were operating:

- Speaker time was fairly evenly distributed among the two spouses and the mediator.
- Mediators tended to address both spouses, whereas husbands and wives usually directed their remarks to the mediator.
- Mediators tended to ask more questions than did either of the parties.
- Mediators expressed statements on procedural issues three times more than did the parties.
- Mediators conveyed more information on what mediation is and made more statements regarding the process itself than did the parties.
- Mediators made the most statements summarizing the spouses' comments. Spouses made more emotionally toned statements than did the mediator.
- One-third of the statements made by both spouses were self-disclosures. A number of statements were about the attitudes, motives, and actions of others, usually the other spouse.
- Perhaps in an effort to establish rapport and encourage the spouses to share their feelings, mediators made statements that showed more empathy than did those uttered by the spouses.
- Mediators attempted to balance proposals by specifying how both parties could be involved, while each spouse tended to specify what he or she could do.
- Very few statements were classified as interruptions (where the thought was not resumed).

Divorce mediation sessions that ended in agreement appeared to progress from differentiation to integration through three phases: information exchange, problem solving, and finally resolution actions.

Structured Mediation: Helping Partners Settle Disputes

To help both parties emphasize cooperation and gain something from mediation, third-party interventionists need a thorough understanding of mediator goals and tactics that include structuring the process of mediation, reframing the disputants' positions, and expanding the information resource.

The Cognitive Approach to the Study of Conflict Communication Strategies

When thinking about the topic of conflict communication in personal relationships, one probably envisions partners engaged in a verbal disagreement. Cognitive researchers view conflict communication in an entirely different perspective – as

mental (cognitive) strategies that range from preferences for direct confrontation to the desire to avoid conflict. As these strategies are mental or psychological in nature, the process of conflict communication is not observable. From the cognitive perspective, to view conflict communication as a process means that one must ask partners to give their own retrospective reports on the selection of conflict communication strategies.

On the Nature of Conflict Communication

The cognitive approach views conflict communication as strategies that are internal responses to perceived sources of conflict. Because some conflict communication strategies involve intention to avoid open confrontation, conflict communication may exist even when partners are not overtly disagreeing.

Research Questions Asked in This Approach

Questions of interest asked by cognitive researchers include the following: What antecedent conditions influence one's choice of a conflict communication strategy? What alternative strategies are best for dealing with different sources of conflict? What beliefs underlie one's predisposition to engage in aggressive conflict communication? This research approach is useful for examining the role played by predispositions in the form of conflict communication strategies in a broad, general model of relationship development and the effects of these strategies on the outcome of the conflict.

Typical Case for Data Collection

Cognitive research focuses on developing relationships (including romantic partners, friends, coworkers, and roommates and also offspring) as the typical case for data collection.

Relevant Theories and Concepts

Some researchers take the position that a great deal of conflict can be explained in terms of attribution processes and efficacy expectations. Attribution refers to the process of assigning reasons or motivations for particular behaviors, while an efficacy expectation refers to the belief that a problem can be solved by confronting it. These researchers argue that attributions of blame or intent give rise to hostile behavior, such as retaliation. However, they go on to argue that regardless of one's attributions of cause, responsibility, and blame, given low efficacy expectations, a partner is unlikely to want to resolve the conflict and will prefer to avoid it or withdraw from it. Given high efficacy expectations, however, the person is likely to undertake such efforts and confront the problem. In such cases, resolution attempts are directed toward that which is perceived as most easily changed and likely to produce satisfactory results.

Sources of Conflict in Developing Relationships

Perceived imbalance in the resources of exchange, perceived inequity, and perceived unequal distribution of power in a relationship likely lead to feelings of relationship

dissatisfaction which itself may be a source of conflict. While studying relationship dissatisfaction in general as a source of conflict, researchers use self-report techniques to assess the degree of dissatisfaction in the relationship. In this approach, cognitive variables like relationship dissatisfaction are believed to be capable of producing other effects. Thus, self-reported relationship dissatisfaction may be seen as a cognition that influences the preference for particular confrontation and conflict avoidance strategies.

Measuring Instruments for Collecting Data in Developing Relationships

One of the most well-known lines of research on alternative strategies for managing conflict in intimate relationships actually grew out of business administration/management research. Rahim proposed a typology for the management of organizational conflict, consisting of the following five strategies: dominating (forcing, competing), integrating (confronting, collaborating), obliging (smoothing, accommodating), avoiding, and compromising (give and take) styles that reflected either a high or low degree of concern for oneself and concern for the other (e.g., partner).

Other researchers view aggressive conflict communication as a self-reported potential for verbal abuse. A few researchers have determined the propensity toward aggressive conflict communication on the basis of scores achieved on the Dysfunctional Beliefs Assessment and on the Child Abuse Inventory. Scores on these measures operationally defined potential verbally abusive parents.

Research Findings

There appear to be important *male-female differences* that affect partners' perceptions of rewards and costs and their role in conflict. Men appear to differ from women in the way they perceive conflict that in turn affects their relationship satisfaction. At least one researcher has asked dating partners to keep daily observation records of conflicts over a 2-week period. Such research reveals that the perception of many unresolved conflicts is most salient to women's perceived relationship satisfaction, whereas the perception of a large number and the stability of conflicts (i.e., the same issues coming up again and again) are most salient to men's relationship satisfaction.

Other male-female differences in perceptual processes have been found to have an impact on conflict in intimate relationships by distorting the intent of the message sent. For instance, the behavior of dissatisfied spouses compared to that of satisfied spouses is perceived more negatively by partners than intended. This confirms an earlier finding that dissatisfied husbands are more inclined to attribute 'negative connotations' to their wives' attempts to communicate affection, happiness, and playfulness than satisfied husbands.

There is evidence that partners may tend to prefer the strategy of avoidance – a tendency for partners in personal relationships like marriage to avoid dealing with conflicts. Yet, a number of research findings support open confrontation as a constructive conflict communication strategy. For example, at least one study reports that black couples and white couples who believe in avoiding conflicts reported lower marital

happiness in the first year of marriage and again 2 years later than those couples who believe in confronting conflicts.

A number of factors that contribute to preferences for open confrontation or conflict avoidance strategies have been observed. People are more likely to prefer to confront when they are committed, equal in power, prepared for confrontation, and the issue is important. Men are more likely than women to blame their mates for problems, avoid emotional involvement, and prefer coercive conflict communication as their way of dealing with conflict. Some personality types are more prone to open confrontation and others to avoidance. Culture and immediate social context are also influencing factors. For example, there is a tendency among male and female managers to prefer more competitive strategies of conflict resolution when dealing with workers and more accommodating strategies with their partners at home.

More recently, researchers found patterns of attributions about a child's behavior that result in dysfunctional child-rearing beliefs, automatically producing in mothers verbally abusive responses to their child's (mis)behavior. Later, researchers related mothers' child abuse potential with the mother and child's play behavior and found that children of high-risk mothers (for aggressive conflict communication behavior) displayed higher levels of involvement combined with lower levels of cooperation compared to children of lower-risk mothers.

Educating Partners on How to Manage Conflicts

Some of the sources of conflict result from faulty perceptions or inferences. Training in cognitive restructuring helps partners deal with the sources of conflicts and improve their relationship. Essentially, cognitive restructuring is a means of increasing relationship satisfaction by relabeling faulty cognition, that is, misperception and unwarranted inference. Of particular interest are perceptions of undesirable behavior and inferences made from them. Cognitive restructuring includes helping partners see the connection between their behavior and a partner's feelings, identifying myths and accepting reality, emphasizing the positive aspects of their relationship, and training in empathy.

The Qualitative Research Approach to the Study of Conflict Communication Perceptual and Evaluative Processes

The qualitative approach can help researchers better understand the sense-making processes parties use to legitimize their conflict communication behavior. To do this, the qualitative research approach relies more on interpretive means of collecting data. By using methods such as participant observation and unstructured interviews, the qualitative approach applies interpretative techniques to narratives (personal stories) and open-ended interviews of people who are in conflict situations. In their search for multiple interpretations, qualitative researchers are known to consider 'alternative voices,' especially the victims of domestic abuse. To increase real-world relevance, qualitative researchers seek to make the research experience a part of the subjects' natural habitat, such as the home environment. It is argued that the understanding

of conflicting parties can assist practitioners, social workers, family, and psychotherapists working with conflicting parties, especially in violence-prone premarital, marital, and parent-child relationships.

On the Nature of Conflict Communication

Conflict communication from this perspective is redefined as each party's subjective perception or assessment of the quality (or the impression) of their own and the other's conflict communication behavior. Implications of this approach are (1) What might seem appropriate verbal and nonverbal behavior to one person may not seem so to the other, and (2) What might be appropriate verbal and nonverbal behavior in one situation may not be appropriate in another.

Research Question Asked in This Approach

Researchers who work within the qualitative research paradigm attempt to answer the following question: How do conflicting parties perceive their own and the other's communication behavior in a conflict situation? This includes the attempt to understand how they legitimize their own behavior as well as how they evaluate their own and the other's conflict communication behavior.

Typical Case for Data Collection

Researchers who adopt this approach can either observe as participants in the conflict situation or interview one or both parties in conflict. In cases of potentially aggressive conflict communication, parties may be interviewed separately; in less threatening situations, however, the parties may be interviewed together. In some studies, people may watch videotapes of their conflicts and provide insight into why they did what they did, how they felt, and what they were hoping to accomplish. The parties involved may be in a premarital, marital, or parent-child (including elderly parent-adult and parent-adolescent) relationship. Recording the interactions of partners in conflict appears to be useful for interpretation later.

Relevant Theories and Key Concepts

According to this approach, conflict communication is the product of people sharing and creating meaning in a conflict situation. *Social construction theory* attempts to gain access to the phenomenology of people's lives. The ways in which people think and use categories to structure their experience and analyze the world are constituted in their communication. Because people learn from the society and times in which they live, conflict communication behavior is said to be socially prescribed.

Ethnography provides descriptions of behavior in cultural groups: behavior that conforms to rules, roles, rites, and rituals. This type of study might take the form of a field study or a case report. As participant observers, ethnographers usually spend time in another society or cultural subgroup, living with the local people and learning about their way of life to better understand their social behavior and thinking processes. They may also apply their methods to families, groups, or couples. Ethnographers focus on relationships and social structure, verbal and

nonverbal language codes, practices, rites, and rituals. Ethnography is useful in identifying rules that govern conflict communication in specific communities, groups, or couples.

Grounded theory is inductive in nature, suggesting that theory emerges from the data. While quantitative research takes a deductive approach (one begins with a theory and then tests or examines it by collecting data), grounded theorists begin by collecting data (observe video taped conflicts). Next they identify a series of codes from the text. Using what they call the constant comparison method, they group these codes into similar categories that may serve as a basis for the creation of a theory.

Story telling and narratives have developed into a theory and study of narrative and narrative structure, and the ways they affect people's perception of events. By collecting individual stories from particular couples/families and other groups, organizations, and cultures; by listening to and comparing different accounts; by examining how narratives are constructed around specific events; by learning which events in a culture, subculture, or group's history generate stories and which ones do not, quantitative researchers gain a deeper understanding of the subjects' realities, which are closely linked to their social experiences. By doing so, they discover the group's political, social, and cultural dynamics.

Sources of Dyadic Conflict

Dialectical tensions are said to lie at the heart of conflict between partners in a personal relationship. The relationship is supported or threatened by the way people manage the dialectical tensions of autonomy versus connection (cohesion) and stability versus change (adaptability) in their everyday lives. People who experience difficulty managing their conflicts are viewed as less balanced in their management of the dialectical tensions than other people, who have more resources, such as communication skills. Those less skilled are also more likely to repeat old patterns rather than learn new ones.

Measuring Instruments for Collecting Data in Dyads

Purely qualitative researchers do not use measures beyond nominal categories, such as those classifications used in content analysis. For example, they may interview couples (living together) and victims in shelters for battered women. In this case, the narratives of people in dysfunctional relationships may be compared with those in more 'normal' relationships. However, other qualitative researchers use measurement at the ordinal, ratio, and interval levels when they incorporate various existing measures of relationship satisfaction, commitment, or trust to identify target groups, whose members they are interested in interviewing. While they may or may not use higher level measurement tools for the independent variables, both groups of qualitative researchers are not inclined to use measures and statistical methods for analyzing the dependent variables.

Research Findings

A researcher reported that an aggressive communication encounter is a process of 'escalating antagonism' between person A and person B: A's action upsets B; B orders A to cease the action; A fails to comply; B and A verbally abuse each other,

making way for physical violence. An implication of this observation is that the conflict communication may increase in intensity until aggressive conflict communication and even physical violence appear justified to at least one of the parties.

In a study of ten couples with a history of abuse and ten couples without, cohesive and adaptability dialectical tensions consisted more specifically of vague versus precise language, opposition versus collaboration, relational versus content talk, despair versus optimism, interfering versus facilitating interdependence, complaints versus compliments, and effective versus ineffective change. The greater the tension on these seven dimensions, the less cohesive and less able they were to adapt to the other.

Other researchers interviewed 15 abusive male spouses to better understand how they perceive themselves and their spouses, and to account for their abusive behavior. The men provided accounts for their abuse in the form of justifications, excuses, denials, or efforts to minimize the significance of their acts, and blamed their wives for their abusive behavior. Meanwhile, another researcher revealed that abused women also provide accounts of their mates' behavior, but they dissociate the 'real him' from his abusive acts – that is, he was not being himself. In both cases, accounts provided by the partners revealed that abusers and their victims perceive the abusive acts differently but in ways that attempted to excuse the abuser.

By interviewing 31 people, another researcher attempted to better understand the sense-making process couples use to legitimize use of aggression. She found that many of the participants assessed their use of verbal and physical aggression according to social customs, finding it inappropriate and ineffective generally. However, many noted their aggression was appropriate and effective, given the circumstances of their relationship. These findings suggest a unique relational culture where verbal and physical aggression are perceived as appropriate, even though such acts deviated from the social norm.

Researchers report that interpersonal violence is more likely when there is verbally aggressive conflict communication. One study found that the first episode of adolescent-to-parent abuse experienced by parents consisted of verbally aggressive conflict communication. Later, these adolescents progressed to more severe types of emotional or physical abuse.

Family researchers found that mothers' patterns of attributions about their child's behavior resulted in dysfunctional child-rearing beliefs and aggressive conflict communication. This cognitive approach has identified factors such as beliefs and attributions, recognized abusers' violence-prone predispositions, and described the mental beliefs and attributions needed to enable one to avoid aggressive communication behavior in conflict situations.

Educating Partners to Better Manage Conflicts

Findings from qualitative research help to resolve existing social problems. They may or may not contribute to the development of theory. Qualitative research lends some support to the effectiveness of treatment programs for those who abuse others with aggressive conflict communication. Results from

these studies provide some evidence that a change in how an abuser perceives his or her responsibility and thinks about the other may persist into the future, if reinforced by his or her relationships.

Although the perspective view conflict in personal relationships, each perspective has its own definition of conflict, theories, and research methods:

- **system-behavior-interactionists** define conflict as a stochastic process relying on behavioral interaction theory using dyadic behavioral research methods;
- **rules-interventionists** define conflict as rule-governed activity relying on rules theory using recorded triadic interaction research methods;
- **cognitive theorists** define conflict as a predisposition to behave relying on social exchange, network, and perception theories using subjective self-report research methods;
- **qualitative researchers** define conflict as a subjective perception/assessment of the quality of one's own and other's conflict communication behavior relying on social construction theory, ethnography, and grounded theory using subjective interviews and narratives as data.

Although researchers tend to adopt one of these views of conflict, they should realize that each perspective adds to a better understanding of the antecedents and consequences of conflict communication behavior.

Conformity and Obedience

Glossary

Conformity Typically defined as occurring when perceived or actual social pressure from others causes a person to alter their opinions, feelings, or behavior. These changes may be public, private, or both.

Descriptive norms Modal patterns in how people (usually in specific groups or contexts) actually think, feel, and behave.

Dissent Nonconformity expressed or exhibited with the intention of changing a norm.

Informational influence A psychological mechanism underlying conformity in which people rely on others for information about the world. Is motivated by a desire for accuracy and efficacy.

Injunctive norms Widely held conceptions regarding how people (again, usually within specific groups or contexts) should think, feel, and behave.

Normative conflict A state of disagreement with group norms, descriptive or injunctive.

Normative influence A psychological mechanism underlying conformity that results from a desire to meet the expectations of others. Is motivated primarily by the need for approval.

Obedience Occurs when a person acquiesces to the request or instruction of someone in authority, changing their opinions, feelings, or behavior.

Social identification A psychological mechanism underlying conformity that involves adopting a normative group prototype as a guide for thought, feeling and action. Is motivated by a desire to express a collective identity, and by solidarity and certainty goals. Under certain circumstances, social identification can also motivate dissent.

Investigations of conformity and obedience are foundational to social psychology. Indeed, early studies examining these phenomena conducted by Solomon Asch (conformity) and Stanley Milgram (obedience) rank among the most famous psychology experiments ever conducted. Both sets of studies are still taught to thousands of college students each year, and policy makers and media commentators routinely draw ostensible lessons from each. This article reviews the literature on conformity and obedience, with particular attention to their underlying psychological mechanisms. Whereas a great deal of research attention has been paid to conformity and there is vast post-Asch empirical literature, the same is not the case for obedience. For a variety of reasons (including the impossibility of ethically replicating his work, at least exactly), our understanding of obedience has not advanced a great deal since Milgram's day.

Conformity

Nineteenth century social scientists were highly attuned to the influence that social pressures could exert on opinions, beliefs, and actions. In his book, *Extraordinary Popular Delusions, and the Madness of Crowds*, journalist Charles Mackay described a series of movements in which popular opinion widely, if sometimes only briefly, swayed in strange and foolish directions. In a variety of crazes, people showed sudden and mass passions for, among other things, investing in tulips, for alchemy, and for peculiar shapes of beard. Beliefs regarding sensible economic decisions, natural and supernatural phenomena, and masculine ideals appeared to be highly flexible and contagious, spreading in waves among a malleable populace. Thus, writing in 1903, Tarde stated that 'society is imitation' and 'social man is a veritable somnambulist.'

The advent of modern psychology in the twentieth century saw the application of scientific methodology to the investigation of the psychological processes that underlie conformity. Muzar Sherif conducted a series of studies in the 1930s that took advantage of a visual phenomenon known as the autokinetic effect. When people are seated in a darkened room and a stationary point of light is directed at the opposite wall, the light appears to move about in arbitrary directions. Employing this ambiguous stimulus, Sherif asked participants to estimate how far the light had moved and found that their distance estimates were influenced by the estimates of others. Experimental stooges giving prespecified answers were able to shift participants' estimates by several inches. There were limits, however, to how far estimates could be pushed around, suggesting that social influence was subject to reality constraints, and that participants' responses reflected a combination of both their own impressions and the ostensible observations of others. Subsequent research showed that the responses of experimental confederates established a type of cultural norm that persisted after all original group members had gradually been replaced by new participants. However, because participants in each generation combined their own impressions with the impressions of others, over successive generations the influence of the norm was steadily attenuated. Still, the experimentally manipulated norm did exert significant power over responses, and this research gave credence to notions of human relations as inherently conformist.

The history of psychological research on conformity can itself be described in terms of normative trends, punctuated by occasional reactions against them. Solomon Asch led the first such reaction. Asch recognized that groups and societies could not expect to function healthily if driven only by conformist processes, and that nonconformity was essential to

creativity, innovation, and social change. Nonconformity by this formulation is a group-oriented and cooperative act, and given its utility, is a behavior that ought to occur with some frequency in human interaction. Asch noted that the autokinetic and related investigations of conformity employed ambiguous stimuli, which put individuals in the awkward position of having no firm ground to stand on when disagreeing with the responses of others. In a classic series of studies, Asch gave participants a less ambiguous task to perform, which he posited would reveal significantly higher rates of disagreement. Naïve participants were placed in a group with a number of confederates and were asked to make a series of visual judgments, matching the length of a line to one of three possibilities. These judgments were exceedingly simple, such that control participants not privy to the responses of others responded with over 99% accuracy. Experimental participants, however, were exposed to others' decisions that were manipulated to be uniformly incorrect on critical trials prior to making their own response. In the face of unanimity from the rest of the group, participants made significantly more errors, indicating a degree of conformity to an incorrect social norm. Critically, however, rates of conformity on critical trials in these and subsequent studies hovered around 30–40% and, consistent with Asch's contention, the modal response was clearly nonconformity.

Given Asch's intentions, it is an historical irony that his work is now most often used to make the opposite point and invoked as an illustration of the extraordinary power of social influence on decision making. Whereas what Asch and his immediate contemporaries found most compelling was strong evidence for disagreement in the face of social pressure, the majority of contemporary references to these experiments focus on conformity as the important finding. As such, the bulk of subsequent research has focused on (a) identifying domains in which conformity accounts for important patterns of behavior and (b) understanding the psychological mechanisms underlying conformity. Both enterprises have been highly successful. In the former case, conformity has been identified as an influential force in almost every conceivable realm of human behavior, including eating, consumer choice, sexual behavior, prejudice, humor and fashion. A variety of contributing mechanisms, which will be reviewed below, have also been identified. In contrast, less attention has been paid to processes underlying nonconformity (although we do know quite a lot about its effects).

Mechanisms Underlying Conformity

Normative Influence

Several classes of mechanism have been proposed to account for conformity to social norms. Normative influence refers to conformity that results from a desire to meet the expectations of others. The motivation underlying conformity in this case is a need for approval. There is a substantial evidence for normative influence processes, such that conformity increases in situations where others are likely to notice and disapprove of deviant behavior, and decreases in the absence of these factors. When participants are able give anonymous responses in the Asch paradigm, for instance, rates of conformity show a

significant decline, although conformity does not disappear entirely. Similarly, individuals are more likely to conform to collective norms when they value the group in which they are situated or when they believe that the group values them. The influence of Asch's work is nowhere more apparent than in the fact that his conformity paradigm has been replicated in countries and cultures around the globe. A meta-analysis of these studies examined national rates of conformity as a function of each country's level of individualism/collectivism. Whereas in individualist cultures, it is considered socially desirable for decisions to be driven by personal opinions and goals, in collectivist cultures it is socially preferable to place collective opinions and goals ahead of one's own. Consistent with normative influence, participants in countries with higher levels of collectivism were found to display greater conformity than participants in individualist nations.

Punishment of Deviance

The type of norms that underlie normative influence have been termed injunctive norms, which refer to widely held conceptions of how people should think, feel, and behave. These are collectively held standards regarding what is appropriate and inappropriate. Normative influence derives part of its force from the fact that people have a striking willingness to enforce these sorts of norms. There is a great deal of evidence, both anecdotal and experimental, that groups react negatively to deviants, punishing norm violations by imposing social costs (e.g., ridicule, rejection), as well as physical and economic hardships. Real-world examples of punishment for deviance abound, particularly in religious and political contexts. In these domains, dissension from official doctrine earns the dissenter a variety of pejorative labels, including heretic and traitor. These are dangerous names to bear, and those who incur them have a distressing tendency to come to sticky ends: condemned in show trials, burned at the stake, assassinated, etc.

Early psychological research found that individuals who expressed divergent opinions in small groups were liked less and received greater attention (e.g., were the targets of more persuasive attempts) than individuals whose opinions matched the group norm, and this was particularly the case in cohesive and valued groups. Generally speaking, the more strongly identified members are with a group, the more likely they are to punish deviance. The propensity to impose heavy costs on deviance in political and religious contexts may reflect the fact that these tend to be particularly cohesive and valued groups. However, it is also likely due to the fact that these sorts of groups are, at least in part, defined by the possession of common beliefs. In groups that are defined by sharing a particular set of beliefs (e.g., regarding the role of the state, abortion or the meaning of the sacraments), anyone who challenges a core belief poses a threat not only to that particular norm, but also to the meaning and viability of the group as a whole.

A related phenomenon known as the black sheep effect illustrates the group-based nature of punishment for deviance. This line of research finds that identical negative acts are regarded more negatively and result in greater rejection when they are committed by an ingroup member as opposed to an outgroup member. As such, it is not the behavior per se that

people are responding to, but rather behavior by members of their own group. There are two potential reasons for this. First, although certain types of injunctive norm (expectations for appropriate behavior) may be applied to everyone regardless of group membership, other norms are regarded as group specific, and punishment is confined to those to whom the norm is perceived to apply. Second, the bad behavior of ingroup members reflects poorly on the group, and other members are motivated to punish and prevent these sorts of acts in order to maintain a positive group image and reputation. As in the research described above, strongly identified group members exhibit the black sheep effect more strongly.

The mechanisms by which cooperation among members of a species evolves has been a persistent puzzle in evolutionary psychology. Although cooperation often bestows collective benefits (e.g., we all benefit if everyone pays their taxes and we can afford safe roads and fire departments), it is, all else being equal, in any individual's interest to avoid cooperating (i.e., to defect). If I do not pay my taxes but everyone else does, I keep a higher proportion of my income and also benefit from safe roads and fire service. Critically, however, if it is in everyone's individual interest to avoid cooperation in this fashion, rates of cooperation will rapidly decay. Anyone who does cooperate will be exploited by others and will suffer reduced fitness; thus, orientations toward selfish behavior are more likely to be selected for than orientations toward cooperation. Recent research has shown, however, that cooperation can be sustained by sanctions for noncooperation, and particularly by third-party punishment in which people who are personally unaffected by noncooperation nevertheless punish defectors. If others reliably punish individuals who attempt to cheat the system, it can change the cost-benefit ratio (and fitness levels) in favor of cooperation. Individuals appear to be willing to punish noncooperators even at some cost to themselves and when there are no costs to not punishing. This behavior has been observed across a wide variety of societies and cultures, although rates of punishment vary quite substantially. It appears that a propensity to punish noncooperation may be partially a genetic predisposition that is itself shaped by local norms and can thus serve as at least a partial solution to the cooperation problem. All things considered, punishment of those perceived to act against the collective interest seems to be a deeply ingrained reaction.

There are, however, boundary conditions to the punishment of deviance. Recognizing that some degree of divergence and dissent is often functional for groups (as will be discussed in further detail below), researchers have recently suggested that groups may not be as allergic to deviance as is often assumed. The intergroup sensitivity model focuses specifically on group criticism and suggests that criticism of an ingroup is likely to be well received and even persuasive to the extent that it is perceived to be constructive. Critically, whether or not criticism is perceived to be constructive is dependent on the person who expresses it; in particular, their standing in the group. Members who are believed to have the interests of the group at heart because, for instance, they have been part of the group for a long time, are given the benefit of the doubt and are responded to positively when they express concern regarding the group and its norms. Similarly, high-status group members have greater latitude in the extent to which they can deviate from group

norms before incurring disapproval and sanction. In contrast, relatively recent or low status group members, as well as the members of outgroups, elicit negative reactions when they direct criticism toward a group.

Informational Influence

Another mechanism underlying conformity is known as informational influence, and reflects a reliance on others for information about the world. Many situations are more ambiguous than the Asch paradigm, and it often makes sense to compare one's own impressions or opinions with those of others in order to better understand the nature of reality. The central motive underlying informational influence is a desire for accuracy. Under many circumstances it is reasonable to assume that although individuals are subject to errors and biases, aggregating information from across individuals is likely to yield a more accurate representation or understanding of what is correct. The type of norms that often underlie informational influence have been termed descriptive norms, and these reflect modal patterns in how people actually think, feel and behave. The notion is, quite simply, that individuals use information from others in combination with their own impressions, preferences or beliefs when rendering judgments and making decisions. The fact that conformity does not disappear (although it is reduced) when participants in Asch-style paradigms can respond entirely anonymously provides evidence consistent with the informational influence mechanism. It has further been shown that as the difficulty or ambiguity of a task increases, conformity also increases, presumably because individuals are less confident in their own perspectives and turn to others for information. Importantly, this effect is stronger when the motivation for accuracy has been increased by providing participants with incentives for correct responding.

Informational influence processes have been incorporated into the economic literature, where theorists have modeled informational cascades. An informational cascade occurs in sequential decision-making situations when individuals possess information about others' prior decisions (e.g., whether they saw movie X or movie Y last night), but not necessarily the reasons for those decisions. A typical cascade model might assume that people weight their own opinions equally with the opinions implied by the actions of others. In this model, when there is disagreement between the two (e.g., I am leaning toward seeing movie X, but I know that you went to see movie Y) the rational response is to engage in a mental coin toss, weighting each option equally. If, as a result, I end up seeing movie Y, our mutual friend Bob can infer with a 0.75 probability that both you and I were of the opinion that movie Y is the superior choice. In this situation, even if Bob privately believes the opposite, it is rational for him to take his date to see movie Y the next night. Although it is unlikely that people engage in precisely these rational computations, the notion of informational cascades highlights the important point that conformity is not necessarily an irrational response; there are many situations in which it may be rational to weight others' information as heavily or perhaps even more heavily than one's own. Put differently, thinking rationally does not necessarily represent an antidote to conformity. These models show that rational computations can result in conformity and thus that conformity is not limited to the somnambulist.

Models of informational cascades further illustrate how once a pattern of behavior is established, it can become self-perpetuating, and they can thus account for why some things (e.g., movies, products, fashions, ideas) become wildly popular whereas others do not. Cascades can occur when there is little *a priori* reason to prefer one thing over another, or even when there are objective reasons to prefer the choice that does not become popular. Critically, these models can also account for the fragility and fluidity of popular trends. As cascades lengthen, the behavior of others carries less information about their personal beliefs and preferences. If Bob made his decision in the manner described above, Cindy can infer nothing about his personal preference from which movie he selected. As a result, the presence of even a single dissenter may be enough to break the cascade because the deviant's choice does provide information about their opinion; in fact, by diverging from the cascade, the dissenter may signal a particularly strong and well-formed point of view. If this happens to coincide with Cindy's own view, she is likely to continue the dissent. In this situation, even a long unbroken string of unanimous choices can be attributed to others 'just following the crowd.' Breaks in cascades and shifts to new ones may be particularly likely in contexts where there is a bias toward recent information or an assumption that newer is better.

Social Identification

An additional mechanism underlying conformity arises from social identification with groups. This mechanism highlights the critical importance of group memberships for conformity processes and stems from the social identity approach to group behavior. Social identity theory and its descendent, self-categorization theory, posit that when individuals enter a group context, they adopt the group membership as a component of their self-concept (i.e., as a social identity). Members will differ in the extent to which they self-categorize in terms of a particular group membership, but to the extent that they value a particular group, their sense of self shifts from an individual to a collective level. The theory posits that group members undergo a process of depersonalization in which idiosyncratic characteristics (e.g., traits and personal values) become less active and exert less influence on behavior, while shared characteristics representative of the group's prototype (e.g., norms and collective values) become more active and more influential. In this formulation, group norms provide information about what prototypic group members do, think, and feel, and to the extent an individual is motivated to be a good group member, he or she is likely to conform to these norms.

The key motive underlying the social identification mechanism thus does not reflect a simple desire to be approved of by others, but rather a desire to express an important aspect of one's identity – to instantiate the characteristics that define and uphold the image of the group in question. Other motives are also involved: identified group members may be interested in maintaining collective solidarity and cohesion because cohesive groups are capable of more efficacious action. Further, identified group members are interested in maintaining a clear set of group norms because consensus implies correctness and reduces uncertainty. Thus, the social identification

mechanism can account for the findings, outlined above, that individuals who value and identify with groups are more likely to conform to normative patterns of group behavior. This approach can also explain why identified members are more willing to derogate and punish other ingroup (but not out-group) members who violate group norms.

Cognitive Principles

Whether one is talking about normative influence, informational influence or social identification, norms are knowledge structures that operate within the cognitive system. In the case of the Asch paradigm, the normative response on each trial is presumably computed online as fellow group members verbalize their decisions, and the extent to which the norm is correctly interpreted and the degree to which it influences behavior is a function of attention. If the norm is not accurately perceived or is unnoticed, it is unlikely to drive behavior. Many norms, however, are more stable than this and reflect stored knowledge about descriptive or injunctive patterns of behavior (e.g., drivers in Paris often honk their horns, one should not wear white after labor day). The influence of this stored knowledge on behavior follows standard cognitive principles, such that it must be activated/accessible to exert effects. Accessibility maybe relatively chronic or may vary as a function of situational salience. A series of clever field studies conducted by Robert Cialdini and colleagues has shown that the behavior of another individual can direct attention to and make accessible both descriptive and injunctive norms. When an experimental confederate was observed to litter (vs. not) in a heavily littered environment, participants littered more frequently. However, participants who observed another person litter in a clean environment (and particularly in an environment where litter had been neatly swept up) were less likely to litter than if they had not observed anyone else litter. These findings indicate that individuals were not simply imitating the behavior of the other; rather others' actions made salient wider norms regarding littering as implied by the cleanliness of the overall environment. The importance of salience and accessibility are further highlighted by the social identification mechanism, in which different norms are active and influential in different group contexts.

Minority Influence

As noted above, the field of social influence itself can be characterized by long normative trends, interrupted by occasional notes of dissent. Despite Asch's original intent, his work inspired a great deal of interest in the processes and effects associated with conformity. This work proved enormously fruitful; however, by the 1970s it seemed to Serge Moscovici that the field was too focused on the influence exerted by majorities. Certainly majorities have powerful effects, but Moscovici believed that minorities also play an important role in collective life and can, under the right circumstances, influence others' opinions and decisions. Moscovici proposed that people expect to achieve consensus on most if not all issues, and believe that there is generally one correct perspective to hold. As such, when someone encounters a perspective that

differs from their own, it generates conflict, which the individual is motivated to resolve. The manner in which this conflict is resolved differs depending on whether the discrepant perspective comes from a majority or a minority. If it comes from a majority, a normative influence mechanism similar to that described above kicks in, such that individuals conform in order to maintain cohesion and acceptance. In contrast, if the discrepant perspective comes from a minority, an informational influence type mechanism operates, such that individuals are motivated to critically evaluate and perhaps validate (if there is enough supporting evidence) the minority's position.

Critically, majority versus minority influence results in different types of opinion change. Because majorities exert influence via normative pressure, majority influence is more likely to affect public than privately held opinions. This response is termed compliance, and reflects the fact that people may publicly express agreement with majority perspectives while maintaining private doubts. Interestingly, however, to the extent that they exert influence, minorities are more likely to have the opposite effects: exerting less influence on public opinions because individuals are reluctant to associate themselves with a minority, but greater influence on private opinions because minorities trigger more rigorous consideration of available information. A change in private but not public responses is termed conversion. Generally speaking, there is good evidence for these hypotheses. Across studies, it is clear that minorities can exert influence and that they are particularly likely to exert indirect effects on opinion. For example, a minority opinion regarding a specific issue may not affect others' perspectives on exactly that issue, but it is likely to affect others' opinions on related issues. Further, minorities exert influence to the extent that they are perceived to be consistent; if one is going against the grain, it pays not to be wishy-washy.

Related lines of research have examined the effects of minorities and dissenters on group functioning more generally. Irving Janis' famous analysis of groupthink during the Cuban Missile Crisis and other events made salient the fact that extreme cohesion and unanimity in groups can lead to poor, even disastrous decisions. Although the groupthink construct itself remains controversial, what is now uncontroversial is the fact that diversity and divergence in group settings often leads to improved collective decisions and group outcomes. Researchers have found, for instance, that the presence of dissent and/or diversity increases creativity and innovation within groups, and reduces the extent to which groups become polarized – moving them away from rather than toward extreme positions. Interestingly, improvement in these sorts of outcomes does not depend on the dissenter or minority being correct. Consistent with Moscovici's model, minorities encourage others to think more divergently and to consider alternate perspectives; it is the consideration given to multiple possibilities that ultimately improves decisions. Although the expression of minority views is largely functional for collectives, it is important to note that there can be costs in terms of reduced cohesion. Recent research has shown that when a minority successfully converts a group to their position (and becomes a majority), the group suffers an overall loss of cohesion as former majority members reduce their level of identification with the group, which is not replaced by an equivalent increase in identification among the new

majority. Interestingly, these ill effects are not observed if the minority achieves its goals by increasing tolerance for their position but does not seek to convert other group members.

Mechanisms Underlying Nonconformity

Although the minority influence literature has illuminated the effects that deviance can have on groups, relatively little research has investigated the mechanisms or motives that might cause individuals to express minority opinions and make nonnormative decisions. Researchers and theorists have generally assumed (at least tacitly) that nonconformity can be accounted for by the absence of the mechanisms that underlie conformity. As such, nonconformity is predicted when individuals are not motivated to seek the approval of others, do not fear social sanctions, do not need or trust others' information and/or are weakly identified with relevant social groups. In each case, a motive that might trigger conformity is replaced by an orientation toward independence and autonomy from others. Although independence and autonomy are undoubtedly the cause of some nonconformity, they seem to miss a whole class of nonconformist behavior in which people act not out of a desire to separate or distinguish themselves from others but rather act on principle or out of concern for others – in particular for important groups. Interestingly, this was how Asch himself conceptualized nonconformity. Intuiting the importance of diversity and divergence for collective functioning (intuitions that, as we have seen, turned out to be correct), he did not believe that nonconformity was an individualistic act, but rather a cooperative, group-oriented one. In this conception, nonconformity is often motivated by a desire to see one's groups succeed, and individuals are likely to express dissent when they think that doing so can improve collective outcomes.

It is, however, difficult to account for this type of nonconformity simply in terms of the absence of mechanisms that underlie conformity, each of which implies social separation. This difficulty is further compounded by the fact that nonconformity often poses individuals with a social dilemma – specifically, a public goods dilemma. Public goods dilemmas of all types pit collective and personal interests against one another, such that by acting to benefit a group, individuals incur personal-level costs. We have already encountered an example of one such dilemma: paying taxes to afford roads and fire departments. We have further seen how social sanctions can be used to ensure cooperation; that is, to ensure that people resolve these dilemmas in favor of the collective interest. Somewhat ironically, however, the ubiquity with which sanctions are applied to deviance may give rise to an entirely new public goods dilemma when it comes to dissent. Dissent is often associated with positive collective outcomes – it is an act that, all things considered, is often beneficial to the collective. At the same time, however, dissent is often associated with significant social costs to the individual – individual dissenters risk their good name, social standing, sometimes even their livelihood and lives by deviating from widely held norms. As such, would-be dissenters must often be willing to sacrifice personal-level interests for potential collective benefits, which seems an unlikely contingency among autonomous individuals standing apart from others. For these reasons, conformity and

nonconformity are unlikely to be reciprocal, fully explainable by a common set of processes working in reverse.

Asch's notions regarding nonconformity have recently been revived, and researchers have started to attend more closely to mechanisms that underlie nonconformity. One such approach is the normative conflict model, which predicts how group members are likely to respond to norms under a variety of conditions. This model represents a refinement and extension of the social identification approach to conformity outlined above, and predicts the likelihood of several conforming and nonconforming responses as a function of three psychological factors:

- (a) social identification,
- (b) normative conflict (i.e., disagreement with group norms), and
- (c) estimates regarding the likely costs and benefits of conformity versus nonconformity.

A great deal of research in the social identity tradition has shown that when people adopt a group membership as an important component of their self-concept (i.e., identify with the group), it alters decision-making processes. When individuals make decisions outside of group contexts or in groups with which they are weakly identified, actions and outcomes are evaluated primarily in terms of their individualistic implications: how will this affect me? In contrast, when individuals make decisions in groups with which they are strongly identified, actions and outcomes are evaluated primarily in terms of their collective implications: How will this affect us? As a result, identified group members are frequently observed to resolve social dilemmas of all kinds by acting in the collective interest, even in the absence of sanctions.

The normative conflict model posits that identified group members may respond in the same way to the dilemma posed by dissent. The key assumption is that all group members are likely, at one time or another, to experience disagreement or conflict with group norms. For weakly identified members, this conflict may stem from a tension between personal and collective interests (e.g., what is good for me vs. good for us). In contrast, for strongly identified members, conflicts are more likely to arise when group norms are perceived to be harmful to the collective itself. This type of normative conflict can come from discrepancies between descriptive and injunctive norms, such that how the group is actually behaving is believed to be at odds with the group's own ideals or standards for behavior. However, normative conflict might also arise from the application of personally held standards (e.g., moral beliefs) to collective behavior or even the application of norms incorporated from other group memberships. Importantly, it is predicted that strongly identified members are often willing to express dissent if they perceive it to be in the collective interest, even if they are likely to incur personal costs for doing so. In contrast, weakly identified group members are not expected to dissent on behalf of the group, and are actually predicted to be more conformist than strong identifiers when dissent carries personal costs. A number of recent studies have provided evidence consistent with these hypotheses.

Types of Conformity and Nonconformity

Although it is possible to talk about conformity versus nonconformity in general terms, theorists and researchers have

often noted that there are various forms of both. We have already encountered the distinction between compliance and conversion, two forms of conformity arising from different psychological processes and with distinct behavioral consequences. The distinction between private and public beliefs forms the basis for a number of taxonomies of social response. The normative conflict model also provides a way of distinguishing between different forms of conformity and nonconformity; specifically, as a function of social identification (low vs. high), normative conflict (low vs. high), and estimates of the pros versus cons of conformity/nonconformity among individuals in each of these four cells (see [Figure 1](#)).

- Weakly identified group members experiencing low levels of normative conflict (i.e., little disagreement with group norms) exhibit either indifference or strategic conformity depending on what they believe to be in their personal self-interest. Generally speaking, these members are not motivated to conform to group norms (are indifferent), but they will conform if they expect to be rewarded for doing so or punished for not.
- Strongly identified members experiencing low normative conflict exhibit either loyal conformity or strategic nonconformity. Generally speaking, these members are happy to conform to group norms with which they agree, although under certain circumstances they may see the collective value of deviance even though they do not disagree with collective norms (e.g., playing devil's advocate).
- Weakly identified group members experiencing high levels of normative conflict (i.e., sharp disagreement with group norms) display either disengagement or personally oriented dissent. Personally oriented dissent reflects an attempt to change group norms in ways that would serve one's individual interests; this is a selfish type of dissent and may be relatively rare due to the fact that others are highly likely to punish dissent that is not perceived to be collectively constructive. Disengagement reflects a class of response in which individuals try to distance themselves from a group that they disagree with; rather than attempting to change the group, these behaviors set one apart from the collective.
- Finally, strongly identified members experiencing high normative conflict display either collectively oriented dissent or uneasy conformity. Collectively oriented dissent reflects attempts to change group norms in ways that are believed to benefit the collective. These group members are, however, not entirely blind to the personal costs associated with dissent, which at times may result in uneasy conformity to group norms – one would like to do something to change them but holds back, deterred by possible consequences.

General Relational Norms Versus Context-Specific Norms

It is important to distinguish between two additional types of norms: norms that apply generally within classes of relationships, and norms that develop as patterns of and prescriptions for behavior within specific relationships. It is, for instance, generally normative to conform in collective contexts – when one joins a group it is with the understanding that one will learn and adopt normative patterns of action

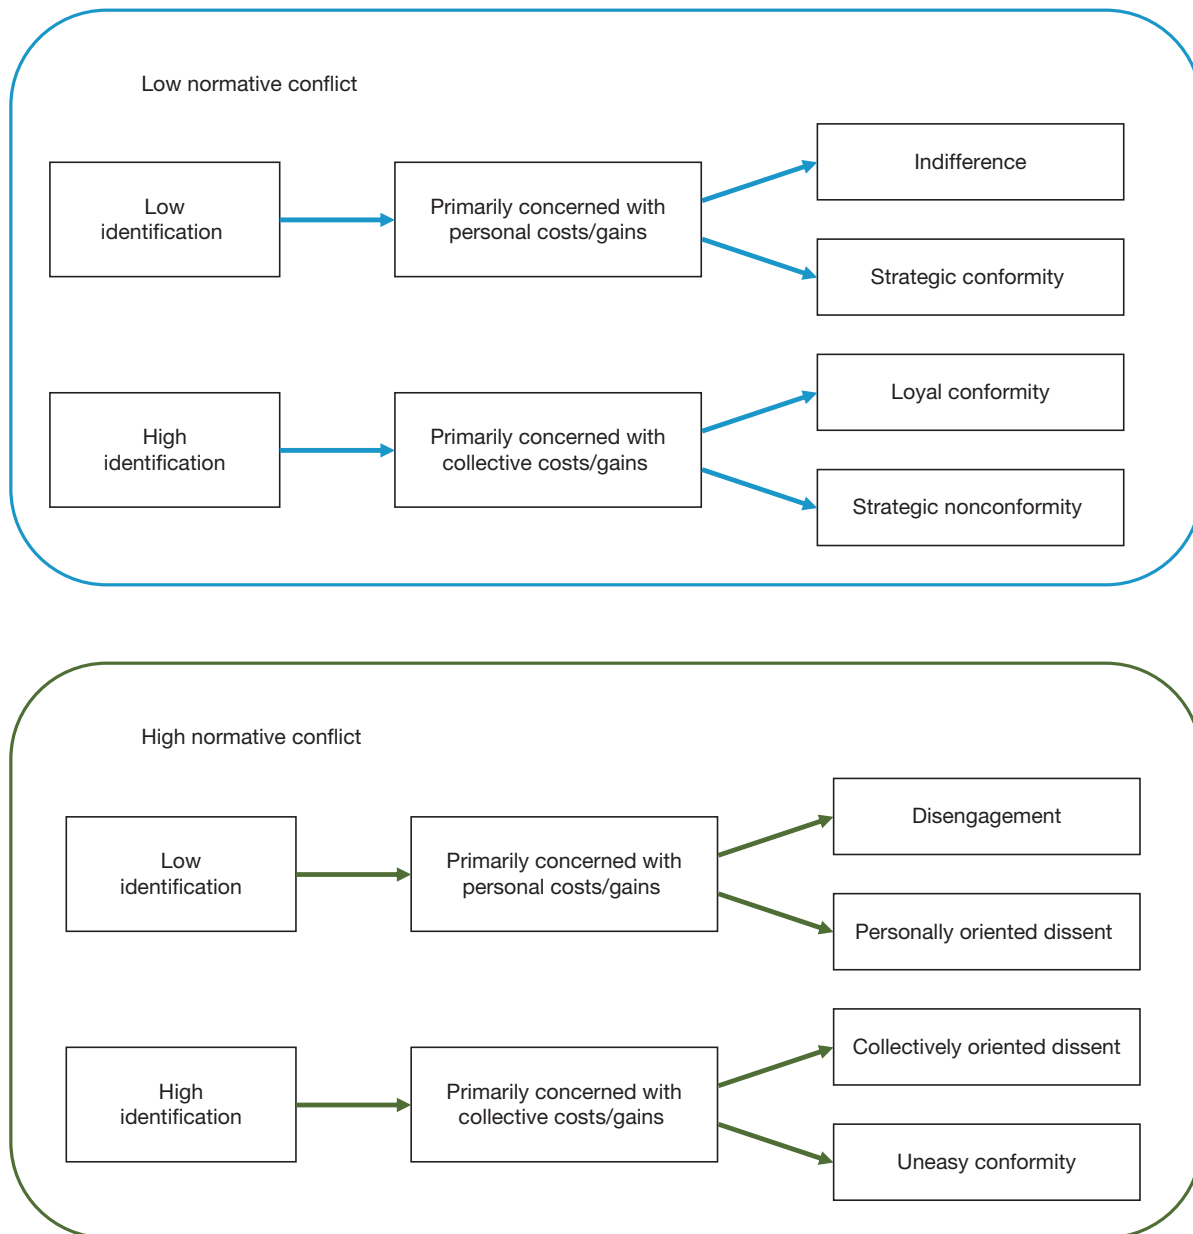

Figure 1 Types of conformity and nonconformity predicted by the normative conflict model.

(through socialization). Interestingly, however, this norm of conformity can itself be revised by group norms, such that in some groups it becomes normative not to conform. Recent research has shown evidence for this paradoxical state of affairs: there are groups in which it is normative to be distinct and where nonconformity represents conformity. Other types of relationships also have general norms associated with them. A particularly powerful general norm is known as the norm of reciprocity. This norm is most powerful in equality matching relationships, where the understanding is that all favors done by one party for another must be reciprocated, sometimes exactly, at a later point in time. The deeply embedded nature of this norm is often exploited by marketers and salespeople, who offer naïve victims a small gift, which triggers in them an

urge to reciprocate – by listening to a sales pitch or even shelling out hard cash. The manifestation of this general norm can also be shaped by local norms. For example, the range of others to whom one is obligated to reciprocate is normatively determined: the small gift trick seems to work well in North American society, but may be less effective in cultures where haggling with salespeople is normative and reciprocity is reserved for friends and family.

Obedience

Obedience to authority also often arises from a general relational norm. It is typically assumed that people should attend

and acquiesce to the requests or instructions of individuals in positions of authority. Obedience is, like conformity, ubiquitous in human life. When your dentist tells you to 'open wide,' you do it even though you know that what is about to ensue is likely to be unpleasant. Different types of authorities get their power to influence from different sources. Some obedience stems from the ability of authorities to affect others' outcomes. On the negative side, an authority may coerce obedience with explicit or implicit threats of punishment; on the positive side, they may reinforce obedience with rewards. However, authority can also arise from other factors, including the legitimacy of a role (e.g., kings, presidents, police officers), charisma and attraction (e.g., celebrities, some politicians), and expertise (e.g., dentists, doctors, professors).

It was at one point widely agreed upon by psychologists that obedience was a good thing – a virtue to be instilled in children from an early age. It was also often assumed that obedience was not a spontaneous behavior, but that it had to be learned and reinforced. The events of the twentieth century, however, changed these conceptions. Obedience to authority became widely recognized as a problem after the Second World War when social scientists tried to understand how vast numbers of seemingly ordinary people became involved in atrocities, culminating in the Holocaust. It became clear that whether obedience is a virtue or a vice depends on the morality or malevolence of the relevant authority figures, and authorities did not come off at all well throughout the last century.

Stanley Milgram initiated a program of research to better understand the psychological processes involved in destructive obedience. In a series of studies, participants were instructed by a lab-coated experimenter (the authority figure) to administer (ostensible) shocks in 15 V increments to a 'learner' whenever he made a mistake; these shocks started off mild (15 V) and rose steadily (to 450 V). As the voltage of ostensible shocks increased, the learner emitted a series of prescribed vocalizations, which included increasingly intense expressions of physical pain (beginning at 75 V), as well as verbal requests to be released (beginning at 150 V). By the middle, the learner was screaming in pain, and by the end, he had fallen silent. Remarkably, in many versions of the study, the majority of participants was fully obedient to the experimenter and continued the procedure to the very end, despite considerable personal discomfort. The original studies were conducted in the 1950s; however, recent partial replications of the paradigm reveal comparable rates of obedience even today.

The Milgram paradigm is complex, and the psychological mechanisms underlying the obedience he observed are multifaceted. A variety of mechanisms have been proposed, and although direct empirical evidence is often lacking, many are plausible contributors. It has been suggested, for instance, that obedience was facilitated by the sequential nature of decision making and the gradual manner in which the shocks increased. Each decision led to the next, and a foot-in-the-door type of process may have made it difficult to justify refusing to administer a shock having agreed to give the previous. Similarly, the gradual increase in severity may have desensitized participants to the learner's expressions of pain. Cognitive dissonance between participants' values and their behavior may have altered conceptions of the harm they were causing (e.g., 'it can't be as bad as all that'). Participants may also have engaged in what

Milgram called an agentic shift, giving up their sense of personal responsibility and allowing the experimenter to take charge. It is also possible that participants looked to the experimenter to define the reality of what was occurring. The experimenter was, after all, supposed to be an expert: if he did not see a problem with what was happening, perhaps there was no problem.

As with nonconformity, less attention has been paid to the opposite response: disobedience. In part, this is because rates of disobedience were relatively low in Milgram's studies, with only a few noncompliant participants to examine in any given study. However, a recent meta-analysis combined data across a series of comparable studies to examine disobedience among a larger sample. What emerged was a previously undocumented systematicity in disobedience, such that disobedience was most likely to occur at the point (150 V) when the learner made his first request to be released. A much higher proportion disobeyed at this point than at any other across studies, and this was the single most frequent point of disobedience within each study. Interestingly, there was no linear relationship between level of shock and obedience as would be expected if increasingly intense expressions of pain were reliably motivating non-compliance. These findings strongly suggest that disobedience to authority in this paradigm was not driven by an empathic response to the suffering of another, but rather may have been due to recognizing the learner's first request for release as a choice point. It appears that those participants who disobeyed the experimenter at this point may have had a different understanding of what was and was not a legitimate use of authority in the experimental situation. When push came to shove, these participants gave the learner authority over his own fate, and were obedient to his rather than the experimenter's request. However, despite these conjectures, much about Milgram's effects and about processes of obedience and disobedience more generally remains, for the moment, unclear.

Glossary

Advertising Paid communication in which a sponsor provides information about products, services, and/or ideas.

Behavioral decision theory The body of research that investigates how people make decisions.

Brand management Making strategic decisions regarding the marketing of products and services.

Consumer psychology The study of how individuals form judgments and make decisions related to the consumption of products and services, and how marketplace phenomena affect attitudes, choices, and personal and group identities.

Inference The act of forming beliefs about unknown attributes about a target based on attributes that are known.

Information processing Consumers' acquisition and use of information to help them form judgments of, and make choices regarding, products and services.

Persuasion The act of trying to influence others' beliefs and attitudes.

Sales promotion Providing an incentive aimed at stimulating purchase of products and services either by intermediaries (e.g., retailers) or the end consumer.

At its most general level, consumer psychology is the study of how individuals navigate myriad judgments and decisions related to the consumption of products and services. Researchers interested in consumer psychology study phenomena as diverse as the determinants of what attracts consumers' attention, how they process incoming information, and how they integrate it with existing knowledge. Moreover, consumer researchers consider what is remembered from consumption experiences, and how these memories guide future judgments and choices. Similar to social psychologists, constructs such as attitudes and motivation are extremely important for consumer psychologists. One key defining feature of consumer psychology is that it is both a basic and an applied science, and is typically taught and practiced in business schools with the ultimate goal of informing and improving marketing management decision-making, and hence organizational outcomes. Moreover, by understanding the psychological principles that govern consumption, researchers also hope to contribute to consumer welfare.

Although consumer psychologists study a diverse set of phenomena, one contribution of researchers in the field is that of a consistent picture of the human decision-maker. In contrast to the assumptions of economic standard value theory, individuals do not act as dispassionate, strictly rational, calculators of utility when they make consumer decisions. Instead, although consumers certainly tend to prefer more utility to less, they do not use all of the information available to them when they form judgments and make decisions, they are heavily influenced by normatively irrelevant aspects of the context in which consumption takes place, and they routinely respond in accordance with social pressure, whether actively imposed by others or imagined. Although consumers' choices are not often strictly rational as per economists' assumptions, consumers display a variety of consistent and predictable tendencies in how they acquire, aggregate, and use information in their decisions that facilitate adaptive navigation of a complicated world. Consumer psychologists endeavor to understand these

tendencies and processes that influence individuals' judgments and ultimately guide their choices.

An overview of core research areas and key findings that are central to consumer psychology follows. After the presentation of basic research, a summary of important implications of consumer psychology for managerial decisions is offered.

Core Principles of Consumer Psychology

Attention and Memory

Consumer researchers expend a great deal of effort researching how to best structure persuasive messages such as advertisements. A number of different models of communication have been proposed, but the first step in any model is capturing consumers' attention. This is not an easy task because consumers are exposed to hundreds, if not thousands, of persuasive messages every day. Some determinants of consumer attention include personal interest in, and knowledge about, a marketing stimulus (consumers attend when they have preexisting interest and are highly knowledgeable). Aspects of marketing stimuli themselves also determine if they will garner attention. Marketing stimuli that are novel, vivid, concrete (i.e., easy to visualize), and close versus distant in sensory, temporal, and spatial proximity are typically readily attended.

Of course, just because an individual has attended to a stimulus does not imply that it will be processed, transferred to memory, and brought to bear in future choice making. The study of memory is fundamental to all of human behavior and is of particular importance for consumer psychologists. Researchers have investigated what and how information is encoded, stored, and retrieved, the processes and likelihood of retrieval failure, and how remembering and forgetting influence behavior. Consumer psychologists have used, and contributed to, this literature in myriad ways. One important attribute of memory is that it is active and constructive, and often what consumers recall is a story that plausibly integrates

bits of retrieved information versus an exact and invariant recalling of experiences akin to watching and rewatching a DVD.

One of the most influential notions to arise from memory research is that memory is associative. That is, memories are created and stored in networks characterized by representations of concepts, or nodes, and links between nodes. The strength of association between nodes is determined by the frequency and recency of associations, as well as by the depth of processing. When one node is activated, either because it has been attended to in context or retrieved from memory, related nodes may also be activated through a process of spreading activation in which related nodes are activated to the extent that they are strongly linked to previously activated nodes. This basic property of memory has been used by consumer psychologists in understanding diverse phenomena, such as attitude formation, structure, change, and the likelihood of attitudes driving behavior, predicting which brands are given consideration prior to choice, how the priming of concepts affects subsequent judgment and decision-making, and how firms' investments in sponsorships may color brand perceptions.

Consumer Information Processing

Consumer psychologists devote a great deal of attention to understanding the processes that underlie the use of information to make judgments and decisions (attention, comprehension, encoding, retrieval, integration), the extent of processing (deep vs. shallow), and the direction of processing (one-sided or belief-consistent vs. two-sided or evenhanded). The nature of how consumers process information depends on their motivation and ability to deliberate. When the motivation and the ability to deliberate are high, the extent of processing increases (consumers are likely to consider more alternatives and more attributes), and the likelihood of two-sided processing, in which consumers consider information that is inconsistent as well as consistent with their beliefs, increases. When motivation or ability is low, fewer alternatives, fewer attributes, and simple heuristic cues that enable consumers to reach judgments and decisions quickly and easily are likely to be used. Furthermore, consumers are likely to focus on information that is readily accessible from memory or that is consistent with their beliefs. Accessibility depends on the recency, frequency, and intensity of information processing.

Consumers can attend to and think about only seven pieces of information at a time. More than about seven pieces overloads consumers and forces them to use heuristics or shortcuts to simplify information processing. Consequently, consumers rarely consider more than seven brands when they need to make a purchase decision, and frequently consider fewer brands. Pioneering brands (i.e., new brands that are the first entrant in a new category) and other salient or attention drawing brands are likely to be considered. Being considered early in a consumer's decision process lends tremendous competitive advantage for a given brand, because brands that receive selective consideration often benefit from a brand positivity effect, in which a focal brand comes to be perceived as superior. As motivation or knowledge increases, the number of brands considered increases. Generally, as the number of brands considered increases, consumers make better decisions.

Information that is easy to process is weighed heavily in judgment, even if other more relevant but more difficult to process information is available. Information is easy to process if it is easy to pronounce, easy to read, attention drawing, encountered frequently, accessible from memory, or if it has straightforward implications for judgment and decision-making. Information that is easy to process seems more familiar, more valid, more relevant, and more esthetically pleasing, and such information leads to more confidently held judgments.

Availability refers to whether information is stored in memory, and accessibility refers to the 'activation potential' of the available information. Accessibility depends on the strength of the association between stored knowledge and situational cues, the recency with which information has been acquired or last activated, the frequency of prior activation, and the intensity with which information has been processed. Rather than using all relevant information stored in memory, consumers frequently use the subset that has been primed by the environment. A wide variety of marketing communications have been shown to serve as priming stimuli (e.g., ads, internet messages, salesperson interactions, retail environments, consumer magazines), and these priming stimuli have been shown to influence a wide variety of judgments (e.g., expensiveness, evaluative, and likelihood judgments) and mindsets (e.g., comparing brands in one product category can increase purchase intentions in a different product category). Consumers often overestimate the likelihood of occupations (e.g., doctors, lawyers), objects (e.g., luxury cars, swimming pools), and behaviors (e.g., having wine with dinner, incidence of crime) shown frequently on television. This is particularly the case for heavy viewers, despite the fact that most consumers do not believe that television reflects reality. Priming can result in either assimilation (a shift in judgment of a target toward the priming stimulus) or contrast (a shift in judgment of a target away from the priming stimulus), depending on the degree of overlap between the priming stimulus and the target. Assimilation occurs when overlap is high, and contrast occurs when overlap is low.

Attitudes

The concept of attitudes, or evaluations of objects, is tremendously important for consumer psychologists. Consumers can hold attitudes toward a variety of very different targets, including products, product categories, firms, advertisements, spokespeople, and so on. To the extent that consumers hold favorable attitudes toward a target, they are likely to engage in approach behaviors such as attending to advertisements for favored products and purchasing them, and remaining loyal to liked brands over time. Negative attitudes, in contrast, drive avoidance behaviors. Measuring attitudes allows consumer psychologists to predict consumers' behavior, and behavior can be influenced if attitudes are changed (e.g., when a consumer is exposed to a persuasive message, or has a good or bad experience after trying a product).

Consumers' attitudes may be formed based on three fundamental processes. First, attitudes can be formed as a result of classical conditioning, in which originally neutral targets come to be evaluated in accordance with other stimuli to which

repeated associations are made. Attitudes can also arise from processes of operant conditioning. The rewards and punishments that drive consumer attitudes are diverse, and include inputs such as direct experience with a product, and the social consequences, or anticipated consequences, of making certain consumer choices. To the extent that consumers feel rewarded after engaging in a given behavior, the behavior is likely to recur, whereas behaviors that evoke punishments, or fail to provide rewards, are unlikely to be repeated. A third, more cognitively intensive, attitude formation process involves breaking a target object down into its attributes, considering how valuable each attribute is, and the likelihood of each outcome occurring. Then, the products of the values and likelihoods are summed to create an overall expected value of the object, which is then compared against other objects. Calculating attitudes in this fashion is central to the Theory of Planned Behavior, a very influential and enduring model of behavior that proposes that the expected value of options, which considered along with social norms, drives behavior.

A critical concern for consumer psychologists is the extent to which attitudes and choices are strongly associated. To the extent that attitudes are strong, they are likely to guide behavioral decision-making, whereas weak attitudes are less likely to play a role in behavior. Measures of attitude strength include extremity (how positive or negative the evaluation is), accessibility (how easily an evaluation of an object is recalled from memory), and certainty (confidence that an attitude held is correct). Attitudes characterized by ambivalence, that is, both positive and negative evaluations, tend to be less likely to guide behavior. Overall, though, as long as the correct attitude is measured, attitudes are of enormous utility in predicting consumers' behavior.

Consumer psychologists are devoting increasing attention to understanding the implications of the distinction between explicit and implicit attitudes. Explicit attitudes are deliberative, and are based on consumers introspecting on, and subsequently self-reporting, their evaluations. Implicit attitudes, in contrast, are much more automatic, and are based on associations in memory that do not necessarily reside in conscious awareness. Explicit and implicit attitudes toward different targets vary in terms of how strongly related they are, and can be manipulated independent of each other. Moreover, explicit and implicit attitudes differ in terms of how they are influenced and how they guide behavioral decision-making.

Persuasion and Attitude Change

The importance of attitudes in determining consumers' choices has driven a long-standing interest in understanding how, and under what circumstances, consumers' attitudes change. Of particular focus is persuasion, the attempt to change another's attitude. The earliest paradigm of attitude change research has been termed the Message Learning approach, and has revealed insights into how attributes of the source of a communication, and the message itself, affect whether a persuasive attempt is successful or not. More persuasion from a message occurs when the source is credible (e.g., trustworthy, has high expertise) and attractive (both socially and physically). Persuasion is also facilitated when the message is constructed to match elements of the argument and the intended audience. Specific

considerations include when a one versus two-sided argument should be used, where to position the strongest evidence in a message, the optimal number of message exposures the audience should receive, whether conclusions should be specified, and how to best use fear as a motivator.

A next paradigm includes dual-process models of persuasion, which have been enormously useful both in understanding persuasion and in stimulating research. Both the Elaboration Likelihood Model and the Heuristic-Systematic Model posit that attitude change may occur along one of the two paths. When consumers have both the motivation and the ability (i.e., there are no time constraints and no distracters) to carefully consider a persuasive communication, the extent of persuasion is determined by their judgments of the quality of the arguments in the message. In contrast, when either motivation or ability is absent, persuasion is driven by peripheral cues in the communication context (i.e., the number of arguments offered to support the communication, aspects of the source of the communication such as expertise, attractiveness, and similarity). Although persuasion may result from either path, when consumers evaluate the merits of the message, more persuasion results, it is more enduring over time, and it is less likely to decay than if persuasion is driven by peripheral cues.

In addition to research on the processes of persuasion, researchers have identified six fundamental influences that contribute to persuasion. First, to the extent that one likes someone, one is likely to be persuaded by that person. Liking often arises when consumers perceive that another is similar to them, when the other offers compliments, and is attractive. A second influence is reciprocity, or the social norm that favors should be repaid. When someone feels indebted, even from an unsolicited favor, they are likely to try to repay the favor. Third, consumers like to be seen by others as well as by themselves as being consistent. Once consumers are committed to an attitude or a course of action, they tend to stick to their commitments. A fourth influence is social proof, or the tendency to follow the lead of similar others. Authority refers to consumers' proclivity to defer to experts. Communications that appeal to expertise often succeed because consumers infer that experts' opinions are valid. A sixth influence is scarcity; to the extent that something is in demand, it seems more valuable. Marketers use these persuasive influences in creative ways in the attempt to convince consumers of the merit of their offerings.

Inference

A challenge that consumers often face is that they do not have complete information about products and services that they are considering purchasing. Consumers are likely to go beyond the given information and draw inferences about missing information when they are sensitive to the omission of important information, and when they have accessible implicit theories or assumptions that link evidence to conclusions in a subjectively logical fashion. For example, most consumers have an implicit theory that links price and quality; as price increases, perceived quality increases. Typically, the relationship between price and quality in consumers' implicit theories is much stronger than the actual relationship between price and quality in the marketplace. Consumers also have implicit

theories about products made in different countries. In the United States, many consumers believe that Japanese electronics, German cars, and French wine are of high quality. Other countries, such as China, Korea, and Mexico, are often associated with low-quality products. Consumers also have implicit theories about product popularity and quality. Highly popular products are often perceived as higher in quality than less popular products. Consequently, consumers like bestselling books, popular restaurants, and products that everyone else seems to use or to like. Consumers have many different implicit theories relevant to persuasion. For example, experts are trustworthy, length implies strength (long messages are more persuasive than short messages), and consensus cues (millions of satisfied customers cannot be wrong) can have a profound impact on persuasion. Unfortunately for marketers, consumers also have an implicit theory that marketers are untrustworthy and that one should not believe everything one sees or hears in marketing communications, which produces resistance to persuasion.

In addition to drawing inferences about global quality, persuasiveness, and trustworthiness, consumers also attempt to draw inferences about specific missing attributes when they realize that information is missing. However, consumers are frequently insensitive to omissions and this can lead to strong judgments (extreme and confidently held judgments) based on weak evidence. High levels of prior knowledge or involvement can increase sensitivity to omissions and lead to more moderate judgments. Comparing products described in terms of different attribute dimensions can also increase sensitivity to omissions. Reading a relatively large amount of information about one product can increase sensitivity to omissions concerning another product described by a relatively small amount of information, even when the two products belong to completely different categories.

Categorical knowledge also helps consumers to fill in missing details. Once a product has been categorized, consumers assume that the product has all of the properties and characteristics that are typically associated with the category. Even if a consumer has never tasted panna cotta, he or she is likely to assume that panna cotta is sweet when they learn that it is a dessert. Prior knowledge and experience is organized into knowledge structures called schemata that are also useful for filling in gaps in knowledge. For example, the linear ordering schema suggests that if A is better than B and B is better than C, then A must be better than C. Similarly, the syllogism schema suggests that if A implies B and B implies C, then A implies C.

Behavioral Decision Theory

Behavioral Decision Theory refers to the research paradigm that explores consumers' decision tendencies. For example, research on the framing effect shows that the manner in which choice alternatives are framed or described has a profound effect on choice, even though consumers typically believe that their preferences are stable. This occurs because consumers think differently about outcomes described in terms of gains (above a reference point) versus losses (below a reference point). Loss aversion, or the tendency to weigh losses more heavily than equivalent gains, can explain the framing effect, the compromise effect, the endowment effect,

the status quo bias, and the sunk cost fallacy. For example, when outcomes are framed in terms of gains, consumers are risk-averse. When outcomes are framed in terms of losses, consumers are risk seeking. Consequently, when asked to choose between a program that would save 200 out of 600 lives for sure and a program that would save 600 with $p = 0.33$ or 0 with $p = 0.67$, most people prefer the former safe option. When asked to choose between a program in which 400 out of 600 would die for sure and a program in which 0 would die with $p = 0.33$ or 600 would die with $p = 0.67$, most people prefer the latter risky option. Of course, the two safe options are identical and the two risky options are identical too.

Consumers often prefer a compromise brand that is average on two equally important attributes over brands that are excellent on one attribute but poor on the other. Poor performance on an attribute is often interpreted as a big loss and loss aversion leads consumers to avoid extreme brands.

Research on the endowment effect shows that owning an object leads consumers to value that object more. This occurs because buying a new object is interpreted as a gain and selling an object one currently owns is interpreted as a loss. Loss aversion makes consumers reluctant to sell objects they currently own. Consequently, selling prices are often much higher than buying prices.

People often prefer the status quo to change (the status quo bias). This occurs because change often involves gains on some dimensions and losses on others, and loss aversion can make people reluctant to accept change. Consequently, when consumers are told that a pharmaceutical product is currently on the market, they recommend keeping it on the market. When they are told that the same product is currently not on the market, they recommend keeping it off the market. People also prefer to keep their current jobs, automobile color, financial investments, and medical insurance policies.

As the amount of time, money, or effort invested in a project increases, the reluctance to abandon the project increases even if people would be better off doing so (the sunk cost fallacy). After spending millions of dollars on a dam, building, or construction project, people are reluctant to abandon the project even when it would be less expensive to do so. After spending millions of dollars on old mixing technologies, many steel companies went out of business because they refused to invest in new superior technologies. Loss aversion makes people reluctant to give up what they have already invested, even when the investment is unlikely to ever pay off.

Motivation

Motivation refers to tension that results from the discrepancy between a current state and needs or wants that consumers are driven to ameliorate. Consumers feel motivation to address both biological (e.g., thirst, hunger, safety) and learned (e.g., prestige) needs, and needs may be utilitarian and practical, or hedonic and emotional. Many classic psychological concepts and theories have been adopted by marketers, including Drive Theory and the motive to maintain homeostasis, motivational conflicts (i.e., approach–approach, approach–avoidance, avoidance–avoidance, and double approach–avoidance), and Maslow's Hierarchy of Needs.

One of the most influential motivational theories in consumer psychology is regulatory focus. Research has explored how individuals' motivation to seek positive outcomes while avoiding negative outcomes affects a host of behaviors. Two self-regulation systems help individuals pursue these motives. The promotion system seeks advancement and growth, and approach strategies are employed in the pursuit of positive outcomes. The prevention system, in contrast, derives from security needs such as safety and protection, and employs avoidance strategies to preclude negative outcomes. Although these systems are independent, one's overall regulatory focus at a given time may vary, and is determined both by individual differences in socialization and by contextual factors such as the framing of behavioral decision problems. Regulatory focus has been shown to play an important role in numerous consumer behavior phenomena, including the evaluation of products, response to advertising, perceptions of the importance of different product attributes, and the propensity to adopt new products.

Although regulatory focus considers general motivation, consumers often behave to address more concrete goals. Goals are representations of desired and undesired states, and proximally activate behavior. In some cases, goals may conflict, in which case the goal associated with more importance (i.e., stronger activation as a function of internal associations and external context) is likely to dominate. Goals may be actively set by consumers and are hierarchical in nature, that is, they vary according to how specific they are. Goal pursuit refers to the actions consumers take to achieve their goals. The goal concept is important for consumer psychologists conceptually because understanding goal-directed activity helps to unravel the complexities of consumer behavior. Marketing practitioners make use of goals in myriad ways; if consumers' goals are known, firms can better address consumers' needs in marketing communications, product development, pricing, and so on.

Individual Differences in Consumer Psychology

A variety of traits that vary across individuals relate to what information they consider, and how they process it, as well as what values and preferences are brought to bear in the consumer choice context. Consumer psychologists care about individual differences for two reasons. When one observes a given consumer behavior, that behavior is influenced both by the context in which the behavior occurs and by variables internal to the consumer. Thus, studying individual differences helps us to better understand the nature of the consumer as a decision-maker. Moreover, studying how consumers who vary on some theoretically relevant dimension respond differentially in a given consumption context can help us to understand the processes that underlie the behavior.

Researchers have considered a wide range of individual differences. Although exhaustive cataloging is beyond the scope of this article, several individual differences that have proved to be of extraordinary utility are discussed. The Need for Cognition, for example, refers to the extent to which consumers like to engage in careful, effortful thinking, and to understand and make sense of the world. Consumers who are high versus low in Need for Cognition engage in more

exhaustive information search and more effortful processing of persuasive communications, are more open-minded, have more persistent attitudes, consider a wider range of prices when making a purchase, and prefer verbal versus visual information.

Conceptually related yet distinct from Need for Cognition is the Need for Closure, which refers to the desire to come to a decision, any decision, quickly versus engage in exhaustive deliberation before making a choice. Other individual differences relevant for consumer psychologists include the Need for Uniqueness, which refers to the pursuit of differentiating oneself from others through the acquisition and use of consumer goods, Romanticism (inspirational, imaginative, intuitive, and creative people for whom feelings come first) versus Classicism (unemotional, straightforward, economical, facts come first types), and, as noted earlier, regulatory focus considered as a trait.

Consumer Neuropsychology

A next generation of consumer decision research involves understanding how brain function guides consumer behavior, often by localizing parts of the brain responsible for different types of information processing. Researchers have used methodologies such as functional magnetic resonance imaging (fMRI) scans, which enable researchers to determine which brain areas are most active when consumers engage in particular tasks, and lesion studies, in which the behavioral decision-making of patients with injuries to specific neural structures is compared to individuals with injuries in other regions, as well as to those without any injury. This is an emerging science, but it has already produced a number of provocative findings regarding the role of particular brain structures, as well as the functions (e.g., emotion) governed by those structures, in decision-making.

Consumer Welfare

Consumer psychologists study a number of behaviors with the goal of enhancing consumer welfare. For example, researchers have explored the harm done by the advertising of unhealthy products such as sugar-laden food and smoking materials. Other research discusses how marketing can propagate racial stereotypes or unrealistic standards of female attractiveness. Social marketing research investigates how to persuade consumers to adopt healthy or prosocial behaviors. Finally, researchers have considered the effects of marketing on disadvantaged and at-risk populations. Overall, although the primary focus in consumer psychology is on understanding consumer behavior to facilitate organizational performance, a great deal of attention is also given to facilitating consumers' well-being.

Managerial Applications of Consumer Psychology

Research in consumer psychology is often applied in industrial settings, most typically in marketing. By understanding how consumers form judgments and make decisions regarding products, services, and marketing communications, marketers hope to be better able to offer products that match consumers'

preferences, price and promote products optimally, and offer products to consumers via distribution channels (e.g., retail, online) that best facilitate sales. Consumer psychology has generated an enormous body of knowledge that can enhance organizational performance. Some examples of how consumer psychology has helped marketers to be more effective follow.

'Brand management,' or 'branding,' refers to a set of key decisions that marketers make in the aim of creating a product that meets consumers' needs, including both tangible needs (e.g., food relieves hunger) and intangible needs (e.g., the prestige of owning a luxury car), and that is associated with favorable attitudes and is likely to be purchased. Understanding consumers' motives as well as the social influences on them is essential. Some examples of marketers' considerations when trying to build brands include creating marketing communications and product packaging that conveys an attractive, clear, consistent, meaning that facilitates awareness of the product, and signals what the product does, and why it is different, and better, than competitors. The 'differentiators' can be on a number of dimensions, including quality, reliability, price, and/or image. Consumers choose products that best meet their needs on these dimensions. The relationships consumers have with brands are dynamic, and in many ways approximate human-to-human relationships.

Consumer psychologists know a great deal about why consumers choose particular products, and this knowledge is very useful in making a variety of brand management decisions. One such set of decisions regards creating and managing brand elements, such as brand name, logos, symbols, slogans, and packaging. Marketers' decisions are made in light of the constructs discussed earlier; brand elements should be attention grabbing, memorable, and contribute to brand salience so that the brand receives consideration. Elements should be likable and correspondingly facilitate likeability of the brand, so that strong, favorable, attitudes that guide choice are developed and maintained. Moreover, brand elements should be meaningful, so that brand associations in memory are forged, facilitating consumers' esteem for, and choice likelihood of, the product.

Marketers also have to set strategies regarding marketing communications that facilitate high purchase likelihood of their brands. Ideally, tools, such as advertising, sales promotion, public relations, publicity, and new media (i.e., social networking Web sites), should be integrated so that consumers can easily attend to and process information about the brand, perceive the product in a way that the marketer wants, and hold consistent, strong attitudes toward the brand. An example of a common persuasion tool studied extensively by consumer psychologists is comparative advertising, in which a comparison is made between the advertised brand and one or more competitors. Researchers have shown that such ads may be very effective in persuading consumers because they are very good at garnering attention, but that in some circumstances they may be ineffective or even harmful to the firm that uses them. In general, when making a comparison in an advertisement, it is more persuasive to make a positive comparison (e.g., their brand is good, our brand is better) than a negative comparison (e.g., their brand is poor, our brand is good) because consumers often infer that a negative comparison is biased and unfair. The exception to this rule is that firms that

are well known and trusted can make negative comparisons without provoking an inference of bias from consumers.

Inference research has been invaluable in helping marketers weigh the potential benefits and risks of sales promotion, a commonly used set of tools that offers some extra value to consumers if they make a purchase. Common sales promotions include coupons, rebates, and free gifts if consumers purchase a given product. Although it is unsurprising that offering such sales inducements often lead to increased sales, consumer psychologists have helped marketers understand how promoting a product can erode consumers' evaluations of it. Specifically, because consumers perceive a strong relationship between price and quality, when a product is offered with a price discount, consumers may infer that it is a bad product. Research has shown when such an inferential process is a threat and how to ameliorate the risk (e.g., one strategy is to advertise when one offers a price promotion to bolster brand attitudes).

A ubiquitous problem in managing brands is how and when to offer brand extensions, that is, launch a new product using an existing brand name (e.g., the parent brand). Businesses often favor this strategy because consumers are often more likely to try a new product if it is associated with a brand name that they know and trust. Moreover, consumers perceive the new product in light of the associations that they have with the existing brand in memory, and thus businesses often can spend less on marketing support for a brand extension versus a new product with a new brand name. Consumer psychologists have devoted extensive study to determining influences on two key criteria for the success of a brand extension: whether consumers will purchase the new product in sufficient frequency for the manufacturing firm to turn a profit, and, importantly, what implications the launch of the new product will have for the existing brand. In general, brand extensions are likely to be successful when there is a strong match between the associations that consumers have in memory regarding the parent brand and the associations that will lead to favorable attitudes for products in the category of the proposed extension, and when associations about the parent brand are strong enough to carry over to the brand extension. Launching a brand extension can have harmful consequences for the parent brand when new associations with the parent brand are developed that undermine consumers' attitudes toward the parent brand. Such a process is likely to occur, for example, when a low-quality brand extension shares the name of a high-quality parent brand, even if objective features of the parent brand do not change.

Although brand extensions are a useful strategy for driving profits, new products are firms' lifeblood and the future. Indeed, one of the most vexing problems faced by business managers today is the successful creation and introduction of new products. Despite the vast resources expended by practitioners and an impressive amount of research on new product introductions, the failure rate of new products is still extremely high; it is estimated that between 60% and 90% of all new products fail. Recently, the focus has shifted from refining the process of new product development from the companies' perspective toward understanding the role of consumer psychology with respect to the precursors and motivations to adopt new products. At a global level, consumer researchers

investigate how core psychological theories (i.e., approach/avoidance, regulatory focus, goals) impact how consumers learn about, evaluate, and ultimately, adopt new products. Some of the topics that are currently being investigated include understanding how consumers evaluate the importance of new benefits (and perceptions of learning costs that are associated with obtaining these new benefits), how consumers integrate multiple sources of information to both learn about and evaluate new products, and how the adoption and use of new products act as core elements of consumers' identities.

Many psychological factors come into play when consumers predict how useful new products will be. For example, there are common biases in the estimation of the benefits provided by new products, whereby consumers overweigh the importance of existing benefits that they know well while underappreciating the value of novel benefits with which they are unfamiliar. Consumers' perceptions of the amount of learning required to extract novel benefits have a huge impact on the adoption of new products. Another important question is associated with understanding the role of multiple sources of information (i.e., company sponsored versus consumer recommendations) on adoption intentions for new products. For example, the emergence of the social media has increased the ability of potential consumers to read reviews and engage in conversations with fellow consumers who are early adopters of new products. How these interactions will shape the adoption pattern for new products has yet to be determined. Finally, the role of new product adoption in presenting oneself to others is an important factor in adoption decisions that is not particularly well understood. Although understanding the connections between consumers and brands has been extremely helpful in the branding domain, defining the connections between new products and multiple levels of the self (i.e., actual, ideal) could be a fruitful avenue for incorporating the core principles of consumer psychology toward furthering one's understanding of the adoption of new products.

Glossary

Coping Behavioral, cognitive, and emotional attempts to mitigate or manage stressful or threatening circumstances; the continual process of interpreting and responding to life's demands.

Emotion-focused coping Coping efforts aimed at managing negative feelings related to a stressor with the goal of reducing the impact of those feelings.

Primary appraisal Initial recognition of a potential threat or source of stress and then consideration of its potential negative impact.

Problem-focused coping Coping efforts aimed directly at changing or managing the stressor itself.

Secondary appraisal Evaluation of coping resources and options available to remove the stressor or mitigate its impact.

Stress/stressor Any change (internal or external) to life patterns and habits typically construed as a threat to life or comfort; also, the physical and psychological manifestations resulting from exposure to these threats.

Introduction

All life seeks a sense of constancy or stability, yet the greatest constant in life is change. As changes occur in the human body, the autonomic nervous system works to restore everything to a state of balance, called homeostasis. This process requires no conscious thought or action by the individual to respond to that change. The external world, that is, daily life, also is filled with new situations and changing circumstances that challenge stability, from everyday irritants such as a bad night's sleep or heavy traffic to acute conditions like flu or a disagreement with a loved one, and ongoing strains such as chronic disability or the death of a spouse. Because these changes are a part of the normal course of life, people must fairly consistently monitor and adjust – themselves, the change factor (stressor), or the environment – in order to regain that sense of stability. Thus, the healthy human body may take care of itself internally. What about changes that require adaptation? Do they 'stress us out'?

Endocrinologist Hans Selye introduced the terms stress and stressor while studying the biological responses of rats to external stimuli. He defined stress as any change to an organism that requires or elicits adjustment from that organism in order to return to homeostasis. Selye did not characterize the factor (stressor) triggering the need to adjust as positive or negative, only that it exists and can result from both pleasant and unpleasant events. So, while studies have shown strong associations between negative life events and symptoms of psychological distress, psychiatric disorders, and even mortality, the stressor itself is not necessarily the culprit. Stress is not inherently bad. Rather, it can provide the impetus for people to learn and grow (see *eustress* [eu = good] also coined by Selye in the mid-1970s). Because it opposes simple stagnation in life, a certain degree of stress is healthy for humans. Selye's biological framework was seminal to the field of human coping because he was the first scholar to conclude that a key determinant in the stress–health relationship is neither the type (good/bad) nor level (a little/a lot) of the stressor itself, but how one reacts to, that is, copes with, that stressor.

Coping is the ongoing behavioral, cognitive, and emotional processes people use to manage those life circumstances that threaten feelings of stability. Coping can also occur proactively in order to limit the threat to future homeostasis. Its goal is to avoid, minimize, master, or manage life's situations in such a way as to decrease any potential negative impact or outcome. In the social sciences, the study of stress and coping encompasses many factors that relate to life changes and how people manage those changes, so scholarly discourse on these topics is both immense and diverse. The goal of this article is to provide a general overview of coping in psychosocial research. First, two historically predominant theoretical frames – coping as a personality disposition and coping as a person–situation process – are reviewed and the current direction of these perspectives is summarized. Next, major coping strategies and coping resources are listed, and finally, a few additional factors that influence the coping process are offered. The material herein relates to adult coping and does not include issues specific to children and chronic psychopathology. It is our hope that this brief discussion will provide readers with general information about the coping literature (i.e., research), as well as help them gain an understanding of their own coping processes.

Theories of Coping

Numerous terms and expressions have been used to convey scholars' beliefs about the origin, or basis, of coping. Nearly all of these conceptualizations can be viewed within a theoretical framework of coping as either part of one's personality, an active process, or most recently, the combination of these two. The following are some main points from each of these theoretical perspectives.

The Personality Framework

The foundation for coping as a part of personality began with the work of Sigmund Freud. According to early psychodynamic/psychoanalytic theory, conflicts between the id and superego create anxiety, and the ego responds by employing

defense mechanisms to repress these negative feelings. Though additions have been made to this list over time, the original Freudian defense mechanisms are denial (refuse to believe despite evidence to the contrary), displacement (act out on someone else rather than the actual target), intellectualization (pay little attention to emotions), projection (place own negative thoughts or feelings on another), rationalization (replace the real reason with a logical one), reaction formation (believe/feel the opposite of the real, unwanted belief/feeling), regression (return to a child-like state/behavior), repression (keep the unwanted in the unconscious), sublimation (act out unacceptable impulses in a socially acceptable way), and suppression (try to put the unwanted into the unconscious).

Though it remained popular for many years, Freud's view of coping was sharply criticized for defining all defense mechanisms as existing completely within the unconscious and as pathological in nature. Personality was considered to be inflexible and driven solely by sexual or aggressive urges of the id. Other scholars defined defense mechanisms in a less negative fashion and held that personality formed the basis for coping in both the conscious and the unconscious. Instead of being pathological in nature, coping and the desire for control are seen as normal, and indeed, healthy, functioning. As part of the individual's conscious world, this frame for coping relates personality to the likelihood of exposure to certain types or numbers of stressful events (e.g., choosing to become a firefighter or emergency room physician), perception and interpretation of the stressor (e.g., an unwanted threat or exciting challenge), responses to the stressor (e.g., learn more about the situation, pray, make a plan), and the availability of resources (e.g., a strong group of friends, sufficient income, health). This definition of coping as being more than an unconscious course of action undeniably advanced our knowledge of coping and personality. Early research on personality, however, was hindered by a lack of consensus on descriptors and other research procedures, which made it difficult for scholars to share results, duplicate one another's work, and establish verifiable results.

To address this issue, researchers systematically created a list of five specific personality traits. Called the Big Five and sometimes known by the acronym OCEAN, those traits are openness to experience, conscientiousness, extraversion, agreeableness, and neuroticism (alternately called emotional stability for its opposing trait on the continuum). Popular among researchers, the Big Five framework provides the solid, common foundation necessary to properly explore relationships between personality and coping. Studies indicate that people are relatively consistent in their choice of coping responses across different situations, and traits are related to the types of coping strategies an individual is likely to use, as well as the order in which the person will try given strategies. The most frequently studied trait has been neuroticism. People high in neuroticism tend to interpret common situations as threatening, emphasize the negative features of a situation (i.e., negative processing bias), and are more likely to recall stimuli associated with failure. Neuroticism also is related to the less effective, passive, or possibly harmful ways of coping: denial, wishful thinking, self-blame, avoidance, hostility, distancing, and distraction. In contrast, extraversion, conscientiousness, agreeableness, and openness to experience are related to more positive appraisals of potentially threatening situations,

interpreting negative events as a challenge, and emphasizing the positive aspects of a situation (i.e., positive processing bias). Extraversion predicts low use of avoidance, denial, or disengagement from goals. Conscientiousness is related to planning and seeking help. Conscientiousness and agreeableness are related to lower substance abuse, and openness to experience is related to planful problem-solving.

Although the Big Five personality traits have received a great deal of scholarly attention, much of the research has examined the associations between a single trait, a particular outcome (e.g., substance abuse, depression), and coping responses. However, individuals possess a combination of these five traits, which may interact to influence the types of experiences they select for themselves and how they respond to the potential stress associated with these experiences. For example, a person who is high in extraversion and neuroticism but low in conscientiousness may be impulsive, pleasure seeking, and have low control over his/her emotions, which may lead to quitting his/her job impulsively. This decision may lead to great stress if another job cannot be found. In addition, these same traits that led to the stress of job loss may also influence subsequent coping strategies selected. In this case, this combination of traits may lead the individual to seek out an entirely new field of employment.

Coping as a Process

The post-World War II social and academic zeitgeist of the 1950s and 1960s saw a shift in focus away from behaviorism, views that reduce human motivation to expectations about rewards and punishments, and toward Richard Lazarus' transactional theory of coping with stress. Lazarus's process model of coping emphasizes an active interplay between the individual and the environment, and accentuates the role of the person's cognitive appraisal of a given stressor and how best to act upon that stressor.

Lazarus' transactional theory is a cyclical process of appraisal and feedback, and the way a person copes with a stressor is largely determined by the meaning that the person attributes to the event in his/her life. Primary appraisal occurs when the individual senses a change in the environment (stress), then determines whether this change is good, has no impact, or poses some sort of threat. If the change is perceived as good or neutral, the process ends. If the change is perceived to be a threat, then secondary appraisal occurs. During secondary appraisal, the individual takes an inventory of available resources (types and amounts), assesses possible courses of action and constraints to these actions, and determines what may provide the greatest likelihood of managing or mitigating the situation. These appraisals result in the use of certain strategies to address (i.e., cope with) the given stressor. Feedback from the evolving situation then triggers a reappraisal of the stressor and available resources. The individual adjusts behaviors, cognitions, and emotions as necessary, and if the situation resolves, the cycle ends. If the situation continues, the cycle repeats. Note that the coping process may involve the individual focusing on (and perhaps adapting) himself or herself, the external environment, or a combination of the two.

Process theory classifies the various behavioral, cognitive, and emotional strategies people use. Lazarus and Susan Folkman

categorized coping strategies as either problem-focused or emotion-focused. Problem-focused coping strategies seek to reduce stress by dealing directly with the stressor to decrease its impact. These strategies tend to be action-oriented with the goal of eliminating or changing the stressor. For example, a woman who lacks reliable transportation to her job can directly resolve her situation by replacing her old car. Problem-focused coping also may involve changing oneself in relation to the stressor, such as a hiker moving to the other side of a trail to avoid a snake while on a nature walk. In comparison, the goal of emotion-focused coping is to reduce the impact of distressing feelings. This method is more effective than problem-focused coping for circumstances over which the individual has no control, such as a severely disabling condition or death of a loved one. It also often occurs when problem-focused coping fails to resolve the situation or when the stressor is so great that problem-focused coping has no real likelihood of helping. For example, a soldier who loses two buddies in an attack cannot control this reality, but he may tell funny stories about his friends to decrease feelings of grief. Emotion-focused coping need not be linked to the specific event. The grieving soldier may increase his workouts to counteract the negative effects of his war experiences, of which death is only one part.

A third category for coping strategies is known as meaning-focused coping, wherein people attempt to understand their stressful experiences in a broader context. Also called cognitive reframing, meaning-focused coping helps people align negative experiences with their belief systems (spiritual or otherwise) or worldviews, attempting to make sense of the stressor by finding a purpose or something good from it. An excellent example is the young woman dying of breast cancer who made her sister promise to educate others about the disease. That promise became Susan G. Komen for the Cure, the world's largest charity for breast cancer that has raised \$1.5 billion since its inception in 1982. Meaning-focused coping is linked primarily to traumatic events; the ability to find meaning in negative events is associated with more positive mental and physical health outcomes. Finding meaning may be a catalyst not only for decreasing distress levels but can also result in cognitive and emotional growth (see, e.g., Richard Tedeschi and Lawrence Calhoun's concept of posttraumatic growth). At the same time, not every person who searches for meaning in a traumatic event is able to make sense of that event in such a way as to make it meaningful. Some events may be perceived as so contrary to one's normal experience that they challenge strong beliefs about the way the world is supposed to be. Events that are uncontrollable, sudden, and violent, such as a random homicide, can have these qualities, as can rape or the sudden death of an infant. These types of events are often perceived as gravely unfair, and the attempt to find meaning without being able to do so has been found to be a stressor in itself.

Current Directions in Coping Theory

In the last decade, powerful statistical software programs have made possible the rapid analyses of very complex sets of data. Similarly, the full-text availability of the majority of coping research (both historic and current) via the World Wide Web has enabled scholars to integrate this information and test

theories in a manner that previously was quite difficult. Current research shows that the situation (e.g., being a single parent, a medical diagnosis), individual differences (e.g., extravert or introvert, life experiences), and environmental factors (e.g., physical safety, cultural standards) are all associated with a person's coping response. Thus, the current refinement of coping theory focuses on the integration of these factors, as well as determining whether certain combinations predict certain coping responses or outcomes.

Coping Strategies

Coping strategies are as numerous and varied as the stressors that precede them. From Folkman and Lazarus' *Ways of Coping Questionnaire* and Charles Carver and colleagues' *Coping Orientation of Problem Experience* (COPE), some common strategies or categories for coping responses are accepting the situation or one's role in it, active/confrontive coping to remove the stressor or oneself from the stressor, anticipatory coping aimed toward an expected but uncontrollable event, avoiding/escaping the stressor or associated feelings of distress, denying the problem or feelings, disengaging mentally or behaviorally (giving up), distancing/detaching from the situation or minimizing its significance, planning the steps to solve the problem, reinterpreting the stressor as a positive or growth-oriented experience, seeking social support (discussed later), controlling one's emotions or waiting for an appropriate time to act, using substances to dull feelings, suppressing competing activities until the problem subsides, turning to religion, using humor, and venting emotions.

Individuals also engage in proactive coping. These future- and action-oriented behaviors can prepare a person not only for specific stressors, but also for those that are likely to arise in the normal course of life. Proactive coping includes building and strengthening all resources (e.g., from practical and academic knowledge, experiences, and sufficient numbers and varied kinds of social contacts; see also direct effects hypothesis of social support). As well, proactive coping involves gaining skills and abilities to assess the changing environment more accurately, from signs of a possible stressor, to appropriate strategies and resource use, to feedback on a given situation. Though it is impossible to make causal claims, future-oriented coping tends to be associated with positive outcomes such as goal achievement and lower levels of distress. However, too great an emphasis on the future may be a sign of hypervigilance, which has been linked to negative outcomes such as anxiety and poor information processing.

As with the other components of coping, research classifies strategies by type, such as problem-focused coping or emotion-focused coping. One needs to bear in mind, however, that people's thoughts, feelings, and behaviors seldom fit into black-or-white categories such as those required for quantitative analytics. For example, a man responds to being laid off by networking with friends to learn of other job opportunities. Networking is active coping and planning, both of which are problem-focused. Networking with friends, however, likely adds the benefit of support from others to decrease his anxiety, which is emotion-focused. This illustration also shows that often the best method of coping is a combination of problem-focused and emotion-focused strategies. Whether it is a single strategy or

a few enacted together, this approach can both reduce the impact of the stressor and the negative emotions it may evoke. Yet, there is no one universal coping strategy that will be effective in all situations. Coping strategies that lessen distress in one situation may be ineffective or even detrimental to the individual in another.

Similarly, one must keep in mind that strict labeling of most strategies and other coping behaviors can result in erroneous interpretations. This is especially true when attempting to categorize responses as effective or ineffective. Seldom is a coping response all good or all bad, and one must well consider the many specifics of the situation and the goals of the individual prior to drawing firm conclusions. For example, considering the time frame during which the strategy is employed (e.g., the duration of the stressor) may be helpful in assessing its efficacy. Denial or substance use (not to be mistaken with abuse or use of illicit drugs) may be adaptive in the immediate aftermath of a traumatic event. However, these strategies rapidly deteriorate as wise choices for coping over time and should be replaced with responses that are more appropriate as time progresses. So, when the laid-off man goes home, he may have a few beers to wash down his sorrows, but continuing this behavior would no doubt exacerbate the problem.

Coping Resources

During secondary appraisal, people identify the types and amounts of resources they can call upon to help manage the stressor or buffer the intensity of their feelings. The presence and absence of resources directly influences the appraisal process because coping strategies may require specific resources in order to be an available option or for particular behaviors to be effective. This is true for both internal resources (e.g., self-esteem, knowledge, health) and external resources (e.g., money, friendships, shelter). Coping resources may be tangible or intangible, and the perceived value (intrinsic/extrinsic) of a given resource can be highly variable depending on the individual, the specific situation, and even the timing of the situation. For example, rapid access to a hospital may be essential immediately after an injury. During recovery, though, the need for emergency care declines while the value of a loved one's presence may increase. The more and varied types of coping resources a person has, the greater the likelihood of coping success. As well, those who lack resources or who are unskilled at identifying or using them are at greater risk for psychological distress and mental illness. Stevan Hobfoll suggests that it is the threat to one's resources, whether material goods or personal relationships, that is the major source of stress in the environment.

Like coping strategies, coping resources have been categorized in the literature. Some are appropriate for problem-focused coping, others are emotional-focused or meaning-focused, and like coping strategies, some can address more than one area. Scholars often use the terms resource and support interchangeably, for example, material support.

Material Resources

Many stressors can effectively be addressed or eliminated, often proactively, with material resources. Material resources typically are tangible, such as a house, vehicle, clothing, a computer, and

other items used in daily life. In modern society, however, the key material resource is money. Sufficient and consistent access to money and its equivalents helps individuals cope in a manner that no other material resource or coping strategy can match. An adequate supply of funds can provide proper shelter, healthy and sufficient food, medical care, and countless other goods and services that both proactively and concurrently address the stresses and strains that result when a person lacks necessities. Socioecological interpretations of deviation amplification illustrate the impact of money across multiple aspects of life. Studies clearly show that those with less money experience a disproportionately high level of exposure to stressors. Some of these consequences are generally apparent, such as the lack of adequate food, shelter, or medical care (preventive or otherwise). Other circumstances are less obvious, however, such as the positive relationship between poverty and living or working around environmental toxins.

Social Support

Research conducted over the last few decades has clearly demonstrated the importance of family and close others in times of stress. Meta-analyses indicate that the influence of social relationships on morbidity and mortality is equal to well-established risk factors such as smoking and obesity. Early humans evolved as social creatures, quickly recognizing the value of pooling resources to cope with harsh environmental demands. Hunter-gatherer societies were more successful when multiple hunters were available to secure food and ward off predators, and multiple females more easily tended to the needs of any offspring. Today, engaging one's social network during stressful times is recognized as one of the most productive coping strategies. Indeed, social support has been shown to be beneficial whether or not one is experiencing increased stress. Support from others can take many forms, including instrumental support (e.g., providing groceries or a ride to work), informational support (e.g., providing information about an illness), and emotional support (e.g., providing comfort and listening). Having the opportunity to talk about an emotional trauma – when one desires to do so – is associated with better health. Even the simple knowledge that family, friends, and others (e.g., counselors, clergy) are available when needed can buffer the physical and psychological effects of stress. Though the mechanisms by which social support works as a defense against the negative effects of stress continue to be examined, research consistently finds that individuals who have a supportive network are better able to cope with stress, and receiving effective social support plays a role in influencing health and well-being.

Whereas a growing body of work describes these significant benefits, a broad conclusion that all social interactions are good for coping would be incorrect. The presence of others is not always a resource for support and may sometimes be its own stressor. Seminal work by Karen Rook and others indicates that not all social interactions are perceived as helpful, and some may even lead to unintended negative outcomes that can be more impactful on the individual than positive outcomes. For instance, outsiders may have specific expectations about the process or coping behaviors that should occur in response to a stressor. A failure to show an expected level of

distress (e.g., length of time to grieve the death of a child), or not engaging in the expected behaviors, may lead others to believe that they are seeing signs of pathology. A loved one's advice may feel more judgmental than assistive, or too many visitors may exhaust a sick person and prolong the recovery period. Sometimes the level of support that is expected does not materialize, or providers offer well-intentioned but ultimately unhelpful comments that minimize the trauma or seem rejecting and alienating. Researchers have found that for social support to be effective, it must be matched both with the environmental demands triggering the distress and the specific needs of the distressed person.

Religiousness/Spirituality

Many people report a belief in God, though constructions of God and worship vary greatly, even within a single country. The study of Western religious philosophies and practices shows that religion serves two principal functions in coping. First, the act of believing in a higher power is associated with individuals finding both emotional comfort and personal meaning from painful events. This is especially true for situations involving loss and over which one has no control. For example, a belief in God may provide comfort upon the death of a loved one, such as through an image of heaven as beautiful, joyful, and believing that the loved one is waiting there for reunion. Similarly, belief in a higher power may help some individuals construct meaning for events that are dissonant to a worldview of justice and fairness. Second, regular attendance at religious services can provide or enhance an individual's social support network. Having others who share the same beliefs can also be comforting during difficult life periods. In this same manner, other religious behaviors, such as being involved in prayer groups or attending church-related functions, can support strategies such as positive reframing, and are negatively associated with typically less effective coping strategies. Religion as a deterrent to alcohol and drug abuse specifically is apparently achieved via two mechanisms. The first is a person's behavioral adherence to the belief held by most religions that the human body should not be misused (e.g., drinking to excess, drug abuse). The second deterrent relates to the person's focus of time and attention on healthy, positive social activities (e.g., a church's softball team) and away from possible negative influences.

Some Additional Factors

In addition to personality, other characteristics have been shown to influence the coping process. One such characteristic is gender. Human subjects research historically focused on the male gender, and conclusions from these studies (e.g., health and physiology) were assumed to apply equally to females. An example specific to stress and coping is Walter B. Cannon's proverbial fight-or-flight response, wherein a threat or challenge initiates a rapid sequence of neuroendocrine events to prepare the individual for maximum effort against danger. While fight-or-flight is a universal physiologic response, Cannon's model did not address the actualities that neither fight nor flight is a reasonable behavioral choice for females, especially when they are

tasked with protecting offspring. More recent studies show distinctively different hormonal responses in females. In particular, lower levels of testosterone and higher levels of oxytocin trigger females' behavioral responses to tend-and-befriend, as coined by Shelley Taylor and colleagues. Tending to the young and befriending others for mutual support offer females the greatest likelihood of success in coping with any threat, whether real or potential. Also to that end, neural (brain) differences in females better enable the development and maintenance of social networks, such as the ability to read body language more accurately and greater verbal skills relative to males. On the other hand, females are more likely to appraise situations in a negative light and tend to rely less on problem-focused strategies than their male counterparts. These differences are a few examples of how gender plays a role in the coping process.

Age is another characteristic that influences coping. Studies have revealed an interesting juxtaposition of generally age-related losses and gains that older adults have learned to manipulate to best maintain a sense of control. For example, older adults are less likely to engage in the active, problem-focused coping strategies; however, they are more likely to have a well-established social network on whom to call for assistance. Older people frequently face losses that hold greater significance than those faced by younger people, from personal independence to the deaths of loved ones and one's own declining health. At the same time, age is related to more positive appraisals of situations, as well as a philosophical acceptance of uncontrollable circumstances. Often related to age, a person's level of experience – both in life in general and with specific or similar events – can influence appraisals. Individuals may experience the same types of stressors several times over the life course. Whereas a novel experience requires a certain amount of energy and resources, repetition of the same or similar situations may be related to feelings of comfort and decreased stress, especially when one has gained wisdom and mastery over the stressor the first time around.

In addition to enduring characteristics such as gender and age range, temporal states, such as a person's mood, are associated with coping with stress. Appraisals of potentially stressful situations can be influenced by mood to the extent that the appraisal is, or becomes, consistent with the current mood state. For example, someone feeling happy may evaluate negative news in a more positive frame, or may pay less attention to signs of a potential threat. Conversely, sadness (and in the longer term, depression) is associated with greater sensitivity to change and people in negative emotional states tend to appraise neutral situations as more stressful or threatening than might be appropriate.

Conclusion

An integral factor in life, stress clearly is unavoidable. Stress, though, is not inherently bad or negative, and may serve as an impetus for personal growth. Of importance to human adaptation and health, then, is understanding the coping process as a whole, as opposed to focusing simply on the stressful circumstance. Two major theoretical perspectives were presented in this article: coping as a function of personality and

coping as a process. Research has demonstrated that both individual characteristics and the person–situation process significantly contribute, individually and in interaction with each other, to how a person adapts to change. Features of the personality influence the coping process by influencing appraisals, strategies, and resources. For nearly all of life's stressful circumstances, the most successful coping responses typically include both problem-focused and emotion-focused strategies. Together, these strategies provide a multifaceted response to stressors, which often tend to be multifaceted themselves. Aside from money, perhaps the most important external resource for coping is social support, which has been shown to decrease the negative effects of stress both from specific causes and in life in general. In the next few years, the field of coping will continue to discover and verify those factors in the individual, in resources, and in the characteristics of the stressor itself that predict better coping outcomes. This information, in turn, will help guide more effective programs or treatment for individuals who may be struggling to cope with a significant trauma or negative event.

Creative and Imaginative Thinking

M A Runco, University of Georgia, Athens, GA, USA

© 2012 Elsevier Inc. All rights reserved.

Glossary

Convergent thinking Cognition that follows conventional pathways and is useful for finding correct answers to closed-ended problems and tasks.

Divergent thinking Cognition that goes in varied and unconventional directions and often leads to original ideas and remote associations.

Meta-cognition Tactical and controlled thinking; thinking about thinking that often contributes to effective creative problem solving.

Primary process Libidinal thought process, characteristic of the unconscious and uncensored by convention and mores.

Secondary process Reality-oriented thought that takes conventions into account.

Stage models Theories of creative cognition that break the processes down into phases or steps.

Introduction

Creative and imaginative thinking are related to one another but far from redundant. This article defines each of them and highlights exactly how they are related to but separate from one another. The emphasis here is on *thinking*, which means that the most relevant theories and research are found in the cognitive sciences. Still, definitions of creative and imaginative thinking are far from homogeneous; they are in fact notably diverse. Some of this is due to the fact that creative thinking often varies from domain to domain. The obvious example of this is that it can be more experiential and logical (in a traditional sense) in mathematics and the sciences and more intuitive and subjective in music and the arts.

Diversity is also indicated by the cognitive and extracognitive processes which have been associated with creative and imaginative thinking. Creative thinking is sometimes intentional, deliberate, tactical, and consciously controlled, but other times it is unintentional, unconscious, and seemingly chaotic. This article touches on each of these possibilities and reviews the range of perspectives on creative and imaginative thinking.

Defining Creativity and Imagination

Although there are variations among the domains in which creativity can be expressed, there is one commonality. Indeed, all definitions of creativity emphasize originality. Creative ideas and products must be original; if originality is lacking, there is no creativity. Most accurately put, originality is necessary but not sufficient for creativity. It is required, but there is always more than mere originality. Things which are merely original but not effective or somehow fitting are not creative. They may in fact be bizarre and useless, odd, weird, or even unrealistic to the point of psychosis. Psychotic individuals can be quite original due to their loose contact with shared reality; but this kind of originality does not constitute creativity since it is merely original and not effective.

Thus, there are two requirements for creativity: originality and effectiveness. The former is often operationalized in terms

of novelty or statistical infrequency. In other words, original things are unique or at least highly unusual. They are unconventional in a literal sense. The second requirement is more difficult because effectiveness can be objective, as in the case when an original idea solves a problem in a manner that is widely appreciated, or it can be fairly subjective, as is the case when one individual sees the esthetic appeal of an idea or work of art, but others do not see the same thing. A painting may convey meaning very effectively to some people, but not to others. Much the same can be said about all kinds of creative things; their effectiveness and appropriateness is often fairly subjective.

These two features of creativity go a long way toward distinguishing it from imagination. That is because imagination is that which allows an individual to explore ideas and options that are outside the boundaries of the objective world. It has been well described as *the capacity to transcend reality*. This can be very useful for creative thinking. Hence, the overlap of creativity and imagination. More specifically, the capacity to transcend reality can be used to find or invent original ideas or perspectives. These may be ineffective, precisely because they are not constrained by reality. That is how creativity and imagination differ. The former requires originality *and* effectiveness.

There is also a strand of research that defines creativity such that it always leads to a product of some sort (e.g., an invention, a work of art, a publication, or perhaps even just an idea), which makes some sense if you think about the word *create* (to bring something into existence). If this product perspective is held, another distinction is suggested: imagination differs from creativity in that it may not lead to a product. Imagination may only allow the transcendence of reality and not result in a product.

Stage Theories

The bipartite nature of creative thinking (originality and effectiveness) may explain why many theories of creative thinking look to stages or components. Simplifying, stage models usually allocate one or more stages specifically to the finding of

original ideas, and then later stages to their refinement or verification as effective.

Wallas presented a four-stage model of creative thinking that is still widely cited. It describes creative thinking as beginning with *preparation*, then moving to *incubation*, *illumination*, and finally *verification*. These four stages are also recognized in more recent theories of creative thinking, though the labels sometimes change.

Preparation is a surprisingly important part of the process. That may be implied by the fact that preparation assumes that experience is useful. After all, if preparation is influential, creativity can be enhanced by the right kind of experiences. Preparation actually takes many forms, depending on the level and domain of creativity. Preparation may involve learning and the collection of resources. This kind of preparation can eventually lead to *expertise*; and the highest levels of creativity (e.g., paradigm shifts) require expertise. Certainly expertise sometimes makes it difficult to think creatively, as is the case when it leads to routine and assumption. Both of these make information processing faster but also can keep the individual from seeing original ideas. Expertise is sometimes helpful for creative thinking, and sometimes detrimental.

Another kind of preparation involves the task or problem rather than the individual. Sometimes the task must be identified and defined such that creative solutions can be applied to it. This kind of preparation fits under the label *problem finding*, the idea being that problems must be found before they can be solved. Empirical work has confirmed that problem finding skills can be reliably assessed and are relatively independent of the skills used for problem *solving*. Problem finding and problem solving can work together, which is probably the ideal, but some people seem to be better at one than the other. What may be most important is the implication that creative thinking is not synonymous with problem solving. It is not just a special case of problem solving. After all, if creative thinking is related to problem finding, it can occur before (and independently of) problem *solving*.

There are other lines of thought that also support a separation of creative thinking from problem solving. Creative thinking may, for example, occur when there is no problem, as is the case when someone is proactively creative. Solutions to problems tend to be reactions to problems, so proactive efforts are independent of problem solving, at least in the sense that they precede and may not be dependent on it. Creativity which is playful or self-expressive rather than an attempt to solve a problem also support the distinctiveness of creativity from problem solving.

E. Paul Torrance and J. P. Guilford, two of the most influential scholars in this field, emphasized that problem finding plays a central role in creative activity. Torrance, for example, included problem *sensitivity* in his definition of creativity. For Guilford, problem finding was targeted in 'Seeing Problems.' This is a psychometric task that begins by informing an examinee, "In each problem of this test you will be given the name of a common object. You are to state problems that occur to you as you think about the object. You do not have to think about any solutions to the problems" (Merrifield and Guilford, 1969: 1). The object given as an illustration to examinees is 'Candle,' with examples such as how to light it, keeping it from falling over, keeping it burning steadily, how long it will burn, and what to do

with the drippings. The actual test includes tree, hammer, wind, envelope, rug, and sun as the objects for 'seeing problems.'

Guilford is well known for distinguishing *divergent thinking* from *convergent thinking*. The former allows ideation to move in different and potentially original directions. The latter characterized ideation moving toward the correct or conventional, and therefore unoriginal, solutions.

Mumford et al. presented a detailed stage model of creative thinking. They identified stages after an extensive review of the literature on creativity. The stages in their model are:

problem definition,
information gathering,
information organization,
conceptual combination,
idea generation,
idea evaluation,
implementation planning, and
solution appraisal.

Runco and Chand presented a stage model that included problem finding as the starting point. This is a unique model in that it acknowledges the impact of both motivation and knowledge. The two of these are on one tier of the model, with (1) problem finding, (2) ideation, and (3) evaluation and valuation on the primary tier. This model acknowledges that cognition does not work on its own. Many cognitive operations are only initiated if there is a reason to do so. These may be extrinsic or intrinsic. Similarly, knowledge can play a role, and it can be either conceptual, factual, and declarative, or procedural. The last of these is especially important for creativity that is intentional and tactical. Indeed, procedural knowledge often provides exactly that – a procedure for finding original ideas (e.g., 'change your perspective on the problem') or know-how.

A great deal of research has focused on one stage or another. Many influences on creative thinking, for example, may only have impact on one stage. Findings suggest that the impact of expected evaluation varies from stage to stage, which is interesting because evaluation is thought to undermine the intrinsic motivation which supports creativity. A second line of studies suggests that the relationship of mood and creative performance also varies from stage to stage. This is a significant finding because, too often, the impact of mood is presumed to apply across the board, but in fact elation or depression (and presumably the moods in between) may hinder or facilitate creative work, depending on the stage in which the individual is working. Just to name one example, it appears that creative thinking may suffer from elation or even mild happiness if this occurs specifically during the evaluation stage of the creative process. The elated individual may be happy about everything and his or her 'rose colored glasses' therefore preclude a detailed, careful examination of options. That individual may tend toward *satisficing*, which occurs during problem solving when one of the first options is accepted, and consideration of other alternatives terminated.

One of the newer models is called *geneplore* because it describes an interplay of generation ('gen') and exploration ('plore'). According to its authors, Ronald Finke, Thomas Ward, and Steve Smith, creative thinking occurs when the individual first generates a *preinventive form*. This is an unconstrained but ambiguous cognitive structure. It is subsequently

extended, elaborated, and evaluated during the exploratory stage of the process. Finke et al. reported impressive support for this model in their empirical work.

Uncontrolled Cognition and Creative Syntheses

The genealogy model is intriguing in part because it assumes that thinking is not entirely controlled, intentional, and directed. This is a very important idea for creative thinking because originality may result precisely from phases of the process which allow uncontrolled ideation. Recall here that Graham Wallas' stage model included incubation. This is by definition a time when the individual is either not thinking about the problem at hand, or, more likely, is working on the problem but not on a conscious and directed level. The illumination included in that same model (also known as the moment of insight or 'ah ha') occurs when the uncontrolled cognition hits something worthwhile and it is brought back to the level of consciousness.

The attractive alternative is that creative thinking reflects a synthesis of controlled and uncontrolled thought, a blend of conscious and unconscious, primary (libidinal, uncensored) and secondary (reality-oriented, censored) thought. This would allow the range of possibilities and motivations of the uncensored mind to work along with the direction, discipline, knowledge, and critical acumen of the logical mind. This seems to be what Arieti described as the *magic synthesis*, an idea later used by Klaus Hoppe to describe why commissurotomy ('split brain') patients have difficulty thinking in a creative fashion. They are unable to synthesize a freedom of thought with directed cognition.

Another kind of creative synthesis occurs on the level of individual ideas or solutions. Arthur Koestler described how different ideas can come together in what he called the *bisociative* process. More recently, Albert Rothenberg demonstrated how creative thinking may benefit from either *Janusian* or *homospatial thinking*. Janusian thinking was named after Janus, the Roman God of doorways; he could look in two directions at once. As is implied by the name, homospatial thinking allows an individual to bring two images together, in the mind's eye, to form a meaningful whole. Rothenberg identified a number of well-known discoveries and insights which could easily have depended on Janusian and homospatial thinking. The Heisenberg Uncertainty Principle, for example, recognizes that the speed and location of a particle cannot be known at the same time, while Existential Philosophy recognizes both the infinite and also the absurdity of mortality. Chaos theory also brings opposites together into 'an orderly disorder' (Glieck, 1987: 15). Most important may be the experimental support presented by Rothenberg demonstrating that many individuals do in fact produce creative ideas, solutions, and images when the synthesis of inputs is experimentally facilitated.

Extra- and Meta-Cognitive Processes

There are, then, a number of ways that creative and imaginative thinking may benefit from undirected, uncensored, uncontrolled thinking. There is at least as much evidence that creative

and imaginative thinking can benefit from controlled, directed, and deliberate processes. This makes a great deal of sense given the observation that high-level creative accomplishment requires work and effort. It can be work and depend on effort. This again is a reminder of the role of motivation. In fact, there are several extracognitive influences on creative performance. For this reason many studies of creativity examine personality and attitude. One view is that the cognitive capacity is by itself not sufficient but must be energized and maintained, which means that the person is motivated to invest the time and effort into thinking in a creative or imaginative fashion. Yet again there is a difference between creativity and imagination. The former is more easily tied to effort, perhaps because it is not enough to have an original idea. That idea must also be effective, and verifying or refining the idea may require the motivation. Imaging alternative realities or experiences, on the other hand, may require less verification and refinement. For the same reason it is easy to see the imaginative worlds and friends of children, even though they do not invest time into preparation, verification, and refinement.

For similar reasons it is clear that creative thinking can benefit from intentionally used tactics and strategies. Many of these have been reported in the literature, including 'work backward,' 'shift your perspective,' 'take time away from the task,' 'turn the situation on its head,' and 'break a large problem down into small ones.' Such tactics and strategies for creative thought are meta-cognitive in that they are intentional. The individual is thinking about and trying to guide his or her own thought. Many programs have been developed to best communicate tactics to persons interested in creative thinking and to allow practice with them. In fact, many organizations do much the same and bring facilitators in for training in creative thinking and practice with tactics. Organizations tend to be more interested in creativity than imagination, probably because the former is clearly connected with effectiveness, and businesses require effective originality. They often see the role of creative thinking in innovation. One view is that innovation is a result of creative thinking. Innovation does seem to require the same two things, originality and effectiveness, though it may be that there is more emphasis on the latter in innovation as compared to creativity.

Conclusions

Although stage theories of creative and imaginative thinking are common, care must be taken not to delineate them into entirely discrete stages, phases, or components. It is a bit like the trade-off of laboratory versus naturalistic research; with each there is a benefit but also a cost. Laboratory research offers control, but application to the natural environment is lost. Similarly, discrete stages may make the process more manageable and testable, but in reality creativity probably depends on a spontaneous flow among stages. No doubt there is recursion rather than a simple step-by-step progression toward a creative insight.

Recall also that cognitive processes do not operate in isolation. There are extra- and meta-cognitive influences. Motivation and affect can be quite influential. This is probably true in a general sense in that some of the directed and intentional

tactics for creative thinking will not be used unless the individual is motivated to expend the necessary effort. It is also true in more specific and idiosyncratic ways, such as when certain affective disorders provide troubled individuals with advantages for creative thinking.

This article suggested that creative and imaginative thinking may differ in that the former depends more heavily on effective thinking. This in turn explains why there are developmental differences (children having less reason to be effective, often think in an imaginative way as part of their play) and why creativity is more often targeted by organizations. They need to be effectively original, not just original, in order to adapt to market changes and to perform in an innovative fashion.

It will be interesting as neurophysiological technologies advance to see if the brain is structured such that there is in fact both overlap and distinctiveness between creativity and imagination.

Creativity

V Drago, IRCCS Centro San Giovanni di Dio Fatebenefratelli, Brescia, Italy

K M Heilman, University of Florida, Gainesville, FL, USA

Published by Elsevier Inc.

Glossary

Convergent thinking Analytical, usually deductive, thinking in which ideas are examined for their logical validity or in which a set of rules is followed.

Depression A psychiatric disorder characterized by an inability to concentrate, insomnia, loss of appetite, anhedonia, feelings of extreme sadness, guilt, helplessness and hopelessness, and thoughts of death.

Divergent thinking Thinking in an unusual way, for example, to generate several possible solutions to a problem.

Dopamine A monoamine neurotransmitter formed in the brain by the decarboxylation of dopa and essential to the normal functioning of the central nervous system.

Norepinephrine A hormone and neurotransmitter, secreted by the adrenal medulla and the nerve endings of the sympathetic nervous system to cause vasoconstriction and increases in heart rate, blood pressure, and the sugar level of the blood. Also called noradrenaline.

Definitions of Creativity

The construct of creativity has received a great deal of interest from a variety of disciplines such as psychology and neuroscience, but often there is not much coherence in the findings across these disciplines. The reason for these inconsistent findings may partially be due to the fact that creativity is a very complex mental process and thus difficult to study. Different researchers have not only defined creativity in different ways but have also approached the study of creativity using different paradigms and have provided different explanations for the mechanisms that might underlie creative thinking.

Investigators and experts who judge creativity have not even come to a consensus about the definition of creativity. When a person states that something is a creative product or someone is a creative person, what does that mean? Webster's II University Dictionary (1988) provides several definitions of creativity: having the power or ability to create, productive, marked by originality, new. While these definitions do contain elements of creativity, they are, however, incomplete. For example, there are many individuals who are musicians, artists, writers, and scientists who are very productive without being creative. A person can have technical expertise, work hard, and be productive but his or her work might not be new or original. Novelty alone does not make a creative product. For instance, a list of nonwords and/or colors randomly applied to a canvas may be novel or original but is not creative.

Another definition of creativity that is widely used in research is that of Bronowski: *Creativity is finding unity in what appears to be diversity*. Great art works have many colors, forms, as well as textures and great musical works have a large variety of melodies and rhythms, but creative artists and composers are able to develop a thread that unifies diverse elements and display order. Although this definition focuses on the crucial importance of a 'global approach' within the construct of creative thinking, it is lacking in concepts such as originality (novelty) as well as productivity and these concepts are considered to be essential to the creative process. The concept of novelty includes two aspects that may be separated: novelty for

a person versus novelty for the world. Researchers often find that their original or new ideas for future studies have already been conducted once they perform a review of the literature and they may learn that they are 'reinventing the wheel.' Are these instances of creativity, even though the idea was not new? The answer is 'yes' for that individual, but 'no' for the society; however, people who perform creative projects need to be aware of prior creative projects. Computer networks have been an important advance in allowing creative people to get to know what has been previously produced.

Many researchers who study creativity believe that, in addition to being novel, a product must also have some value in order to be considered creative. Thus, an invention must carry out the task for which it was designed, a scientific theory must help us understand the domain in question, a creative work of art must be appreciated by some audience beyond the artist, and a creative solution of a problem has to solve the problem.

Csikszentmihalyi and Csikszentmihalyi have presented a detailed analysis of how novelty and value are both relevant to creativity. A novel product becomes creative only after it has become part of the domain, that is, only after it has been positively valued by the field. In this view, if a product is rejected by the field, that product is not creative, whether or not it is novel.

Weisberg as well as Heilman, however, disagree with the concept that products must be valued to be considered creative. Often, a product is not valued at the time it is produced but then becomes valued by later generations, or vice versa. For example, the impressionist painters were criticized when they first painted using this style. Galileo Galilei was accused of being a heretic and confined in jail in 1633 when he first supported the heliocentric theory of Copernicus. It was not until 180 years later that the Catholic Church officially recognized the Copernican theory as compatible with the Christian faith. Further, in 1992 the cardinal Poupard finally wrote that the persecution of Galileo Galilei was a mistake.

For all of these reasons, it may be more useful to separate the creativity of a product from the value of the product and to consider a product as creative if it is novel and produced intentionally.

Another aspect of creativity that many believe is important is that the product must in some way be beneficial and available, such that people other than the creator should benefit from the creative process. Benefit, as used here, does not mean solely profit and can mean anything from healing (Fleming's penicillin) to enjoyment (Puccini's *Madame Butterfly*). For those who include 'beneficial' in the definition of creativity, innovative products would not be considered creative if they are not followed by objective verification, independently of the value of the idea itself. Thus, for those who believe that 'beneficial' should be a part of the definition of creativity, productivity is an essential element and if an idea remains solely in the mind of the researcher or the artist and never becomes a reality by being produced and judged to be beneficial then there will be no means of knowing if that idea was indeed creative.

Even to those who believe that ideas, even in the absence of production can be creative, having a creative idea without a product, such as a scientific paper, a piece of art, or music, is like leaving a treasure under the sea.

In this article, we define creativity as the ability to understand (see unity in what appear to be diversity), develop, construct, and express in a systematic fashion, novel orderly relationships.

Methods of Studying Creativity

Just as there are difficulties in defining creativity there are also difficulties in finding the right method to study creativity. Here we will describe some of the methods that have been used to study creativity, explaining the limitations and the strengths that apply to each method.

Autobiographical Self-Reports

The oldest method to study creativity consists of personal reports from individuals with extraordinary creative accomplishments, including detailed descriptions of how the individuals conducted their work. These reports come from a range of creative people across a spectrum of fields, and are in the form of letters, books, and articles, addresses before scientific societies or other groups, as well as responses to questionnaires or interviews. Although these autobiographical self-reports are produced by people who have been highly creative, these reports are uncontrolled, as well as being subjective, and they cannot be fully assessed for reliability or validity. Even when there is no intent to deceive, sometimes these reports are even factually inaccurate. Self-reports are based on introspection and while introspection can provide some hints as to brain function, neuropsychological studies, such as those with callosal disconnection, have revealed that introspection often does not elucidate the brain mechanisms underlying a behavior. Finally, self-reports provide us with only qualitative descriptions of the creative processes, and hence they cannot test a-priori hypotheses and they do not provide data that can be used for rigorous scientific analysis.

Biographical Studies

Another way to approach the study of creativity has been through biographical studies such as Gardner, who collected

data from the biography of many creative individuals such as Einstein, Picasso, Gandhi, etc. Biographies are based on verifiable historical records and provide a method of directly studying individuals with the highest level of creative accomplishment. One possible limitation of this method, however, is the quality of the data that is available. Incomplete or inaccurate records may severely restrict the findings and conclusions of these studies. Additionally, biographical studies have many of the same limitations as do the autobiographical self-reports discussed above.

Historical Case Studies

Historical case studies are often more focused on the products of the creator, as opposed to the personal characteristics and the brain mechanisms that allowed individuals to be creative. Thus, analysis of historical case studies makes it difficult to discover the neuropsychological basis of the creative process or how it can be generalized. Case studies also have the same limitations as do the autobiographical and biographical studies as discussed above.

Historiometry

Throughout history there were certain eras and geographic localities where there was more successful creative productivity than during other eras and in other locations. These eras and centers of creativity were often associated with creativity in certain domains. These observations suggest that environmental factors can influence creativity. A number of researchers have applied quantitative methods to historical data in order to formulate and test casual hypotheses concerning creativity, using what has been called historiometric analysis. The term historiometry means 'measuring history.' As an example of historiometric analysis, Simonton was interested about how war and other sources of social upheaval might influence creative productivity. For example, during World War II there was a flurry of creativity. In medicine, penicillin was first used and it was learned that it was healthy to mobilize patients shortly after their surgery. We also learned much about atomic physics. Simonton divided the last two millennia into 20-year 'epochs' and determined the frequency of creative accomplishments within each of these epochs and assessed the influence of environmental factors such as war. For example, the frequency of creative accomplishment was based on such measures as the number of years of active warfare within each epoch and the number of creative individuals who flourished during each epoch.

Using statistical methods, Simonton attempted to infer causal relationships from historical data and concluded that the occurrence of war involving a nation results in a decrease in creative accomplishments in that nation for the following epoch. The strength of the historiometric method is that it directly involves creative accomplishments at the highest level. However, this method is also limited by the availability of the data and although it might provide data about the influence of environmental factors on creative production it does not help elucidate the brain mechanisms underlying creativity.

Quantitative Case Studies

This method applies quantitative measurements to the analysis of individuals or groups of individuals over a period of time. Quantitative approaches to case reports sometimes result in discoveries that would not have been apparent from a more qualitative presentation of historical information. However, a potential problem of this approach consists of the serious threats to external validity that result from generalizing the results of a single case to a wider range of individuals and circumstances. Thus, it is of paramount importance for other researchers to replicate the findings from case studies using a range of creative domains, settings, fields, and individuals. Systematic replication will result in enhanced generalization and understanding of the creative process.

Empirical Investigations

Empirical investigations of creativity appear to be the premier means of learning why people are creative. Empirical studies require the development of an a-priori hypothesis, the development of the tests and methods to test the hypothesis, the analysis of the data, and the interpretation of results. These studies require the recruitment of participants as well as the apparatus and procedures that can test the a-priori hypothesis. These experimental investigations include attempts to directly manipulate creativity through random subject assignments and typically require subjects to perform various tests of creativity under a variety of conditions.

Experimental approaches have the advantage of exerting the highest level of control over potential confounds, thereby permitting investigators to draw cause and effect relationships. Although these are widely used methods to study creative thinking in normal individuals, there are limitations on the data that are derived from laboratory studies, as well as questions as to its ecological validity.

As we have discussed, each of the aforementioned methods have strengths and weaknesses. Thus, depending on the question that has been posed and the answer that is sought, researchers will use one method or another, while bearing in mind the potential strengths and limitations of the selected method.

Stages of Creativity

Socrates thought that 'inspired thinking' arrived from divinities, specifically the muses or the nine daughters of Zeus, each of whom was responsible for a separate domain. According to this belief savants are inspired instruments through which Nature shows humanity the secrets of underlying discoveries. Contemporary views, however, regard creative ideas as emanating from within the individual rather than from outside. Consistent with this more modern view, many studies have focused on identifying the brain mechanisms that underlie creativity. Helmholtz and Wallas suggested that creativity has four stages: preparation, incubation, illumination, and verification.

Preparation

In order to be creative an individual has to acquire the basic knowledge needed to develop creative ideas and skills

necessary to develop novel and creative products. Kuhn who wrote a very influential book on creativity noted that many important discoveries are initiated by the observation of an anomaly. An example would include a scientist perceiving significance in an accidental occurrence, such as Alexander Fleming's discovery of penicillin. Fleming left bacterial cultures (staphylococci) in his lab exposed to the air and did not close the windows in his laboratory. The fungus mold penicillin flew into his laboratory and landed on these cultures. When he looked at the cultures he noted that the penicillin mold had killed the adjacent bacteria. Although these types of discoveries are based on accidents, it is the 'prepared mind' that enables scientists, such as Fleming, to perceive the importance of the phenomenon they observed. Fleming was a well-trained bacteriologist who during World War I saw many men die of infection and found that antiseptics would not cure these infections. Creative imagination takes advantage of the ability of our brain to displace different life events in a new and original way, and the more rich and varied the experiences of a person, the more his or her imagination will have material from which to consider the problem.

Incubation and Illumination

When a person such as a scientist is confronted with a problem, the creative solution of this problem is often not immediately apparent. Then after a period of time the solution to the problem may enter this scientist's consciousness. Thus, it is highly probable that this creative scientist was incubating his or her ideas about the phenomena prior to becoming aware of the solution. This sudden awareness of a solution has been called the 'Aha!' experience and it is this 'Aha' experience or epiphany that Helmholtz and Wallas termed illumination. Whereas Fleming's 'Aha' experience was aided by observing an anomaly, many scientists and artists develop an illumination even without observing an anomaly. Henri Poincaré (1854–1912), a world-renowned mathematician and physicist, reported that he had several illuminations when describing his creative achievements. The occurrence of illuminations may then be considered evidence for unconscious processing. If 'Aha!' experiences do not originate from conscious thinking, then there has to be an unconscious incubation as an explanation for sudden illumination. Support for the concept that unconscious or subconscious incubation or thinking may lead to solutions come from more recent work by Strick et al., who demonstrated that following distraction from the problem for a period of time there was an improvement of some judgments. Weisberg, however, also noted that creativity does not always require great leaps following unconscious processing and the processes that lead to many great discoveries did not involve subconscious incubation, but rather a series of conscious steps.

Verification and Production

After illumination, creative people, such as scientists, perform experiments that attempt to test their new hypotheses, artists paint their pictures, writers write their books or poems, and composers write or play their music.

Intelligence and Creativity

There was a significant change in the direction of research on creativity around 1950 when Guilford, an expert on intelligence testing, surprised many people by proposing that psychology had not spent enough time examining thinking that went beyond the kind of cognitive processes and knowledge measured by intelligence or IQ test, namely, creative thinking.

Definition of Intelligence and Relationship to Creativity

There are many definitions of intelligence, but for most psychologists, intelligence is the measure of a person's ability to acquire and apply knowledge. Sternberg and O'Hara suggested four possible relationships between intelligence and creativity: (1) intelligence is the same as creativity; (2) creativity is a subset of intelligence; (3) intelligence and creativity are unrelated; (4) these are overlapping but independent constructs. If intelligence is considered a measure of a person's cognitive ability to adapt, then creativity is a gift that might enhance one's ability to use their cognitive resources to better adapt. Whereas this statement would hold for certain forms of creativity, such as medical science (i.e., discovery of penicillin) and engineering, this definition would not hold true for other forms of creativity, such as the arts, including music, dance, painting, writing of poetry and fiction, etc. If, however, the definition was expanded so that intelligence is both a measure of a person's ability to adapt and to enhance the quality of life, then the arts could also be included.

One of the founders of intelligence tests, Alfred Binet, must have initially thought that creativity and intelligence were the same or closely overlapping constructs because the first intelligence test he devised in 1896 used inkblots to explore the imagination of children. Later, according to Sternberg and O'Hara, he discontinued this inkblot test because he was unable to develop a reliable means of scoring it. This test, however, has been subsequently used as a measure of creativity.

Guilford and Christensen, who are among the first to study and help increase psychologists' interest in creativity, thought that creativity was a subset of intelligence and Guilford attempted to develop psychometric tests that could measure creativity. These tests are similar to those developed by Torrance. Most of these tests assess the ability to develop novel uses of common objects. For example, subjects would be asked to name in a fixed time interval the different ways in which they might be able to use a brick.

Another means of studying the relationship between creativity and intelligence is studying the intelligence of creative individuals. Barron and Harrington in their article 'Creativity, intelligence and personality' suggest that there is a curvilinear relationship between intelligence and creativity, with intelligence presumably becoming less and less influential as one moves to the higher levels of intelligence. This observation suggests that there might be an IQ threshold, such that a person needs to be above this threshold for him or her to have sufficient intelligence to acquire the knowledge about the domain of his or her creativity and to acquire the skills needed to be creative in that domain. Thus, intelligence is a necessary but not sufficient component of creativity.

Other investigators, such as Herr et al. and Simonton, have also studied populations of known creative people and

attempted to learn if there is a strong correlation between their estimated eminence as creators and their intelligence. They found that the correlation between intelligence and creativity is weak. This weak correlation, however, might be related to the tests that were used to measure intelligence.

Crystallized and Fluid Intelligence

Cattell posited that there are two types of intelligence, which he termed, 'crystallized' and 'fluid.' Crystallized intelligence is basically declarative memories, such as knowing that Rome is the capital of Italy or lexical-semantic knowledge, such as knowing the meaning of the word 'impale.' In contrast, fluid intelligence is defined as the ability to solve problems. Most intelligence tests, such as the Wechsler Adult Intelligence Scale (WAIS), assess both crystallized (e.g., vocabulary definitions), and fluid intelligence (e.g., similarities – How are a fly and a tree similar?). Cattell thought that while crystallized knowledge is important in creativity, it is fluid intelligence that primarily determines creativity. Although fluid intelligence may be the best predictor of creativity, we know of no formal studies that have studied this relationship and there may be different domains of fluid intelligence. In addition, there has been little written about the brain mechanisms of fluid intelligence and cognitive flexibility.

Divergent and Convergent Thinking in the Assessment of Creativity

Divergent Thinking

Guilford reasoned that an important step in the creative process must be a breaking away from the past, which is the function of what he called divergent thinking. Divergent thinking is the ability to take different directions from the prevailing modes of thought or expression. As the name implies, this type of thinking breaks away from established concepts and produces novel ideas, which can serve as the basis for the development of a creative product. Divergent thinking often produces multiple new ideas.

Convergent Thinking

In contrast to divergent thinking, convergent thinking involves seeing–recognizing the similarity or the commonality of phenomena that appear to be different or combining and joining two or more different observations or ideas together so that they provide additional information, for example, putting the pieces of a puzzle together so they make a complete picture. One of the best and classic examples of a paradigmatic shift using convergent reasoning is the Copernican heliocentric theory of planetary motion. Convergent reasoning or thinking is similar to that which has been termed deductive reasoning. Unlike divergent thinking with convergent thinking there is usually a correct answer. Almost all multiple choice tests that assess reasoning rather than knowledge require the person taking the test to use convergent reasoning.

Tests Assessing Components of Creativity

Guilford's work was the stimulus to the psychometric stream of creativity research, which has focused on measuring the

psychological characteristics of creative people (psychometric meaning 'measuring the mind'). Guilford and others have used their tests in attempting to measure the thought processes underlying creative thinking. Additionally, other investigators have developed other tests to conduct similar investigations.

As mentioned, creative endeavors require preparation, innovation, and production. Innovative thinking requires that a person first break away from prior solutions (disengagement), develop alternative solutions (divergent and associative thinking), and then learn which solution works best (convergent thinking). In this and the next section we will briefly describe some of the tests that have been used to study creative thinking, with the understanding that different tests explore different components of the creative process. The tests mentioned here represent only a portion of the tests that are widely used to investigate creativity and there may be many other tests.

The Wisconsin Card Sorting Test

The Wisconsin Card Sorting Test is a test of disengagement and divergent thinking. The task involves presenting a series of cards containing stimuli that vary along several dimensions, including shape, color, and form. The subjects are asked to sort the cards by matching the stimulus cards with a key card that has the same characteristic (e.g., shape). Once the subject demonstrates the ability to sort on one variable the examiner switches to a new sorting principle and the subject taking this test must find the new sorting principle (e.g., color). This process is repeated until all the cards are sorted. The score on this test represents the ability of subject to successfully disengage and switch sorting strategies. Patients with frontal lobe damage exhibit impaired performance on this test.

Alternative use of objects task

In this test the subjects are given three different objects (e.g., a brick) and are asked to name as many different uses for the object as possible in a specified time. The individuals are informed that their performance will be scored based on the number of uses as well as the degree of novelty-innovation for the uses they identify.

Each specified use is scored as a 1 for a common use (such as using the brick to build), 2 for a minimally innovative use (use the brick as a door stop or book end), and a 3 for moderately or highly innovative uses (grind the brick up and using it as a cleaning abrasive or as make-up.) The total score is the sum of the item scores.

When an area of brain is active and its neurons are firing, more blood is carried to that area. Carlsson et al. conducted a study looking at cerebral perfusion in low versus high creative individuals during the alternate use of object task. The results appear to indicate an increase in bilateral frontal activation in the highly creative individuals.

Alternative meanings test

Many words in English have multiple meanings. For example, the word pen can mean a writing instrument or it can be a place where animals (e.g., pigs) are kept. This test involves providing subjects with a series of words and having these subjects provide two sentences using each word, but in each sentence the word should have a different meaning. After the subject produces two sentences a new word is given. If the two sentences are not

given within 60s, the examiner provides the next word. The score is the time taken to successfully complete the test.

Tests Assessing Convergent Thinking

Verbal-word anagram task

Anagram tests involve providing individuals with words where the letters that comprise the words are arranged out of order. The task is then to recognize the word that would be spelled if the letters were in the correct order (such as LPSENID being identified as SPINDLE). This task has been used in several studies in our laboratories where we examined the effects of central norepinephrine blockade on creativity. The anagram test is often composed of 10 words and contains five 5-letter words, three 6-letter words, and two 7-letter words. Subjects are shown the scrambled letters of a word printed on a sheet of paper and asked to write down on an answer sheet the word that these letters spelled. The score for each word is the number of seconds required to identify the correct word. If the subject makes an error or does not write the correct word in 100s, a maximum score of 100 is given. The lower the score the better the ability to perform convergent reasoning.

Verbal-remote associates tests

The remote associates test (RAT) requires respondents to access the semantic representations for three presented words and find the one correct fourth word that is linked with the three presented words. The presented words may be related to the solution words in a number of ways, they can be semantically or associatively related, they may be two parts of a compound word, or they may be words used as synonyms. For example, the subject may be provided with the words 'falling,' 'famous,' and 'dust,' with the solution word of 'star.' 'Falling' and 'star' are associatively linked, 'famous' and 'star' are synonyms, and 'stardust' is a compound word. There are often 20 items in this task and the response to each item is scored for accuracy and time to respond.

Tests Assessing Both Divergent and Convergent Thinking

Insight problems

The concept of insight problems began with Gestalt psychology. Insight problems are problems which are simple to state but relatively difficult to solve, and require some sort of 'insight' (creative thinking) to solve them. Such problems initially seem overwhelming and without solution. However, insight may suddenly occur, giving a new perspective on the situation and an answer that clearly fits. There are different kinds of insight problems, some of them are verbal problems and others are more based on mathematical or spatial tasks.

An example of an insight problem is the 'Nine Dot Problem' or 'Thinking Out of the Box.' The subject is asked to connect nine dots in a 3×3 matrix with four connected straight lines without lifting the pen from the paper (see [Figure 1\(a\)](#)). The solution can be seen in [Figure 1\(b\)](#).

Revised Torrance Test of Creativity

The standard Abbreviated Torrance Test for Adults (ATTA) consists of three activities, one verbal and two visual. During the verbal activity the subject is asked the following question.

Figure 1 'Thinking out of the box.' The person performing this test is asked to connect all the dots in (a) with four straight lines, without removing the pen from the paper. The solution to this problem is show in (b). In order to correctly perform this test, a person must go 'outside the box' formed by the dots on the perimeter.

"Just suppose you could walk on air or fly without being in an airplane or similar vehicle. What problems might this create? List as many as you can."

The second activity consists of giving the subject a paper on which there are two incomplete drawings. The subjects are then asked to create meaningful drawings that incorporate these incomplete figures and to title their drawings. The third activity consists of giving the subjects a sheet of paper that contains nine isosceles triangles. The subjects are asked to make as many pictures as possible using these triangles or lines. The subjects are told that every picture should have a meaning and a title. Subjects are given three minutes to complete each activity.

Neurological Diseases, the Right Hemisphere, and Creativity

As mentioned in the introduction, through investigating the behavioral changes associated with brain dysfunction, scientists can understand the components that constitute complex cognitive functions and behaviors. We also mentioned the critical components of creative thinking including disengagement, divergent, associative, and convergent thinking with incubation and illumination (finding the thread that unites), as well as productivity. In the following section we will provide examples of the effects of neurological diseases on various cognitive mechanisms that are important in creative thinking.

Bruce Miller and his coworkers wrote a series of reports on the emergence of visual artistic talents in patients affected by frontotemporal lobar atrophy (FTLA). Two of the most common forms of degenerative dementia that are seen in clinics are Alzheimer's disease and FTLA. Most patients with Alzheimer's disease initially experience problems with episodic memory and then develop other cognitive deficits, such as problems with naming, route finding, constructional apraxia (drawing, copying), and even performing learned skilled movements (ideomotor apraxia). The signs and symptoms associated with frontotemporal or dysexecutive form of FTLA are different from those seen with Alzheimer's disease. In one form, patients lose their social skills and engage in socially inappropriate behaviors. Other patients may become abulic and sit around all day doing nothing useful. Still other patients with frontotemporal dementia might experience language deficits that

cause speech to become progressively less fluent (progressive nonfluent aphasia) or they might experience difficulty with naming and comprehension (semantic dementia). Additionally, unlike patients with Alzheimer's disease, patients with FTLA dementia may have relatively intact visual-spatial memory.

Brain imaging, such as magnetic resonance imaging (MRI), of patients with Alzheimer's disease usually demonstrate evidence of atrophy, primarily in the medial temporal lobes and in the parietal lobes. Conversely, patients with FTLA often evidence atrophy of the frontal lobes or the anterior temporal lobes or both. Further, FTLA might be asymmetric and primarily involve only one side of the brain. For example, patients with the semantic dementia form of FTLA most often have atrophy of the left anterior temporal lobe.

Microscopic examination of the brain in patients with Alzheimer's disease reveals the presence of amyloid depositions (plaques) and neurofibrillary tangles in the neurons. Patients with FTLA have a variety of different microscopic changes, including intraneuronal inclusions called Pick bodies (after the neurologist who first described this syndrome), ballooned neurons that stain poorly, or even no specific pathological markers.

Although it is often difficult to know, in retrospect, when a dementing disease has started several of the artists described by Miller and his coworkers (1998–2000) appeared to have started drawing or painting prior to the time they had the symptoms and signs of FTLA dementia or at the time when the disease was just beginning. What was remarkable about these patients is that in spite of their dementia they continued to paint and some even improved their artistic skills.

Whereas the left hemisphere, in right-handed individuals, is dominant for language and primarily mediates verbal activities, the right hemisphere appears to be more important for the type of spatial skills needed when painting. Miller and his coworkers noted that the brain atrophy of most of these artistic people was limited to the left frontotemporal lobes, sparing the right side of the brain, and their creative skills were nonverbal. Based on the reports by Miller et al. however, we cannot ascertain whether these patients' talents existed before the onset of the dementia.

Similar reports have been subsequently described from other authors. Finney and Heilman conducted a study with a patient with the progressive nonfluent aphasia form of FTLA by having independent judges score a variety of artistic qualities of seven of this patient's paintings completed before the onset of this disorder and seven paintings completed after the onset of the disease. The qualities scored included: (1) Novelty: 'How original is this painting?' (2) Aesthetics: 'How beautiful or attractive is this painting?' (3) Representation: 'How well is the subject of this painting rendered?' and (4) Closure: 'How complete is this painting?' The results of this assessment indicated that the patient's artistic ability neither diminished nor improved with the onset and progression of the disease, with the exception of novelty, which declined over time.

Drago et al. conducted a similar investigation by studying 40 paintings of an artist affected by the semantic dementia form of FTLD. Their findings showed an increase of some visual artistic skills over time. To help explain why brain dysfunction can result in the emergence of a new or improved skill, Kapur suggested that facilitation of a function might be

induced by a lesion that destroys an inhibitory circuit (i.e., a 'paradoxical functional facilitation'). Miller and his coworkers suggested that perhaps a similar phenomenon was occurring in their patients and the left anterior temporal lobe degeneration "contributed to the unexpected emergence of talent ...". This disinhibition hypothesis has also been used to explain creativity in individuals who are without dementia. For example, Einstein noted that he often used spatial reasoning to develop his creative theories. Einstein did not start speaking until the age of three, was probably dyslexic, and had abnormal development of his left parietal lobe. It is possible that these left hemisphere developmental abnormalities allowed his right hemisphere to develop exceptional spatial skills and talents. Although these aforementioned studies provide some important insights concerning visuospatial abilities, this right hemisphere disinhibition hypothesis has not been experimentally tested.

Some support for the hypothesis that the right hemisphere is important in creativity comes from a recent imaging study by Asari et al., who examined unique perception using functional MRI (fMRI). During the study 68 normal subjects were asked to look at ten ambiguous figures taken from the Rorschach inkblot test and state what the figures resembled. The responses were then classified as frequent, infrequent, or unique. The results indicated a greater activity in the right temporopolar region at the time of the unique response, as compared to the frequent responses. These results provide support for the idea that the right hemisphere is integrally involved in the visuospatial creative process.

Based on the hypothesis of a 'paradoxical functional facilitation,' Drago et al. studied an artist affected by Parkinson's disease (PD) who had a left deep brain stimulator (DBS) implanted. DBS can induce activation of one or both hemispheres. Thus the purpose of the study was to learn if DBS of the left hemisphere, presumably inducing left hemisphere activation, would alter the creativity of a professional artist as well as her ability to judge somebody else's art. The authors had the patient perform a test of creativity with the stimulator 'on' versus 'off.' The patient was also asked to judge the art of other individuals when the stimulator was both on and off. The results suggested that left ventral subthalamic nuclei/substantia nigra reticular deep brain stimulation (STN/SNr DBS) reduces creativity as well as appreciation of art. The reason for these alterations is not known, but might be related to enhanced activation of the left hemisphere and reciprocal deactivation of the right hemisphere. The right hemisphere is thought to mediate visuospatial skills and global attention, both of which might be important in artistic creativity and appreciation of art.

The hemispheric lateralization model grew in the 1970s. Researchers espousing this model postulated that the nondominant hemisphere was specialized for creative activities such as art and music. At the beginning of the article when creativity was defined we raised the concept of 'finding the thread that unites' and 'finding unity in what appears to be diversity.' The right hemisphere appears to be more important in global than local processing and a global approach may be important in finding the thread that unites. The right hemisphere is also important in mediating visual-spatial functions and as mentioned, many extremely creative people, such as Einstein, claim to have used visual-spatial strategies to help find creative solutions. Thus, the hemispheric lateralization model suggests

that the right hemisphere mediates functions that are crucial for creative processing.

An EEG study conducted by Jausovec and Jausovec recorded from 115 normal participants during resting, 'eyes open' and 'eyes closed' conditions. He found that when his subjects were stratified across measures of creativity and intelligence, EEG coherence (obtained during 'rest' with eyes open) was significantly related to creativity scores, particularly across the right hemisphere. Coherence provides information about the cooperation of different areas of the brain as well as the functional relations between brain regions. Finding 'the thread that unites' might require the cooperation of a variety of modular networks that are distributed in different anatomic areas and thus measures of coherence might provide evidence of modular coordination, ie associative thinking that is important in creativity.

The Role of the Frontal Lobes and the Influence of Dopamine on Creativity

According to Beals, Thomas Edison said that being a creative genius required "ninety-nine percent perspiration and one percent inspiration." Almost all creative people, independent of the domain in which they create, may be characterized by perseverance and persistence.

Goal-oriented behaviors or volition permeates almost all aspects of creativity, and the major organ of volition appears to be the frontal lobes. Clinically, patients with degeneration or injury of the frontal lobes present with a loss of initiative and drive, and this loss is called 'abulia.' Harlow, in 1868, reported the famous case of Phineas Gage, one of the best-known descriptions of a person who developed abulia from a brain injury. The ability to have long-term goals and to suppress biological drives when they interfere with long-term goals, as well as the ability to persist and not be distracted, is what Heilman calls 'frontal intelligence.' Frontal intelligence is one of the major factors underlying success in any profession, including those that require creativity. However, the frontal lobe networks have another function that appears to be important for creativity, namely, disengagement and divergent thinking. As we mentioned above, divergent thinking is the ability to take a different direction from the prevailing modes of thought or expression and as also mentioned, Zangwill and Milner suggested that frontal lobe damage or dysfunction would disrupt divergent thinking.

Electromagnetic studies demonstrate that frontal lobe activity appear to be important in creativity. Comparing subjects with high and low creativity has revealed that the highly creative individuals possess higher baseline frontal lobe activity and greater increases in frontal lobe activity while performing creative tasks. Further, there is preliminary evidence that transcranial magnetic stimulation applied over frontal lobes can increase frontal activation as well as creativity in normal subjects during both drawing and writing tasks. There are also case reports of patients whose creativity increased after receiving subcortical deep brain stimulation with the electrodes placed near the nucleus accumbens. The connections of the nucleus accumbens to the frontal and temporal lobes, and its role in limbic generation of drives and reward may help explain this effect. The dorsolateral prefrontal cortex supports

the planning and organization of artistic efforts, while the cingulate cortex modulates attention, drive, and emotion. Also, the motor and premotor frontal regions (along with the basal ganglia and cerebellum) carry out the precise movements needed for great art, dance, and playing of musical instruments. In addition, there is some evidence suggesting that creative drive may be controlled through interactions among the temporal lobes, the frontal lobes, and the limbic system. Particularly, creative drive increases with temporal lobe dysfunction and increasing dopaminergic activity. In contrast, reduced creativity (creative block) is associated with deficits in frontal lobe activity, or decreasing dopaminergic activity.

Creative people have also been shown to have higher baseline arousal and heightened responses to sensory stimulation. Dopamine decreases latent inhibition, a behavioral index of the ability to habituate to sensation and raises baseline arousal. Thus, the focused aspect of creative drive may be modulated by mesolimbic dopaminergic activity. Dopamine also mediates reward seeking activity, ranging from gambling and cocaine addiction to the appreciation of beautiful faces and music. Conversely, too much dopamine may cause excessively focused, highly complex motor stereotypes, such as repeatedly disassembling and reassembling one's motorcycle engine. Dopamine may also play a role in creative discovery through its effect on novelty seeking. An allele of the D4 receptors has been postulated, somewhat controversially, to be a novelty-seeking gene.

A recent study by Drago et al. examined patients affected by PD performance on a test of creativity. The patients were grouped based on side of onset, with the hypothesis that when compared to healthy controls, patients with a right hemibody onset would be more impaired in verbal creativity and patients with left hemibody onset would have more problems with visuospatial creativity. The results indicated when compared to control participants there was a decline in verbal creativity in the group of patients with right hemibody onset PD.

The neurobiology of creativity has also been addressed using single photon emission computerized tomography (SPECT), positron emission tomography (PET), and fMRI. Chávez-Eakle et al. used SPECT to study 12 highly creative subjects while performing figural and verbal creative tasks. These authors found a positive relationship between the creativity index and cerebral blood flow in the right post central gyrus, bilateral rectus gyri, right inferior parietal lobule, and right parahippocampal gyrus. These findings were interpreted as supporting a 'highly distributed brain system' underlying creativity. PET was used to study normal subjects as they performed verbal creativity tasks, with significant brain activation being observed in the left parietal-temporal brain regions (Brodmann's areas 39 and 40), which are considered to be 'crucial' to the creative process. An fMRI study attempted to localize creative story generation within the brains of a cohort of eight normal subjects. The results indicated that when creative story generation was contrasted to uncreative story generation, significant activations were observed within bilateral medial frontal gyri (Brodmann's areas 9 and 10) and the left anterior cingulate gyrus (BA 32). Across all studies, however, no clear consensus has emerged as to whether frontal or more posterior brain regions are more central to creative processes. There appears to be no single creativity node, but rather a complex of interactive modular networks.

The Role of White Matter Connectivity in Creativity

Creativity was defined in the beginning of this chapter as the ability to understand, develop, and express in a systematic fashion novel, orderly relationships. This ability might require intra- and interhemispheric communication between several brain modules. Works of scientific or artistic creativity often require the skills and knowledge mediated by both cerebral hemispheres. For example, the sculptor must imagine the rotation of spatial images mediated by the right hemisphere while he or she uses the motor skills mediated by the left hemisphere. Thus, intra and interhemispheric communication might be crucial for integrating the knowledge and skills that are important for creative innovation.

Corpus Callosum

The largest structure connecting independent modular systems is the corpus callosum. Lewis administered the Rorschach test to eight patients affected by medication-resistant epilepsy before and after they had undergone a cerebral commissurotomy and noted that disconnection of the two cerebral hemispheres tended to destroy creativity as measured by this test. Frederic Bremer suggested that the corpus callosum subserves the highest and most elaborate activities of the brain, in a word, creativity.

The corpus callosum is primarily comprised of myelinated axons whose cell bodies are in the pyramidal layers of the cerebral cortex. The cerebral connections important for creativity, however, might not only be interhemispheric, but also intrahemispheric.

Intrahemispheric Connectivity

In addition to the myelinated axons that carry information between the hemispheres, there are white matter connections between the thalamus, basal ganglia, brain stem, and the cortex. Myelinated axons also carry information between cortical regions in the same hemisphere. These intrahemispheric connections facilitate intrahemispheric communication, which also might be important for creative innovation because widespread connectivity allows creative people to combine the representations of ideas that have been previously isolated. In addition, these intrahemispheric white matter connections, that include connections between the frontal lobes and the posterior association areas in the temporal, parietal, and occipital lobes, might allow the selective activation or inhibition of cognitive modules.

Connectionist, or parallel distributed processing (PDP) models, suggest that there are processing units or nodes that are similar to the neurons found in the brain and PDP models strongly emulate the fundamental properties of neural networks. Information in PDP networks is stored in the strengths of connections between units (as in the brain). Concepts are represented as patterns of activity involving many units (i.e., as distributed representations) and large number of units linked by a set of connections define a domain of knowledge from which any one of a large number of concepts can be generated.

Psychological studies of priming effects on the latency of lexical decision tasks are a good demonstration of the ability of this model to account for empirical results. In a lexical decision task, words are flashed, one at a time, on a screen and the subject has to indicate, as rapidly as possible, if the word displayed is a real word or a pseudo word. In a priming paradigm, before the target word or a nonword appears on the screen, a prime word appears. If the prime is strongly related to the target (e.g., the prime is stripes and the target is tiger), the response time for word (e.g., tiger) is less than when the prime and target are unrelated (e.g., doctor-zebra). This reduction of reaction time to primed words is thought to occur because when a related prime appears it generates a distributed concept representation that involves activation of many of the units that define the distributed representation of the target. As much of the target's distributed representation is already activated when the target appears, response latency to the target is reduced.

Mednick suggested that in generating associative responses to a stimulus, creative individuals are characterized by a more flat associative hierarchy than are less creative individuals. Hence, creative people might have the ability to activate more highly distributed networks and this ability allows them to see 'the thread that unites.'

Relaxation, Depression, and Creativity

Sleep and Arousal

Several scientists reported being able to solve difficult scientific problems during sleep or when they were either falling asleep or awakening from sleep. One of the most famous examples of this phenomenon is August Kekulé, who in 1865, while attempting to understand the structure of benzene, had a vision, during a dreamy state, of a snake chasing its own tail. This vision provided Kekulé with the idea that benzene was a ring-like structure.

Before and after sleep, people who are actively working on a problem describe moments of insight when they were able to solve previously insoluble problems. Often the solution to difficult problems is aided by the ability to make remote associations and these moments of insight often come at time when the person is relaxed and at rest. Eysenck suggested that during conscious problem solving, cortical arousal is often high. This high level of cortical arousal narrows associative fields and suppresses the ability to make remote associations. A lowering of arousal, however, might allow these remote associations to emerge.

Support for the postulate that the level of arousal might determine the size of neural networks comes from some research performed by Contreras and Llinas. Using high-speed optical imaging, they performed electrical stimulation of subcortical white matters in slices of brain from a guinea pig and recorded the portions of the neocortex that were activated by this subcortical stimulation. They found that with low-frequency stimulation cortical activation was initially limited but then after few milliseconds the activation spreads into nearby areas. After high-frequency stimulation the excitation remained fixed to a small column of neurons that were directly above the stimulating electrode. Recordings from the neurons

around the excited column during rapid stimulation revealed increased inhibitory synaptic activity that probably inhibited the spread of activation.

Depression and Bipolar Disorder

Several researchers have investigated the relationship between depression and bipolar disorders in otherwise healthy creative individuals who were or are composers, scientists, artists, and writers and found a high incidence of affective disorders in this population and in their families.

To find a connection between all these different states that influence creativity, such as relaxation, depression, and resting, it has been hypothesized that alteration of the brain's neurotransmitter systems, primarily a reduction of the catecholamine norepinephrine might enhance creative thinking.

As mentioned above, the simultaneous and full activation of multiple modular networks appear to be important in creative innovation. Partial support for the postulate that catecholamines modulate the size of neuronal networks comes from the priming study of Kischka and coworkers who used a lexical priming task. As mentioned, either real words or pseudo words were flashed on a screen and the participants were asked to press a computer key as rapidly as possible when they determined that the word on the screen was a real word, but not to press the key if a pseudo word was seen. Sometimes these real words and pseudo words were preceded by another word that is called 'a prime.' If this preceding word is related to the real target word, the prime word will help the participants more rapidly recognize the real target word. The closer the prime and the target word are associated the more rapid will be the recognition of the real target word (direct priming). In contrast, if the words are weakly or distantly related the priming will be less robust (indirect priming) and the reaction will be only slightly reduced by these primes. When Kischka et al. administered levodopa to normal participants, the indirect priming effect decreased, suggesting that dopamine reduces the spread of semantic activation induced by the prime. Although Kischka et al. attributed this effect to the dopaminergic system, levodopa is also precursor of norepinephrine, and the administration of levodopa to these individuals may have also increased the level of norepinephrine.

To study the influence of norepinephrine on cognitive flexibility, Beversdorf et al. tested the ability of normal participants to solve anagrams when treated with placebo, ephedrine, or propranolol. Ephedrine increases the level of norepinephrine whereas propranolol is a beta-noradrenergic blocker and thus interferes with the influence of norepinephrine in the brain. They found that performance on the anagrams task was better after participants took propranolol than after they took ephedrine.

During stressful conditions, where normally there is an increase of catecholamines such as norepinephrine, the performance on the Remote Association Test declines. Further support for the postulate that high levels of catecholamine might reduce associative and convergent reasoning comes from a study where students with test anxiety improved their score on the Scholastic Aptitude Test when they took the beta-adrennergic blocker propranolol.

When performing the Controlled Oral Word Association Test subjects are asked to produce as many words as they can that begin with a certain letter in one minute. Foster et al. performed a study examining lexical-semantic activation in a population of Parkinson's patients. They sought to investigate the effects of PD, which is associated with dopamine and norepinephrine depletion, on spreading activation in the lexical-semantic networks. If these lexical-semantic networks are constricted, subjects would be more likely to use high-frequency words and if the network was expanded the subjects would be more likely to recall low-frequency words. Hence, Foster et al. examined the average word frequency on the words produced on the Controlled Oral Word Association Test in patients with PD and compared their performance to that of controls. These investigators found that the participants with PD exhibited a lower average word frequency than did control subjects, suggesting the subjects with PD had a more expansive activation of their lexical-semantic networks than did the control participants.

Ghacibeh et al. performed a study examining the effect of vagus nerve stimulation versus sham stimulation on creativity and cognitive flexibility in people affected by medically intractable partial epilepsy. Their hypothesis was that since vagus nerve stimulation activates the neurons in the locus coeruleus (LC), and results in increased release of brain norepinephrine, vagus nerve stimulation should reduce creativity and cognitive flexibility. These investigators had their patients perform tests of creativity such as the Torrance Test as well as cognitive control tests such as the Hopkins Verbal Learning Test. They found that when compared to sham stimulation, vagal stimulation reduced creativity but did not impair memory. These investigators concluded that the reason vagus nerve stimulation impairs cognitive flexibility and creative thinking is probably related to increased activity of the LC-central noradrenergic system that increases the signal-to-noise ratio and improves the brain's ability to attend to sensory input, but decreases its ability to recruit large-scaled networks. Depression is associated with a reduction of brain norepinephrine and based on this literature, it would be reasonable to think that depression with a decrease in norepinephrine would facilitate creative innovation; however, as we mentioned earlier, the verification and productivity portion of the creative process do need high level of arousal and thus it might be that depressed individuals have very creative ideas but have difficulty producing creative products until their depression remits.

Summary

Creativity is defined as the ability to understand, develop, construct, and express in a systematic fashion, novel orderly relationships. There are three or four major steps in the creative process, the first step is preparation, the second is innovation, including incubation and illumination, and the final is productivity. There are several means of studying how the brain allows humans to be creative and these include studies of creative people and patients with neurological diseases, as well as physiological studies (including functional imaging and electrophysiology (EEG and evoked potentials)), cognitive

psychological studies, and pharmacological studies. In regard to preparation, to be creative a person needs an adequate level of general intelligence as well as domain-specific knowledge and special skills that are dependent upon the domain of creativity. In the human brain knowledge is, for the most part, stored in the temporal, parietal, and occipital association cortex. In the human brain some forms of knowledge (language) are stored in the dominant left hemisphere whereas other forms of knowledge (visuospatial) are stored in the right hemisphere. There is some evidence that either faulty development or degeneration of one portion of one hemisphere might disinhibit other areas of the brain, particularly in the other hemisphere, and this disinhibition might enhance domain-specific creativity. Domain-specific knowledge and special skills alone are, however, are not sufficient for creativity. The ability to disengage from accepted solutions and develop alternative solutions or divergent thinking is an important aspect of creativity. Clinical as well as functional imaging studies suggest that the frontal lobes are critical for divergent thinking. The frontal lobes have strong connections with the posterior cortical association areas where concepts and various forms of knowledge are stored. White matter connects the right with the left hemisphere and white matter pathways connect the frontal lobes with the more posterior cortical association areas. These connections might allow the selective activation and inhibition of portions of posterior neocortex in both hemispheres and thus be important for developing alternative solutions. Although extensive knowledge and divergent thinking are critical for creative innovation they alone are insufficient for allowing a person to find 'the thread that unites.' Finding unity requires the binding of different forms of knowledge and these different forms of knowledge are often stored in separate cortical modules. Thus, creative innovation requires both the coactivation and communication between regions of the brain and thus is highly dependent on white matter pathways, both inter- and intrahemispheric. In addition, creative innovation most often occurs during levels of low arousal. High arousal is associated with high levels of brain norepinephrine produced by high rates of LC firing. This high rate of firing normally allows people to focus on external stimuli by restricting the breadth of activated concept representations. Low levels of norepinephrine shift the brain toward intrinsic neuronal activation with an increase in the size of distributed concept representations and coactivation across modular networks, a state that enhances creative innovation. Many people with depression are creative and this relationship may be related to the alterations of neurotransmitters such as norepinephrine that are associated with depression. In addition to being important in divergent thinking, the frontal lobes also help control the activity of the LC-norepinephrine system. Highly creative people may have brains that are capable of storing extensive specialized knowledge in their posterior association cortex, are capable of frontal mediated divergent thinking, and have an ability to modulate the frontal lobe-LC (norepinephrine) system allowing them to find the thread that unites.

Crisis Management

A M Legg and K Sweeny, University of California, Riverside, CA, USA

© 2012 Elsevier Inc. All rights reserved.

Glossary

Crisis Any negative event or situation that a person or organization perceives as such.

Crisis decision theory A framework developed by Kate Sweeny in which that describes the decision-making processes people undergo when faced with a crisis.

Crisis management The process a person or organization uses to deal with a crisis. The process includes preparation and prevention processes, detection of crisis, responding, and postcrisis responding.

Crisis signal detection The process through which people and organizations recognize or predict crises.

Damage containment The process through which people and organizations attempt to minimize the damage associated with a crisis.

Proactive coping A set of behaviors including acquiring resources, recognizing potential negative events, and taking action before an event occurs that prevents the negative event from happening or changes its course or outcome.

Introduction

Crises arise in many forms. For example, a company suffers a privacy breach in which their customers' financial information is accessed by outside parties. A woman realizes that her car is no longer in its parking space and wonders if someone stole or towed the car. A teacher overhears a student threatening to bring a gun to school. How do people manage crises such as these? This article focuses on the decision-making processes associated with managing crises in a variety of circumstances. Although much of the crisis management literature focuses on organizational behavior, this article also devotes substantial attention to the way individuals manage personal crises and draws connections between crisis management in individuals and organizations.

Definition of Crisis

The definition of a crisis depends in part on whether it is a crisis for an individual or an organization. The business and management literature typically defines a crisis as an event that damages a company's financial situation or reputation. In the case of medical research on crisis management, the definition of a crisis is any potentially life-threatening situation such as anaphylaxis or cardiac arrest. Further, education researchers define a crisis as any event that threatens the safety, and well-being of the students, or faculty, and staff or the students' ability to learn. However, when focusing on crises occurring at the individual or small group level, the definition becomes much broader and more subjective and includes any negative event or situation that a person perceives to be a crisis. The severity of individual crises can vary and do not necessarily threaten the person's life, safety, or well-being, or impact financial stability or social reputation. In other words, a crisis is, to a large extent, in the eye of the beholder.

A variety of crisis management models put forth in the past few decades address a wide range of factors associated with preparing for, preventing, and responding to crises. Despite the diverse research areas from which these models derive

(e.g., health, education, social psychology, and organizational behavior), they include many common and overlapping features. This article provides an overview of the full process of crisis management, including the detection of crises, the preparation for and prevention of crises, the decision-making processes engaged in crisis response, and recovery from crises. The goal of this article is to draw parallels between the various crisis management models and to merge previously disconnected areas in which crisis management has been studied.

Detection of Potential Crises

A significant segment of the crisis management literature comes from the fields of management and business and focuses on early detection of potential crises. Signal detection and issues management, two frequently used terms that refer to this stage of crisis management, involve information gathering, monitoring, and scanning of the environment in an attempt to predict potential crises. Additionally, Lisa Aspinwall and Shelley Taylor's proactive coping framework provides a social psychological conceptualization of how individuals acquire resources and attempt to recognize stressors that could potentially lead to a crisis.

Regardless of whether a crisis affects an individual or organization, four types of information can signal an impending crisis, according to frameworks described by Ian Mitroff and Gus Anagnos. Signals can be internal or external and derive from technological sources or from people. *Internal technological signals* monitor internal operations, such as virus scans on a computer. *External technological signals* can come from outside organizations such as government agencies or weather monitoring institutions, and they typically alert people to impending natural disasters or other external crises. *Internal people signals* involve information provided by personnel within an organization but may also refer to an individual's thoughts and emotions. For instance, a woman who finds a lump in her breast would likely respond to her awareness of the problem (i.e., internal information) by making an appointment to get a mammogram. Finally, *external people signals* come from

community members, customers, or friends and family. For example, a friend may communicate news of the death of a mutual friend, or community members may alert their city government about increased gang activity in a part of their city.

Even when signals exist to cue individuals or organizations to the potential for a crisis, the question remains as to whether they will seek out and acknowledge this information. In fact, research finds that although some people seek out information in the face of a potential crisis, many others prefer to avoid such information. At the individual level, information seeking in the face of a crisis involves activities like reading about symptoms, prognosis, and treatment for a medical illness or comparing home insurance policies to gain the best coverage. Businesses, too, can seek out information to aid in their prediction of potential crises. For instance, they may collect stock market trend data to foretell financial woes or examine employee satisfaction surveys to anticipate potential employee discontent.

Information avoidance, on the other hand, is a defensive strategy to avoid acquiring unwanted or aversive information. For example, a large percentage (up to 55%) of people tested for HIV do not return to the testing clinic to receive their results. In such cases, choosing to avoid information may postpone the onset of a potential crisis (e.g., facing a diagnosis of HIV). Although attending to information that potentially predicts an impending crisis is typically quite beneficial, individuals and organizations may ignore accessible information for a variety of reasons. That is, people are most likely to avoid information when it could lead to an unwanted or difficult change in their attitudes, beliefs, or actions, or when the information will induce aversive or negative emotions. Similarly, people also avoid crisis-provoking information if they perceive that they have little control over the outcomes of the information, if they lack sufficient coping resources to deal with the information, or if the information is difficult to access or hard to interpret.

As an illustration of the potential consequences of information avoidance, the crisis associated with the Space Shuttle Challenger disaster provides a prime example of crisis-predicting information avoidance. The conclusions of the investigating committee, the Rogers Commission, determined that there was a plethora of available information, namely indicators of defective parts on the shuttle and expert warnings against launching the shuttle, that NASA officials chose to ignore and that ultimately contributed to the occurrence of the tragedy. Although information avoidance may protect people from unpleasant feelings of anxiety and fear, the consequences in the context of crisis management can be dire.

Even if individuals or organizations are receptive to information that might indicate an impending crisis, they may face another barrier to crisis detection. Ian Mitroff notes that a psychological bias can occur in organizations such that they perceive an unrealistically low risk of experiencing a crisis. Organizations with this perspective tend to take fewer preparatory and preventative actions and thus, ironically, become more crisis prone. Similarly, individuals who are unrealistically optimistic about their likelihood of, for example, facing a health crisis also tend to engage in fewer preventative health actions. Thus, a critical aspect of crisis management is overcoming the biases that prevent individuals and organizations from realistically assessing their risk of experiencing a crisis.

Preparation and Prevention of Crises

Effective crisis management requires preparatory and preventative actions. A number of models include preparation and prevention as key components of crisis management, and many business and management scholars argue that the preparatory and prevention stage is the most critical for good crisis management. The goals of the preparation and prevention stage of crisis management are preparing oneself and others for a potential crisis and developing and implementing contingency plans for crisis responding.

Even when individuals and organizations recognize the necessity of preventative action, they often have limited resources to prepare for all possible crises. Mitroff and Anagnos' business frameworks of crisis management typically distinguish different categories of crises. The seven most frequently discussed crises are economic (e.g., labor strikes or market crashes), informational (e.g., loss of customer information or other confidential documentation), physical (e.g., loss of materials or facilities), human resource related (e.g., loss of staff or decrease in productivity), reputational (e.g., slander or gossip), psychopathic acts (e.g., violence, kidnapping, or terrorism), and natural disasters. The developers of such crisis frameworks recommend that organizations prepare for at least one crisis in each category.

Preparation for crises often entails simulation and training experiences. For example, in the case of hurricane preparation an organization might establish a meeting destination in case of evacuation, determine how members will communicate with each other, and post information about where emergency supplies are located. Similarly, schools conduct fire, earthquake, and tornado drills in order to prepare faculty, staff, and students to respond to natural disasters. Other preventive actions include implementing strong security systems, scheduling, planning and training workshops, engaging in mental health counseling, and encouraging activities that promote well-being, among others.

Unfortunately, individuals and organizations at times do not engage in preparatory or preventative actions even when they detect the possibility of a crisis. For example, women often fail to get recommended mammograms to proactively scan for breast cancer. Similarly, prior to the 2007 Virginia Tech campus shooting many college campuses failed to invest resources in preventative programs focusing on college student mental health and response plans for violence in the school. Similar to information avoidance, organizations engage in a number of defense mechanisms that hinder proper proactive responding. Mitroff and Anagnos point out several of the typically used defense mechanisms of crisis-prone organizations. For example, both individuals and organizations can fall victim to the 'just world' thinking by believing that good people/organizations do not face crises, or that all people/organizations in crisis must have done something to deserve their fate. Similarly, organizations often have a sense of perceived grandiosity, or the feeling that they are immune to crises. Both the 'just world' thinking and grandiosity can lead to denial in the face of crises, which undermines the motivation to prepare and respond effectively. Other defense mechanisms that can undermine the motivation to prepare for a crisis include disavowal

(i.e., thinking that a crisis will not significantly impact the organization), projection (i.e., thoughts about how evil people or organizations want to hurt the targeted organization), intellectualization (i.e., believing that the chances of a crisis are statistically small), and compartmentalization (i.e., thinking that a crisis can only affect a small part of the organization and not the entire company).

When a Crisis Happens

Despite the best efforts to detect and prepare for crises, they may nonetheless occur, and often unexpectedly. When a crisis occurs, people must then decide how best to respond. Kate Sweeny proposed the *crisis decision theory* to conceptualize the decision-making process that individuals and organizations use when dealing with a crisis. The following sections of this article explore how people make choices when responding to a crisis. Specifically, crisis decision theory proposes three stages of responding: assessment of severity, determination of response options, and evaluation of response options. Although crisis decision theory primarily describes individual's decision-making processes in the face of a crisis, the theory is broad enough to encompass the crisis response options that confront business, medical, and education organizations.

Assessment of Severity

As mentioned at the outset of this article, a crisis can be defined as any negative event that a person or organization perceives as a crisis. This broad definition can encompass such a wide variety of crises that the severity of crises also varies widely. Crisis decision theory describes that three types of information inform perceptions of a crisis's severity: information about the causes of a crisis, information about how the crisis compares to other outcomes, and information about the potential consequences of the crisis.

Crisis decision theory further proposes that the severity of a given crisis affects the extent to which people invest time and effort in responding to the crisis. According to the theory, responding occurs in an inverted U-shaped pattern such that nonsevere crises and extremely severe crises both result in low response effort. For example, one employee stealing a single pen from the office supply closet (a nonsevere event) is not likely to warrant a response from the management. At the other extreme, individuals or organizations can become paralyzed by very severe crises. A diagnosis of a severe and incurable disease may be so traumatic for the patient that s/he will not seek out ways to cope with or respond to the crisis. Similarly, an organization facing a financial crisis that could lead to the downfall of the entire organization may be unable to face the implications of the crisis, and thus unable to respond. Accordingly, moderately severe crises are most likely to prompt an effective response.

Determination of Response Options

Some crises may lack the severity necessary to prompt a response. However, when an individual or organization deems an event severe enough to warrant a response, they then turn to the second stage of crisis decision theory: determining available response

options. At this stage, people focus on two components of the crisis: the controllability of the consequences of the crisis and the feasibility of the available response options. Turning first to controllability, a crisis may have short- or long-term consequences that are controllable or uncontrollable. For example, the company responsible for the Gulf oil spill in 2010 faced some consequences that they could mitigate or control (e.g., the financial impact of the crisis on industries in the region) and other consequences over which they had little control (e.g., the effectiveness of various attempts to stop the oil from spilling into the Gulf). Crisis decision theory proposes that to the extent that individuals or organizations evaluate the consequences of a crisis as controllable, they will consider more active response options (i.e., responses that tackle the crisis itself). If the consequences of a crisis are primarily uncontrollable, individuals and organizations are left with few response options other than protecting themselves from the full impact of the crisis.

In addition, the extent of available resources limits crisis response options by making many options unfeasible. If individuals or organizations were effective at the preparation and prevention stage of crisis management, they are likely to have more response options available once a crisis occurs. For example, a school that employs security guards on campus has more response options in the face of a violent incident than does a school without extra security resources. Likewise, an elderly person who gathers a social support network in advance of the diagnosis of a terminal illness will have more options when facing the illness than will a person who is not prepared for the diagnosis.

Evaluation of Response Options

Having determined the available options for responding to a crisis, individuals and organizations must then evaluate the potential effectiveness of their various response options. This stage of crisis management is essentially a cost–benefit analysis of the resources required to engage in each response and the consequences associated with each response, including both direct and indirect consequences. All else being equal, people typically prefer the response option that requires the fewest resources (e.g., time, money, effort, etc.).

However, people must also consider the consequences of each response option. *Direct consequences* are outcomes of a response that affect the status of the crisis (i.e., make the crisis better or worse). Crisis decision theory describes three important aspects of direct consequences: the likelihood that the consequences of a response will be positive and avoid making the crisis worse, the magnitude of the potential consequences, and whether the consequences are reversible.

Indirect consequences of responses to a crisis are any outcomes of the response that do not affect the status of the crisis. Indirect consequences include public image consequences, consequences in other areas of life or infrastructure, and consequences for other people or organizations. Public image consequences are especially important to organizations facing public crises. It is at this stage in crisis management that businesses and other organizations must decide whether to communicate with the media about their current crisis. Even when the media is already aware of the crisis, organizations must determine how their response to the crisis will affect the media's

coverage of the crisis and ultimately their public image. Similarly, social psychology reveals that individuals constantly monitor the impressions they make on others, and these impression management concerns come into play when people evaluate their response options in the face of a crisis. People and organizations also evaluate how various responses to a crisis are likely to affect other aspects of their lives or other parts of their organization. For example, choosing to lay off a number of low-level employees may mean that senior-level employees work more hours, take on more responsibilities, and carry a heavier work burden. In addition, responses to a crisis can have far-reaching consequences for people other than the individual or organization facing the crisis. For example, an organization's response to a crisis could affect employees and their families, customers, suppliers, and stockholders.

Selection of a Response

Finally, individuals and organizations facing a crisis ultimately must choose a response. Although the chosen response typically reflects the cost-benefit evaluation just described, people may also prefer responses that they used in the past, regardless of their prior efficacy. Put simply, the known is often more comfortable than the unknown, even if the familiar response is imperfect from a rational, cost-benefit perspective.

In addition to selecting an appropriate response to the crisis, individuals and organizations may also benefit from engaging in *damage containment*. The goal of damage containment is to minimize the impact of the crisis and prevent the situation from negatively affecting other areas of an individual's life, or other departments, procedures, and individuals within an organization. For example, damage containment played an important role in the reaction of the company responsible for the 2010 Gulf oil spill, despite the fact that the company was heavily criticized for not engaging in sufficient damage containment at the onset of the crisis. In the months following the onset of the oil spill, the company engaged in damage containment by circulating press releases and producing television commercials that attempted to repair the company's reputation. In addition, they implemented a plan to provide monetary aid for people suffering financial loss due to the spill. Despite these efforts, critics still argued that the delayed response severely harmed the organization's reputation as well as the financial stability and well-being of individuals and businesses impacted by the oil spill. For instance, environmentalist groups accused the company of being responsible for withholding information regarding the severity of the oil spill that potentially slowed the response action to help save wildlife in the Gulf region. To reiterate, the goal of damage containment is to minimize the crisis's impact, and thus BP's efficacy in achieving that goal is perhaps debatable.

Postcrisis Responding

Fortunately, most crises eventually resolve and come to an end. However, crisis management may not cease with the end of the crisis. In fact, many crisis management models include the recovery period as an important phase in the experience of a crisis.

Recovering from a crisis involves numerous strategies including replenishing resources, attempts to recover losses, and revising crisis management programs. In addition, people must deal with the emotional consequences of experiencing a crisis. For example, after traumatic school shootings such as the Virginia Tech massacre or the Columbine shootings, schools typically hire counselors to talk with students and faculty about their reactions to the crisis.

Can individuals and organizations truly and fully recover from a crisis? Research from the health domain suggests that they can. Although cancer patients report lower quality of life during the acute phases of their illness, cancer patients in remission report similar quality of life as that of cancer-free individuals. Similarly, some schools and businesses report greater cohesion and a stronger sense of community between students, faculty, and/or employees following a crisis. This enhanced sense of well-being and connectedness can serve to replenish resources such as energy and mental health that may have been depleted during the crisis.

Reflecting on and learning from the crisis are critical processes to prepare for future crises. Although reflecting on a crisis may provoke anxiety, especially in the case of severe or traumatic crises, reflection may also promote renewed confidence and feelings of self-efficacy regarding the ability to handle future crises. Furthermore, people's perceptions of the causes and implications of a crisis may change once the crisis is over. It may be difficult to evaluate all aspects of a crisis while in the midst of it, so reevaluating the crisis once it ends can provide insight into the most effective ways to prevent future crises and to mitigate the consequences of crises that are unavoidable.

Glossary

Acculturation The process of acquiring a new culture's symbols and practices by an individual whose prior cultural learning has taken place elsewhere.

Adaptation The process of internal modification of individuals that enables them to attain a relatively stable, reciprocal, and functional relationship with a particular environment.

Assimilation The absorption process of foreign-born individuals into the native population by cultural, social, and economic mainstreaming.

Communication The process by which information is exchanged between individuals through the encoding and

decoding activities employing verbal and nonverbal symbols, signs, or behavior.

Culture shock Psychological and physiological stress responses to being placed in an unfamiliar cultural environment.

Deculturation The process by which individuals at least temporarily suspend, or unlearn over time, some of the symbols and habitual practices of one's native culture and replace them with new symbols and practices of the host culture.

Enculturation The primary socialization process whereby individuals learn and internalize their native culture.

Background

Millions of immigrants and refugees change homes each year seeking better hopes of safety, freedom, or economic betterment, or simply looking for a more desirable environment in which to live. Many others temporarily relocate in a foreign land to carry out religious activities, or to serve as diplomats, military personnel, and other governmental, intergovernmental, and nongovernmental agency employees on overseas assignments. Researchers, professors, and students visit and study at foreign academic institutions, along with the employees of multinational corporations. Increasingly, individual accountants, teachers, construction workers, athletes, artists, musicians, and writers seek employment in foreign lands on their own. Although varied in individual circumstances, all of these groups of people and many others share the common project called cross-cultural adaptation. They find themselves straddled between two worlds, the familiar milieu of the home culture and their new locus in the host society, and recognize that many of their previously held beliefs, taken-for-granted assumptions, and routinized behaviors no longer relevant or effectual.

Long-Term Adaptation

The process of cross-cultural adaptation among long-term settlers has been one of the most salient research issues across social science disciplines. Studies addressing this phenomenon have been continuous and extensive, particularly in the United States and more recently in European countries. In the 1930s, the Social Science Research Council appointed a Subcommittee on Acculturation and charged it with the task of analyzing and defining the parameters for this new field of inquiry within the domain of cultural anthropology. As a result, the concept, acculturation, was formally adopted as a new area of study dealing with those phenomena that result

when individuals and groups from one culture come into direct contact with another culture.

Subsequent academic inquiry into cross-cultural adaptation has evolved into a vast and diverse field. Such has been the case due to the application of concepts, definitions, and methodologies pertaining to differing disciplinary and individual perspectives and research foci. Many sociologists, for example, have approached immigrant adaptation focusing on macrolevel issues pertaining to the patterns and processes in which minority groups are integrated into the political, social, and economic structure of the new, or host, society. Studies in urban sociology and urban anthropology have added the dimension of ethnographic explorations into the issues related to political, social, and economic dynamics in immigrant or ethnic communities and neighborhoods.

In comparison, studies in social psychology, sociolinguistics, and communication have concentrated on the microlevel phenomenon of long-term adaptive change in individual immigrants. In this approach, emphases have been placed on the psychological, social, and cultural integration of individual newcomers into their host society. By and large, such studies have revealed that an individual's adaptive change is cumulative and progressive over time, thereby affirming the traditional 'melting-pot' perspective on the history of immigration in the United States.

The linear-progressive understanding of long-term adaptation, however, has been increasingly challenged since the 1960s and 1970s. With the rise of the ideology of pluralism in the United States and elsewhere, pluralistic conceptions of long-term adaptation have been proposed to reflect the viewpoint that assimilation into the dominant mainstream culture on the part of immigrants and ethnic minorities need not, or should not, take place. Instead, scholars upholding or sympathetic to this view have emphasized alternative choices for individuals or groups such as maintaining a distinct identity or seeking a dual identity with respect to their original culture and the host society.

Short-Term Adaptation

Studies of temporary sojourners have been largely exempt from the above-described ideological controversy over the phenomenon of assimilation. Since the 1960s, studies of sojourner adaptation have been motivated mainly by practical, problem-centered concerns of easing the temporary but often difficult transition into a new cultural environment. The problem-centered perspective is evident in the many studies that have addressed the phenomenon of culture shock. This concept, as well as related terms such as transition shock, cultural fatigue, and self-shock have been employed to investigate various stress reactions to cultural dislocation, from irritability, insomnia, and an acute sense of loss, to feelings of anxiety, insecurity, and impotence.

While focused on the problematic nature of life in a foreign land, sojourn research findings have shown discernible patterns of change in psychological states over time. A variety of studies have reported a 'U-curve' of psychological adaptation during a sojourn, depicting the general tendency for sojourners to experience initial optimism and elation, the subsequent emotional dip or trough, followed by a gradual recovery to higher adaptation levels. This U-curve description has been extended to the 'W-curve,' that includes the reentry phase during which the sojourner, once again, undergo a similar psychological adaptation process upon returning home. Despite their intuitive appeal, the U-curve and W-curve hypotheses have produced inconsistent findings when applied to different research contexts. Comprehensive reviews of pertinent research have concluded that evidence for the theories' claims are inconclusive and overgeneralized.

Sojourner adaptation studies have also highlighted some of the positive and beneficial aspects of crossing cultures. Arguments have been made that the cultural shock experience must be viewed in a broader context of profound learning and growth that leads to an increased self-awareness. Highlighting such positive aspects of sojourn, some studies have shown that the intensity and magnitude of initial culture shock is either unrelated to, or even positively related to, the level of subsequent psychological adjustment and social and professional effectiveness within the host environment.

The Process of Cross-Cultural Adaptation

Clearly, there are differences between long-term and short-term adaptation associated with the duration of the adaptation process itself. Unlike immigrants, most short-term sojourners are more likely to limit their contact with the new culture to mostly peripheral areas, such as to pursue a career, obtain a degree, or merely enhance one's prestige in the eyes of the folks at home. Compared to long-term settlers, their commitment to the host environment is likely to be weaker given their more specific and narrowly defined goals for sojourn.

Differences such as these, however, are largely a matter of degree, and not of kind. That is, immigrants and sojourners alike undergo at least some level of the common project of cross-cultural adaptation as they begin their life in the host society as strangers. As strangers, all newcomers embark on a cross-cultural journey as outsiders. They are challenged to

undergo at least some level of modifications in their original cultural habits, at least to the extent that is called for by the specific circumstance under which they have entered the host culture, so as to navigate their unfamiliar milieu and carry out their daily life activities.

This notion of strangers can be extended to include those who return home after a sojourn in a foreign culture or subculture. Generally, readapting to one's original culture is less demanding than adapting to a foreign culture. Yet, to the extent that the returnee has been changed by the sojourn experience, and to the extent that the original culture has changed during the sojourn, the returnee, once again, goes through essentially the same process of cross-cultural adaptation. Strangers further include those native-born individuals who cross subcultural or ethnic boundaries within a society and face significant adaptive pressures from the new subcultural environment. Such would be the case, for example, for American Indians leaving an Indian reservation to find employment in an urban environment. Also included in the domain of strangers are those individuals who find their local community rapidly changing in its demographic composition. For example, existing African American inner city residents may find themselves changing from being a majority group to becoming a minority group due to a significant influx of Asian immigrants.

The following discussion addresses the essential nature of the adaptation process that applies to all of the above-described categories of strangers who share the common challenge of the practical necessity to bridge the gap between their internalized cultural habits and those of the new environment.

Enculturation, Acculturation, Deculturation, Assimilation

The unwritten task of every culture is to organize, integrate, and maintain the home world of the individual primarily in the formative years of childhood. Children grow up in their native culture learning what they need to know to function acceptably in a given culture. Through continuous interaction with the various aspects of the environment, they are socialized to live in the company of others around them who share a similar image of reality and self. This process is commonly called enculturation.

In many ways, entering a new culture is like starting an enculturation process all over again. Only this time, strangers are faced with situations that deviate from the familiar and internalized original cultural script. They become more aware of the previously taken-for-granted habits of mind. Now, as strangers, they discover that they lack a sufficient level of understanding of the new communication system of the host society. They are challenged to suspend, or even abandon, some of the cultural patterns that have symbolized who they are and what they are. Such inner conflicts, in turn, make strangers susceptible to external influence and compel them to learn the new cultural system. This activity of new learning is the essence of the process known as acculturation, that is, the learning and acquisition of the new cultural patterns and practices, particularly in those areas of direct relevance to their everyday living.

Acculturation, however, is not a process in which new cultural elements are simply added to prior internal conditions. As new learning accumulates, some deculturation also

takes place, at least in the sense that new cultural responses are adopted in situations that previously would have evoked old ones. As the interplay of acculturation and deculturation continues for a prolonged period, strangers undergo an internal transformation, from visible changes in superficial areas such as overt role behavior to more intangible but more profound changes such as changes in previously held cultural beliefs, values, outlooks on life, and even cultural identity.

The ultimate directionality of the internal change driven by the continual processes of acculturation and deculturation is toward assimilation, a state of the maximum possible convergence of our internal and external conditions to those of the natives. Whether by choice or by circumstance, individual settlers vary in the distance that they travel in their own adaptation process. For most strangers, assimilation remains a lifetime goal than an obtainable outcome, one that often requires the efforts of multiple generations.

Stress, Adaptation, and Growth

Acculturation and deculturation processes inevitably produce in individual strangers stress, the experience of temporary internal disturbance and even breakdown in extreme cases. As parts of their internal organization undergo adaptive modifications, strangers are temporarily in a state of disequilibrium manifested in varying levels of confusion and anxiety. The state of internal flux is often met by the tendency to use various defense mechanisms such as denial, hostility, cynicism, avoidance, and withdrawal, all of which are particularly acute during the initial phase of sojourn or immigration, as indicated by the difficulties and disruptions documented in culture shock studies.

At the same time, however, stress experiences are the very force that drives strangers to adaptation. The interplay of stress and adaptation can be understood as a dialectic between integration and disintegration, between progression and regression, or between permanence and change. Each stress experience presents strangers with an opportunity to recreate themselves. It is through the impetus of stress that they are compelled to engage in activities of new learning that enables them to handle the transactions of daily living. Stress, in this regard, is intrinsic to complex open systems and essential in the adaptation process – one that allows for self-(re)organization and self-renewal. The state of misfit and a heightened awareness in the state of stress serve as the very forces that propel individuals to overcome the predicament and partake in the act of adaptation through active new learning.

Out of these activities, some aspects of the environment may be incorporated into an individual's internal structure, gradually increasing its overall fitness to the external realities. Over time, most strangers manage to achieve an increasing capacity to detect similarities and differences between the new surrounding and the home culture and are better able to manage their changed circumstances. What follows a successful, long-term, and cumulative management of the stress-adaptation disequilibrium is a subtle and often imperceptible psychological growth, a form of internal change in the direction of increased perceptual and intellectual complexity with respect to the host culture.

Together, stress, adaptation, and growth constitute a three-pronged conceptual representation of the psychological

underpinning of the cross-cultural adaptation process. As depicted in **Figure 1**, the stress-adaptation-growth process continues as long as there are new environmental challenges, with the overall forward and upward movement in the direction of greater adaptation and growth. The process does not unfold in a smooth, arrow-like linear progression, but in a cyclic and fluctuating pattern of drawback to leap: each stressful experience is responded to with a temporary setback, which, in turn, activates adaptive energy to reorganize and reengage in the activities of cultural learning and internal change, bringing about a new self-reintegration. Large and sudden changes occur during the initial phase when the severity of difficulties and disruptions are likely to be high. Over a prolonged period of undergoing internal change, the fluctuations of stress and adaptation are likely to become less intense, leading to an overall calming in the individual experiences of interacting with the host environment.

Factors Influencing the Process

We now turn to the question of differential adaptation rates, or speeds, at which cross-cultural adaptation occurs in individual cases. Although strangers, by and large, manage cross-cultural challenges successfully over time, the degree and pace of their individual adaptive change vary. Some may suffer more from hostility or indifference among the natives that makes it difficult to find ways to overcome the challenges they face in the host environment. Some may resist the idea of having to change their original cultural habits more, thereby raising psychological barriers to work against their own adaptive change. Others may be less capable of dealing with states of adaptive stress, leading to a more extreme withdrawal and alienation from the host society or a decision to return to their home country prematurely.

The fact that individual cases of cross-cultural adaptation vary in terms of the level of success begs the question, 'What factors facilitate or impede the adaptation process?'

This question is addressed below through an examination of the key factors of the communicative interface between the individual and the host environment, of the host environment, and of the individual's own background predisposition.

Figure 1 The stress-adaptation-growth dynamic. Reproduced from Kim YY (2001) *Becoming Intercultural: An Integrative Theory of Communication and Cross-Cultural Adaptation*, p. 59. Thousand Oaks, CA: Sage.

Communication Factors

Like all human-social activities, cross-cultural adaptation occurs in and through the communication interface between the stranger and the surrounding environment. Just as the natives acquire their capacity to function in their social world through communicative interactions throughout their lives, it is through communication that strangers come to learn and internalize the significant symbols and practices of the host culture. Through communicative engagement, nonnatives gain insights and skills that are necessary to achieving a level of success in their adaptive endeavor.

Communication activities comprise two basic, inseparable dimensions, personal communication and social communication. Through personal (or intrapersonal) communication, individuals organize themselves internally with respect to their surroundings, developing ways of engaging themselves in social communication activities. If the personal communication can be compared to the 'off-line functions' of computer systems, social communication carries out the 'on-line' functions of interfacing with the computer environment through input-output transactions of messages.

Personal communication

In the context of cross-cultural adaptation, personal communication can be best understood in terms of 'host communication competence,' that is, the overall internal capacity of a stranger to decode and encode information in accordance with the host cultural practices of communication. Host communication competence serves as the main engine that drives the adaptation process. Successful adaptation of strangers can be realized only when their internal communication systems sufficiently overlap with those of the natives. An individual's level of host communication competence at a given time reflects his or her overall capacity to participate in host social communication activities, whereas the lack of such competence manifests itself in various forms of miscommunication, social inadequacies, and, in some cases, marginalization.

Host communication competence comprise three interrelated subcategories: cognitive, affective, and operational. Cognitive competence refers to an individual's overall intellectual capacity to deal with the host culture, including the knowledge of the host culture, history, social institutions, and rules of interpersonal conduct. Knowledge of the host language, in particular, serves as the primary conduit for adaptation, one that enables strangers to access the accumulated records of the host culture and learn to think in the way the native speakers think. Knowledge of the local language means not just technical knowledge such as phonetics, syntax, and vocabulary. It also includes pragmatic knowledge about the everyday use of the language including the many subtleties in the way the language is spoken and interpreted in various formal and informal social contexts.

Affective competence refers to the emotional and motivational capacity to deal with the various challenges of living in the host environment. Specifically, it includes positive attitude (acceptance of the host culture) and adaptation motivation (the willingness to learn and participate in it). A positive, willing, and flexible self-other orientation helps engender greater openness and lessen unwarranted prejudicial cynicism

toward new cultural experiences. The affective competence also includes the development of a capacity to understand, and participate in, the local people's emotional and esthetic sensibilities, thereby making it possible for strangers to establish a deeper-level psychological connection with the natives. Although initially difficult, strangers become better able to participate in the surrounding landscape of art, food, music, sports, and other everyday experiences of fun, joy, humor, and happiness, and of anger, despair, and disappointment. In this visceral connection, strangers are on their way to being 'insiders' who are capable of forming close relationships with the natives.

The cognitive and affective capabilities work side by side the operational competence, the capacity to express outwardly by choosing a 'right' combination of verbal and nonverbal acts in specific social transactions of the host environment. As strangers become increasingly competent cognitively and affectively, they are better able to act in greater consonance with the natives' actions and display greater resourcefulness with which to negotiate and reconcile cultural differences and to form appropriate and effective action plans for accomplishing personal and social goals.

Social communication

Host communication competence is directly and reciprocally linked to participation in the social communication activities of the host society. An individual's host social communication activities are enabled or constrained by his or her capacity to communicate effectively and appropriately. Conversely, the individual's host communication competence cannot be developed without participating in the social communication processes.

Interpersonal communication activities with natives offer opportunities for learning the host cultural practices and for engaging in 'corrective exchanges' with respect to the use of the host communication system, including its verbal and nonverbal codes. Through experiences of direct engagement with native-born individuals, strangers obtain vital information and insight into the mindsets and behaviors of the local people. The natives' behaviors provide strangers with points of reference or a check and validation of their own communication behaviors. By conferring with the natives, strangers can confirm or reject presumed meanings and motives in natives' communication behaviors. They learn not only what to do but also some of the relevant cultural and personal values.

Notwithstanding cross-cultural barriers, strangers develop at least a limited number of interpersonal ties with host nationals over time. As their host communication competence improves, so does their self-confidence to participate in host interpersonal communication activities. Through active engagement in host interpersonal communication activities, strangers also begin the process of constructing a set of satisfying and supportive relationships with natives. Newly arrived immigrants and sojourners tend to be drawn to coethnics when they are available nearby. Over time, however, more ties with local people are likely to be incorporated into their personal networks, replacing some of the coethnic ties.

Cross-cultural adaptation is further facilitated by participation in mass communication activities of the host society. Through a wide range of mediated and public forms of

communication such as radio, television, newspaper, magazine, movie, art, literature, music, and drama, strangers interact with their host milieu without direct interpersonal involvements. Such mass communication activities help broaden the scope of cultural learning opportunities beyond the immediate social context with which a stranger routinely comes into contact. Compared to host interpersonal communication activities, host mass communication activities render less opportunity for direct feedback, serving as an important source of cultural and language learning, particularly during the early phases of the adaptation process.

In many societies and communities today, strangers' interpersonal and mass communication activities involve their coethnics or conationals and home cultural experiences, as well. Some form of ethnic mutual-aid or self-help organizations, including religious organizations, may be available to render assistance to those who need material, informational, emotional, and other forms of social support. In addition, ethnic mass media such as newspapers, radio stations, and television programs may be accessible via the Internet or in prerecorded audio- and videotapes and computer disks.

Findings from studies of long-term cross-cultural adaptation generally indicate that participation in ethnic interpersonal and mass communication activities can be helpful to the initial phase of the cross-cultural adaptation process when newly arrived strangers lack host communication competence and access to host interpersonal resources. Beyond the initial phase, however, heavy and prolonged reliance on coethnics have been found to be either an insignificant influence on, or impede, the long-term adaptation process with respect to the host society at large.

Environmental Factors

The adaptation function of the strangers' personal and social (interpersonal, mass) communication cannot be fully explained in isolation from the conditions of the host environment. Since different societies and communities present different environments for cross-cultural adaptation, a given stranger can be more successful in adapting to a certain environment than to another one.

Of various environmental characteristics, three key factors are discussed below as particularly important to individual strangers' adaptive efforts (1) host receptivity, (2) host conformity pressure, and (3) ethnic group strength. These three factors help define the relative degrees of 'push and pull' that a given host environment presents to strangers.

Host receptivity

Host receptivity refers to the degree to which the receiving environment welcomes and accepts strangers into its interpersonal networks and offer them various forms of informational, technical, material, and emotional support. A society or a community can be more receptive toward certain groups of strangers while unwelcoming toward certain others. For example, Canadian visitors arriving in a small town in the United States are likely to find a largely receptive environment. On the other hand, the same town may show less receptivity toward visitors from lesser known and vastly different cultures. Differences in host receptivity toward different groups of strangers

can be attributed to a number of plausible reasons such as the nature of the relationship, friendly or hostile, between the host country and the stranger's home country; cultural and ideological difference and incompatibility between the two cultures; and the racial/ethnic prejudice predominantly held by the society against strangers in general or the particular group.

Host conformity pressure

Along with receptivity, individuals face differing levels of conformity pressure from the host environment. Conformity pressure refers to the extent to which the society challenges strangers to adopt the normative patterns of the host culture. Different host environments show different levels of acceptance and appreciation of strangers and their ethnic characteristics. In general, people in heterogeneous and cosmopolitan societies such as the United States tend to hold more pluralistic and tolerant attitudes toward ethnic differences, thereby exerting less pressure on strangers to change their habitual ways. Even within a country, ethnically more heterogeneous metropolitan areas tend to display lower levels of host conformity pressure than do smaller, ethnically more homogeneous rural towns.

Ethnic group strength

The third environmental factor that influences strangers' cross-cultural adaptation is the strength of their ethnic group in the context of other groups in the host society or community. Depending on relative group size, status, or power, stronger ethnic groups are likely to provide their members with a more vibrant subculture and practical services to its members. In doing so, however, a strong ethnic community is likely to encourage the maintenance of ethnic culture and communication, and even exert a subtle or explicit pressure to conform to the ethnic cultural norms. A long-term consequence of such ethnic community influences is likely to be an impediment, intended or not, to individual community members' active participation in host social communication processes and long-term cross-cultural adaptation to the host culture at large.

Predisposition Factors

Each stranger begins the cross-cultural adaptation process with a different set of preexisting characteristics. The internal conditions with which they begin their life in the host society help set the parameters for the way they relate to the new environment and their own subsequent adaptive changes. The various predispositional differences in which strangers differ in their background conditions can be organized into three categories: (1) preparedness, (2) ethnic proximity/distance, and (3) personality predisposition. Together, these characteristics help define the degree of a stranger's 'adaptive potential.'

Preparedness for change

Strangers come to their new environment with differing levels of preparedness for dealing with that environment. Preparedness is directly linked to the level of readiness to develop host communication competence. Influencing the strangers' readiness are a wide range of formal and informal learning experiences they may have had prior to moving to the host society. Included in such activities are the schooling and training in,

and the media exposure to, the host language and culture, as well as their prior cross-cultural adaptation experiences, particularly contacts with members of the host society. In addition, the strangers' preparedness is often influenced by whether their move to the host society is voluntary or involuntary and for how long. Voluntary, long-term immigrants, for example, are likely to enter the host society with greater readiness and willingness for making necessary efforts to adapt, compared to the temporary visitors who unwillingly relocate for reasons other than their own volition.

Ethnic proximity/distance

The ethnicity of a stranger plays a role in the cross-cultural adaptation process by serving as a certain level of advantage or handicap. It does so by affecting the ease or difficulty with which the stranger is able to develop the communication competence in a given host society, and to participate in its social communication activities. For instance, many Japanese business executives in the United States face a greater amount of challenge in overcoming their language barrier than are their counterparts from the United Kingdom. The strangers' visual ethnic markers (such as height, skin color, and facial features) and audible ethnic markers (such as accents and other speech patterns) influence the degree to which the natives are psychologically prepared to welcome them into their interpersonal networks. Accordingly, ethnicity influences the cross-cultural adaptation process in at least two interrelated manners. First, each stranger faces a level of linguistic and cultural distance for the stranger to overcome in order to develop host communication competence and to participate in the host social communication activities. Second, each stranger creates a certain level of psychological distance (or affinity) in the minds of the natives, which, in turn, would affect the natives' receptivity toward the stranger.

Adaptive personality

Along with preparedness and ethnicity, strangers enter a host environment with a personality, or a set of more or less enduring traits of sensibilities. Their existing personality serves as the inner resource, based on which they pursue new cultural experiences with varying degrees of enthusiasm and success. Of particular interest are three interrelated personality resources that would help facilitate the strangers' adaptation by enabling them to endure stressful challenges and to maximize new learning: (1) openness, (2) strength, and (3) positivity. Openness is an internal posture that is receptive to new information. Openness enables strangers to minimize their resistance and to maximize their willingness to attend to the new and changed circumstances. It is a psychological orientation that allows for greater tolerance for ambiguity, intellectual flexibility, and cultural and interpersonal sensitivity. The strength of personality reflects the inner quality of resilience, hardiness, patience, and persistence. Individuals with high levels of personality strength tend to be stimulated by new challenges and remain confident. Openness and strength of personality is closely associated with positivity, an affirmative and optimistic outlook of mind, or the internal capacity to defy negative prediction. Strangers with a positive personality are better able to endure stressful events with a belief in the possibilities of life in general as opposed to being overcome by unwarranted defeatist cynicism.

Facets of Adaptive Change

Through the interactive workings of the above-described factors of the communication activities, of the environment, and of the background of an individual stranger, the process of cross-cultural adaptation unfolds. Emerging in the adaptation process, over time, are three interrelated facets of internal change in the stranger (1) increased functional fitness in carrying out daily transactions; (2) improved psychological health in dealing with the environment; and (3) emergence of an intercultural identity orientation. These three facets are interrelated developmental continua, in which individual strangers can be placed at different locations reflecting the different levels of adaptive change at a given point in time.

Functional Fitness

As previously noted, strangers conduct continuous experiments in the host environment. They instinctively strive to 'know their way around,' so that they may effectively control their own behavior and the behavior of others in the host environment. Through repeated activities resulting in new learning and internal reorganizing, strangers achieve an increasing functional fitness between their internal responses and the external demands of the host environment. Well adapted strangers would be those who have accomplished a desired level of appropriate and effective communication relationship to the host environment – particularly with those individuals with whom the strangers carry out their daily activities. As they achieve increased communication competence, they are also better able to meet their personal and social needs.

Psychological Health

Everyone requires the ongoing validation of his or her social experience. Being unable to meet this basic human need can lead to symptoms of mental, emotional, and physical disturbance. The shifting of the self-world relationship brings about heightened levels of inner conflict due to the gap between the internal and external reality. In the absence of adequate host communication competence, engagement in host social communication activities, and functional fitness, strangers are subject to frustration, leading to the symptoms of poor psychological health. The very meaning of the term culture shock employed in studies of temporary sojourners suggests lack of psychological health, stemming from the poor fit of a stranger's intrapsychic system to that of the natives. Most strangers, however, are able to achieve, over time, a higher level of psychological health and a subsiding level of disturbances in dealing with the host environment. They achieve an increased internal integration – a sense of inner cohesiveness and confidence.

Intercultural Identity

Long-term adaptive change also includes the gradual emergence of an intercultural identity, a psychological orientation toward self and others that is no longer clearly and rigidly defined by either the original cultural identity or the identity of the host culture. As the host cultural elements are

increasingly incorporated into their self-concept, the stranger's self-other orientation becomes more flexible. While rooted in the original cultural identity, the stranger's identity is broadened to incorporate new dimensions of perception and experience in which the original cultural identity begins to lose its distinctiveness and rigidity. More than likely, this kind of identity transformation is unlikely to be a matter of conscious decision but simply an aspect of the natural psychological evolution beyond the boundaries of childhood enculturation.

Terms close to intercultural identity include 'metaindentity,' 'cosmopolitan identity,' or 'transcultural identity,' all of which indicate an identity orientation that is less dualistic and more inclusive, less categorical and more individuated, less parochial and more universalized. The development of an intercultural identity does not come about without certain 'costs' that may be deemed too high by some. The process can be filled with ambivalence and internal conflict between one's loyalty to the original identity and a necessity to embrace a new one that is rooted in, embracing, and not discarding, the original cultural identity, just as acquiring knowledge and skill in the host language does not necessarily result in corresponding loss in the original language.

Conclusion

Cross-cultural adaptation is, in essence, a largely unconscious process of cultural learning and personal change that takes place over time. It is a dynamic unfolding of the natural human tendency to struggle for an internal equilibrium in the face of adversarial environmental conditions. It is a process in which, over a prolonged period, a newcomer can potentially become a fully functioning insider. The process unfolds in the fluctuating experiences of stress, adaptation, and growth, a process in which the newcomer advances toward achieving a higher level of personal and social efficacy with respect to the environment that was once new and unfamiliar. The pursuit of cross-cultural adaptation opens up a path of personal development, in which individuals stretch themselves out of the familiar and reach for a deepened and more inclusive understanding of human conditions, including their own.

Central to this process is the individual's ability to communicate in accordance to the norms and practices of the host culture and his active engagement in its social communication processes. Multiple forces are simultaneously at work surrounding the communicative interface between the individual and the host environment, from the conditions of the environment and the ethnic and personal predispositions of the individual. Like a locomotive engine, each unit operating in this process affects, and is affected by, the workings of all other units. Some of the factors may be more pertinent than others in specific cases of cross-cultural adaptation. In some cases, adaptive successes may be almost entirely due to the openness, strength, and positivity of the stranger's personality, which enable the stranger to overcome even the most severely unresponsive host environment. In other cases, very little adaptive change may take place in strangers whose ethnic community offers an almost complete insulation from having to face the host cultural challenges.

Should strangers choose to adapt successfully, they would benefit from being prepared and willing to face the stressful experiences that are part and parcel of the adaptation process. They would need to concentrate on acquiring new cultural communication practices and be willing to put aside some of the old ones, recognizing the critical importance of host communication competence as the fundamental mechanism that drives their own adaptation. They would also need to participate actively in the interpersonal and mass communication processes of the host environment. In addition, through cultivating the adaptive personality of openness, strength, and positivity, they are likely to be more successful in overcoming temporary setbacks and attaining greater success in pursuing their personal and social goals.

With the advent of globalization, we no longer have to leave home to experience new cultural learning and cross-cultural adaptation. For many people in the world, physical distance no longer dictates the extent of exposure to the images and sounds of once distant cultures. Many urban centers present their own contexts of cross-cultural adaptation, the natives are routinely coming in face-to-face contacts with nonnatives. Such encounters often compel everyone involved to put aside and even unlearn at least some of the original cultural patterns. The rapidly changing reality can be threatening to many people, provoking a keen sense of unsettling discontinuity, malaise, and nostalgia for the age of certainty, permanence, and a fixed and unitary cultural identity.

In the end, then, cross-cultural adaptation is a journey that compels individuals to make choices and to be accountable for the outcomes. Those who have successfully crossed cultural and subcultural boundaries are likely to be those who chose to adapt and to be changed by that choice. Although their tribulations can be staggering, they have worked through the setbacks and come out victorious with an increased capacity to see others, themselves, and situations in a new light. They are the ones who bear witness to the promise of the cross-cultural adaptation process. Their personal achievements are a tribute to the ever-present human capacity to adapt – the capacity to face challenges, learn from them, and evolve into a greater self-integration that defies the simplistic and conventional categorizations of people and reveals a new, intercultural way of being in the world.

Crowd Psychology

S Reicher, University of St. Andrews, Fife, UK

© 2012 Elsevier Inc. All rights reserved.

Glossary

Collective empowerment An increased sense that the group has the ability to do what it wishes, even against the opposition of outgroups.

Collective self-objectification The transformation of the group's idea of how society *should* be organized into the *actual* organization of society.

Contagion The notion that people automatically follow the ideas and emotions of those around them.

Crowd A large face-to-face assembly of people who consider themselves to be members of a common social group.

Deindividuation The idea that identity is lost in the group and that, as a consequence, people lose control over their behavior.

Elaborated social identity model of crowds (ESIM) A theory of how crowd identities and crowd action develop through the intergroup interaction between crowd members and outgroups.

Emergent norm theory A theory of how norms emerge in crowds through the interactions of members and the actions of prominent individuals or 'keynoters.'

Social identity One's sense of oneself as a member of a particular social group (e.g., 'I am an American') along with the significance attached to that membership.

Social identity model of crowds (SIM) A theory of how crowd behavior derives from the transition from individual to social identity and the process of defining identity-appropriate behavior in context.

Introduction

In his 1988 textbook on Group Processes, Rupert Brown notes that "there is a widespread view both in our society and in our discipline that groups are bad for you." If this is true of groups in general, it is particularly true of crowds. Indeed, the very language used to denote crowds – terms such as 'the mad mob,' 'the herd,' 'the rabble' – speaks in equal measure of fear and derision. This is entirely understandable if one considers the contexts in which a science of crowd psychology emerged.

Crowd psychology centers on the question of how people are transformed when they assemble together in large numbers. Although, as we shall see, when authors refer to crowds, they are generally referring not simply to large numbers of individuals but rather to assemblies of people who share some common sense of who they are and some common purpose: crowds of demonstrators, crowds of sports fans, revolutionary crowds. We shall also see that there are important psychological differences between masses who are merely copresent and copresent masses who perceive themselves as sharing a group membership.

Interest in crowds goes as far back as one cares to look – and the general consensus seems to be that whatever transformations are wrought by crowds, they are inevitably negative. Herodotus, sometimes styled 'the father of history,' declared that "there is nothing less understanding and more proud than the blind mass". He was but the first of a long line of eminent thinkers who made disparaging comments about crowds and crowd psychology. However, a distinctive crowd science developed only during the late nineteenth century.

This period was dominated by a crisis of social order. Industrialization had transformed a largely agrarian population into urban masses. New forms of social organization such as trade unions and new political movements, such as syndicalism, anarchism and, above all, socialism, were leading these masses to challenge gaping social inequalities. How, then, were

the elite to maintain their dominance? How were they to face down the challenge of the masses and even engage them in defense of the existing order? These were the dominant questions of the day.

But if the masses in general were seen as a potential threat to the status quo, the crowd was the radicalized mass in action. It was the potential catastrophe made actual. And so the crowd became a dense symbol which regrouped all the bourgeois fears and fantasies of chaos. If social discipline seemed under threat from alcoholism, the crowd was characterized as drunken, either metaphorically or literally. If the patriarchal order seemed under assault from independent women, the crowd was described metaphorically as feminine, while the worst of crowds were seen to be crowds of women – such as the 'petroleuses' of the 1871 Paris Commune.

Indeed, the Paris Commune has a particular prominence in the history of crowd psychology. For, to take progression one step further, where the masses were a potential threat and crowds in general an actual threat to the elite, the Commune crowds had, at least temporarily, overthrown the elite and created what has been described as the first socialist republic in history. Those of the elite who had experienced the Commune had witnessed a future they did not like and which they would do everything to prevent. A key part of this was to find ways of mitigating against crowd action. It is hardly surprising, then, that French theorists dominated early crowd science and that they presupposed that crowd psychology and crowd action are a purely negative phenomena.

I shall start by analyzing this early crowd science and showing how its social concerns are embedded deep within its core assumptions. I shall then outline alternative approaches which, rather than seeking to pathologize crowd psychology (and hence crowd action), pay attention to the perspectives of crowd participants, analyze the patterns of crowd action, and seek to understand the relationship between the two. Above all, I shall seek to demonstrate that the early crowd theorists

have done us a disservice by characterizing crowd members as mindless and crowds as irrelevant to the normal functioning of society. For crowds provide a particularly productive site in which to understand how people are constituted and act as social subjects. Crowds are critical to the formation of the social identities and social relationships which regulate everyday life.

Classic Crowd Science: A Tale of Loss

Early crowd science was a vibrant field. Many theorists such as Fournial, Tarde, Sighele, Rossi, and others debated crowd behavior, not only in academic texts but also in the society magazines of the day. But these names have largely disappeared. Only one remains, that of Gustave Le Bon. His book *The Crowd: A Study of the Popular Mind*, first published in 1895, is still cited in psychology journals, in official reports, and in the popular media. It has been described as the most influential psychology text of all time in that it not only analyzed mass behavior, but also that it helped create the mass politics of the twentieth and twenty-first centuries.

Le Bon – both the man himself and the basis for his enduring influence – exemplify the general themes of fear, hostility, and repression which frame the emergence of crowd science. Le Bon's first experience of crowds was as the head of ambulance services in the Paris Commune. That experience bred him in a deep hatred and contempt for the masses. The rest of his career was devoted to understanding how crowds could be tamed and engaged for – not against – the nation. Indeed, the text of which he was most proud was not 'The crowd' but a far more obscure book called 'La Psychologie Politique et la Defence Social' published in 1910.

What made Le Bon stand out from his fellow theorists was not so much his conceptual originality as his practicality. Where others documented the bestiality of crowds and did little more than throw their hands up in horror, Le Bon sought to show how leaders could take advantage of crowd psychology and use it to their own ends. His book was only in small part a theoretical analysis. The larger part reads like a primer for leaders who wish to exploit the power of crowds. And the leaders he sought to educate were the right wing leaders of his time – for whom he ran a regular weekly luncheon club. Moreover, these leaders reciprocated his enthusiasm. The list of those who praised Le Bon reads like a roll call of the autocrats of the early twentieth century. Mussolini, for instance, after praising Le Bon to the skies, declares that he built the principles of the (fascist) Italian state on the basis of 'The crowd.'

When it comes to Le Bon's actual crowd psychology, the predominant theme is one of loss. His starting point lies in the notion that, on entering the crowd, people become anonymous and lose their sense of personal identity. This first process submergence is termed *submergence*. Submergence, in turn, leads people in crowds to lose control over what they feel and do. Because they can no longer access the personal values and standards that allow them to judge what is and is not appropriate, crowd members simply follow passing ideas and emotions – particularly emotions, since the self as the seat of the intellect has been occluded. This second process is termed *contagion*.

Finally, submergence and contagion lead the crowd members to lose their civilized standards. Because people's conscious access to internal standards has been blocked, the emotions and ideas that govern action come predominantly from the 'racial unconscious' – an atavistic residue which people share in common from a distant past. And because this residue is ancient and primitive, so are the actions to which it leads. This third and last process is termed *suggestion*.

Altogether, the picture that emerges of crowd psychology and of crowd behavior is unrelentingly bleak. Crowds, says Le Bon, are only powerful for destruction. The crowd member, he declares, is a barbarian who descends several rungs on the ladder of civilization simply by virtue of becoming part of the crowd. Most revealingly, in a passage that reveals much of both Le Bon's 'science' and his politics, he remarks that

among the special characteristics of crowds there are several – such as impulsiveness, irritability, incapacity to reason, the absence of judgement and of the critical spirit, the exaggeration of the sentiments and others besides – which are almost always observed in beings belonging to inferior forms of evolution – in women children and savages for instance.

There is only one exception to this analytic negativity. Le Bon acknowledges that crowd members can be extraordinarily heroic at times. Moreover, this flows not only from the loss of self (and hence a loss of concern for self-preservation) but also from the one element of gain in Le Bon's account. That is, on becoming submerged in the mass, people might forget their individuality, but they become part of something much bigger and hence they evince a sense of immense power which allows them to do almost anything – thus making crowds the ultimate nightmare for those who have stakes in the social order: total power without any sense of responsibility.

Le Bon's work continues to be cited in contemporary texts. What is more, his work continues to have relevance through the development of deindividuation theory. This approach is derived directly from the idea of submergence and is most centrally concerned with the effects of anonymity (or 'perceptual immersion') in a group. There are a number of variants of the theory. One, most associated with Zimbardo, suggests that anonymity leads to a lowered concern with social standards and a lowered threshold for exhibiting antisocial behaviors. A second, associated with Diener, suggests that immersion in a group leads to a lowered awareness of internal standards and increased domination by external stimuli. In effect, people become uncontrolled and simply go along with whatever is suggested to them. A third variant effectively integrates the other two and argues that, in the group, people become less aware of both internal and social standards and hence both more uncontrolled and more willing to behave in antisocial ways. For all these differences, all the variants equate collective participation with the loss of self and of the loss of self with the loss of reasoned or socially responsible action.

Not surprisingly, Le Bon's approach evoked strong opposition from early on. Floyd Allport in particular strongly attacked the notion of a 'racial unconscious' or 'group mind' as an empty and meaningless concept. His 1924 book, often (mistakenly) seen as the first social psychology text, and certainly a seminal influence in the development of the discipline in North America, is written largely as a rebuttal of Le Bon's ideas.

However, paradoxically, it is arguable that Le Bon's influence was enhanced rather than diminished by those, like Allport, who challenged him. For, in challenging his explanation of crowd action, they accept his description of such action as mindless and destructive. What is more, the difference at the explanatory level is more a matter of displacing rather than discarding the Le Bonian narrative of loss.

To be more concrete, Allport – and the so-called 'convergence' approach to crowd action which derived from his work – suggests that crowd action reflects the preexisting individual characteristics of crowd members. If crowds are violent or destructive, it is because flawed individuals are drawn to such events. All that has happened here is that the locus of crowd pathology and loss has shifted from the group to the individual level. People become crowd members because they lack something already, they do not come to lack something because they have become crowd members.

For all the sharp debates that divided classic crowd science, then, the commonalities are ultimately more telling. Crowds either create a pathological psychology or else attract individuals with psychopathologies. As a result, crowds are pathological entities. There is no place here for understanding how social and cultural factors might shape the understandings and actions of people in collective settings. There is no basis for addressing, let alone understanding the socially meaningful nature of crowd action.

Crowd Patterns and Crowd Norms

There are many criticisms that can be made of Le Bon's work and classic crowd science more generally. But at their root lies yet another loss – the loss of context. In both Allport's and Le Bon's accounts, the focus is exclusively on the crowd. Although the crowds that they reference are drawn from important social groups – crowds of socialists or trades unionists or miners – they write as if mere physical assembly is enough to explain how crowd members behave. They make no reference to the broad social context of struggles between these groups and others for power and resources in society. Equally, they make no reference to the immediate context of struggles between these groups and others (the army, the police, private security forces) on the streets. And once the context is lost, we can no longer see how action might make sense as an attempt to challenge the other or as a reaction to the acts of the other. Instead, behavior can only be attributed as reflecting something inherent about crowd members or crowd process, something universal that holds for all time and all places. In short, decontextualization pathologizes and essentializes and eternalizes the results of specific social processes.

By the latter half of the twentieth century, however, things were changing. Academia was changing from an elite system to more of a mass system. Academics who experienced crowds were more likely to be positioned as engaged insiders as horrified outsiders, whether (in the United States) within the civil rights movement, the anti-Vietnam protests, or (in Europe) in the events of 1968 and its aftermath. And, from this perspective, crowds were to be welcomed rather than to be feared, they were healthy rather than pathological phenomena, and, above all, they were meaningful rather than meaningless.

This was true across the humanities and human sciences. A series of seminal historical studies demonstrated that crowd members are not those who stand at the margins or against society – in more pejorative parlance, 'riff-raff.' Rather, they characteristically come from more stable, integrated, and 'respectable' layers. They also showed that crowd action, far from being inchoate and universally destructive, is typically highly patterned and that the patterns are highly socially meaningful. Crowds act in ways that reflect shared social belief systems. Indeed for many historians, who face the problem of recovering the perspective of those groups in society who, in the past, did not leave written records, crowds provide a uniquely valuable resource.

Similar conclusions were drawn by those political scientists and sociologists studying contemporary events such as the wave of black urban riots across many US cities in the 1960s and 1970s. The massive report of the US Riot Commission in 1968, using a database of 1200 interviews from 20 cities, noted that the average rioter was more socially integrated and better educated than the average black person. The evidence also shows that, far from being random or impulsive, riots were articulate protests against specific grievances. Finally, and perhaps most importantly, a close examination of events showed that crowds were neither wild nor orgiastic. They were discriminating in their choice of targets, they only attacked those state officials they viewed as enemies (notably, the police), they only looted shops of outsiders against which they had concrete grievances. Fogelson sums up this evidence in a phrase that contrasts markedly and memorably with the prevalent image of mob madness: "Restraint and selectivity were among the most crucial features of the riots."

In sum, even the most violent of crowd events are subject to normative constraint, even if the norms (attacking particular people and property) are at odds with those that regulate everyday life. These conclusions, drawn from the field, have been corroborated by experimental evidence. Thus, a meta-analysis of deindividuation studies suggests that, far from acting in uncontrolled or antisocial ways, those made anonymous in groups tend to increase their adherence to situational norms.

How then are such norms created? The first answer was provided by Turner & Killian's aptly named 'emergent norm theory' (ENT) first published in 1957. This theory suggests that crowds do not become homogenous entities in an instant. Rather, there is an extended period where people mill about. They are addressed by many would-be influence agents, or 'keynoters.' Gradually, particular keynoters who are more striking than others begin to gain sway and norms begin to spread through the crowd. Homogeneity, like normativity, is therefore an emergent property of encounters among crowd members.

ENT provided a nuanced and compelling portrait of the micro interactions in the crowd out of which shared understandings emerge. This is its legacy from the symbolic interactionist tradition. However, it is less successful in explaining why particular keynoters become successful leaders and why some norms rather than others come to shape crowd action. This can be traced to Turner & Killian's reliance on a desocialized model of influence deriving from the small group psychology of the time. Such models root influence in the

personal qualities and interpersonal relations between individual crowd members. As a consequence, it is hard to see how group (and crowd) norms relate to broad cultural belief systems. Such a model can explain the patterned nature of crowd action; however, it cannot explain why such patterns should be socially meaningful and reflect broader conceptions of society. In effect, the micro is divorced from the macrosocial. Although ENT and other normative accounts mark a great step forward from classic crowd psychology, they, like Le Bon, still face the problem of relating crowd action to the larger social context in which it occurs.

The Social Identity Model and Intragroup Dynamics in Crowds

Over recent decades, the social identity has become the dominant psychological approach to group processes in general. This approach aims explicitly to understand how ideological and structural factors shape group action and it is formulated to be as relevant to large-scale social categories (such as nation, religion, or 'race') as to small groups of familiars. It is understandable, then, that social identity tenets have proved successful in addressing the specific issues of crowd psychology. Indeed, the social identity model (SIM) of crowd behavior has, by now, itself become the dominant contemporary approach to crowd psychology.

SIM contests the classic models of crowd psychology as lost through the very concept of social identity which lies at its heart. It will be recalled that Le Bon's analysis starts from the idea that selfhood is lost upon entering a crowd. This derives from a singular and individualistic notion of selfhood: people have a unique personal identity which is the sole basis of behavioral control. If this personal identity is compromised (as in the crowd), then control over behavior is lost. By contrast, social identity theorists view self as a rich and varied system which exists at different levels of abstraction. Sometimes, I think of myself in terms of how I, as an individual, differ from other individuals (personal identity: 'I' vs. 'you'). At other times, I may think of myself in terms of belonging to a social category – I am an American, a Catholic, a woman, a Mets fan . . . – and in terms of how my group differs from other groups (social identity – 'we' vs. 'they').

The foundational assumption of social identity research is that when people act as group members, they shift from acting in terms of personal identity to acting in terms of social identity. That is, the eclipse of one's sense of oneself as a unique individual is not a *loss* but a *refocusing* of identity. Hence, as intimated at the start, an important psychological distinction is implicitly made between a *physical* group – a set of people who happen to be copresent at the same place and time – and a *psychological* group – a set of people who share a sense of themselves as belonging to the same social category. The difference between the two can best be illustrated by a simple thought experiment: imagine you are on a crowded commuter train heading home. People are squeezed together in a carriage, but each remains psychologically an individual, seeking to avoid eye contact with others, reading the same paper as others but resenting anyone looking at theirs, and feeling discomfort or even disgust at any physical contact with others. Then, the

train stops. After a long delay, there is an insufficient excuse for what has happened. Now, people begin to think of themselves together as aggrieved commuters against the train company. And that shared identification transforms their behavior. They start turning toward one another, talking to one another, even sharing their sandwiches.

In a similar vein, SIM draws an explicit distinction between physical crowds based on copresence (aggregates) and psychological crowds based on social identification. These, as has been argued previously, are the types of assembly that all crowd psychologists have been concerned with (even if this is not made explicit in their models) and therefore, this is the type of assembly for which the term 'crowd' will henceforth be reserved. SIM proposes three transformations that occur when people join a crowd and these are detailed in the following section.

The Cognitive Transformation

Just as identity is not lost in crowds but refocused from the personal to the social level, so control is not lost but shifted from personal norms and values to those that define the relevant social category. This means that the behavior of crowds will vary as a function of what categories are involved. The norms and values – and hence the actions – of, say, a crowd of environmentalist protestors will be different from those of a crowd of soccer fans which, in turn will be different from those of a Catholic crowd welcoming the Pope. The process of conformity to group standards may be general, but the behaviors it leads to will always depend upon contextually relevant belief systems.

There are two important implications of this process which need to be stressed. The one is that, insofar as crowd members act in terms of their social identities and that social identities invoke category-based belief systems, here is a mechanism for understanding how the behaviors of specific crowds relate to broad conceptions of society – a key requirement for any adequate model of crowd action. The other is that this process is not mechanical or routinized. Crowd situations are typically either novel or uncertain – and made all the more so by the fact that they are interactions in which the behavior of the other side is unpredictable (a point developed in much more detail in the next section). Consequently, one cannot just apply preformed rules and norms of action. Rather, one has to determine what the general category means in the concrete situation.

The creation of situationally appropriate norms can happen through a process of induction. That is, people infer group norms from the behaviors of those who are unambiguously ingroup members – as long, that is, that these behaviors are consonant with the broad terms of group identity. So, for instance, in a British urban riot, when someone threw a stone at the police, it was followed by a hail of stones. However, when someone stoned a bus, not only did others not follow, but they actively intervened to prevent further stoning. Or, equally, when someone smashed the windows of a bank (one of the external institutions seen to keep the local community in penury) others joined in, but when the windows of a local shop were smashed, others spontaneously defended the shop from looting. This is very different from the process of contagion.

It also elaborates upon ENT, both by showing how norm creation can be rapid and responsive to events and by showing that, while there is space for variability in the interpretation of what is appropriate, there are clear limits set by social identity to the norms that form in crowd events.

This is not to say that the deliberative processes described by emergent norm theorists are irrelevant, merely that they are not always necessary. Where there is time – particularly at the start of events – people do mill around, listening to others and trying to determine what they should be doing. But even here, social identity is crucial in framing the emergence of norms. The keynoter who is influential (i.e., the leader) is the one who can best represent his or her proposals as instantiations of ‘who we are’ and ‘what we believe in’ – of group identity that is. Conversely, the basis on which members deliberate is not simply ‘what should we do here,’ but rather ‘what should we do here as *environmentalists*’ (or whatever the situationally relevant category might be). Altogether, the task of keynoters/leaders and group members is jointly to develop a situationally appropriate elaboration of a preexisting identity.

The Relational Transformation

In crowds, the relationships between individual members undergo a profound shift. This is not simply as a function of the fact that crowd members identify with a social category. It occurs to the extent that people share a common identity with others in the crowd and also that they are aware of this commonality. Under such conditions, fellow crowd members shift from being ‘other’ at the individual level to being part of a shared collective self. Hence, personal boundaries between people are dissolved and the boundary shifts to that between ingroup (‘us’) and outgroup (‘them’).

On the one hand, then, the sense of difference to others in the group is dissolved. We expect them to share similar norms, values, and beliefs with ourselves. ‘We’ will all see things the same way and strive for the same goals. As a consequence, we will both trust and respect our fellow ingroup members more and we will look for agreement rather than disagreement with them. We will also feel more confident and validated in our own beliefs. Unlike everyday life where venturing an opinion, especially a strong stance, may evoke the disagreement, disapproval, even rejection by the other, in crowds, we can express ourselves in the full expectation that others will support our views. More than that, for those in the midst of a crowd, they will be surrounded by others who chant the same chants as them, who look and dress like them, who even smell like them: their sensuous universe is one that affirms their identity.

On the other hand, our sense of ‘interest’ and of ‘fate’ is extended to encompass other group members. That is, our self being the collective self, then ‘self-interest’ becomes a matter of advancing the interest of the group as a whole, and a detriment to any group member becomes a detriment to our (collective) selves. Correspondingly, the act of ‘self-defense’ is a matter of defending not only one’s own body from injury but also that of any other group member from attack, especially where that comes from the outgroup. Often, in crowds, people will put themselves at considerable risk to help and support fellow group members who, for instance, are under threat of being attacked or seized by the police.

In combination, these various consequences of the relational transformation that occurs in crowds create the conditions where people can coordinate their actions. People are able to integrate their efforts, to support one another, and to initiate action in the confidence that they will be supported by others. Whereas, outside the crowd, people may feel isolated and unable to enact their beliefs due to the power of others, in the crowd they feel united and able to overcome any potential resistance of others. That is, they feel empowered as group members. In this sense, Le Bon provides an important insight about crowds. However, *contra* Le Bon, this empowerment is highly focussed. It is a power to translate the norms and values of the group into objective social practices. Accordingly, Drury and Reicher refer to this process as *collective self-objectification*. To paraphrase the historian of the French Revolution, Georges Lefebvre, perhaps it is only in crowds that people are able to become the subjects of history.

The Affective Transformation

One criticism of the early social identity approach to crowd psychology was that it was a very cold approach which emphasized the mindful and meaningful nature of crowd action but which neglected the emotional dimension. Empirically, this would be to leave out one of the most striking things about crowd events: they are often highly passionate affairs. People who watch sports at a stadium scream and shout and chant far more than at home or alone. Any model that leaves this out is necessarily deficient. Conceptually, this would be to buy into the Le Bonian duality between reason and emotion (one which is widespread within and beyond psychology) and simply reverse the polarity: from all emotion and no reason to all reason and no emotion.

There are many bases for the strength of emotional experience in crowds. Many of the relevant processes have been clarified by recent research in the area of collective emotions. That is, when people identify highly with a group, they can feel things not only because of what they have done or what was done to them as individuals, but because what their group has done or what was done to members of their group. Thus, for instance, acts by outgroups (such as the police) which are seen either to attack the group or else to deny the group its legitimate rights evoke strong feelings of anger. However, when talking about their feelings, crowd members lay particular stress on the importance of empowerment and collective self-objectification discussed previously. After living one’s life in a world made by others and having to trim one’s behavior to what is acceptable to others, at last, in crowds, people can shape the world in their own terms. This is not only an occasion for joy, it also leads to increased commitment to the group and even to increased individual well-being.

Once again, then, we can find value in Le Bon’s work – in this instance, his emphasis on passion in crowds. But the explanation of this passion is the precise opposite of Le Bon’s. It does not derive from a loss of mind, a loss of judgement, and a loss of individual agency. Rather it flows from the fact that, perhaps uniquely in our experience, ordinary people are able to make their own history. Insofar as we define ourselves in terms of our group membership and that, through joint action, our groups are able to impact on social reality,

then we feel ourselves to be agents. And because crowds make us agents, we are passionate about them.

The Elaborated Social Identity Model and Intergroup Dynamics in Crowds

The focus of the social identity model is predominantly upon intragroup relations in crowds: the model analyzes how individuals and interindividual relations are transformed within crowds and how this impacts on what they do and feel. And yet, throughout the analysis, there is an implicit recognition of the importance of the outgroup – whether it be a matter of the salient presence of an outgroup transforming a disparate set of people into a psychological crowd with shared identity (as in the example of the train carriage), of the perceived illegitimacy of outgroup action inspiring crowd solidarity and crowd reaction, or else of crowds empowering their members and hence transforming relations with the outgroup.

Nonetheless, there remains the danger that SIM, like preceding models of crowd behavior, will seek to analyze crowd action without (explicitly) recognizing that crowd events are typically interactions between at least two groups (one group of sports fans against another, the police against rioters, company security guards against strikers) and that it will be impossible to fully understand the behavior of any one party without looking at both and the ways each impacts on the other. To make the same point slightly differently, if the core problem with classic crowd psychology lies with decontextualizing crowd action, then it can be argued that SIM links crowd action to the broader context (by rooting crowd action in broad category-based beliefs, norms, and values) but that it neglects the immediate interactive context.

The elaborated SIM (ESIM) of crowd action extends SIM by explicitly analyzing the intergroup dynamics of crowd events and placing intragroup dynamics in this interactive context. Moreover, through its focus on intergroup dynamics, ESIM lays more stress on change processes in crowds than the earlier social identity work.

ESIM derives from a common pattern of action observed across a number of crowd events, including such different groups as students, environmental protesters, antitax protesters, and football fans. In each case, events started with heterogeneous crowds comprising multiple psychological groups, most of whom were opposed to conflict and violence. However, all those present were perceived as at least a potential threat by the police who then acted to contain the crowd and prevent them from progressing as they wished. This common experience of being denied what they perceived to be their legitimate rights led to the formation of a single psychological group united around opposition to the police. Moreover, this unified crowd felt thereby empowered to contest police actions, which in turn validated the police's original conception of the crowd as dangerous. In this way, a spiral of escalating conflict occurred, often resulting in overt violence.

In order to explain this pattern, ESIM conceptualizes social identity as a representation of the nature of social relations in our world and where we stand within them along with the behaviors that are proper and possible given that position. Many protestors, for instance, see themselves as living in a

liberal democratic society where the police are neutral arbiters who uphold the social order. They themselves may be opposed to certain other groups but they do not view the police as an outgroup. Most of the time, the different parties to a crowd event share the same representations of one another. Hence, their interactions serve to confirm and stabilize the views of participants.

However, under certain (rare) circumstances, there is an asymmetry, such as when protestors do not see the police as an outgroup but the police see all protestors as an outgroup (in part because of the continuing dominance of models which portray all crowd members as dangerous). What is more, when one of these parties (the police) has the power to act upon its perception (by erecting cordons and stopping crowd members from doing what they want), then the perception of one group becomes an experiential reality for the other. Protestors experience being positioned as 'oppositional.' And, from this experience, they begin to reconceptualize their relationship to the police and hence their own identity. That is, they begin to see themselves as oppositional.

This shift of identification sets in train a whole series of associated changes. First, new norms and values emerge. Those behaviors that make sense in a world where the police and state are neutral – persuasion and patience – no longer make sense where the police and state stand against one. Hence, those voices (leaders/keynoters) calling for conflict who were earlier shunned are listened to more, and there is greater potential for more than a small minority to become involved in conflict. In other words, outgroup actions alter the relative success of contending sources of influence in the ingroup. The irony, often, is that the police, fearing violence, act in ways that make those calling for violence more impactful.

Second, as crowd members redefine their own identities, their relations to others outside as well as inside the actual crowd may shift. Thus, in seeing themselves as oppositional, a common ingroup bond may be formed with other oppositional groups which, previously, had been rejected. For instance, in one antiroads campaign, an early division between local protestors who simply wanted to preserve their amenities and committed environmentalists who were opposed to the overall roads program was overcome after the police were equally hostile to all involved in trying to stop the tree on the town green being felled. But the 'locals' not only came to see themselves as part of a wider protest and hence included the environmentalists as ingroup, they also started to see groups like striking miners, black people, and feminists as part of a common cause against injustice.

Third, even the goals and the concept of success of crowd members can shift. To continue with the aforementioned example, locals originally conceptualized success as saving their green and its tree. But as they began to see the police and state as arraigned against them and in favor of the roads lobby, they looked at the act of simply standing up against the police and publicizing the nature of what they were up against as an end in itself. Even if the tree was cut down, in this latter sense, the protest had been a success, it was celebrated as such and it led to increased commitment to future protests.

Theoretically, the core message here is that crowd identities and hence crowd action are not simple givens but rather products of intergroup interaction. It is important to recognize this

in order to understand how identities are reproduced and come to be seen as stable or even natural and in understanding the conditions where rupture and change occur. Practically, the core message is that the interventions of the authorities, the police in particular, do not simply serve to contain collective violence. They are a critical part of the escalation or the de-escalation of violence. In recent years, ESIM has been applied practically to design forms of police intervention which distinguish between groups in the crowd and which seek to facilitate those with lawful intentions. In this way, the influence of those promoting violence can be reduced and the prospects of peaceful democratic protest maximized.

Conclusion

I began this piece by noting how crowds have long been seen as aberrant – a social aberration caused by psychological aberration – and by suggesting that this has prevented us from learning about both society and psychology from the study of crowds. By now, it should be clear that one cannot understand crowd action if one divorces it from its social context. Even if crowd action is occasionally extreme, this reflects long-standing patterns of social belief about what is acceptable and unacceptable. And crowd action does more than reflect existing social beliefs and social identities. Crowds play a critical role in forming the identities of participants and creating new unexpected identities in the crucible of collective interaction.

But even here, we are only beginning to appreciate the wider importance of crowds. There are two ways, at least, in which crowd psychology has much to contribute. First, at a theoretical level, crowds provide a particularly clear example of how intergroup dynamics frame intragroup relations. However, this is not because crowds are unique but rather because (a) in crowds, the intergroup dimension is particularly obvious since the police are physically present, whereas in everyday life, the impact of outgroups may be more subtle (enshrined, for instance, in the ways that institutions are structured) and less easy to see, and (b) the copresence of both ingroup members and outgroup members in crowds renders the impact of the inter- on the intragroup immediate, general, and hence easy to see. However, it is reasonable to suppose that similar processes occur in everyday life, albeit more distributed through multiple encounters between individuals or small numbers of ingroup and outgroup members, and then disseminated slowly through the telling of stories which are disseminated through social networks. In this way, ESIM may provide a model for intergroup relations in general, and the practical insights of the model may help us understand the conditions under which members of certain groups disengage from authority and support conflict against authority.

Second, if crowds are important to the formation of wider social identities, this need not be limited simply to those who

participate in them. For crowds are often the embodied reality of broad social categories that are abstractions – groups like nations, classes, religions, ‘races,’ – which are too large for all the members to congregate and which are therefore, in Anderson’s terms, ‘imagined communities.’ What happens in crowd events is therefore often emblematic for all members of the relevant categories whether they themselves were there or not and can therefore impact on the identities of all. Such events tell them about the world, about who they are, and how they are treated in society. What is more, crowd events are high-profile. They are likely to be covered on the television, in the papers, and hence be visible to the broader category membership. In this way, for instance, the US riots of the 1960s impacted on all black people in the United States just like the British riots of the 1980s affected the overall views of black people in the United Kingdom.

To sum up, crowd psychology has come a long way over the last century or so. There is still a long way to go. But at least we now recognize that when many members of a social group assemble together, then what they do has much to tell us about our society and where it is going. At least the value of pursuing crowd studies is more apparent than it once was.

Glossary

Community density Number of people in a community area or proportion of people per available dwellings or space in a community.

Crowding A negative psychological state that results from perceiving that there are too many people present in the available space.

Density Number of people in a specified amount of space or proportion of people per available space.

Household density Number of people in a residential dwelling or proportion of people per available rooms or space in a residential dwelling.

Distinction Between Density and Crowding

It is important to distinguish between the subjective, psychological experience of crowding and the objective, environmental source of the crowding experience: high-population density. Daniel Stokols has noted that density is a property of the physical environment whereas crowding is primarily a psychological experience. The negative effects of high density on human health and behavior are strongest and most prevalent when individuals are uncomfortable or stressed by the high density. That is, high density might only affect health and behavior when individuals appraise the high-density setting as being crowded. Density is an important antecedent to the experience of crowding but is often not sufficient to explain everyone's feeling of crowding or a particular individual's experience of crowding in different settings or at different times.

Density is typically measured by calculating a ratio score of the number of people to a given amount of space. There are two broad types of density studied by social scientists, *household density* and *community density* (see Table 1). Household density can be determined in several ways. For example, one could calculate the number of people per room or square footage within a household. According to the US census, households with more than 1.0 persons-per-room are overpopulated. Absolute number of people in a household in a residence also can be used as indicators of objective levels of household crowding. Community density measures reflect the amount of space for a given population over a wider space than an individual's residence. Community density can be determined by calculating the number of people per acre, people per square mile, or people per census tract. Occasionally, community density will be defined as the ratio of dwellings or buildings to a given area or the total number of dwellings in a community area.

Public, health officials, city planners, housing developers, and policy analysts in charge of setting housing standards are particularly interested in understanding the effects of household and community density levels on human health and behavior. In general, ratio measures of density are better predictors of health, especially mental health, than are absolute measures, such as number of persons or number of rooms. In addition, measures of density in a dwelling, such as persons per room, are better predictors of individual health and behavior problems than are community measures of density, such as

dwellings per square mile or persons per acre. These latter two findings may be explained by the fact that individuals will tend to have greater difficulty escaping from or avoiding unwanted interactions with other people when they are inside a highly populated dwelling with little available space than when they are in the outside world or in a highly populated dwelling with lots of space. The different behavioral and health effects of density in a dwelling versus density outside of a dwelling are discussed in more detail below.

Role of Social and Personal Characteristics

The correspondence between density and the psychological experience of crowding often depends upon the individual and the social situation. For example, people can be exposed to high levels of density in a bustling city street, a cramped apartment, a sporting event, a concert, a supermarket, or a political rally. Some of these crowded situations are exciting and inviting and some are threatening and foreboding. While many people would concede that the throngs of people cheering at a football stadium contribute to the excitement of the sport, few would agree that the clanging and banging of shopping carts and waiting in long lines to make a purchase in a crowded supermarket are enjoyable experiences.

Why do different situations evoke different experiences of and feelings toward high density? There are, of course, important differences between high density in different settings, like stadiums, or supermarkets. For example, in a stadium the cheers and enthusiasm of a crowd can be stimulating and help a spectator to have a good time. In the supermarket, the presence of many people can interfere with or constrain a shopper's movement through the supermarket and his or her ability to finish shopping. When high density thwarts goal-directed behavior, it is more likely to be experienced as stressful and crowded than when it does not block goal-directed behaviors. Interference with goal-directed behaviors can diminish individuals' actual and perceived control over their environment. Lack of control over the environment can cause some people to feel psychologically distressed. The role of control in explaining the negative effects of crowding is discussed in more detail below.

There are also wide differences in peoples' reactions to high density. For example, men and women appear to experience

Table 1 Different environmental sources of crowding

<i>Types of household density</i>
Number of people per household area ^a
Number of rooms per household square footage per household
Number of persons per room in a household
<i>Types of community density</i>
Number of residents per community area ^b
Number of households per community area
Number of commercial buildings per residential community area
Number of multiunit housing structures per community area
Proportion of households with more than one person per room in a community area
Proportion of households with five or more persons in a community area
Number of persons per 10 000 ft ² of residential space in a community area
Number of persons living on a street per 1000 ft

^aHousehold areas can be measured in square footage or meters.^bCommunity areas can be measured in acres, square miles, or by census tract.

high density quite differently. When men and women are required to interact in small groups, men are more uncomfortable and less social than are women. Thus, men appear to prefer a larger amount of personal space or physical distance between themselves and other people than do women. Different cultural groups also may experience density differently. For example, American college students appear to be less tolerant of residential crowding than are adult males in India or Turkish college students. Many Chinese and Japanese families appear to be relatively unaffected by living in very high-density homes. Among different American ethnic groups, household density tends to have a stronger negative effect on the mental health and social relations of black Americans than white Americans, and only a weak effect on Americans of Hispanic descent. On the other hand, researchers also have found equally strong positive associations between household density on psychological distress across diverse racial and ethnic groups, including African Americans, Anglo Americans, Vietnamese Americans, and Mexican Americans.

Why do individuals have unique reactions to similar levels of density? One explanation is that people develop methods of coping with the crowding. For example, gender differences in reaction to high density might be explained by adaptation to different levels of closeness in interpersonal interactions. In comparison with males, females might be socialized to expect and to engage in contact with others in closer physical proximity. As they mature, males might become more accustomed than females to having large interpersonal distances between themselves and others. Thus, experience with high-density settings potentially can diminish the negative psychological experience of crowding because individuals can learn how to cope with the undesirable aspects of high density or they become accustomed to close physical contact with others.

Effects of Crowding on Health and Behavior

There has been a long history of interest in the effects of crowding on human health and behavior. The spread of various diseases and social pathologies is often attributed to the vast numbers of people living in urban areas. High-population

density is often cited as a reason for the very high rates of mental and physical health problems and various deviant social behaviors found in cities. Living in close proximity to others can obviously facilitate the spread of infectious diseases. However, transmission of infection through close contact with others is not the only way in which high density contributes to social and biological health problems.

Observations of the negative effects of overpopulation in nonhuman animal species have fueled some of the concern over the effects of high density and crowding in human populations. Much of what has been learned about density and disease processes has been through experimentation with animals because of ethical constraints in experimenting with humans. However, even in animal populations it is difficult to ascertain the exact causes for the negative effects of density on health and behavior. Take, for example, the observation that high density is associated with higher rates of mortality in many animal species. Many animal species exhibit cycles of population escalation followed by a sudden and tremendous mortality, or a 'population crash.' Different pathways have been identified that may link density to mortality. For example, food shortages or the rapid spread of disease, as in plagues and other epidemics, could explain population crashes in high-density settings. However, starvation and contagious disease do not fully explain the effects of high-population density on mortality. One group of scientists observed that deer living on an island multiplied quite rapidly until their population reached about one deer per acre, then their mortality rate skyrocketed. The deer population crashed, even though the deer had plenty of food and water and showed no signs of contagious disease spread. Examinations of the deer's internal organs, however, revealed signs of stress-related disease processes, which suggested another explanation of why high density can increase mortality: social stress.

Social stress can be caused by uncontrollable, threatening, unwanted, or otherwise negative social contacts and interactions with other organisms in an environment. High density can increase social stress, which can induce fighting between animals, interfere with reproductive behaviors, and cause unhealthy metabolic disturbances. Under high-density conditions, rodents' reproduction rates drop, cannibalism and deviant sexual behavior increase, and other social and biological pathologies all increase. In some animal studies, higher mortality among animals in high-density pens appears to be caused by overactive adrenal glandular systems. Many of the biological pathologies manifest in crowded rodents are similar to those observed in many species of animals after they have been exposed to noxious environmental stimuli, or stressors. Thus, it appears that the stress-related disease processes that might be caused by high-population density could contribute to death and illness in different animal species.

It is tempting to draw analogies between overpopulated animal populations and overpopulation that occurs in human settlements. For example, birth and mortality rates of high-density human communities could be compared to similar outcomes in high-density rat colonies. However, many outcomes, such as criminal behavior in humans versus aggression in rats, are not so directly comparable. In addition, it is more difficult to prove that density is the cause of deviant behaviors in humans than it is to do so in animals. In animal research,

scientists can control the effects of external factors other than high density that could influence the behaviors of crowded animals. Researchers studying human crowding can seldom control other factors, such as poverty and noise, which tend to accompany high density and influence humans' health and behaviors independent of density. In social science terms, the uncontrollable factors could cause a 'spurious,' or illusory, relation between density and human health and behaviors. Some researchers use statistical techniques to attempt to examine the effects of density independent of other social factors. The problem with making such statistical judgments is that researchers never know for certain whether they have identified all possible factors that could influence both density and the outcome of interest. These points should be kept in mind when reading the next section on the evidence relating high density to human health and behaviors.

Chronic Versus Acute Crowding

The effects of high-population density on humans do not appear to be as dramatic as in animals. This is partly due to the sophisticated and complex ways which humans experience and adapt to noxious environmental stimuli like high density. For example, humans can hoard food supplies or increase food production to avoid starvation under high-population conditions. Humans also can modify their environments, perhaps through scheduling or architectural interventions, to minimize social stress in high-density settings. Nevertheless, social research has revealed some relations between density and various health and social problems in humans.

In discussing the effects of crowding on humans, it is important to distinguish between *chronic crowding* and *acute crowding*. Chronic crowding takes place in settings where people tend to spend much of their time, like work places, residential settings, or institutional settings such as dormitories, prisons, and military barracks. Acute crowding takes place in settings where people tend to spend very little time, like stores, elevators, sidewalks, restaurants, theaters, stadiums, and other public places. The effects of acute crowding also have been examined by researchers in laboratory settings modified to represent different levels of density.

Effects of chronic community crowding on social pathology

Social pathology can be defined as those phenomena that contribute to the demise of a society, typically by reducing its population, but also by disrupting its institutions and social relations. Thus, high rates of crime, mortality, accidents, disease, and divorce are indicators of social pathology. In the minds of many, social pathologies are linked to large cities, where they seem to proliferate and concentrate. Because large cities are both highly populated and full of social pathology, scientists have attempted to determine whether community crowding is at the root of the pathology evident in cities.

Interest in the relation between community density and pathology has been apparent since at least the end of the nineteenth century. Along with the industrial revolution came a rapid growth in cities throughout the western world. Some social theorists thought that the diversity of people, the personal anonymity, and high levels of individual autonomy existing between people in large cities would lead to

psychological distress and anomie. In contrast, people from small towns and agrarian societies were expected to have richer social lives and greater morale because of familiarity and close interaction with similar others. Other social theorists argued that the high density of cities would expose people to overwhelming amounts of stimulation. In response to the stimulus overload, city-people would socially withdraw. Social withdrawal could be a strategy for reducing stimulus overload. By reducing concern for others and by interacting at a superficial level, there would be fewer stimulus inputs to cope with in day-to-day life. However, there would naturally be social costs if everyone acted this way, including apathy, frustration, conflict, and competition.

Contemporary social scientists pursue many of the same questions regarding community crowding and pathology as did their counterparts from a hundred years ago. Typically, researchers researching on crowding investigate whether areas with high levels of community density also have high concentrations of social, psychological, and biological pathologies or problems. Community population density has been studied in relation to rates of death, infant mortality, perinatal mortality, accidental death, suicide, tuberculosis, venereal disease, mental hospitalization, birth, illegitimate birth, juvenile delinquency, imprisonment, crimes, public welfare, admissions to general hospitals, and divorce. The current evidence suggests that there is little or no relation between population density and major indicators of social pathology, such as mortality, crime, and juvenile delinquency. One research group observed that a higher ratio of persons per acre was associated with slightly elevated rates of mortality, fertility, juvenile delinquency, admissions to mental hospitals, and public assistance. However, the researchers also noted that certain ethnic and economic groups were over represented in the high-density areas. Thus, factors such as poverty, rather than density, could have caused the higher rates of pathology observed among individuals living in high-density areas. Indeed, when the researchers controlled for the effects of social class and ethnic background on the pathological outcomes, the relations between density and the outcomes disappeared.

On the other hand, it is possible that some community-crowding studies have underestimated the effects of high density on human pathology. Aggregate measures of density, such as persons per square mile, and aggregate measures of pathology, such as number of hospital admissions, do not precisely reveal the exposure to high density or its effects on individuals. For example, a person living in a high-density community might spend most of his or her waking hours at a job in a community that has a low level of density. Or, a person from a low-density suburb might work all day in a high-density city. The actual exposure of these respective individuals to high density is different than what one would expect based on the density of their communities. In one instance, the negative effects of living in a high-density community could be underestimated. In the other instance, the benefits of living in a low-density community could be overestimated. If there are many of these peculiar cases in a study population, then an aggregate measure of community density will not be a good estimate of exposure to crowding. Nor would such a measure be useful for examining the effects of crowding on human health and behavior. There are also problems with aggregate measures of

pathology. The principle problem is that data on social pathology originate from official public records, which can be incomplete and inaccurate.

To make matters more complicated, researchers can never know whether the relations between density and pathology are overestimated or underestimated when analyzing aggregate data. That is, the data errors caused by using aggregate measures could make the effects of density on pathology look stronger or weaker than they are in reality. One way around the problems associated with aggregate data is to study the effects of high density on individuals rather than on whole communities. That is, one could carefully measure individuals' exposure to density and their health and behaviors. This is usually done by surveying individuals about the levels of density in their households and about their health, behavior, and psychological well-being. Findings from this type of research are discussed in the next section.

Effects of chronic household crowding on health and behavior

Household crowding stems from high density in the residential environment. Residential environments include individuals' homes and apartments, as well as institutional settings such as prisons, dormitories, and military bases. Household density appears to have a wide range of effects on human health, behavior, and general well-being. Research in institutional settings such as prisons and dormitories is especially compelling because it helps to control for selection biases: prisoners and college students typically cannot choose or control whether they will be in a more or less crowded room.

Prisoners in high-density cells, for instance, report more negative moods, discomfort, and illness symptoms than those in single-person cells or relatively low-density cells. Disciplinary problems, psychiatric commitment rates, suicide rates, and death rates also appear to increase in prison populations that grow in size without increases in the size of prison facilities. Crowding also is a frequent problem in student populations. This often occurs because of a shortage of desirable housing near colleges or because students often double-up in apartments to save money on rent. In comparison with students in low-density dormitories or off-campus apartments, students in high-density residences feel more crowded, have more unwanted social contact and interactions, have more frequent negative moods, are less happy, and try to avoid interactions by socially withdrawing. In comparison with their uncrowded counterparts, crowded students are less sensitive to others' needs, less willing to help others, and less aware that others are available to provide emotional support or help to them when they need it.

People living in high-density residences can become insensitive to social cues even when they are not in high-density setting. That is, the social insensitivity cultivated in high-density environments can carry over into low-density settings. College students who are withdrawn and insensitive to social cues in their high-density residences also act this way in low-density laboratory settings. Crowded students exhibit their withdrawn behaviors by sitting far away from others, not initiating conversation, making little eye contact with others, and not being helpful to others in need.

High household density in noninstitutional settings also results in antisocial behaviors and complaints of excessive

social interaction. High household density is also related to increased negative mood and symptoms of depression and anxiety among adults. People from high-density households tend to have fewer friends and greater difficulty getting along with their neighbors than do people from relatively low-density homes. Parents tend to interact less with their young when they live in high-density homes than when they live in relatively low-density homes.

Children appear to be more negatively affected by high density than are adults, partly because they have less control over their environment than do adults. In comparison with children from low-density homes, those from high-density homes tend to have more behavioral problems in school, more anxiety, greater distractibility, more conflicts, lower achievement motivation, and poorer verbal abilities. However, caution must be applied when interpreting these results. As discussed above, density often accompanies other environmental conditions that could influence children's behaviors. Noise, for example, is likely to be greater in high-density households than in low-density households; and noise can interfere with children's attention, hearing, and learning abilities. Uncoupling the effects of density from those of noise is nearly impossible in naturalistic settings. In studying the effects of crowding on children it is also important to consider the role of other adults, particularly parent, in the environment. Research suggests that parents in crowded households are less responsive to their children relative to parents in less crowded households.

Earlier in this article, it was noted that social factors could influence whether an individual would perceive a particular setting as crowded. The social environment also can have a strong influence on the relation between crowding and psychological distress symptoms. For example, students living in high-density households who have frequent hassles from roommates are more likely to be psychologically distressed than are students living in high-density households with relatively few hassles. Students living in low-density homes do not appear to be adversely affected by social hassles. People living in high-density households may be particularly distressed by roommate hassles because it is more difficult to avoid or escape from the hassles in a high-density home than in a low-density home. In contrast to the effects of social hassles, positive social relations can counteract the negative psychological effects of high-density living situations. For example, college students living in high-density households who have supportive roommates are less likely to be distressed than are students living in high-density households with relatively unsupportive roommates or students living in low-density households. However, as mentioned earlier, chronic household crowding can undermine socially supportive relations because people become withdrawn and insensitive to social cues. Thus, although positive social relations may be beneficial to crowded individuals, such relations may be rare in households that are chronically overpopulated.

Effects of acute crowding on physiology and behavior

Acute crowding has been studied in scientific laboratories and in natural settings, like trains and elevators. In the animal studies discussed above, it was noted that many animals living in high-density populations showed biological signs of stress, such as enlarged adrenal glands. Elevated and sustained

physiological arousal is another sign of stress that is commonly observed in organisms under stress. In high-density laboratory settings, arousal has been exhibited in human subjects using many different measures. People exposed to acute crowding in laboratories exhibit increased perspiration, skin conductance, and blood pressure. Passengers in crowded commuter trains exhibit increases in blood levels of adrenaline. Interestingly, passengers who board a train when it is already near capacity are more negatively affected by the crowded conditions than passengers who board early, when the train is nearly empty. Even though the latter passengers ride the train longer, they had more choice, or control, over where they could sit on the train than passengers who board the train when it is already loaded with other passengers.

It should be noted that although acute exposure to high-density settings usually increases physiological arousal, it is not clear whether there are negative health consequences of the increased arousal. It is possible that elevated and prolonged arousal can wear down the body's defenses against illness and generate illness itself, such as hypertension or ulcers. However, there is not enough evidence at this point to state unequivocally whether the arousing effects of high density have health implications.

Impaired task performance is another common side-effect of acute exposure to high density. Mostly, this research has been conducted in laboratory settings that manipulate individuals' exposure to high or low density and then measure performance on problem-solving tasks or assess one's ability to concentrate or persist on a task. Although high density does not seem to interfere with performance on simple tasks, it does diminish complex task performance. It also appears that individuals are more easily distracted and are less persistent at completing challenging tasks under high- versus low-density conditions.

Short-term exposure to high density produces many of the same withdrawal behaviors observed in people chronically exposed to high density. It is not uncommon, for example, for people on crowded subways to read newspapers and books as a way of avoiding interaction with others. In laboratory settings, crowded people are more likely to leave the settings, increase social distance, withdraw from social interactions, increase defensive posturing, and reduce eye contact than uncrowded people. Another way to maintain space from others is to be aggressive and threatening. Several studies have shown increased competition and aggression between individuals in high-density settings. Interestingly, crowding is more likely to evoke aggression in men than in women and when resources in the environment are scarce rather than plentiful. The adaptive value of withdrawal and aggression in high-density settings is not completely understood, but it does appear that these social behaviors may help people to cope with crowding. For example, social withdrawal might be a way of minimizing physiological arousal by avoiding unwanted social interactions and the excessive social stimulation that is common in high-density settings.

Explaining the Negative Effects of Crowding

Several theoretical explanations of the effects of crowding on human health and behavior have been alluded to throughout

this article. Below we discuss four of the more prominent of these theories: behavioral constraint, control, social withdrawal, and overload/arousal theories.

Behavioral Constraint

According to this theory, high density interferes with individuals' goal attainment by restricting or inhibiting their movements and behaviors. The diminished freedom makes the high density noxious and undesirable. When people are in high-density settings that do not thwart their goal-directed behaviors, they tend to be less negatively affected by the high density than when their goals are thwarted. Imagine, for instance, two groups of individuals performing a task in a crowded room, but one group has to complete the task while sitting still and the other group has to complete the task while moving around the room. It is more likely that crowding will interfere with the task performance of the moving group than of the still group because the crowded group will be coping with the task and the constraints on their movements caused by the crowding.

Behavioral constraints do not refer only to restrictions in bodily movement. Sometimes high density can create resource shortages, such as food shortages, which constrain behavioral choices. That is, density can restrict access to valued resources. In the case of food shortages, behaviors such as eating might be inhibited. In addition, people in such situations might act aggressively to get valued resources. Finally, it should be noted, that high density often can have negative effects on mood and performance because people perceive that there are behavioral constraints in high-density environments. That is, simply believing that high density can limit one's behaviors or access to valued resources is sufficient to diminish task performance or increase discomfort in high-density settings.

Control

Limits to behavioral freedom also can be construed as limits in personal control over the self and the environment. Control models of crowding hypothesize that high density is undesirable and harmful because it renders the environment more unpredictable and exposes individuals to situations over which they have little or no control. A lack of control in high-density settings has been shown to exacerbate the negative effects of density on humans, whereas the availability of control has been shown to reduce the negative effects of density.

One group of researchers tested the control hypothesis by examining the effects of control on people's moods in crowded elevators. Control in the elevator was manipulated by giving some people access to the elevator control panel and other people no access. Those who had panel access, or more control, in the crowded elevators felt less crowded and had more positive moods than those without control. As with behavioral constraint, sometimes it is enough to simply perceive, or believe, that control is available to reduce the negative effects of high density on performance or mood. However, if one's expectations for control in a high-density situation do not match the actual availability of control, then the high density can be more disturbing than if one expected little control in the situation. Thus, it appears that control or beliefs

and expectations about control in high-density environments influence how strongly humans are affected by crowding.

Social Withdrawal

One consequence of crowding is excessive and unwanted social interaction and interference. Social withdrawal is a practical behavioral response for reducing unwanted social interaction. For example, commuters on a crowded subway will often bury their heads in a newspaper and listen to music through headphones rather than engage with fellow commuters. Sometimes individuals will avoid the unwanted social interaction associated with crowding altogether by avoiding the crowded space. For example, college students who are forced to double-up in a small dormitory room might spend more time at the library or gym to reduce time spent in the room. Residents in a crowded apartment might isolate themselves by closing doors between rooms or spending lots of time alone in a bathroom or other private area in the apartment. Whereas social withdrawal is effective at reducing unwanted social interactions, it also can have potentially unintended and undesirable consequences, including reductions in social support and companionship.

As discussed above, several studies have shown that among people living in crowded households social withdrawal is associated with a lower level of social support, which, in turn, is associated with a higher level of psychological distress. Although there is no evidence to date, it is also likely that social withdrawal between intimates could lead to feelings of neglect and social strains, which might have their own adverse health effects. Additional evidence is needed to determine whether social withdrawal and its unintended negative social consequences have any implications for physical health.

Overload/Arousal

A final theory posits that high density increases pathology because of sensory overload from excessive stimulation. Humans have a limited capacity to process information; in high-density settings, the information available in the environment exceeds that capacity. This process is similar to information overload in a computer system, which can cause a computer to make errors or shut-down operations. In humans, overarousal is often unpleasant, can diminish complex task performance, and could contribute to health problems.

Evidence for the overload/arousal model of crowding is found in studies such as those discussed above that have shown increased sympathetic arousal under high-density situations. Some scholars have suggested that heightened social withdrawal in high-density settings is a method of reducing arousal. At present, however, there is no strong evidence that social withdrawal can actually lower sympathetic arousal in crowded people. In addition, there is no evidence that the levels or duration of arousal people experience in high-density settings is significant enough to compromise health or contribute to disease processes.

Conclusions

Crowding in humans is a syndrome of stress associated with exposure to high-density households, community, or laboratory settings. A distinction exists between the subjective experience of crowding and the objective source of that feeling: high-population density. Overpopulation in nonhuman animals leads to deviant social behaviors and health problems. However, exposure to high density and overpopulation in humans seldom results in extreme social pathologies. Unlike lower animals, humans appear to be able to adapt to and cope with high-density situations with a good deal of tolerance. Humans can adapt by limiting their exposure to high density through many means, including architectural interventions, careful scheduling and planning of space usage, and by engaging in distracting or withdrawal behaviors. Unfortunately, some adaptations to density, such as social withdrawal, can have unintended consequences, such as loneliness or deterioration of interpersonal relations.

The research evidence to date suggests that people do have undesirable psychological, social, and biological responses to crowding. However, it is also clear that crowding is more or less aversive and detrimental to people depending on their personal experiences with and preferences for particular levels of density. In addition, social conditions, such as the presence of supportive others or undesirable social hassles from others, can influence the strength of the relation between density and various outcomes, such as psychological well-being. Thus, density does not necessarily increase social pathology in humans. Indeed, low levels of density can be undesirable at some occasions, such as parties, sporting events, or concerts. It appears that density is most detrimental to human behavior and health when individuals feel a lack of control over their own behaviors or the environment, or when they experience excessive stimulation and arousal from the density.

Glossary

Behaviorism A school of research in psychology that explains behavior in terms of the association between a stimulus in the environment and a behavioral response.

Cognitive Revolution An intellectual movement in the 1950s that was oriented toward establishing meaning as a central concept in psychology.

Cultural tools Culturally and historically based artifacts, symbols, technologies, and forms of language which impact on modes of thought.

Executive functioning The cognitive processes that regulate the ability to organize thoughts and activities, prioritize tasks, and make decisions.

Information processing approaches A perspective on cognitive development that focuses on the operations by which people mentally manipulate information.

Priming The implicit memory process in which a stimulus activates or makes more retrievable one or more memories or associations held by an individual.

Cultural psychology refers to a perspective on psychological research which recognizes the essential role of culture in the formulation of basic psychological theory. The perspective of cultural psychology captures the core psychological insight that psychological processes always occur in socioculturally, historically situated contexts and depends on the individual's participation in those contexts for their emergence; that is, without culture advanced psychological processes would not exist, just as they would not exist without biology. While it is well understood that people are inherently biological beings, the insight of cultural psychology is to recognize that they are also inherently and simultaneously cultural ones. The discussion here provides an overview of the key theoretical assumptions of cultural psychology followed by a select overview of major traditions of research associated with cultural psychology and of the types of empirical findings emerging. Consideration is also given to challenges facing contemporary work in cultural psychology as well as to the contributions and promise of research in this tradition.

Core Premises of Cultural Psychology

The perspective of cultural psychology calls into question the dominant theoretical position that has long dominated work in psychology, which is to downplay the importance of culture in the formulation of basic psychological theory. This theoretical position that has tended to characterize most psychological research treats culture as content or context and assumes that psychological development is not only fundamentally universal but can be understood without taking into account cultural considerations. It is assumed that the basic nature of psychological processes and structures is unaffected by the culturally dependent content on which they operate or by the culturally structured contexts in which they occur. From this type of perspective, cultural variation in human behavior is considered to be of limited interest in that it is viewed as leading away from the search for underlying regularities to a focus on outward appearances. This type of stance has been associated with programs of research in psychology that have tended to present

psychological theory in culture-free terms and to tap culturally skewed populations, focusing predominately on American research participants and neglecting to study the vast majority of the world's populations.

The theoretical stances adopted in cultural psychology differentiate it not only from this mainstream approach in psychology but also distinguish it from earlier traditions of cross-cultural research that were prominent in the mid-twentieth century and that tended to focus on testing the assumed universality of existing psychological theories. These theoretical stances include adoption of symbolic views of culture, acknowledgment of the essential role of cultural mediation in the emergence of higher order psychological processes, and recognition of the mutual constitution of culture and self.

Symbolic Views of Culture

The emphasis on meaning that occurred with the rejection of behaviorism in the mid-twentieth century constituted an important foundation for cultural psychology. This emphasis, which emerged with the transition in psychology known as the Cognitive Revolution, underscored the role of the individual in going beyond the objective information given in making sense of experience. Within behaviorism, the individual had been portrayed as passively responding to objective stimuli in the environment. The Cognitive Revolution, however, made clear that this point of view fails to recognize the individual's role in actively contributing meanings to experience, with the same information potentially giving rise to different interpretations and having contrasting implications for the individual's affective, cognitive, and behavioral reactions. Notably, there was no straight path from this insight of the Cognitive Revolution to contemporary work in cultural psychology, as the emphasis on meaning-making of the Cognitive Revolution was waylaid for many years as more passive information processing approaches came to dominate the field. However, this recognition that an act of interpretation intervenes between the stimulus and the response established an important theoretical basis, which was later drawn upon as investigators came to appreciate the role of culture as a necessary component of meaning.

The emergence of symbolic views of culture in work in anthropology and linguistics formed a key foundation for cultural psychology in making clear not only the collective aspects of meanings but that meaning could not be reduced to objective properties of the situation. In this view, cultural systems are understood to do more than merely provide information about experience or convey norms for behavior. Rather, they are seen as creating social realities whose existence depends, in part, on these cultural definitions and the practices that instantiate them. This meaning creating role of culture extends not only to recognized social institutions (e.g., marriage, school) and their associated roles (e.g., bride, student) and artifacts (e.g., wedding ring, grades), all of which depend on socially shared definitions and activities, but also to core concepts in psychological theory, such as categories of mind, emotion, and self, which also depend, in part, on socially shared concepts and practices.

The theoretical importance of recognizing the role of culture as a system of meanings and practices was that it highlighted the need to take culture into account in psychological explanation. Contexts for psychological development could no longer be understood merely in terms of objective constraints and affordances, but required consideration of culturally shared beliefs and values through which the contexts were interpreted and structured.

This role of culture as a system of meanings and practices may be illustrated through research undertaken by Tobin, Wu, and Davidson on Japanese and US teachers' views of preschool classrooms. US teachers were observed to be highly critical of practices in a Japanese classroom that included a ratio of one teacher per 30–40 students, and to much prefer the ratio found in a US classroom that included 2 teachers per 8–10 students, making the observation that teachers can devote more attention to individual students in the latter setting. However, whereas Japanese teachers recognized this objective affordance provided by the US preschool classroom, they appraised the classroom structure negatively, as not providing children with opportunities to function as part of a larger social group.

Cultural Mediation of Psychological Processes

In addition to recognizing the nature of culture as a system of meanings and practices, the perspective of cultural psychology includes the recognition that human thought and behavior is mediated by culture and that it is only through activity in sociocultural environments that higher order psychological processes emerge. This insight is termed the incompleteness thesis to capture its core assumption that human psychological development cannot be completed without cultural experience.

The incompleteness thesis is based on the recognition that culture is ever-present in human experience. Individuals, it is noted, always act in culturally and historically specific environments and utilize culturally and historically specific tools. They also carry with them in their language and understanding systems, culturally specific assumptions through which they interpret experience. This omnipresent enculturative structure is understood to introduce a cultural–historical grounding to psychological functioning with the assumption made that it is virtually impossible for individuals to act in ways that are not culturally mediated. Even the highly controlled context of a

scientific laboratory, it is recognized, does not fully control for culture and is not culture-free, but rather itself constitutes a highly particular cultural environment. While individuals are assumed to show instinctual responses and other inborn propensities that are not culturally mediated, their environmental experiences (even in utero), reflect a cultural patterning and it is only by the gradual internalization of the tools of a culture that advanced psychological processes emerge.

Importantly, this type of perspective does not assume that all psychological processes are culturally variable. However, it does assume that advanced psychological processes will invariably reflect a cultural patterning, and thus in many more cases than presently recognized will show cultural variability. From the perspective of cultural psychology the acknowledgement that a particular psychological process is culturally dependent or culturally variable is not, however, invariably regarded as a flaw given that it is assumed that many basic psychological theories are likely to reflect a cultural–historical specificity. In fact, a core part of the agenda of contemporary work in cultural psychology is to make this cultural patterning of psychological theories explicit. Work in cultural psychology, in this way, is as much about achieving a greater understanding of the often implicit cultural underpinnings of present psychological theories as it is about gaining insight into cultural diversity in psychological functioning. Rather than being relegated to the role of a footnote, qualification, or exception in the formulation of basic psychological theory, as cultural work is currently presented in many textbooks or handbooks of psychology, cultural evidence is recognized to be an essential basis for the formulation of psychological theory. While cultural psychology is at times portrayed as a subfield of psychology, this constitutes a misnomer. Cultural psychology is coterminous with all of psychology, in sharing its fundamental agenda of contributing to the formulation of psychological theories and in explaining the processes of human development. This recognition of the inherently cultural nature of all fields of psychology implies that there could never be an adequate psychology that is culture-free, just as it cannot be assumed that there could ever be an adequate psychology that fails to take into account the biological foundations of self.

Mutual Constitution of Culture and Self

In addition to recognizing the culturally mediated nature of psychological processes, the perspective of cultural psychology highlights the mutual interdependence of culture and self. Notably, the conjoint term 'cultural psychology' was selected by theorists to convey this insight that, just as psychological processes need to be understood as always based in particular cultural–historical contexts that impact on their form and patterning, cultural meanings and practices depend on the existence and activities of communities of intentional agents. While culture cannot be reduced to individual psychology nor individual psychology understood as purely culturally patterned, culture and psychology are recognized to be mutually interdependent.

This assumption of the mutual constitution of culture and self underscores the need to approach culture in dynamic terms just as psychological processes themselves are understood to develop and change. Cultural meanings and practices are not

static but rather transform over time, in ways that reflect both adaptive functional constraints, such as survival pressures, as well as historical continuities and discontinuities, as traditions are transformed and altered, even as they are forwarded and preserved.

The assumption of the mutual constitution of culture and self also highlights the compatibility, if not the fundamental necessity, of a consideration of both biological and cultural influences on psychological development. It is recognized that just as individual psychological development depends on biological processes, biological phenomena are affected by cultural processes, such as demonstrated in the impact of tool use on the evolution of modern humans. This fundamental compatibility of biological and cultural aspects in constituting the self is seen in the increasing attention being paid to neurological and other biological considerations in research in cultural psychology.

Research Traditions and Findings

Work that shares the theoretical assumptions and goals of cultural psychology is found in all subfields of the discipline, with this work, in cases, being undertaken by theorists who do not explicitly adopt the self designation of cultural psychology, or even by investigators identified with related disciplines, including anthropology, linguistics, and sociology. This work incorporates all types of methodology, and is not restricted to research that is either comparative or ethnographic in nature. While the present discussion cannot cover all of the various traditions of work in cultural psychology, brief consideration will be given here to some of the major areas of work in cultural psychology and to the types of empirical findings emerging.

Sociocultural Approaches

One of the most longstanding traditions of research in cultural psychology is the tradition identified originally with the cultural-historical approach of Vygotsky and his Russian colleagues. This tradition has been extended in recent years by investigators such as Cole, Rogoff, and Wertsch, among many others, and is generally referred to by the contemporary designation of 'sociocultural' perspectives. Within this tradition, extensive consideration is given to the role of cultural tools and other mediational means in qualitatively affecting the form of human cognition and behavior. From this perspective, human activity is understood in a broad-based way that takes into account historical, individual developmental, phylogenetic, and microgenetic levels of analysis. There is also a shift away from an exclusive focus on psychological processes as internal to individuals to a focus on their instantiation in everyday social activities.

A major direction of work in this tradition is to examine how participation in everyday cultural practices leads to changes in thought that are qualitative in form while also contextually dependent. For example, it has been shown that individuals who have extensive experience in using the abacus are more successful in solving math problems and employ more complex and qualitatively different cognitive processing

strategies in their solutions than do individuals who have no experience using this cultural tool, with these contrasting cognitive strategies showing only limited generality to other types of cognitive tasks. Likewise, research conducted in Brazil on children with little education who work selling fruits on the streets has documented their impressive and highly flexible strategies for solving the everyday math problems that they employ in their trade – strategies, however, that do not transfer to their performance on school-based arithmetic tasks. Studies by Michael Cole and his colleagues who have examined the impact of literacy and schooling on cognitive development have also uncovered the powerful, yet localized, impact of exposure to cultural tools on cognition. Thus, it has been demonstrated, for example, that while marked effects of schooling are observed on conventional cognitive measures, these measures are similar in form to the types of tasks that tend to be practiced in school contexts. It is further shown that individuals who have had extensive schooling or who have scored high on cognitive tests are no better than their unschooled or low scoring counterparts in solving everyday cognitive tasks, such as making the most successful bets at the racetrack or the most economical purchases in the supermarket. Providing insight into the processes through which experience with cultural tools and in culturally structured contexts impacts cognition, this work challenges early global stage models that had linked modernization to global differences in thought – a paradigm known as the hypothesis of the primitive versus modern mind.

Work in this tradition also provides insight into the links between social and developmental change. A dramatic example of this type of work may be seen in the variation in everyday practices and in associated styles of cognitive activity observed to occur in Chiapas, Mexico, which was studied by Patricia Greefield and her colleagues over a period of more than two decades from 1969 to 1991. During the early period in which the local economy was heavily agricultural, emphasis was placed on subsistence activities, such as weaving of all the family's clothing, and girls were taught to weave in a process closely guided by their caregivers who were present in the context. However, during the later period in which there had been a shift to an economy based on commerce and money, not only was there a reduction in the economic importance of weaving (since clothes were now more frequently purchased), but the activity of girls in learning to weave had changed to a more trial and error process that was no longer characterized by the hands-on attention and direct involvement of the caregivers. During this historical period, there was also a modification in the weaving products, from a more detailed to a more abstract style of visual representation, and adolescent girls were found to show enhanced abilities in representing novel visual patterns. This type of research notably underscores the dynamic nature both of sociocultural environments and of their impact on developmental outcomes.

Research in the sociocultural tradition has also led to a rethinking of conceptions of development. For example, in research on the teaching of reading, Michael Cole provided a new solution to what is known as the paradox of qualitative developmental change, that is, the problem of accounting for how individuals can acquire more powerful cognitive structures if they do not already possess these structures.

The research demonstrated that a range of meditational means are available in cultures that support reading, including not only literacy activities like storytelling, but artifacts like computer games. This made clear that many of the structures entailed in the achievement of reading exist between persons in the sociocultural context before they appear as individual competencies. In another example, work by Barbara Rogoff has highlighted the role of cultural practices in underlying developmental change. She provides evidence to indicate that the marked cognitive shifts that have been documented by developmental psychologists occur over the age range of 5–7 years old and that have classically been explained solely in cognitive terms to result, in part, from changes in the sociocultural settings and types of cultural supports provided to children during this age period. It is during this period that children commonly move more fully into the school context and gain greater exposure to the peer group, with attendant variation in their activities, which has implications for their emerging cognitive competencies.

Developmental Approaches

The tradition of cultural psychology discussed here includes approaches that draw their inspiration primarily from work in the contemporary mainstream tradition of developmental psychology. Theorists in this tradition focus on the impact of culture on the path of developmental change, and on culturally broadening the theoretical constructs of developmental psychology.

Work in this tradition of cultural psychology has documented that the direction and endpoints of developmental change are, in cases, culturally variable, and thus, that explanations of developmental change need to take into account cultural considerations and universal cognitive or experiential factors. Psychological research that had been conducted primarily on US cultural samples had uncovered an assumed universal developmental change for young children to shift from a focus on viewing the self and others in concrete terms, such as by reference to their physical characteristics, to a focus by adolescence on viewing the self in terms of traits – a developmental trend that was explained as resulting from children's increasing abilities to engage in abstract thought. However, in comparative developmental research conducted among US and Hindu Indian populations by Joan Miller, it was found that not only did Hindu Indian populations not show this developmental increase in emphasis on traits, but they showed a significant developmental increase not found among US populations to give increasing emphasis to contextual considerations. Thus, whereas an American adult might explain behavior in terms of the agent's personality (e.g., that an individual was helpful), Indian adults would show a greater tendency to explain it in terms of features of the situation (e.g., that no one else was around, or that the individuals involved were friends).

This same type of interest in uncovering cross-cultural developmental variation may be seen in a recent program of cross-cultural developmental research by Qi Wang and her colleagues that points to the role of cultural beliefs and practices, such as everyday discourse routines, in the development of autobiographical memory. Wang and her colleagues found

that not only is the age of earliest autobiographical memories later among Chinese than among US child and adult populations, but the form of autobiographical memories is culturally variable, with US respondents tending to recount earliest memories which are emotionally intense and positive and that focus on their individual psychological reactions, and Chinese respondents tending to recount earliest memories that are less emotionally laden and less self-focused and that tend to center on everyday social routines, such as a caregiver's behavior in cooking the daily meal.

A related thrust of work in this tradition is to formulate developmental theories that are more culturally inclusive. An example of this type of stance may be seen in work by Fred Rothbaum and his colleagues that points to the need to broaden conceptions of attachment theory to encompass concerns with *amae* that are salient in Japanese cultural contexts. *Amae* is a culturally grounded Japanese concept that involves positive feelings of depending on another's benevolence. This argument for the need to culturally broaden attachment theory, one of the most central theories of social development, is based not only on the research by Rothbaum but on a growing body of research by a range of investigators that provides evidence of cultural variation in the incidence of secure attachment as well as of uncovering cultural variation in styles of everyday social interaction, such as the greater emphasis found in Japanese families on nonverbal styles of parent-child interchange that promote the development of empathy, a dimension that is not emphasized in attachment theory.

Another example of this focus on culturally broadening theoretical concepts in developmental psychology may be seen in the growing body of work on culture and parenting. For example, one of the most influential contemporary theories of parenting, which was developed by the theorist Diana Baumrind, conceptualizes parental control in terms of a category of assumed harsh authoritarian parenting. However, as theorists such as Ruth Chiao have observed in their research, there exist highly directive forms of parenting among Chinese families that combine an emphasis on standards of conduct and preserving the integrity of the family with deep affective concern and caring for the child. To capture this type of stance on parenting, a stance that notably is associated with positive adaptive outcomes, such as higher levels of educational achievement, it is crucial to conceptually broaden present psychological models of parenting. Cross-cultural developmental research has also demonstrated that, in contrast to the tendency observed among European American children and adolescents, Korean cultural populations show a greater tendency to associate greater parental warmth with greater perceived parental involvement in the child's decision making. Theorists point out the need to recognize that in portraying control exclusively in negative terms, present theories of parenting fail to capture the extent to which parental involvement may be expressed and experienced in positive terms as conveying warmth and a welcome involvement.

Social Psychological Approaches

The tradition of work in cultural psychology under consideration here shares a similar agenda to that just discussed in the area of developmental psychology. However, in this case,

the focus is on culturally broadening theory and research being undertaken in the area of social psychology. Theorists in this tradition center their research on highlighting the role of culture in the formulation of basic social psychological theory, with particular attention given to issues of cognition, motivation, and self.

In terms of cognition, work in this tradition has provided support for claims that there is a greater emphasis on holistic modes of cognition in Eastern cultural settings, with a greater emphasis on analytic modes of cognition in Western cultural contexts. The former perspective privileges a deductive logic, which emphasizes breaking up objects into their component elements, whereas the latter stresses a more dialectical logic, which stresses viewing objects in relational terms. In support of this claim, it has been observed, for example, that Chinese adults perform less successfully than do American adults on category learning that requires the application of formal rules, while performing more successfully than do American adults in detection of covariation, an activity that demands attending closely to the environment. In another example, related cultural differences have been documented in the processes of attention, with the recall of East Asian populations for objects less than that of Americans if the background has been switched, suggesting that European-Americans more fully process contextual information. This difference in attention notably has also been observed in saccadic eye-movements, as assessed with eye-trackers, with East Asians relative to Americans gazing longer at background material.

In the area of motivation, cultural research is highlighting the need to broaden psychological theory to take into account the more social nature of internalization processes in collectivist cultural settings. For example, research has demonstrated that Brazilian adults more fully internalize social norms than do American adults, linking fulfilling a role related request for help by a family member more strongly not only with social expectations but also with satisfaction. Similar cross-cultural differences have been documented in comparisons between Indian and US populations with Indians associating fulfilling role based social expectations to family and friends with choice and US populations experiencing it in less freely chosen terms. While this and other related research does not challenge the existence of a concern with choice universally, it does highlight the need to recognize that the motivational salience of choice varies cross-culturally in ways that are not presently fully accounted for in psychological theory.

In terms of self, recent cultural research is also identifying cultural influences on the determinants of positive self-regard and of psychological well-being. Research, for example, documents the existence of marked cultural variability in the tendency to self enhance. For example, it has been demonstrated that whereas Americans tend to rate their self esteem as higher than that of others, Japanese tend to rate their self esteem as similar in level to their peers. As another example, whereas the self-descriptions of American adults tend to include four to five times as many positive attributes as negative ones, those of Japanese tend to give greater emphasis to their shortcomings. It has also been documented that self esteem as well as the experience of positive emotions correlate more strongly with life satisfaction in individualistic as compared with collectivist cultural populations. While work on this topic does not call

into question the importance of maintaining a positive sense of self in all cultural populations, it does suggest that constructs such as self-esteem, which assume a tendency toward self enhancement, reflect a culturally specific stance and need to be broadened to account for the cultural beliefs and practices of different cultural populations.

Cultural Neuroscience

The perspective of cultural neuroscience is concerned with understanding the cultural underpinnings of brain-behavior relationships. Representing a new direction for research in cultural psychology, this work forms part of the exponential growth over the last two decades in interest in neuroscience in all subfields of psychology, with the advent of functional neuroimaging. Cultural neuroscience provides insight into both common and culturally variable brain-behavior pathways and into the nature and extent of brain plasticity.

A central focus of research in cultural neuroscience is to provide information about the role of cultural contexts in mediating brain-behavior relationships. This work builds on the growing body of evidence of cultural variability in basic psychological processes and documents ways that this variability impacts the brain mechanisms recruited. Recent work in cultural neuroscience has revealed, for example, that the neural correlates of processes of perception, attention, and social understanding show cultural variability that is related to the cultural variability observed in these areas in psychological performance. For example, congruent with recent findings that US adult populations show greater object-focused processing than do East Asian adult populations, work in cultural neuroscience demonstrates that stronger and more distributed neural activation occurs during object processing among US cultural groups than among East Asian cultural groups. Research in this area has also revealed that brain mechanisms are recruited in ways that reflect perceptual tasks which are more culturally preferred being easier and thus requiring less attention than do nonculturally preferred tasks. Thus, it is observed that whereas East Asian adults recruit prefrontal and parietal regions of the brain associated with attention more for culturally nonpreferred context-independent judgments than for culturally preferred context-dependent judgments, the opposite pattern of neural activation is observed among US adults. In another example, in accord with findings that collectivist cultural populations tend to maintain outlooks that incorporate others more fully into the self concept, research has demonstrated that whereas the medial prefrontal cortex of the brain is activated by judgments made about the self among US cultural groups, it is activated by judgments made about both the self and about one's mother among Chinese cultural groups. Such work importantly provides evidence that these two cultural groups use the same part of the brain in different ways.

Work in cultural neuroscience is also addressing key conceptual questions such as the extent to which maturation of the brain is affected by experience in contrasting cultural environments. For example, work on human aging is demonstrating that elderly Asian populations show greater deficits in object processing areas of the brain than do elderly Americans, a pattern of findings that is congruent with the observed

tendencies for Asian cultural groups to less fully process object information than do US cultural groups. Such work provides insight into processes of brain plasticity and lends support to what is known as a use it or lose it view of human aging.

Cultural developmental neuroscience is also demonstrating that neural functioning is not invariably the same in all samples of healthy children but reflects the influence of culturally variable experiences. To give an example, cross-cultural developmental research has demonstrated that Asian children tend to perform better than do North American children on measures of executive functioning. In research conducted with Chinese-Canadian and European-Canadian children who were matched in terms of their performance on a reaction time test of executive functioning, it was shown that the two groups of children showed differential patterns of brain lateralization compatible with the cross-cultural differences observed in executive performance.

Challenges

As work in cultural psychology is gaining in prominence and scope, it is also increasingly embodying a self critical perspective in which investigators work to recognize and address certain limitations of past approaches and to identify important directions for further work. These challenges faced by contemporary researchers in cultural psychology center on developing more adequate understandings of culture and the self, and on more effectively integrating work in cultural psychology with work in the larger discipline of psychology.

Enhanced Understandings of Culture

A major challenge in contemporary work in cultural psychology is to develop more sophisticated and culturally sensitive approaches to culture. With the exception of research from a sociocultural perspective, much of the work in cultural psychology to date has been informed by the interdependent/independent or East-West dichotomy. This distinction gained in prominence with a seminal review paper on culture and the self coauthored by Hazel Markus and Shinbou Kitayama in 1991, with the distinction further promoted in the field by the subsequent development of psychological scales to measure this dichotomy. More recently, this perspective on culture has grown in prominence with the emergence of approaches that utilize priming techniques to assess culture. For example, one of the tasks that has been developed to prime an independent as compared with interdependent cultural view of self presents individuals with a paragraph that describes the behaviors of an individual who is referred to either only with the pronoun *I*, in the independent case, as compared with only by the pronoun *We*, in the interdependent case. As critics have noted, however, this type of approach to culture emphasized to date in much work in cultural psychology tends to gloss over important distinctions between and within cultures, to give limited attention to the impact of context on behavior, and to embody conceptions that treat individual perspectives as isomorphic with trends at a cultural level.

One way that theorists are working to develop more nuanced approaches to culture is through research that is

more fully tapping within and between culture variation in outlooks. Thus, not only are more studies being undertaken that assess psychological variation between different individualistic and collectivistic cultures, such as comparisons of North American with Western European samples, or comparisons that contrast collectivist populations outside of East Asia, but increasing attention is being given to sampling cultural groups who vary in socioeconomic status and/or ethnic background. For example, in research on attachment that was undertaken by Robin Harwood, it was demonstrated that ethnicity and socioeconomic status make distinctive contributions, with the impact of socioeconomic status showing both common and culturally variable patterns in different ethnic groups.

Theorists are also rethinking the assumption that cultural outlooks can be tapped by individual difference measures. It is increasingly recognized that individual differences do not vary in a one to one relationship with cultural differences, a stance that it can be argued reduces one level of analysis to that of another, as well as recognizes that culture impacts behavior in ways that are often implicit and is not the kind of tendency that can be tapped by explicit psychological scale measures. More attention is also being given to assessing cultural processes, such as by attention to discourse routines and other everyday social practices, as well as by tapping cultural products and their associated meanings. While there remains an appeal to the use of priming techniques in social psychological work in cultural psychology, given the amenability of this type of method to experimentation, increasing concern is also being given to the limitations of priming, with calls for greater attention to be paid to the culturally variable knowledge that is elicited by particular priming stimuli.

Greater Impact on Psychological Theory and Research

Work in cultural psychology remains sensitive to the challenges entailed in its goal to culturally broaden theory and research in mainstream psychology. While work in cultural psychology has increased in quantity in recent years, it remains, as it has been historically, in a marginal position in the discipline. In most departments of psychology, little or no attention is given to representing culture in the curriculum or in the hiring of faculty, with culture in many departments relegated only to the important, but still marginal, role of an approach to be applied solely in understanding diversity and not in formulating basic psychological theory. This downplaying of the importance of culture is illustrated, for example, in the contrasting response of departments of psychology to the advent of neuroscience as compared to cultural psychology. While both of these perspectives have gained in prominence in recent years, neuroscience has quickly become fully integrated into the discipline, as seen in departments of psychology not only hiring neuroscientists but frequently restructuring their departments to incorporate sub-divisions devoted to neuroscience, while cultural psychology has not seen a comparable growth in acceptance or influence.

While this marginalization of cultural approaches has roots in the idealized natural science ideal of the discipline and is not likely to change in a dramatic way, the increasing quantity of cultural research being undertaken as well as its increasingly international grounding represents one way for this work to

have a greater impact on the discipline. In recent years, the population of individuals trained as psychologists is becoming more international, with investigators of diverse cultural background more frequently engaging in productive collaborations, and with the growth of psychology journals that are based in non-Western cultural settings. Also, while there is increasing awareness of certain pitfalls associated with the recent wholesale embrace of neuroscience in psychology, such as its adoption by theorists to support arguments that are deterministic or circular in nature, it is also increasingly recognized that taking culture into account is essential in neuroscience work and, thus, that culture must be a key part of any psychology of the future that is grounded in an understanding of brain processes. To the extent that a particular psychological process has been shown to be culturally variable, an account of the neurological correlates of that process will be incomplete, if not misleading, without taking into account this cultural variability. Also, as a growing number of theorists are pointing out that meanings are not given in brain processes but rather require the consideration of culturally shared social concepts and practices.

Promise of Cultural Psychology

Even while facing challenges, this represents an exciting time for research in cultural psychology. Work in cultural psychology continues to pursue its central agenda of making the implicit cultural processes that impact on psychological functioning more transparent, thereby contributing to the creation of basic psychological theory. This work also continues to be integral to developing psychology in ways that increase its social relevance and applicability to solving real world social problems. In this respect, work in cultural psychology is essential in the efforts of the field to give back the insights of psychology to the community. Finally, work in cultural psychology continues to be integral to attempts to develop a more sophisticated understanding of what can be designated as basic psychological mechanisms. While enhancing current understanding of cultural variability in psychological processes and

outcomes, cultural psychology is vital in furthering the goal of creating a truly universal psychology.

Glossary

Affect A feeling state that is distinguished by valence (positive vs. negative) and sometimes arousal and other dimensions.

Cognitive reflection test A set of three questions, to which people give a response that is assumed to be either automatic and seemingly obvious (but incorrect) or effortful and deliberative (and correct).

Expected utility Similar to expected value, but outcomes are nonlinearly transformed into utilities (indices of relative value).

Expected value The average outcome of a risky choice. For example, a coin-toss for \$200 or \$0 has an expected value of \$100 (i.e., $0.5 \times 200 + 0.5 \times 0 = 100$).

Framing effects Shifts in preferences for objectively identical options when outcomes are described as gains versus losses.

Invariance An axiom stating that individuals should show equal preference for options that have equal consequences.

Numeracy The ability to understand and use numbers.

Preferences In psychology, an underlying construct thought to reflect the value of options; in economics, revealed by choices.

Risk Can be defined in many ways. One version is the possibility of, or variance among, multiple outcomes.

System 1 and 2 Two modes of thought in standard dual-process theories. System 1 is characterized as fast, automatic, effortless, and intuitive, whereas System 2 is characterized as slow, deliberate, controlled, and effortful. Standard dual-process models posit that System 1 is responsible for many cognitive errors and that System 2 can sometimes override System 1 in order to avoid such errors.

Temporal discounting Devaluing of future outcomes relative to immediate ones.

Utility In economics, a measure of relative satisfaction or pleasure associated with an outcome.

Introduction

Decision making can be defined as the selection of a course of action among options. Those options can range from selecting a marriage partner to selecting a political party affiliation. Scholars who study decision making come from many disciplines. For example, decision making has long been of interest in economics and psychology. Early models of the decision making process were mathematical. These mathematical models described the decision making process as a matter of performing calculations, involving such concepts as probabilities of outcomes and the monetary values of outcomes, to select the best course of action. Many modern models of decision making are variations of these original mathematical formulations.

However, recent conceptions of decision making emphasize psychological factors. Among these factors are relatively stable characteristics of people, which are called individual differences. Numeracy, or the ability to understand and use numbers, is a popular example of an individual difference that is thought to influence the quality of financial and health decision making. Intelligence, or cognitive ability, is another. In addition, emotion has received a great deal of attention recently, especially in dual-process theories that contrast emotional with deliberative decision making. Process models of memory are also increasingly influential in research on decision making. For example, how people remember features of options affects their preferences for the options. For these and other topics, neuroscience has become a useful tool for revealing the mental processes that underlie preferences and choices.

There are many societies and organizations dedicated to studying and improving decision making, such as the Society

for Judgment and Decision Making (www.sjdm.org) and the Decision Analysis Society (<http://www.informs.org/Community/DAS>). Decision making is also sometimes studied within particular professional domains, such as business or medical decision making. For example, the Society for Medical Decision Making (www.smdm.org) is an interdisciplinary group of academicians (health economists, psychologists, and others) and health professionals. These societies hold annual meetings and publish journals.

History: Expected Value, Expected Utility, and Prospect Theory

Psychophysical Approaches: Translating Reality into Perceptions

From mathematics to economics

An early decision rule compared the expected values of options. The expected value is calculated as the outcome value multiplied by the probability of that outcome (e.g., a 0.5 probability of winning \$10 is equivalent to winning \$5 for sure, with 1.0 probability, because $0.5 \times \$10 = \5). In the 1700s, Daniel Bernoulli suggested that the utility or personal value of wealth is not simply its monetary value. He suggested that the value of an additional quantity of money (say, \$100) is less for people who start out with more money. An extra \$100 means more to a starving student making \$9000 a year than it means to a successful executive making \$900 000 a year. This idea of declining marginal utility or diminishing returns was captured with a logarithmic function. In other words, utility of additional money does not increase linearly with increasing

wealth, but falls short increasingly as the magnitude of wealth increases. Thus, expected utility, not expected value, was thought to govern decision making.

Expected utility was mainly used by economists to study the behaviors of buyers and sellers. As with expected value, if a decision maker makes choices consistently based on maximizing expected utility, his or her total wealth will be higher (compared to choosing inconsistently or not choosing so as to maximize utility). The idea that choices should be made consistently has been formalized in terms of certain axioms or rules of coherence. Debate continues to this day about which axioms are the most fundamental. For example, the axiom of transitivity holds that if someone preferred A to B and preferred B to C, then the person must prefer A to C. Another axiom called invariance means that if two options have the same consequences, then individuals should show equal preferences for those options.

For most people, the expected utility of a sure bet exceeds the expected utility of the gamble that offers the same expected payout; in other words, people are typically risk averse. Given a sure option of winning \$1000 versus a gamble option that offers a 0.50 probability of winning \$2000, most people will prefer the sure option. (In the rare event that a person is risk seeking, he or she should prefer the fair gamble of equal expected value to the sure bet.) The more common preference for \$1000 can be explained by Bernoulli's decreasing marginal utility of money. Alternatively, various other models attempt to explain it. In expected utility theory, a given utility is reference independent; that is, utility does not depend on the description of the options. Expected utility theorists assumed that people were rational, meaning that they maximized expected utility, obeying axioms of internal coherence, and therefore had consistent preferences for risk. Subsequent research, however, suggests that decisions are based on the decision maker's initial frame of reference.

Prospect theory

In the late 1970s, Daniel Kahneman and Amos Tversky challenged the rational view of decision making. They introduced prospect theory, which was based on psychological research indicating that individuals are not consistently risk seeking or risk averse. Rather, individuals interpret gains and losses relative to a reference point, which is usually the status quo (e.g., the amount of money that they have initially). People tend to be risk averse for gains relative to the status quo (money won) but risk seeking for losses relative to the status quo (money lost). For example, imagine that you were given \$2000, but you had to then choose between two options: losing \$1000 for sure or gambling on a 0.50 probability of losing \$2000 and a 0.50 probability of losing nothing. In response to this problem, which describes the options in terms of losses relative to an original sum, most people prefer to gamble (they are risk seeking). Of course, once you subtract your losses from the \$2000 you were initially given, you are facing exactly the same options as in the previous paragraph, where the options were described as gains to an original sum. However, whereas most people prefer the gamble in the loss problem, they tend to prefer the sure option in the gain problem. In light of this result, Kahneman and Tversky proposed an alternative theory of risk in which utility is based on changes in

wealth rather than absolute states of wealth. This new theory was called prospect theory.

The prospect theory model looked like an S curve; it was concave in the first quadrant (representing gain) and convex in the third quadrant (representing loss). Crucially, the slope of the loss function was steeper than the slope of the gain function, indicating that people place a higher value per unit on loss than they do on gain. That is, people are more upset about losing something than they are happy about gaining the identical amount. This asymmetry between losses and gains is called loss aversion.

Prospect theory fits some hard-to-explain data such as the endowment effect, in which people require more money to give up something they already have than they are willing to pay to get the identical object. This effect is also explained in terms of loss aversion. For example, in one study, subjects were randomly assigned to be buyers or sellers. Sellers were given a coffee mug valued at \$6 and were asked whether they were willing to sell their mugs at a range of prices between \$0.25 and \$9.25. Buyers were not given mugs and were asked whether they were willing to buy mugs from the sellers at the same range of prices. The results of the study demonstrated that sellers consistently valued the mugs higher (\$7.12 on average) than the value the buyers (\$2.87) were willing to pay for the mugs. In some cases, the sellers preferred to keep their coffee cups, rather than to sell them. People are often unwilling to give up what they have to get something else that they might otherwise prefer because a loss has a greater psychological impact than a gain.

Framing

Frames are ways of describing choices. In the example above in which \$2000 is given initially and then dollar amounts are subtracted, the options are described in terms of losses. In an earlier example, the same options were described in terms of gains. Despite being objectively identical, the two versions of the choices are not psychologically equivalent because they result in different preferences for risk (i.e., preferring risk in the gain frame but avoiding risk in the loss frame). Different decision making theories offer alternative reasons as to why frames result in inconsistent preferences, even in the same individual. According to prospect theory, the distortion in the psychological value of gains contributes to perceiving the gamble outcomes (which are larger) as discounted relative to the sure outcomes (which are smaller). The same types of distortions for losses make the losses seem smaller in the gamble than in the sure option. More recent findings have cast doubt on the generality of the prospect theory explanation, although the explanation holds in some circumstances.

There are individual differences in susceptibility to framing effects. For example, framing has been shown to interact with numeracy (the ability to understand and use numbers). The more people understand numbers and probabilities, the less likely they are to shift preferences when numerically identical options are presented. This interaction between framing and numeracy has been obtained with what is called attribute framing, in which the same attribute is described in different but objectively equivalent ways (e.g., test performance is described as 80% correct vs. as 20% wrong) as opposed to risky choice framing as in the examples discussed earlier.

It suggests that people high in numeracy might notice the numerical equivalence of the options by spontaneously converting positively framed attributes into negatively framed attributes, and vice versa, because they are good at such computations. People who score higher on the cognitive reflection test also show less of a framing effect. The cognitive reflection test is a three-item math test in which intuitive answers are wrong and need to be overridden by correct analytical processes.

Contemporary Approaches

Global Models

Global models, in contrast to dual-process models, assume that one or more sets of processes (i.e., a single system) govern decision making. Many resemble the traditional psychophysical approaches already discussed (e.g., expected utility theory and prospect theory). Some recent global models, for example, add multiple reference points in addition to the status quo. New global models include memory theories, such as Query Theory, which predicts a wide range of effects based on the order in which memory is queried or interrogated. For example, asymmetries in buying and selling prices can be predicted by the order in which buyers and sellers think of reasons to have the good versus reasons to have the money. Whichever set of features is retrieved first tends to inhibit the set of features that is retrieved second, producing preference reversals when the order of retrieval is varied.

Standard Dual-Process Theories

Sigmund Freud proposed an early dual process theory on which some contemporary theories are based (e.g., Seymour Epstein's cognitive experiential self theory). According to Freud, primary and secondary processes designated two opposed yet complementary models of psychic functioning. The primary process is driven directly by one's basic needs and serves the pleasure principle without inhibition. The secondary process, in contrast, is the intervening rational system of control and regulation that functions in service of the reality principle. Contemporary dual-process theories similarly posit two opposing processes, one more visceral and the other more reflective. These processes are often called System 1 and System 2, respectively.

System 1 and System 2

There are some judgments that are formulated upon reflection, based on systematic and calculative operations of decision making. Alternatively, there are decisions that are made quickly and automatically. Dual-process theories suggest that at different times, responses can reflect the operations of either the fast, automatic, and intuitive System 1 or the slower, serial, and rule-governed System 2, as they were labeled by Keith Stanovich and Richard West. Because System 1 is faster than System 2, intuitive impressions can outrace rational deliberation, producing wrong or biased responses that would be censored on reflection.

In contrast to System 1, System 2 is conscious and effortful. For example, when cognitive load is high (e.g., people have a lot of information they have to keep in mind), people may revert to System 1 thinking because it is less effortful. System 1

is a source of errors, biases, and fallacies in decision making, although it does not necessarily result in poor performance.

Some standard dual-process theories make slightly different dual-process distinctions. For example, some dual-process theories contrast associative (mindless associations) versus rule-based (mindful rules, such as logic) thinking, others contrast concrete experiential thinking with rational analytical thinking (as in the cognitive experiential self theory of Seymour Epstein), and still others contrast affect (or emotion) and cognition (or rationality).

Affect versus cognition

In standard dual-process approaches, as in Freudian dualism, when people use affect or emotion to make decisions, their thinking is illogical, irrational, or quantitatively inaccurate. For example, relying on affect, people will donate more money to save one starving child than to save eight starving children. It is suggested that portraying a single child stirs stronger emotions than portraying a group; the former seems more personal, whereas the latter seems like a statistic. Thus, the single child elicits more donations. Paul Slovic has suggested that these processes are implicated in the insensitivity that people seem to have to genocide.

This approach has also been called the dual-process valuation model. This model posits that people assess the value of a target in different ways, namely by affect (i.e., valuation by feeling) or by analytic cognition (i.e., valuation by calculation). In one study, participants were asked how much they would be willing to pay for a bundle of either five or ten Madonna CDs. Subjects in the valuation-by-calculation conditions performed mathematical calculations prior to pricing the CDs. They were willing to pay more (on average) for ten CDs than for five CDs. Subjects in the valuation-by-feeling condition engaged in activities designed to generate emotions. The latter group reported no difference in the amount they were willing to pay for ten CDs versus five. In all of these approaches, emotion is expected to flatten the discrimination of quantity (e.g., perceptions of the numbers of CDs) so that it is more distorted away from linearity.

Fuzzy-trace theory

Approaches to rationality differ and include Piagetian logicism (thinking as logic), information-processing formalism (thinking as computation), and intuitionism (thinking as intuition, as exemplified in fuzzy-trace theory). The core assumptions of fuzzy-trace theory are rooted in research on memory, judgment, and decision making, and they take into account the social, cognitive, affective, and developmental factors involved in decision making. According to fuzzy-trace theory, people encode multiple mental representations of their experience at the same time. These representations range in specificity from low (gist representations) to high (verbatim representations). A gist representation is a fuzzy impression of the general meaning of information or experience, supporting intuitive thinking. A verbatim representation is a mental representation of exact details, supporting precise analysis. These assumptions are required in order to account for specific counterintuitive and seemingly contradictory results.

Intuition in fuzzy-trace theory is defined as fuzzy, impressionistic thinking using vague gist representations.

Thus, mindless impulsive reaction (e.g., System 1 in standard dual-process models) is distinguished from insightful intuition that reflects understanding (e.g., gist in fuzzy-trace theory). In other words, there are two kinds of fast and simple ways of thinking: a stupid kind that represents the most primitive form of thinking (e.g., System 1) and a smart kind that represents the highest form of thinking, insightful intuition (i.e., gist). In the foundations of mathematics (i.e., the basic assumptions of the field), mathematical intuition is characterized as a similarly advanced form of thinking.

Fuzzy-trace theory draws on evidence for independent gist (basic meaning) and verbatim-memory (exact detail) representations of information, but it differs from other dual-process models in emphasizing that there are degrees of rationality and that intuition is an advanced form of reasoning. Such claims are based on empirical evidence about the development of reasoning (e.g., evidence comparing reasoning by children and adolescents to that of adults and reasoning of adult novices to that of experts). Research has supported the theory that children's cognitive processes progress from detail-oriented computational reasoning to more intuitive processing: in other words, people process less information more categorically and qualitatively with age. Similar predicted trends were found among experts versus nonexperts. For example, Valerie Reyna and colleagues found that expert cardiologists processed fewer dimensions of information than less expert physicians when deciding whether to admit patients with chest pain to the hospital. Crucially, experts were able to identify the few most influential factors and focus on those in order to make faster and more accurate decisions.

The theory also predicts parallel development of verbatim-based analysis and gist-based intuition, which produces developmental reversals (e.g., children outperform adults) under specific circumstances. As an example, despite increasing competence in reasoning, some biases in decision making grow with age, producing more 'irrational' violations of coherence among adults than among adolescents and younger children. The latter phenomena are linked to developmental increases in gist processing with age. The first framing study in children was conducted to test predictions of fuzzy-trace theory. As predicted, framing effects actually increased from childhood to adulthood, as do other biases that rely on semantic gist. With greater experience and knowledge, decision making is predicted to become more simple and straightforward, that is, based on gist.

These developments have implications for health and well-being, especially regarding adolescent risk taking. Fuzzy-trace theory has been applied to understanding how risk taking changes from childhood to adulthood. In particular, adolescence is a period of vulnerability to risk taking and poor decisions, vulnerabilities that only increase bad outcomes in young adulthood when parental supervision lessens. Surprisingly, across many domains of problem behavior, adolescents who take risks engage in more verbatim-based analysis, but risk avoiders use gist-based intuition.

Fuzzy-trace theory, therefore, differs from other dual-process approaches in three respects. First, intuitions are considered an advanced form of reasoning. Developmental research on children's learning and on expert decision making supports this view.

Second, in addition to inculcating the bottom line meaning of an experience, gist representations also incorporate emotion, including valence (positive/negative; good/bad), arousal (high/low), and feeling states. Emotion can color the interpretation of a stimulus (i.e., its gist), especially when the stimulus is ambiguous. In particular, emotion influences the encoding of stimuli (i.e., how the choice is represented), the retrieval of values and principles, and the implementation of values and principles (i.e., their application to option representations). Research supports the claim that decisions about risk made in the presence of emotion are different from those made in its absence.

Third, fuzzy-trace theory provides specific predictions about rationality that contradict predictions made by standard dual-process and other theories. Most notably, fuzzy-trace theory predicts framing effects, but under a theoretical justification different from that provided by prospect theory. In addition, some effects predicted by fuzzy-trace theory cannot be predicted by prospect theory. According to fuzzy-trace theory, invariance is achieved through gist processing because decision making is based on the substance of information rather than on superficial details.

Subjective understanding: Construal level theory

Drawing on fuzzy-trace theory as well as other approaches, construal level theory posits that people can have two different subjective interpretations (construals) of the same event: abstract and concrete. Moreover, each type of construal affects decisions differently. High-level construals, like gist representations, are broad, abstract generalizations that capture the central immutable features of an event and that help generate the event's general meaning. Low-level construals, in contrast, are like verbatim representations in that they consist of multiple, narrow, concrete categorizations that direct attention to the details of an event. The concept of psychological distance is measured by construal level, such that low-level construals are psychologically proximal (close) and high-level construals are psychologically distal (far).

Construal level theory predicts that, as psychological distance increases, detailed information from that event becomes less accessible, less accurate, and less reliable, whereas the overall understanding becomes more abstract. For example, in one study that tested high-level versus low-level construals, individuals were asked to imagine a set of scenarios (e.g., a camping trip or a friend's visit to NY) that would occur in either the proximal or distant future. For each scenario, participants grouped a set of related objects (e.g., a snorkel or a tent) into as many conceptual piles as they deemed appropriate. In line with the research hypotheses, people in the high-level construal group (i.e., those who received the distal cue) created fewer piles with broader, more abstract criteria than did the low-level group (i.e., those who received the proximal cue). Research based on construal level theory suggests that people are often overly optimistic about choice options in the future because such events are represented in an abstract (high-level) manner and are not readily accessible for cognitive processing at a concrete (low) level.

Construal level theory also makes predictions about temporal discounting, which is the phenomenon in which people devalue (i.e., discount) outcomes that will occur in the future.

For example, people are willing to pay the retail price for a computer they can take home immediately, but they expect a discount if they have to wait for it. Research on temporal discounting reveals that, faced with the choice between receiving a small reward now and receiving a larger reward received 2 weeks from now, most people opt for the immediate reward. However, when both options involve a delay (e.g., receiving the reward 2 weeks from now vs. 4 weeks from now), preferences reverse in favor of the larger reward. In both examples, the options differ by the same amount of time (2 weeks); so, the reversal of preferences suggests a categorical difference in the way people value (construe) rewards that are available immediately versus those they must wait for.

Research combining temporal discounting and construal level theory tested how high- versus low-level construals affect patience and self-control. Results over a series of experiments demonstrated that people who used high-level construals showed greater optimism about their future choices, greater physical endurance over time (indicated by their ability to squeeze a handgrip longer), and more self-control (indicated by their preference for larger delayed rewards over smaller immediate rewards) than did people who used low-level construals.

According to construal level theory, different aspects of a reward's desirability are more salient (i.e., cognitively accessible) at different delays. Specifically, for decisions about the present, low-level, specific, and concrete features such as practicality should be most influential. In contrast, for decisions about the distant future, high-level, abstract, and broad features, such as compatibility with one's ideal self, should be most influential. Accordingly, different decisions should be attractive at different delays. Decisions whose low-level value outweighs their high-level value should be more attractive in the short term. Decisions whose high-level value outweighs their low-level value should be more attractive in the long term.

One experiment that tested how different construals affected self-control asked participants, "Right now, if you had to choose between an apple and a candy bar, which would you choose?" Subjects who preferred apples were defined as having greater self-control in relation to dieting goals. After a pretest activity that primed participants to either a high-level or a low-level construal condition, the study showed that people in the high-level construal condition chose apples over candy bars more often than did those in the low-level condition. This suggests that high-level construals support greater self-control. By changing the cognitive construals that research subjects used, researchers were able to alter the nature of temptation impulses. Construal level theory, therefore, has implications for reducing impulsive decision making.

Emotional Influences on Decision Making

Emotions as Content in Decision Making

Affective or emotional processes have received increasing emphasis in models of decision making. Affect cannot be reduced to only valence (good–bad) and intensity. The appraisal of affect, how it is interpreted, also depends on the situation and the specific emotion that is elicited. Specific emotions are associated with specific action tendencies (e.g., fear with

the action of escaping). For example, risk taking has been shown to be influenced by affect; people experiencing anger or happiness tend to be risk taking, whereas people experiencing fear or sadness tend to be risk averse. Positive emotions result in approach (i.e., increases in the value of associated options), but negative emotions result in avoidance (i.e., decreases in the value of associated options). General feelings of arousal can affect the choices being made even when the choices did not actually generate the feelings. For example, men who were aroused by pictures of attractive women were more likely to choose a sooner smaller amount of money relative to a later larger amount of money. Economists describe this as impatience and psychologists describe it as impulsivity.

Emotion: Supporting or Derailing Adaptive Decisions

Emotions can impair judgments, preventing goal attainment by increasing susceptibility to environmental temptations. However, emotions also provide clear evolutionary advantages to decision making, despite their ability to interfere with higher-level thinking. For example, the intrusion of emotion on attention, which can interrupt goal-directed behavior, is important in supporting the ability to detect and attend to urgent threats. Emotional stimuli are detected more quickly than are neutral stimuli, and people can maintain their focus better on emotional relative to neutral stimuli in the presence of distracters.

Affect as information

Affective signals can, consciously or unconsciously, facilitate memory of past rewards and aversive experiences, compressing this knowledge into a quickly accessible format. This is advantageous to rational decision making because analytical attempts to reason through all relevant past experiences would require a prohibitive amount of time and working memory capacity. In this way, emotional or affective signals automate the application of knowledge from past situations to current situations without straining cognitive resources. Consistent with this helping role of emotion is that, per fuzzy-trace theory, gist-based evaluation of risk leads to more adaptive decisions and increases with both age and expertise.

Common currency

Emotional and affective reactions to different types of stimuli, both primary (e.g., food, sex, or drugs) and secondary (e.g., money or gambling chips), provide a way to assess the relative value of disparate items on a single scale of subjective value. Affective reactions can be used to evaluate current options against counterfactual scenarios, past experiences, and imagined future rewards or punishments (although such imagined rewards are subject to temporal discounting).

Affective priming, mood congruency, and misattribution

In affective priming, an initial stimulus induces a mood that persists and affects the evaluation of the second stimulus in a valence-consistent manner. Subjects who experience a negative mood in response to an initial stimulus often misattribute the negative mood to the second stimulus. Even after the experimenter alerts subjects to the alternate explanation (i.e., that the

first stimulus, not the second, induced the negative mood), subjects persist in their negative evaluations of the second stimulus. Mood congruency is similar to affective priming except that the subject's incidental emotions, rather than a reaction to a prior stimulus, are what color the evaluation of a novel stimulus in a manner consistent with the subject's preexisting mood state.

Impulsivity and the Somatic Marker Hypothesis

Physiological cues of emotional state

One emotion-based model of decision making is the somatic marker hypothesis, according to which decision making in normal individuals is guided by emotional states produced by bioregulatory processes. For example, while playing a gambling card game, normal subjects develop a measurable physiological (skin conductance) response in anticipation of risky outcomes. Drug addicts and people with damage to the frontal lobe of the brain fail to create an anticipatory skin conductance response before drawing a card from a risky deck, and some researchers take this to suggest that their impaired emotional function and suboptimal decision making are connected via an altered physiological response to risk.

The Neuroscience of Decision Making

Measurement Techniques

Neuroscientific models attempt to identify the brain mechanisms that are associated with reasoning. Recent technology has developed methods for correlating neural (i.e., brain) activity with different types of thinking. These techniques include functional magnetic resonance imaging (fMRI), positron emission tomography (PET), and electroencephalography (EEG). Additionally, diffusion tensor imaging (DTI) and magnetic resonance imaging (MRI) are used to infer structural differences or developmental changes in brain regions. Although decision making is one of the most extensively investigated areas using these new techniques, it is important to understand the limitations of the inferences that may be drawn from such studies. Results associating brain activity with decision making are correlational; that is, although brain activation may co-occur with certain behaviors, there is insufficient evidence to infer a causal relationship. Nonetheless, techniques such as fMRI, PET, EEG, and DTI have the potential to greatly inform models of decision making.

Brain Regions

The integration and evaluation of information from memory, emotional cues, and sensorimotor stimuli is thought to occur in the lateral prefrontal cortex and parts of the anterior cingulate cortex. These regions, dubbed areas of executive function, relate to critical decision making behaviors, such as inhibiting unnecessary or goal-defeating information, planning ahead, and contemplating risks and rewards.

Areas including the amygdala, nucleus accumbens, and medial prefrontal cortex are implicated in the processing of salient social information, such as faces, attractiveness, and other social judgments. Whereas the orbitofrontal cortex is associated with simple emotional reactions such as fear, there

is evidence of selective activation of the anterior cingulate cortex when considering the outcome of a decision requires assessment of another person's attitude or behavior. For example, the anterior cingulate cortex is active during cooperation and trust games and is associated with better memory for social versus nonsocial information. Since most real-life decisions occur in a social context, this is an important component of the decision making network.

Reward and Incentive

Another component of social and emotional decision processing is how much the individual values the reward that is likely to result from a particular decision. Research suggests that activity in the nucleus accumbens is linked to reward sensitivity. Further, dopamine, a neurotransmitter implicated in learning and reward, is concentrated in the nucleus accumbens and has been strongly associated with reward-related behavior.

Incentive salience

Dopamine is not thought to be essential to the intrinsic evaluation of a reward. Rather, its function is thought to lie in the connection between that reward and the action (or series of actions) necessary to obtaining it. The association of motivational (reward) value with a behavior is called incentive salience, or value binding. The generation and execution of a reward-oriented action plan is associated with activity in the dorsal striatum. The processing of the magnitude of the reward obtained from an action, particularly if it differed from the expected reward, is associated with activity in the anterior cingulate cortex and ventral tegmental area.

Reward-prediction-error hypothesis

Some researchers have found evidence that changes in the pattern of dopamine release in the ventral tegmental area of the brain reflect the difference between the expected and the actual reward obtained for a given behavior. These phasic surges form a record of reward prediction accuracy. Thus, if a reward is better than expected, there is a burst of dopamine, which indicates a positive reward-prediction error. If a reward is worse (i.e., either less valuable or more aversive) than expected, there is a pause in the pattern of dopamine release, indicating a negative reward-prediction error. Baseline-level dopamine activity indicates that the reward was as expected. Thus, the difference between what you got and what you thought you would get (i.e., the reward-prediction error) is thought to be recorded in the brain by corresponding increases or decreases in dopamine release. The reward-prediction-error hypothesis, supported by evidence from rodents and primates, is thought to describe the way people learn the association between a particular action and the magnitude and desirability of the consequence.

Risk Taking in Adolescence

Adolescents are widely assumed to make riskier decisions than either children or adults. This phenomenon is not explained by theories of decision making that assume that the capacity for rational decision making increases linearly with age, prompting attempts to explain this developmental incongruity. Two classes of explanations have emerged.

Developmental asymmetry

One hypothesis posits that two brain networks important in decision making develop at different rates and that, during the period when one is more mature than the other, adolescents are less able to make adaptive decisions. Some researchers attribute adolescents' proneness to risky decision making to a developmental asymmetry between the socioemotional system (located in limbic areas of the brain), which matures earlier and determines reward sensitivity, and the cognitive control system (located in the prefrontal cortex), which matures later and governs planning and inhibition. According to this account, over the course of development, the functional connectivity of these two regions improves. As a result, it is thought to be the reliance on affect over cognition in adolescence and a deficit in connectivity between areas of emotional processing and areas of cognitive control which cause this group's proclivity for risky decision making. Naturally, brain anatomy and connectivity are thought to be important in risky decision making, but the details of this mechanism are far from established.

Gist versus verbatim processing

Adolescents do not, as many believe, underestimate risks or consider themselves to be invincible. Converging data show that they tend to overestimate risk and often overestimate their vulnerability to negative outcomes. Adolescents possess the basic cognitive capacities to distinguish risky from riskless decisions; their deficiency lies in overanalyzing the situation – that is, in tending to favor calculative over gist-based decision making when it comes to risk. In terms of fuzzy-trace theory, adolescents tend to use verbatim processes more often than do adults (who use gist processes) to make decisions involving risk.

As an example, consider the proposition to play Russian roulette with a six-chamber gun for a gamble of 6 million dollars. In Russian roulette, a gun is loaded with only one bullet and fired to the player's head. If the chamber containing the bullet comes up when the trigger is pulled, the player dies. Otherwise, one of the empty chambers comes up, and the player wins the money. Gist and verbatim thinking result in drastically different approaches to the proposition to play Russian roulette.

A verbatim thinker will calculate the expected reward of the risk, that is, the desired outcome weighted by the probability of attaining that outcome. In this example, this means that there is a five-sixths chance of winning a 6 million dollar prize, which equals an expected reward of 5 million dollars. Given this high expected reward, a verbatim thinker might accept the risk and play the game. By choosing to play, the verbatim thinker elects to take a risk that has a potentially disastrous outcome (i.e., death) so long as there is also the chance for a very high reward. Verbatim thinkers do factor in the high negative value of death; however, there is a price that can be paid that will compensate for it.

To the contrary, a gist thinker will extract the bottom-line meaning from each option. Since the bottom line of Russian roulette is that you could die, gist-based thinkers will refuse to play, no matter what the potential reward is, because the negative outcome is catastrophic. Gist thinkers are able to tolerate a small chance of death for necessary risks (such as crossing the street) but not for unnecessary ones (like having unprotected sex).

According to multiple experiments, adolescents tend to approach risky decisions with verbatim-based analysis, whereas adults take a gist-based approach to the same risk. Studies of real-life risk taking also are consistent with this view; adolescents' perceived risks and perceived benefits predict self-reported risk taking (e.g., substance use), in contrast to hypotheses that such behavior is mainly impulsive and unintentional.

The better decision outcomes associated with gist-based thinking suggest that intervention programs should foster this type of thinking. The idea that risk taking tendencies cannot be altered, nor outcomes improved, because of the immaturity of brain development has been falsified by the effectiveness of gist-based and other educational programs. As a result, intervention programs might do best to shelter younger adolescents from opportunities to engage in risky behaviors, given that they are not fully equipped to make healthy decisions, but to instruct older adolescents in better decision making skills. Recent evidence supports the efficacy of this approach.

Summary

Although scholars continue to debate key aspects of the decision making process, theories have historically shifted from single-process and psychophysical approaches to a variety of dual-process approaches. Current dual-process models such as fuzzy-trace and construal level theories are based on evidence that people mentally encode multiple representations of the same event, and cuing different representations can result in different decisions. This observation is especially relevant in the area of risk taking among adolescents; in particular, adolescents who trade off risks for rewards seem to take more risks than do those who take a categorical stance of avoiding unnecessary risk. Current theories also account for the complex role of emotion in the decision process, acknowledging that this influence is sometimes beneficial and sometimes detrimental. Recent neuroscience research has produced neural hypotheses about several phenomena, including reward valuation and cognitive control. As future research explores synergies between behavioral psychology and behavioral neuroscience, theories from both realms should be mutually constraining.

Defense Mechanisms

G E Vaillant, Massachusetts General Hospital, Boston, MA, USA

© 2012 Elsevier Inc. All rights reserved.

The boundary between pathology and adaptation is ambiguous. Whereas early nineteenth-century medical phenomenologists viewed pus, fever, pain, and coughing as evidence of disease, late nineteenth-century pathophysiologists learned to regard these symptoms as evidence of the body's healthy efforts to cope with physical or infectious insult. Similarly, defense mechanisms (often termed involuntary coping mechanisms) produce behaviors that appear pathological but in fact reflect the brain's homeostatic effort to cope with sudden changes in its internal and external environment.

In 1856, Claude Bernard, a French physiologist and a founder of experimental medicine, started us on our understanding of adaptation to stress when he wrote, "We shall never have a science of medicine as long as we separate the explanation of the pathological from the explanation of normal, vital phenomena." Put differently, it is not stress that kills us as much as the homeostatic, often seemingly pathologic, response to stress that permits us to survive.

In 1925, Adolph Meyer, a founder of modern American psychiatry, asserted that there were no mental diseases; there were only characteristic reaction patterns to stress. Meyer's point was that although adaptive mental 'reaction patterns' like denial, phobias, and even projections can appear to reflect illness, they may in fact be 'normal, vital phenomena' related to healing. Just as immune mechanisms and clotting mechanisms heal by distorting bodily equilibrium, defense mechanisms heal by distorting mental processes.

Of course, the symptoms of organic brain damage usually reflect disease and not adaptation. Manic-depressive psychosis is due to a genetic defect; the mental devastation produced by alcoholism is due to poisoning; and the negative symptoms of schizophrenia reflect brain pathology and not adaptation. Nevertheless, much of the so-called mental illness, including some delusions and hallucinations, makes the disruption of disordered brain function easier to bear; and defenses are often analogous to the healthy, but red, hot, and tender swelling – the rubor, color, dolor, and turgor – that immobilizes a fracture so that it may heal.

Much of what is called mental illness in our diagnostic nomenclature – the symptoms of many anxiety disorders, some depressions, and most personality disorders – is the outward manifestation of homeostatic struggles to adapt to life. Admittedly, analogous to acne and autoimmune disease, such reaction patterns often reflect rigid, poorly modulated, and pathologic efforts at adaptation.

Norman Sartorius, the director of the Division of Mental Health of the World Health Organization, wrote,

Research during the past two decades failed to provide evidence that could help to create disease concepts and disease entities in psychiatry . . . Other ways of thinking about health and disease, mind and body, mental and physical, individual and social are needed. . . I believe that in selected instances a return to the allegedly outdated Meyerian reaction patterns and Freudian Defense mechanisms is warranted.

Defense mechanisms are patterns of emotions, thoughts, or behaviors that are relatively involuntary. They arise in response to perceptions of psychic danger or conflict to unexpected change or threat in the internal or external environment or in response to cognitive dissonance. Defense mechanisms obscure or diminish cognitive, emotional, and physiological response to stress that if unmitigated would give rise to depression, anxiety, or impulsive behavior. There is increasing evidence that choice of defensive styles makes a major contribution to individual differences in response to stressful environments. Consider the differing response of individuals riding on a rollercoaster that range from severe anxiety to stress relieving excitement.

Defense mechanisms can alter our perception of any or all of the following: subject (self), object (other), idea, or feeling (affect). Defenses alter the relationship between *self* and *object* and between *idea* and *affect*. In projection, for example, 'I hate him' becomes 'He hates me.'

The task of homeostatic mechanisms, in general, is to buffer sudden change. The task of the defenses is to buffer sudden change in the four 'lode stars' of mental conflict. These lode-stars are relationships, emotions, conscience, and reality. The use of defense mechanisms usually alters perception of both internal and external reality, and often, as with hypnosis, the use of such mechanisms compromises other facets of cognition (Figure 1).

Thus, defenses can mitigate sudden unresolvable conflict with important people, living or dead. Defenses serve to keep affects and ideation within bearable limits during sudden changes in relationships, such as following the unexpected death of a loved one. People become a lodestar of conflict when we cannot live with them and yet cannot live without them; as people exist within us as well as without, internal representations of important people may continue to haunt us and to cause conflict for decades after we have ceased to live with them and thus evoke defensive behavior. Ghosts, ancestor worship, and demonic possession would be such examples.

Defenses can deflect or deny sudden increases in emotions and biological instinct, such as heightened sexual awareness and aggression during adolescence. Psychoanalysts call this lodestar of conflict 'id,' fundamentalists call it 'sin,' cognitive psychologists call it 'hot cognition,' and neuroanatomists point to the hypothalamic and limbic regions of brain.

Defenses enables individuals to mitigate sudden upsurges in conscience or guilt such as might occur for a doctor faced with a malpractice suit. Psychoanalysts call it 'super ego,' anthropologists call it 'taboos,' behaviorists call it 'conditioning,' and neuroanatomists point to the frontal lobe and the amygdala. This lodestar is not just the result of admonitions from our parents that we absorb before age five, but is formed by our whole identification with our culture, and sometimes by irreversible learning resulting from overwhelming trauma.

Finally, defenses allow individuals a period of respite to master reality, such as the events surrounding 9/11 or changes

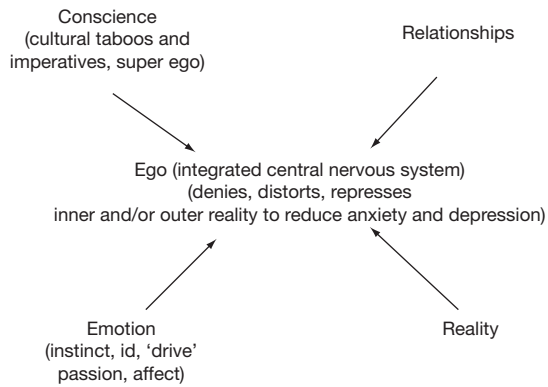

Figure 1 The four sources of intrapsychic conflict.

in self-image that cannot be immediately integrated, as might result from an amputation, or a promotion. Such involuntary mental mechanisms can provide a mental time out to adjust to sudden changes in *reality* and self-image, which cannot be immediately integrated. Sudden good news – the instant transition from student to physician or winning the lottery – can evoke involuntary mental mechanisms as often as can an unexpected accident or a diagnosis of leukemia.

Sudden change in any of the four lodestars produces depression, anxiety, or impulsive disorder. Involuntary ‘denial,’ ‘distortion,’ or ‘repression’ of the lodestars mitigates such dysphoria. However, used indiscriminately, terms like *repression* and *denial* lose the explanatory power of the conceptual scheme – ego mechanisms of defense.

A final reason for paying attention to defenses can be illustrated by the internist’s understanding of *referred* pain. A pain in the right shoulder may reflect an inflamed gall bladder; a pain in the left shoulder may reflect coronary thrombosis. Proper diagnosis depends upon the internist’s seeing behind a symptom often identified as arthritic. By understanding that a function of much of the psychopathology is to distort, displace, and deny the conflict, we learn not to take psychological symptoms too literally. In short, defenses provide a diagnostic template for understanding the distress and for guiding the clinical management of psychology’s most ‘unreasonable’ and baffling clients.

At first, the observer may call the user of a defense stupid, then wicked, and then mentally ill. All such responses are as useless as scolding a child for sneezing. Yet, we can neither condemn a tubercular patient for coughing nor ignore the internal disorder that it portends. Similarly, we must neither condemn the lawful eccentricities of the ego’s mechanisms of defense as sins nor dismiss them as mere chance events. As with the cough of the consumptive, attention must be paid to the odd behaviors of people with emotional disease.

It is important to place defense mechanisms within the broader framework of stress and coping. Psychopathological response to stress may be considered from two perspectives. The first perspective emphasizes relatively nonspecific psychophysiological responses to stress, such as an elevated Hamilton depression scale or elevations in blood epinephrine levels. This is the perspective of Hans Selye and other phenomenologists. Stress kills. The second perspective focuses on how an individual’s integrated central nervous system perceives and copes with the stressor. In this case, the result of stress is

seen not as nonspecific depression and anxiety but as highly differentiated synthetic behaviors that may range from arcane delusional systems to the writing of a great novel. What does not kill us makes us stronger. This second perspective, that of ego psychology, is the orientation of this article.

If stress can be viewed from two vantage points, coping responses to stress can be viewed as divided into three broad categories. The first coping category involves eliciting help from appropriate others, for example, by mobilizing social supports. The second coping category involves voluntary cognitive efforts like information gathering, anticipating danger, and rehearsing responses to danger. The third coping category entails deploying involuntary adaptive mechanisms or automatic psychological processes that protect the individual from the disorganizing effects of internal or external dangers or stressors. These coping processes are often subsumed under the psychoanalytic term *ego mechanisms of defense*.

The first class of coping mechanisms, seeking social support, is analogous to calling 911 in response to one’s own bleeding. The second class, cognitive coping strategies, can be taught and rehearsed; they are analogous to consciously using a tourniquet to stop one’s own bleeding. The third class of coping mechanisms, the involuntary defense mechanisms, are analogous to depending upon one’s own very complex and quite involuntary clotting mechanisms in order to stop bleeding.

Freud’s Discovery of the Concept of Defense

Perhaps, Freud’s most original contribution to human psychology was his inductive postulation that unconscious ‘defense mechanisms’ protect the individual from painful emotions, ideas, and drives. In delineating the nature of ego mechanisms of defense, Freud established not only that upsetting *affects*, as well as *ideas*, underlay psychopathology, but also that much of what is perceived as psychopathology reflects a potentially healing process.

That emotions were significant to humans had been known since ancient times, but our understanding of their modulation through unconscious mechanisms of defense, rather than will-power, originated with Sigmund Freud, who was trained in both neurology and physiology.

It was difficult to develop a concept of defense, however, until psychology could imagine that ideas gain their color, temperature, and importance from emotion. For example, the influential textbooks of the two greatest psychologists of the nineteenth century, Wilhelm Wundt and William James persisted in discussing a psychology that consisted of only cognition, not emotion. Psychology needed to replace neutral terms like intellect, will, moral sentiment, higher feelings, and cognition with terms suffused with emotional color, for example, sadness, lust, rage, and guilty fantasy. From the beginning, Freud’s work effected this change. In 1894, Freud observed that not only could affect be ‘dislocated or transposed’ from ideas (by the mechanism that Freud would later call isolation) but also that affect could be ‘reattached’ to other ideas (i.e., by displacement).

Over a period of 40 years, Freud discovered most of the defense mechanisms that we speak of today and identified five of their important properties.

(1) Defenses are a major means of mitigating the distressing effects of both emotion and cognitive dissonance. (2) They are unconscious. (3) They are discrete from one another. (4) Although often the hallmarks of major psychiatric syndromes, defenses are dynamic and reversible. (5) Finally, they can be adaptive, even creative, as well as pathological. To this list must be added that to the user defenses are invisible, but to the observer defenses usually appear odd.

Unlike most of the defense mechanisms, the concept of repression was not original to Freud. J.F. Herbart had written extensively on 'verdrängung' (Freud's term for repression also) of ideas. Herbart's *Psychology as a Science* (1824) may have influenced Freud indirectly through Freud's psychiatric mentor, Theodor Meynert. Schopenhauer had also perceived that defensive forgetting had something to do with psychopathology; but he, too, wrote of forgetting ideas and circumstances, not feelings.

In 1905, Freud conceived of a special class of defense mechanisms – sublimations – that could transmute conflictual affect, not into a source of pathology, but into culture and virtue. For example, Beethoven was often angry, depressed, lonely, and suicidal. Nevertheless, instead of killing himself, in his Ninth Symphony he put Schiller's 'Ode to Joy' to music. To call such unusual behavior 'being in denial' is to sell the ingenuity of the central nervous system short.

Humor, like sublimation, was another defense that Freud and students of adaptation in general have perceived as having more of an adaptive than a pathogenic quality. In *Jokes and Their Relation to the Unconscious*, by hinting at a hierarchy of defenses, Freud developed the idea of humor as a more mature defense mechanism than wit. Freud viewed wit and practical jokes as inextricably linked with the less adaptive, less mature, and less empathic mechanism of displacement. Freud wrote, "humor is a means of obtaining pleasure in spite of the distressing affects that interfere with it; it acts as a substitute for the generation of these affects; it puts itself in their place. It arises from an economy in the expenditure of affect."

Freud also introduced the concept of an ontogeny of defenses. Defenses such as projection, repression, and sublimation not only lay along a continuum of relative psychopathology but also along a continuum of personality development. Reaction formation, Freud said, reminded him of the proverb *Junge Hure, alte Betschwester* (a young whore makes an old nun). With the passage of decades and the continuing myelination of frontal lobe's connections to the limbic system, the defense of adolescent acting out (e.g., impulsive, temporarily comforting tantrums) could become the parent of reaction formation (anger is bad and should be punished by spanking and jail) and a potential grandparent of altruism (nonviolence, creative parole and believing that conflict mediation is good).

In 1936, Freud advised the interested student that there are "an extraordinarily large number of methods (or mechanisms, as we say) used by our ego in the discharge of its defensive function . . . my daughter, the child analyst, is writing a book upon them." He was referring, of course, to Anna Freud's *The Ego and Mechanisms of Defense* (1936), which to this day remains one of the definitive texts on the subject.

Clinicians have often been reluctant to view defenses as adaptive as well as pathological. This Encyclopedia, for example, has a separate article for 'coping.' This difficulty has slowed

our understanding of the more mature ego mechanisms of defense. The difficulty, of course, is that with brain maturation comes complexity. Thus, self-deception or conflict resolution via humor and sublimation reflects a different level of mental complexity than via the more concrete defenses of projection or turning-against-the-self.

Modern Conceptualizations of Defense

All defenses involve creative synthesis. Defenses often manifest themselves in paintings and in dreams, in phobias and in hallucinations, in humor and in religious experience. As such, defenses reflect the building blocks of interesting behavior, of madness and of art. They help explain the unreason of both the sinner and the saint. However, if defenses integrate, make sense out of and master conflict, they still remain difficult to describe. Like rainbows and shooting stars, now we see them, now we do not.

From the beginning, defenses have posed a problem for experimental psychology. First, there is no clear line between character (enduring traits) and defense (shorter lived response to environmental stress), between behavior and mental mechanism, and between neuropathology and unconscious coping process. Is the self-attack of major depression a result of genetically disordered brain chemistry or anger turned against the self – or both? Second, 'defense mechanisms' can serve other purposes; and conversely, any of the mind's functions, not just standard defenses, can be employed in the service of defense. Third, in any effort to produce a comprehensive list of defenses there will be enormous semantic disagreement.

Differentiated mechanisms of defense become most clear when one can study the psychopathology of healthy everyday life in detail and over time. Our appreciation of the defensive nature of mature behavior awaited studies of normal populations. Over the last 30 years, several longitudinal studies at Berkeley (Norma Haan) and at Harvard (George Vaillant) have clarified our understanding of defenses with experimental and developmental studies. By offering a tentative hierarchy and glossary of consensually validated definitions, DSM-IV has set the stage for further progress. In the last 20 years, several empirical studies reviewed by Cramer (1991) and Skodol and Perry (1993) finally organized defenses into a hierarchy of relative psychopathology.

The *Diagnostic and Statistical Manual of Mental Disorders*, fourth edition (DSM-IV), has included a Defensive Functioning Scale as a proposed diagnostic axis for further study. **Table 1** arranges these defense mechanisms into seven general classes of relative psychopathology. The so-called 'immature' defenses (Levels II–V) in **Table 1** are the ones that underlie much of personality disorder.

There are many ways that we can ignore or distort one or more of these four lodestars in order to mitigate intrapsychic conflict. For semantic consistency, the Defensive Function Scale of DSM-IV has labeled these involuntary mental mechanisms, *defenses* (**Table 1**). These coping mechanisms or 'defenses' can abolish impulse (e.g., by reaction formation), or social learning (e.g., by acting out), or other people (e.g., by schizoid fantasy), or reality (e.g., by psychotic denial). They can abolish our conscious recognition of the subject (e.g., by projection), or the object of a conflict (e.g., by turning against

Table 1 Defensive functioning scale (adapted from DSM-IV) (pp. 751–753)**A. Psychotic defenses**

I. Level of defensive deregulation. This level is characterized by failure of defensive regulation to contain the individual's reaction to stressors, leading to a pronounced break with objective reality. Examples are as follows:

- Delusional projection
- Psychotic denial
- Psychotic distortion

B. Immature defenses

II. Action level. This level is characterized by defensive functioning that deals with internal or external stressors by action or withdrawal. Examples are as follows:

- Acting out
- Apathetic withdrawal
- Passive aggression (turning against the self)

III. Major image-distorting level. This level is characterized by gross distortion or misattribution of the image of self or others. Examples are as follows:

- Autistic fantasy
- Projective identification
- Splitting of self-image or image of others

IV. Disavowal level. This level is characterized by keeping unpleasant or unacceptable stressors, impulses, ideas, affects, or responsibility out of awareness with or without a misattribution of these to external causes. Examples are as follows:

- Denial
- Projection
- Rationalization

V. Minor image-distorting level. This level is characterized by distortions in the image of the self, body, or others that may be employed to regulate self-esteem. Examples are as follows:

- Devaluation (hypochondriasis)
- Idealization
- Omnipotence

C. Neurotic defenses

VI. Mental inhibitions (compromise formation) level. Defensive functioning at this level keeps potentially threatening ideas, feelings, memories, wishes, or fears out of awareness. Examples are as follows:

- Displacement
- Dissociation (empirically placed with the II–V 'immature' defenses)
- Intellectualization
- Isolation of affect
- Reaction formation
- Repression
- Undoing

D. Mature defenses

VII. High adaptive level. This level of defensive functioning results in optimal adaptation in the handling of stressors. These defenses usually maximize gratification and allow the conscious awareness of feelings, ideas, and their consequences. They also promote an optimum balance among conflicting motives. Examples of defenses at this level are as follows:

- Anticipation
- Affiliation (seeking social support)
- Altruism
- Humor
- Self-assertion (cognitive coping strategy)
- Self-observation (cognitive coping strategy)
- Sublimation
- Suppression

the self), or awareness of the idea (e.g., by repression), or of the affect associated with the idea (e.g., isolation of affect).

All classes of defenses in [Table 1](#) are effective in 'denying' or defusing conflict and in 'repressing' or minimizing stress; but they differ greatly in the psychiatric diagnoses assigned to their users and in their consequences for long-term biopsychosocial adaptation. In Level I, the most pathological category, are found denial and distortion of external reality. These mechanisms are common in young children, in our dreams, and in psychosis. To breach them requires altering the brain by neuroleptics or waking the dreamer.

More common to everyday life are the relatively maladaptive defenses found in Levels II–V. Defenses in these categories

are common in adolescents, in immature and substance abusing adults, and in individuals with personality disorders. They often make others more uncomfortable than the user. Such defenses are consistently and negatively correlated with global assessment of mental health, and they profoundly distort the affective component of interpersonal relationships. Like cigarette smoking in a crowded elevator, such behavior seems innocent to the user and deliberately irritating and provocative to the observer. Immature defenses externalize responsibility and allow individuals with personality disorders to refuse help. Defenses in this category rarely respond to verbal interpretation alone. The projection of the paranoid by which unacknowledged feelings are attributed to others is well

known, and so is the capacity of schizoid individuals to relieve loneliness by creating fantasized human relationships within their own minds. The capacity of histrionic personalities to disassociate themselves from painful emotion and to replace unpleasant with pleasant affect, as if they were on stage, is familiar; and so is the fact that passive-aggressive and masochistic characters turn anger against themselves in a most annoying and provocative manner.

The mechanisms of acting out and hypochondriasis are less familiar. In the antisocial personality, acting out reflects a process whereby the direct motor expression of an unconscious wish or conflict allows the individual to remain unaware of either the idea or the affect that the action accompanies. Thus, acting out produces the clinical illusion that all sociopaths do not experience the painful affects of guilt, anxiety, or depression. In fact, nothing could be further from the truth.

Hypochondriasis disguises reproach. The 'borderline's' help rejecting complaints that clinicians make him/her worse may conceal grief, longing, and unacceptable aggressive impulses. By exaggerated focus upon current somatic or psychic pain that cannot be relieved, the hypochondriac attempts to manage past unbearable grief or abuse.

Immature defenses can be breached in two ways. First, by confrontation – often by a group of supportive peers – or by videotaped empathic but focused psychotherapy. Second, immature defenses can be breached by improving intrapsychic competence by rendering the individual less anxious and lonely through empathy, less tired and hungry through food and rest, or less intoxicated through abstinence.

The third class of defenses, those in Level VI, are often associated with what DSM-IV calls Axis I anxiety disorders and with the psychopathology of everyday life. These include mechanisms like repression, intellectualization, reaction formation (i.e., turning the other cheek), and displacement (i.e., directing affect at a more neutral object). In contrast to the 'immature' defenses, these 'intermediate' defenses are manifested clinically by phobias, compulsions, obsessions, somatizations, and amnesias. Also, in contrast to the immature defenses, 'intermediate' defenses usually make the user more uncomfortable than the observer. Such users often seek psychological help and respond more consistently to psychotherapeutic interpretation. Intermediate defenses are common in everyone from 5 years old until death. They are neither healthy nor unhealthy. Across studies, the intermediate (Level VI or 'neurotic') defenses show mixed positive and negative correlations with outcome of only minimal statistical significance.

The mechanisms at Level VII still distort and alter feelings, conscience, relationships, and reality; but they achieve these alterations gracefully and flexibly. These mechanisms allow the individual consciously to experience the affective component of interpersonal relationships, but in a tempered empathic fashion. Thus, the beholder regards Level VII adaptive defenses as virtues, just as the beholder may regard common immature defenses like the prejudice of projection and the tantrums of acting out as sins.

Doing as one would be done by (altruism), keeping a stiff upper lip (suppression), keeping future pain in awareness (anticipation), the ability not to take one's self too seriously (humor), and turning lemons into lemonade (sublimation) are the very stuff from which positive mental health is made.

Unfortunately, like tightrope walking, mature mechanisms cannot easily be deployed; their deployment is facilitated by empathy, safety, and exemplars.

Deciphering a nomenclature of defenses is like translating a foreign language. Thus, the terms that I have found useful in my longitudinal research (given in bold in Table 1) are translated in Table 2 from label into process. As is clear from Table 2, I have found it useful to condense the behaviors listed in Levels II–V into a single level – immature defenses. Rather than dispute my or DSM-IV choice of words, readers are asked to substitute terms that suit them. The fictional defensive processes described for the cases depicted in Table 2 are extensively illustrated by cases from true longitudinal study in *Adaptation to Life and Wisdom of the Ego*.

All classes of defenses are effective in 'repressing' conflict and in 'denying' stress, but the individual defenses differ greatly in the diagnoses associated with their use and perhaps in their consequences for long-term biopsychosocial adaptation.

Writing great tragedy (i.e., sublimation), for example, is financially rewarding, instinctually gratifying, and sometimes life saving for the author. The 'distortion' involved in stoicism (suppression), humor, and altruism seems as ethical and as mentally healthy to an observer as the immature defenses seem immoral and antisocial. Living one's life by laughter, the Golden Mean, and the Golden Rule is not just the stuff of morality tales but can empirically make the user healthy, wealthy, and wise.

Less mature defenses may evolve into more mature defenses. The adolescent's autistic fantasies may become the scholar's intellectualized obsession. Mary Baker Eddy's hypochondriasis evolved first into reaction formation against any complaint of physical illness and then into the highly rewarding altruistic founding of the Christian Science Church. Just as some children outgrow allergies, the second-grader's irritating sadomasochistic pleasure of putting thumbtacks on chairs may evolve into the adolescent's enjoyment of the displaced hostility of cartoon movies and finally into mature, enjoyable humor where the hostile intent is invisible.

However, if defenses are the building blocks of psychopathology, their division into 'levels' or categories is as arbitrary as our division of colors. There will always be as many different colors – and as many defenses – as the taxonomist has imagination.

Identification of Defenses

Identification of defenses is difficult. Rarely can we identify our own defenses, and we often fail to recognize them in others or, still worse, 'project' our own defenses onto others. To identify a defense, an objective observer needs to triangulate past truth with present behavior and subjective report. First, we need to know the biological facts. Second, we need a behavior or symptom or a creative product (that may seem odd, sinful, or amazing). Third, we need the subjects' autobiographical account. In short, we must contrast a patient's *symptoms* (or a healthy person's creative product) with his self-report (mental content) and with someone else's *objective report* (biography, or old charts). Ultimately, like other facets of mental health, the reliable identification of healthy but involuntary coping mechanisms requires longitudinal study. For example, one

Table 2 Case illustration

A woman, married at age 30, after one miscarriage tried for 7 years to have children, which she wished for intensely (*limbic emotion*). Then, following a cervical biopsy that showed cancer, at age 38 she is still hospitalized after a total hysterectomy (*reality*). She had always felt inadequate in relation to her younger sister, who already had four children and had been the one in the family who won praise as 'being good with kids' (relationship). The woman's husband also desperately wanted children (conscience). Below are a number of possible responses to her surgery.

D. 'Mature' defenses

Altruism: The woman, a month after surgery, organized a group of other women who had breast and uterine surgery to counsel and to visit patients undergoing gynecological surgery. They tried to give information, advice, and comfort, and from their experience provide answers to questions and fears that such new patients might have. Diagnosis: Altruist

Suppression: She read Marcus Aurelius and Ecclesiastes in the hospital. She took great care to hide her tear-stained tissues from her husband and made no complaint (even though the process was painful) while her sutures were removed. Knowing that baby pictures upset her, she deliberately gave away an unread copy of her favorite magazine, which featured an article on childcare. Diagnosis: Stoic

Sublimation: She got great pleasure from 'get well' cards from her sister's children, agreed to teach a Sunday School class of preschoolers, and got a poem published in her hometown weekly on the bittersweet joys of the maiden aunt. Diagnosis: Artist

Anticipation: Her doctor was surprised to find out how relaxed and practical she was about her postoperative course and the calm frankness with which she could express her regret at being cheated of children. His surprise was due to the fact that she had spent her preoperative visit anxiously worrying about possible surgical complications and weeping over the fact that she would never be able to bear children. Diagnosis: None

Humor: She laughed so hard that tears came to her eyes and her ribs ached when she read the *Playboy* definition of hysterectomy: "throwing out the baby carriage but keeping the playpen." She explained her private mirth to a startled and curious nurse with, "The whole thing is just so damned ironic." Diagnosis: None

C. 'Neurotic' defenses

Reaction formation: She renewed her old college interest in Planned Parenthood and passionately argued with her younger friends to limit their families. She suddenly 'remembered' that she had always been afraid of the pain of childbirth and remarked to her husband how lucky she was to be spared the burden. Diagnosis: Pollyanna

Isolation (Intellectualization): She read a lot about uterine cancer and asked the doctor a great many questions about the nature of the operation. She concerned herself with minute details preventing postoperative infection and caring for her operative wound. She made a hobby in the hospital of learning medical words. Diagnosis: Obsessive Compulsive

Repression: She found herself unable to remember the name of the operation except that it was for 'a little nubbin in my tumtum.' She 'forgot' her first follow-up visit to the physician. On coming home, she broke into tears when she broke an inexpensive, amphora-shaped flower vase; she had no idea why. Diagnosis: Hysterical

Displacement: She became very interested in growing tulips and daffodils in her hospital window. Although she never asked the doctor questions about her own hospital course, she worried about a funny mold on the bulbs she was growing. Knowing his hobby was gardening, she repeatedly asked her surgeon's advice about the growth on her bulbs. Diagnosis: Anxiety Disorder or Phobia

B. 'Immature' defenses

Projection: Following a slight postoperative wound infection, she wrote long, angry letters to the papers blaming the hospital for unsanitary conditions. Blaming her doctor for not doing a Pap smear earlier, she threatened to institute malpractice proceedings. Diagnosis: Paranoid Personality

Dissociation: Emerging from anesthesia, she felt no regret but instead enjoyed what she felt was a religious experience. Postoperatively, she told all her friends that her pain gave herself a sense of joyous communion with sufferers everywhere. She felt an intense inward sense of good fortune that she had been favored by God to have had her cancer discovered so soon and to have come through surgery so well. Diagnosis: Dissociative Disorder

Fantasy: She asked the nurse not to permit visitors because they made her 'sad.' She threw out all her flowers and instead read and reread a copy of *Parent's Magazine* and looked repeatedly at *The Family of Man*. She would go down the corridor to the newborn nursery daydreaming about what she would call each child if it were hers, and once a floor nurse had to ask her not to whistle lullabies so loudly. Diagnosis: Schizoid Personality

Hypochondriasis: She became worried that the cancer might have spread to her lymph nodes and belabored her visitors with accounts of the tiny lumps in her groin and neck. When her sister came to visit, the patient angrily accused her of caring so much for her own children that she did not care if her own sister died of cancer. Diagnosis: Borderline Personality
