There are two principal ways in which gestures are related to speech: in terms of their temporal coordination, and also in terms of meaning. In terms of temporal coordination, gestures have been shown to be related to both syntax and vocal stress.

Syntax

The relationship between syntax and body movement was studied by analyzing the speech of a patient in a psychotherapy session. Observations were made of the number of postural

shifts, leg movements, and foot movements and it was noted whether they coincided with syntactic boundaries. A movement was scored as coinciding with syntax if it took place within but not across the duration of a clause. It was found that most of the observed body movements fell within syntactic boundaries, and hence it was concluded that body movement is closely related to syntax.

Vocal stress

Discourse has a discernible structure based on strings of words which seem to be spoken as a unit, known as the phonemic clause or tone group. A phonemic clause consists of a group of words, averaging five in length, in which there is only one primary (or tonic) stress indicated by changes in pitch, rhythm or loudness, and which is terminated by a juncture, where these changes in pitch, rhythm and loudness level off before the beginning of the next phonemic clause. It has been observed that most speakers of American English accompany their primary stresses with slight jerks of the head or hand, while junctures are accompanied by a movement of the head, eyes or hands. In a study of British informal conversations, it was found that over 90% of tonic stresses were accompanied by body movements, not only of the head or hands, but also of the trunk and legs/feet. In a study of political speeches, it was found that repeated movements (where, e.g., the speaker extends and flexes his forearm continuously for two or more occasions) always occurred within the duration of a tone group and never violated tone group boundaries. These movements seem to serve a dual function: they both pick out stressed words and demarcate the extent of the tone group. Such gestures are sometimes referred to as 'beats,' movements which may look as if they are beating out musical time, and pick out important words and phrases.

Meaning

Gesture and speech convey meaning in radically different ways. Speech relies on a lexicon, whereby words may have particular meanings, which may be combined into full sentences through the rules of syntax. In contrast, gestures convey meaning through their visual appearance. Some gestures, referred to as 'iconic,' seek to resemble the object or event they depict. Others, referred to as 'metaphoric,' seek to depict an abstract idea rather than a concrete object or event. In addition, gestures can represent multidimensional aspects of meaning. For example, a gesture may convey the appearance of an object as well as its size. It may also convey information about movement, for example, speed and trajectory, all at the same time. In spoken language, this information would have to be conveyed sequentially, but in gesture this information can be conveyed simultaneously, through one single powerful iconic image.

Gestures may also contribute to meaning by showing how an utterance is to be interpreted. Speech in itself can be understood as a form of social action. Through different kinds of speech acts, speakers may threaten, plead, apologize, joke, refuse, disagree, evaluate, or do many other things. Notably, the nature of that speech act may be indicated through associated gestures. For example, pointing is commonly understood as being performed with one finger, but it may also be accomplished with the thumb, the head, or with certain movements of the eyes. Furthermore, different forms of pointing

may have different meanings. An index finger point may be used to threaten or accuse. A wagging finger may be used to reprimand or scold. A thumb may be used to disparage whatever is being pointed out. Slight movements of the head or eyes in pointing may be used to keep the act of pointing inconspicuous, thereby indicating the need for discretion. Obviously, pointing is integral to the comprehension of an utterance, which necessitates knowing the direction of the point. But pointing can do much more than this, the type of the point can indicate how an utterance is to be taken.

The Functions of Gesture in Conversation

It has been argued that gestures serve a variety of functions in relation to speech, which can be divided into emblems, illustrators and regulators. The term 'emblem' refers to those nonverbal acts which have a direct verbal translation, such as nodding the head when meaning 'yes,' or shaking the head when meaning 'no'; their function is communicative and explicitly recognized as such. Illustrators are movements directly tied to speech, which amplify and elaborate the verbal content of the message. Regulators are movements which guide and control the flow of conversation, influencing both who is to speak and how much is said.

Emblems

Emblems are generally assumed to be specific to particular cultures or occupations, but there do appear to be pan-cultural emblems such as the 'eyebrow flash,' where a person raises his eyebrows for about a sixth of a second as a greeting; this has been observed in a wide number of differing cultures. In one study, the geographical distribution of 20 emblems was mapped across western and southern Europe and the Mediterranean. The findings showed that whereas some emblems were specific to one particular culture, others were much more widespread. In Italy, for example, pressing and rotating a straightened forefinger against the cheek (sometimes referred to as the cheek-screw) is a gesture of praise; it is, however, little known elsewhere in Europe. Another gesture referred to as the nose thumb, in which the thumb touches the tip of the nose with the fingers pointing upwards spread out in a fan, is widely known throughout Europe as a form of mockery. The meanings of other emblems vary between cultures. For example, a gesture sometimes called the ring, where the thumb and forefinger touch to form a circle, means in Britain something is good, in parts of France something is worthless, while in Sardinia it is an obscene sexual insult!

Some emblems have a long history. The Roman author Quintilian, writing in first century AD, describes a hand gesture which is formed by the first finger touching the middle of the right-hand edge of the thumb nail; this graceful gesture he says was well suited to express approval. It seems to correspond almost exactly to the ring emblem described above, since Quintilian's precise description of the relationship between the thumb and the first finger almost necessitates the adoption of a circular ring-like position. Again, the emblem known as the nose thumb is referred to as early as 1532 in the writings of the celebrated French author, Francois Rabelais, who devotes a whole chapter to a duel of gestures between

two of his characters. The nose thumb is also depicted in a 1560 print entitled 'La Fete des fous' by Pieter Brueghel. Bulwer in his *Chirologia ... Chironomia* (1644) gave a detailed description of a whole number of emblems.

Clearly the function of emblems is communicative, and they constitute a form of nonverbal communication of which people have explicit awareness. The question arises, however, why emblems should have emerged as an alternative form of communication to speech. It has been argued that they are often used when speech is difficult or impossible, and hence function as an alternative system to speech. For example, the policeman directing traffic on points duty, or the deaf-and-dumb person using sign language can both be said to be using emblems in situations where speech is not possible. Emblems are also useful for communication at a distance; many familiar signing systems are used in a variety of sports by officials communicating at a distance with other officials, players and spectators.

Some of the most notorious emblems are, of course, insults; it may be advisable to use emblematic insults at a distance, since it makes it more difficult for the insulted person to retaliate!

Regulators

Regulators are movements which are assumed to guide and control the flow of conversation, for example, in the way in which people exchange speaking turns. In an intensive set of studies of turn-taking it was found that attempts by the listener to take over the turn could be essentially eliminated by the speaker continuing to gesture; this was called the attempt-suppressing signal. Observations also showed that ceasing to gesture was one of five turn-yielding cues, signals that offer a speaking turn to the other person. It was proposed that the effect of these five cues is additive: a linear relationship was found between the number of turn-yielding cues displayed and a smooth switch between speakers. The other cues were the completion of a grammatical clause, a rise or fall in pitch at the end of a clause, a drawl on the final syllable and stereotyped expressions such as 'but er' and 'you know.'

Illustrators

Illustrators are movements directly tied to speech, and it is maintained that they facilitate communication by amplifying and elaborating the verbal content of the message. Whether illustrators do in fact facilitate communication was tested in a series of experiments that were conducted based on video recordings of participants narrating cartoon stories. These descriptions were then replayed either with speech or with speech and gestures to another set of participants who were subsequently asked a series of detailed questions about the stories. For example, in one experiment, observers were asked questions about the actions and objects described in the cartoons. These questions covered such things as the identity of people or objects reported, as well as their size, their shape and their relative position, also the nature of any actions described and the speed of such actions. Results consistently showed that participants who saw the gestures got significantly more information about the original story than those who heard only the speech.

Emotions and Interpersonal Attitudes

Cultural Universals in the Facial Expression of Emotion

Particular importance is commonly ascribed to nonverbal cues in the communication of emotion. In this respect, however, gesture appears to play an essentially subordinate role to the face. Charles Darwin proposed that if emotions are expressed in the same way in different cultures, then these expressions are probably inherited, whereas if they differ between cultures, then they are probably learned. Modern research has shown that facial expressions associated with seven emotions (anger, fear, happiness, sadness, surprise, disgust, and contempt) are decoded in the same way by members of both literate and preliterate cultures. However, even if one accepts the existence of universals in decoding, it is only necessary to hypothesize that whatever is responsible for common facial expressions is constant for all mankind: inheritance is one such factor, but learning experiences common to all mankind could equally well be another. Nevertheless, children born both deaf and blind show the basic repertoire of facial expressions of emotion, and all but one of the discrete facial muscle actions visible in adults can be identified in neonates born without such handicaps. We can also learn to control our facial expressions according to what are called display rules – norms governing the expression of emotion in different contexts. These rules may take the form of attenuation, amplification, substitution or concealment of particular expressions. It is now generally accepted that there are at least seven fundamental emotions with innate facial expressions, but that these can also be modified through the display rules described above.

Gesture and Facial Expression

There is no such evidence for cultural universals in gestural expression. However, a number of studies have been carried out in which people were asked to make judgements of emotion from the face alone, the body alone and from the whole person. If body movement is important in the judgement of emotion, then the accuracy of judgements from the whole person should be superior to that from the face alone. But in practice this seems not to be the case. Decoders appear to base their judgements on the face more than on the body; they found it easier to agree on the face, and their judgements from the face were more accurate.

Nevertheless, one potential problem with these studies is that the facial expressions and body movements may have differed in their degree of informativeness; the decoders may simply have paid more attention to whichever feature was carrying the most information. Moreover, there seems to be no reason in principle why gesture should not convey information about particular emotions, since we speak of people jumping for joy, or clenching their fists in anger, or cowering in fear. It is possible these gestures only occur under conditions of intense emotion, and were not reflected in the studies described above.

In fact, in certain situations, gestures do convey significant information about emotions and interpersonal attitudes. One such situation is deceptive communication. Because the face is so visible and has the capacity to send many different sorts of messages quickly, it is important to control facial expression

when engaged in deception. In one study, students of nursing were asked to watch two films, one intended to be pleasant, the other intended to be stressful (showing amputations and the treatment of severe burns). The nurses were interviewed after seeing the films and asked to describe their reactions to the pleasant film honestly, but to conceal any negative reaction they might have had to the stressful film. Videotapes of the interviews were shown to observers, who were asked to guess which film the nurses had just seen; they were significantly more accurate when making these judgments from the body than from the face. When the nurses were asked what expressions they should control or what they should do in order to avoid detection, significantly more of them mentioned the face than the body.

Embarrassment is another emotion which people often try to conceal. One ingenious experimenter contrived to study embarrassment in the laboratory by arranging a structured interview: the participant was asked to select from a collection of pictures the one which he/she most disliked and was then asked a series of 15 questions concerning the reasons for that choice. In the eighth question, the interviewer revealed that he himself had painted the picture (he had in fact painted all the pictures in the original collection). After the interview was over, each subject was shown a videotape of the interview and asked to rate their response to the 8th question on a list of 19 emotion categories which included embarrassment, to check that the experimental manipulation had been successful. Subsequently, the videotapes were shown to another group of observers, who were asked to identify embarrassment or amusement from either the face, the body, or the face and the body together. Accurate recognition of embarrassment required both facial and body cues, while amusement required only facial cues; in fact, embarrassment was incorrectly identified as amusement by those observers who saw the face alone. The decoders who saw both the face and the body were also asked which cues they had used to identify embarrassment; those which were significantly associated with accurate recognition were the eyes, the hands, the mouth and the lower legs.

Gender Identification Signals

Gestures are important in conveying information about sexual attitudes, through what are sometimes called 'gender identification signals.' In one study, on the basis of a questionnaire intended to measure sex-role attitudes, three groups of men and women were selected: one with strongly masculine characteristics, another with strongly feminine characteristics and a third described as 'androgynous' (with characteristics of both sexes). Each subject was then asked to role play being a junior high school maths teacher, and each performance was video recorded. The videotapes were then shown to observers, who rated the encoders in terms of masculinity/femininity under five different conditions: from the vision alone (head and body), the head only, the body only, the voice and from a still photograph. The observers were able to accurately guess the sex-role attitudes of the encoders only in the vision alone and the body alone conditions. Physical appearance or clothing seemed to be unimportant, since the observers could not make accurate guesses when they saw just the still photographs. Thus, movements of the body seem to be important in conveying information about sex-role identification.

In fact, sex differences in the use of gesture seem to occur at an age as young as 4 or 5 years. This has been highlighted by studies of children with sexual identity problems, who appear to make exaggerated use of gestures which are associated with the opposite gender. In two studies of normal children, researchers found that girls did make significantly greater use of five of the 'effeminate' movements used by gender-disturbed boys. These were referred to as the limp wrist, flutters (rapidly moving the arms up and down), walking with a flexed elbow (where the angle between the upper arm and forearm is between 0 and 135°), the hand clasp (touching the hands together in front of the body) and palming (a grooming movement which involves touching the palm to the back, front or sides of the head above the level of the ears). Thus, it appears that there are significant differences between the sexes in the use of gesture, and furthermore, that gesture is of considerable importance in conveying information about sex-role attitudes and sex-role identification.

Dominance and Submission

Gesture conveys information about other interpersonal attitudes, such as dominance and submission. It was Charles Darwin who proposed that 'making oneself smaller' appeases and inhibits human aggression. This suggestion has been taken up by modern researchers studying how fights between boys are resolved. They found that just before the fighting stopped, the boy under attack would often reduce his body stature in some way, for example, by bowing his head, slumping his shoulders, lying motionless on the ground, kneeling, or through what was called 'waxy flexibility' (the child allows the aggressor to manipulate his body without offering muscular resistance). An interesting alternative which indirectly achieved the aim of reducing body stature was the use of shoe tying.

In another study, the researchers observed fights which were terminated by the intervention of a third person. In a significant number of cases, the third person intervened against an antagonist who continued to attack a child exhibiting some kind of appeasement display, which involved a diminution of body stature. Thus, both these studies suggest that making oneself smaller does function as an appeasement gesture in human conflicts, which is also likely to provoke intervention by other people if the signals are ignored by the aggressor. In fact, the way in which these boys inhibit aggression by making themselves smaller finds obvious parallels in formal status systems where an inferior greets a superior by bowing, kneeling or even by kowtowing, a custom in Imperial China whereby the inferior touched the ground with his forehead in absolute submission.

The Role of Gesture in Interpersonal Communication

Gesture clearly has a variety of functions in interpersonal communication, but the question naturally arises as to why it is used in addition to speech. The concepts of 'illustrators' and 'regulators' imply that gesture is essentially subordinate to speech, amplifying and elaborating the spoken word. However, gesture and speech have very different characteristics as media of communication. First, since gesture requires vision for its transmission whereas speech requires hearing, the conditions that are

suitable for the reception of the two do not necessarily coincide. Secondly, whereas with speech it is the sequential and syntactic structure which is important, this is not the case with gesture, although it can be used to directly represent action sequences. Despite these radical differences, however, it is important to note that these two modes of expression are employed together in a highly integrated fashion, participants often freely choosing between them to meet the requirements of the communication task at hand. The distinctive features of gesture are discussed below and their implications for interaction considered.

Gesture as a Visual Means of Communication

The most obvious feature of gesture is that it is a visual means of communication. It is often easier or quicker, for example, to point to an object, rather than to describe it verbally. Because gestures can provide spatial and orientational information that is not available in words, they may make a verbal account more specific and precise, or provide information that was not included in the verbal account.

Gesture as a Silent Means of Communication

Because gesture is visual, it is also of course a silent means of communication. Hence, for example, gesture is often employed when it is difficult or impossible to use speech because of distance or noise. The speech channel may be momentarily blocked by noise, but it may also be blocked because it is already occupied. In multiparty conversations, the use of gesture may occasionally be observed by people who are not participating in the conversation. In this context, gesture may be used to comment on an interaction, without interrupting the flow of speech. This may be done cooperatively or critically, so that the commentator does not have to take a speaking turn.

An additional feature of gesture is that for its use people do not seem to have to enter into the same kind of mutual obligation as they do in conversation. As a consequence, in certain circumstances gesture may be a quicker means of communication, because gestural exchanges do not require the ritual conduct associated with conversation. Gesture may also be used in situations where the speaker seeks to be less fully bound or committed to what he/she has to say. So gesture is sometimes adopted as a substitute for speech, where speech might be regarded as too explicit or indelicate.

Gesture as a Form of Bodily Action

Gesture by its very nature is a form of bodily action and this also gives it certain advantages in communication. The appearance of an action can never be as adequately described in words as it can be represented through gesture. So, for example, gesture may be of particular importance in mimicry or in demonstrating how particular skills should be performed. Gesture may provide visual animation, thereby enriching the quality of the verbal account. Again, because gestures can be reminiscent of physical actions, they may acquire additional forcefulness as a consequence: a clenched fist may convey anger more effectively than a torrent of words. This may give gesture especial importance in the communication of emotions and interpersonal attitudes.

Gesture as a Visible Means of Communication

Another important feature of gesture is that it is not only visual but a highly visible means of communication. So, for example, one study of a birthday party showed how people used gesture as an initial salutation to capture one another's attention before entering further into conversation. In a study of medical consultations, it was found that when the doctor's attention was focussed on his notes, patients would use more flamboyant gestures as a means of attracting his attention. In this context, gesture has the additional advantage of indirectness as well as visibility, since a direct request for attention from a higher status figure like a doctor might well prove unacceptable.

A situation characteristically associated with the flamboyant use of gesture is that of public speaking. In this context, gesture has distinct advantages over other forms of nonverbal communication such as facial expression or gaze which may be less discernible to a distant audience. This can be illustrated through the detailed analysis of a political speech delivered in the 1983 British General Election campaign by the leader of the National Union of Mineworkers, Arthur Scargill. Scargill made extensive use of a number of rhetorical devices which have been identified as being effective in evoking applause, in particular, contrasts (e.g., 'there is something criminally insane about a government which puts war before peace') and three-part lists (e.g., 'Soviet Marxism is ideologically, politically, and morally bankrupt'). The analysis showed how Scargill used gesture to illustrate both these devices. In the case of contrasts, he employed ambidextrous gesturing, switching from one hand to the other as he moved on to the second part of the contrast: through his gesture he was literally saying 'on the one hand' and 'on the other hand.' With regard to three-part lists, the three items in each list were invariably marked out by carefully synchronized gestures. Where the list comprised three words, each word was stressed vocally and accompanied with a single hand gesture: where the list includes a phrase or clause with more than one vocal stress, then a repeated movement was usually employed picking out two or more vocal stresses and terminating at the end of the list item, a new gesture starting on the next item.

Another common rhetorical device which Scargill used to evoke applause was what has been called the 'headline-punchline' device, in which the speaker states that he is going to make a declaration, pledge or announcement, and then proceeds to make it (e.g., 'I'll tell you the most important task [headline]: it's to say to the Lord Matthews, it's to say to the Lord Rothermeres, it's to say to the Rupert Murdochs that the first obligation of a new Labour government will be to take into common ownership the press' [punchline]). On three occasions, Scargill progresses from unilateral to bilateral gestures for the final part of the punchline. This seems to have the effect of bringing the rhetorical device to a climax, highlighting the fact that here was an appropriate point in the speech for the audience to applaud.

If Scargill's hand gestures were closely intertwined with rhetorical devices which have the effect of inviting applause, they also constituted a significant part of the way in which he attempted to control applause. On 12 occasions, he used gesture to control applause either by holding his hand or his index finger outstretched; on two-thirds of these occasions, he used such a gesture just before a point in the speech where

applause might have been considered appropriate, in that he was about to present a statement in one of the rhetorical devices discussed above. This is a noteworthy example of the use of gesture as a regulator, since the speech channel is, so to speak, 'jammed' by the applause; in effect, he cannot make himself heard, so he uses gesture instead as a means of controlling the applause. In fact, Scargill actually seemed to conduct his audience: his gestures not only accompanied rhetorical devices which evoked applause but also curtailed the applause once it has been aroused – even to the extent of indicating to the audience the points at which they should, or should not, applaud.

Differences in Visibility Between Different Gestures

Arthur Scargill's use of two-handed movements in relation to the climax of the headline-punchline device can be used to illustrate another of the distinctive properties of gesture. Not only is gesture a highly visible form of communication, there are also differences in visibility between different forms of gesture, so that more important aspects of speech can be indicated by larger movements and/or movements involving more than one part of the body. This can be further illustrated from studies of conversation, where it has been shown that making a point may be indicated by a movement of the head or eyes, whereas the more important semantic unit of changing the point of view that a person takes may be indicated by a much larger postural shift involving at least half the body.

Gesture as an Optional Means of Communication

A further feature of gesture is that it is to some extent optional. Whereas features like vocalization, speech rate and amplitude are intrinsic to speech, that is, it is impossible to converse without them, it is perfectly possible to converse without the use of gesture. Thus, the presence or absence of gesture may in itself be seen as a form of communication. Certainly, gestures related to speech are clearly intended to be communicative. For example, gesture is used more frequently face to face than when talking over an intercom. Gesture is also part of the turn-taking system in conversation; it may be used as an attempt-suppressing signal to prevent someone else taking a turn, while ceasing to gesture acts as a turn-yielding cue.

These findings can all be taken as supporting the view that gesture is intended to be communicative; but the use of gesture in conversational turn-taking also suggests a further proposition: that gesture may be taken as indicating a wish to communicate. This proposition has a number of intriguing implications. Gesture may be used when a person is interested in the topic he is talking about, or to accompany certain parts of speech which the person regards as more important. Gesture may also be used when a person is interested in communicating to another person or group of people: for example, it has been found that people attempting to be persuasive used significantly more gesture than when asked to present a message in a neutral fashion. Conversely, an absence of gesture may indicate a lack of desire to communicate; for example, people suffering from depression used significantly fewer illustrators on admission to hospital than on discharge.

Gesture as Part of a Multichannel System of Communication

Finally, it needs to be stressed that gesture forms part of a multichannel system of communication, operating principally not as an alternative to speech, but essentially in conjunction with it. This view is supported by recent cognitive research on gesture: it has been argued that gesture and speech are part of the same psychological structure and share a common computational stage. This is because not only do gestures occur primarily during speech, they are also synchronized with linguistic units; indeed, they have semantic and pragmatic functions that parallel those of speech. In addition, gesture develops simultaneously with speech in children, and dissolves together with speech in aphasia.

That gesture is part of a multichannel system has important implications for its role in communication. Four main functions of nonverbal signs in conversation have been distinguished: semantic, syntactic, pragmatic and dialogic. Thus, nonverbal signs may either affect the meaning of speech or signify meaning in themselves (semantic function); they may regulate the simultaneous and sequential occurrence and organization of verbal signs and other nonverbal signs (syntactic function); they may indicate characteristics of the message sender and receiver (pragmatic function); finally, they may indicate the nature of the relationship between the conversationalists (dialogic function). Gesture can convey any or all of these functions; hence, by using gesture in conjunction with speech it is possible to communicate simultaneously on a number of different levels.

Lack of Standardization

Gestures can also convey meaning in a different way from speech, because there are no standard forms with gesture. Standards of form are a defining feature of all spoken languages to which utterances must conform, otherwise they will be dismissed as not proper or grammatical. Gestures have no standards of form. Thus, different speakers may convey meaning in idiosyncratic but still recognizable ways.

Conclusions

Interest in gesture has a long history, but it is only in recent years that it has become the focus of systematic scientific

investigation. Research has shown that gesture is closely synchronized with speech in terms of syntax, meaning and vocal stress; it is also important in communicating emotions and interpersonal attitudes. Three main types of gesture have been identified, referred to as emblems, illustrators and regulators. The concepts of illustrators and regulators, however, seem to imply that gesture is essentially secondary to speech, amplifying and elaborating the spoken word. However, when considered as media of communication, gesture, and speech have very different properties. Through a consideration of its distinctive features, gesture can be shown to be not so much subordinate to speech, as different. The key elements are that gesture is visual, that it is silent, and that it constitutes a series of bodily actions. In addition, it is highly visible, and there are also differences in visibility between different types of gesture. Furthermore, it is to some extent optional; it constitutes part of a multichannel system of communication and unlike speech, it lack standard forms. As a consequence, gesture is particularly useful for communicating certain kinds of information and this has significant consequences for the way in which it is used in social interaction.

Glial Cells

R D Fields, National Institutes of Health (NICHD), Bethesda, MD, USA

Published by Elsevier Inc.

Glossary

Astrocyte Astrocytes are glial cells found only in the central nervous system, where they exhibit a wide variety of cellular properties and shapes. These cells are involved in a broad range of functions in disease and normal brain function.

Microglia Microglia are the immune system cells of the brain, protecting the central nervous system from infection and disease.

Oligodendrocyte One of the four major types of glia cells, oligodendrocytes form myelin electrical insulation on axons in the central nervous system, but they are not present in the peripheral nervous system.

Schwann cell Schwann cells are the glia in nerves of the peripheral nervous system. These cells form electrical insulation (myelin) on nerve fibers and perform all the functions of the three types of glia recognized in the central nervous system.

White matter One of two types of brain tissue, white matter is the densely packed core of nerve fibers (axons) located beneath the gray matter in the cerebral cortex, connecting neurons in different regions into circuits. The white color is due to the electrical insulation on axons (myelin) that is formed by oligodendrocytes.

The Predominant Cells in the Brain are Glia

Brain tissue is comprised of two types of resident cells: neurons, which are electrically excitable, and glia, which are not. Although neurons comprise only 15% of cells in the brain, the other 85% has attracted much less interest, because glia were generally regarded as an interstitial constituent, with no role in information processing. This fundamental conceptual bias is preserved indelibly in the language. Rudolf Virchow (1821–1902), a pathologist with a special interest in connective tissue, coined the name ‘neuroglia’ in 1858, from the root meaning ‘glue.’ There is no single noun equivalent to ‘neuron’ to refer to an individual glial cell. As a consequence of viewing glia as ‘stuff’ between neurons, thinking about glia has been constrained for 100 years.

Glia are far from inert interstitial brain cells. All types of glia can respond to activity in neural circuits by sensing ions, neurotransmitters, or other adhesive or diffusible cell–cell signaling molecules. Some types of glia are involved in synaptic transmission, which implicates these glial cells in many aspects of information processing and in nervous system dysfunction, including both neurological and psychological disorders. Glia cannot generate action potentials, so they lack the cellular structures identified with neurons, including axons, dendrites, and synapses. However, glia communicate with each other and with neurons by using chemical signaling. Ions and other small molecules are spread from cell to cell through gap junction channels coupling the cell membranes of adjacent glial cells, but glia also communicate by releasing signaling molecules. This includes many of the same neurotransmitter neurons used for synaptic transmission, as well as growth factors, cytokines, and chemokines. These chemical messages are detected by membrane receptors on other glia and on neurons.

In broad outline, glia perform three general functions, and distinct types of glia are primarily associated with each of these activities. Astrocytes maintain homeostasis of neuronal function. Microglia fight infection and respond to injury.

Oligodendrocytes and Schwann cells form the electrical insulation on nerve fibers (axons), which is essential for transmitting electrical impulses (action potentials). It is likely, however, that within the broad categories of astrocytes, microglia, oligodendrocytes, and Schwann cells, there are many different subtypes of glia yet to be characterized. There may be as many different kinds of glial cells as there are different kinds of neurons. A possible fifth category of glia are those with the intriguing and incompletely understood stem-cell-like properties that enable them to differentiate into astrocytes, oligodendrocytes, or neurons under the right conditions. These cells are called NG2 glia, a reference to a glycoprotein expressed on the surface of these cells, but these cells are also referred to as OPCs (oligodendrocyte progenitor cells), and polydendrocytes.

Astrocytes

The renowned Spanish neuroanatomist, Santiago Ramon y Cajal (1852–1934) originally referred to cells that are now called astrocytes as ‘spider cells,’ because of the multiple cell processes radiating from a cell body like spider legs. This structure also resembles stars, which is the root for their modern name. These descriptions only pertain to cellular appearance after histological staining of the cytoskeleton (Figure 1). Modern techniques reveal an extremely complicated cellular morphology, with fine busy cell processes that associate intricately with neurons and synapses.

Astrocytes were believed to provide physical support and nutrition to neurons and to respond to neural injury. We now know that they participate with neurons in nearly every aspect of nervous system function. Providing nutritional support for neurons was deduced from the close association of some astrocytes with small blood vessels (Figure 2). Astrocytes near blood vessels extend processes called ‘end feet’ that surround blood vessels, and through which substances are transported between the bloodstream and neurons. The astrocytes near blood vessels help regulate local blood flow in response to neural

Figure 1 Astrocytes provide a supportive and homeostatic function in the brain, and they communicate with each other through chemical signaling. Astrocytes sense and control the transmission of information between neurons. The cytoskeleton of astrocytes is revealed by chemical stains and antibodies recognizing proteins in the cytoskeleton of astrocytes, such as GFAP, shown on the left. The true shape of the cells is revealed in the middle panel by filling an astrocyte with a green dye. The right panel superimposes the two images to show how much larger and more complicated the true structure of astrocytes is. This complex shape enables astrocytes to associate with hundreds of synapses and other structures. Figure 2 Astrocytes near blood vessels extend long processes (red arrows) to ensheath blood vessels in the brain. Specialized structures in astrocytes called ‘end feet’ allow them to transport ions, nutrients, and water between the bloodstream and brain tissue to maintain the optimal chemical environment for neurons. Astrocytes near blood vessels also release substances that constrict or dilate blood vessels to regulate the local delivery of blood to neurons according to neuronal activity. Reprinted with permission from Simard M, et al. (2003) Signaling at the gliovascular interface. *Journal of Neuroscience* 23: 1529–2401.

demand by sensing neuronal activity and releasing compounds that either dilate or constrict blood vessels in their vicinity. This local regulation of blood flow to supply active neurons is the basis for functional brain imaging using fMRI (functional magnetic resonance imaging). Astrocytes also regulate the exchange of ions and other materials and cells through the blood–brain barrier that separates brain tissue from the bloodstream.

Oligodendrocytes

Pio del Rio-Hortega (1882–1945), who studied with Ramon y Cajal, developed staining methods that revealed two additional types of glia. Oligodendrocytes, named for the numerous short cellular processes extending from the small cell body, were not easily identified by the unreliable stains of the time, making the existence of these glia controversial until 1924. Appropriate stains revealed that oligodendrocytes have long cellular extensions. Each cell process grips an individual segment of an axon and wraps layers of compacted cell membrane around it forming the electrical insulation called myelin (Figure 3). The myelin sheath on axons accelerates the speed of signal transmission by 10–100 times. Rather than propagating continuously down the axon, as in axons that lack myelin, the impulse (action potential) is generated at bare regions between adjacent segments of axons that are myelinated. These are the nodes of Ranvier, where sodium channels are highly concentrated, and where an action potential is generated upon depolarization to induce an impulse in sequential nodes, much like repeater stations in a communication system. Only vertebrates have myelin.

Microglia

Pio del Rio-Hortega first identified microglia (Figure 4) and correctly distinguished these cells as a different type of glia involved with nervous system pathology and inflammation. Microglia defend against infection and help repair damaged brain tissue. His observations clearly identified two major states of microglial cells: the ameboid form that migrates through tissue, and the ramified state, in which the cells have many actively extending and retracting cellular processes. Alois Alzheimer (1864–1915) described microglia surrounding the senile plaques in the brains of patients suffering from dementia from the disease that now bears his name.

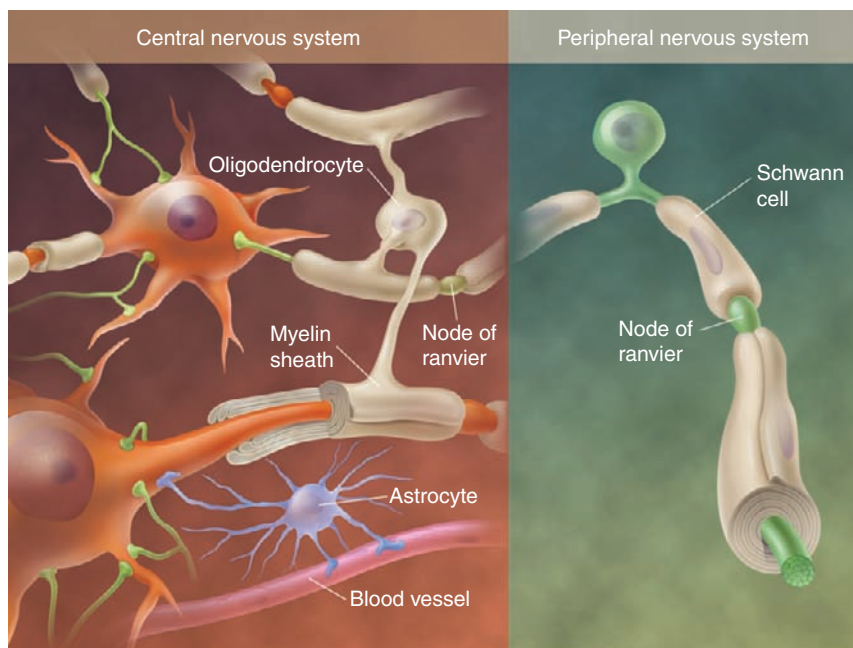

Figure 3 Myelinating glia form the electrical insulation on axons that is essential for high-speed transmission of impulses through nerve fibers (axons). Different types of glia form myelin in the CNS and PNS (oligodendrocytes and Schwann cells, respectively). Oligodendrocytes have multiple cellular extensions that can wrap myelin insulation around up to 50 axons, whereas Schwann cells ensheath axons individually. The gaps between the myelin insulation are the nodes of Ranvier where the electrical impulse is generated and propagated rapidly from node-to-node. Reprinted with permission from Fields RD (2006) Nerve impulses regulate myelination through purinergic signalling. *Novartis Foundation Symposium* 276: 148–158.

Figure 4 Microglia are the immune cells of the brain. Microglia fight infection and respond to injury to protect and repair the central nervous system. Reprinted with permission from Miller KR and Streit WJ (2007) The effects of aging, injury and disease on microglial function: A case for cellular senescence. *Neuron Glia Biology* 3: 245–253.

Schwann Cells

Schwann cells are the glial cells that form the myelin sheath on axons outside the brain. Unlike oligodendrocytes, Schwann cells do not have multiple cellular extensions, but instead each cell engulfs a segment of axon and forms a multilayered myelin sheath around it (Figure 3). Small diameter axons, which conduct impulses slowly, do not have a myelin sheath, yet they are not bare. Other Schwann cells, which do not form myelin, engulf multiple small diameter axons into bundles. Another type of specialized nonmyelin forming Schwann cell

encases the synaptic endings on muscles, much like astrocytes surrounding synapses in the brain. Schwann cells perform most of the functions of astrocytes, oligodendrocytes, and microglia in the brain, as none of these glia exists outside the CNS. Schwann cells are not found in the CNS, so they will not be discussed in the context of this article, which is concerned with glia in human behavior. These cells are named after Theodore Schwann (1810–1882), who also expounded the theory that all organisms are composed of cells.

Functions of Glia

Glia perform a broad range of functions (Table 1). In addition to the functions already mentioned, glia in the fetal brain guide the development and migration of neurons to reach their proper locations. Some glia have multipotent stem-cell-like properties. Astrocytes transport ions and neurotransmitters from the extracellular space into the cell to maintain the proper levels of ions and neurotransmitter in the extracellular space surrounding neurons. These functions are essential for maintaining the membrane potential of neurons necessary to fire electrical impulses and communicate by synaptic transmission. Cellular coupling among populations of astrocytes via gap junction channels siphons away potassium ions released by electrically active axons and disperses them through an astrocytic network for disposal in the bloodstream. Astrocytes provide physical support as well as metabolic support to neurons by delivering lactate and glucose. Microglia are the resident immune cells in the brain, which together with astrocytes,

Table 1 Functions of glia in the central nervous system

<i>Function</i>	<i>Type of glial cell</i>
1. Nervous system development	
Guide development and migration of neurons	Astrocytes
Multipotent stem cell properties	Astrocytes, NG2 glia
Axon pathfinding	Astrocytes
Inhibit axon sprouting	Oligodendrocytes
Help close the critical period	Oligodendrocytes
2. Homeostasis	
Regulation of ion concentration brain in tissue	Astrocytes
Provide physical support for neurons	Astrocytes
Provide physical support for axons	Oligodendrocytes
Provide glucose and lactate to neurons	Astrocytes
Regulate water and pH balance in brain tissue	Astrocytes
Control volume of extracellular space	Astrocytes
Contribute to extracellular matrix	Astrocytes
Detect foreign antigens	Microglia
Contribute to and regulate the blood–brain barrier	Astrocytes
Regulate local blood flow according to neural demand	Astrocytes
Provide antioxidants and reactive oxygen species	Astrocytes and Microglia
3. Synaptic function and information processing	
Remove neurotransmitters after release at synapses	Astrocytes
Release neurotransmitters	Astrocytes
Increase or decrease synaptic transmission strength	Astrocytes and microglia
Remove synapses	Microglia
Stimulate formation of new synapses	Astrocytes
Form electrical insulation (myelin) on axons	Oligodendrocytes
Control the release of hormones from neurons	Astrocytes
Sense and respond to neural impulse activity	Astrocytes, oligodendrocytes, microglia, NG2 glia
Release growth factors and cytokines	Astrocytes, oligodendrocytes, microglia
Have receptors for neurotransmitters	Astrocytes, oligodendrocytes, microglia, NG2 glia
Have receptors for hormones	Astrocytes, oligodendrocytes, microglia
Have ion channels	Astrocytes, oligodendrocytes, microglia, NG2 glia
Receive synaptic inputs	NG2 glia
4. Injury and disease	
Resident immune cells of the brain	Microglia
Multipotent stem cell properties	Astrocytes, NG2 glia

(Continued)

Table 1 (Continued)

<i>Function</i>	<i>Type of glial cell</i>
Respond to disease and injury	Astrocytes, microglia, oligodendrocytes
Targets of AIDS and other infectious diseases	Astrocytes and microglia, control neural excitability in chronic pain, epilepsy and other chronic states, astrocytes and microglia
Give rise to cancerous cells	Astrocytes, oligodendrocytes, NG2 glia
Inhibit axon sprouting	Oligodendrocytes
Participate in nerve regenerations	Astrocytes, oligodendrocytes, microglia, participate in Parkinson's disease, Alzheimer's disease, ALS, astrocytes, microglia, involved in multiple sclerosis, oligodendrocytes, microglia
Participate in other neurodegenerative disorders	Astrocytes, oligodendrocytes, microglia
Involved in chronic depression, schizophrenia	Astrocytes, microglia, oligodendrocytes, abnormalities seen in developmental disorders, such as autism, ADHD, oligodendrocytes
Receptors for opiates and cannabinoids	Microglia, astrocytes
Contribute to cognitive decline in aging	Oligodendrocytes, astrocytes, microglia

detect and respond to injury and infection. In addition to insulating axons, inhibitory proteins in myelin block axon sprouting and outgrowth, which helps close the critical period for learning and neuronal remodeling after injury. Many of these glial functions affect human behavior.

Glial Involvement in Mental Health and Behavior

Several cellular functions performed by glia involve them in many cognitive functions mediating normal and dysfunctional human behavior. Most pharmacological treatments for mental illness are based on regulating neurotransmission. SSRIs (selective serotonin reuptake inhibitors) used to treat depression, anxiety, and other psychiatric disorders, increase levels of the neurotransmitter serotonin in the synaptic cleft by inhibiting the reuptake of the neurotransmitter after it is released. Astrocytes at synapses, however, normally perform this function together with neurons (Figure 5). Many psychoactive drugs modulate neurotransmitter function. The psychotic behaviors of individuals under the influence of these compounds overlap with behaviors exhibited by people with mental illnesses such as schizophrenia. Similar cognitive effects may occur if astrocytes fail to properly regulate levels of neurotransmitters such as acetylcholine. Changes in astrocytes are seen in postmortem tissue of people with various mental illnesses. The decrease in the number of astrocytes in the cerebral cortex of people with chronic depression and schizophrenia, observed by Ladislav von Meduna in the 1930s, inspired electroconvulsive shock treatment, which remains the most effective treatment for medically refractory depression. In epilepsy, the number of astrocytes is increased and the astrocytes develop a more robust

Figure 5 Astrocytes at synapses participate in synaptic transmission. Astrocytes at synapses have neurotransmitter receptors to detect the same chemical substances that allow neurons to communicate by synaptic transmission. Synaptic astrocytes also remove neurotransmitter from the synapse and release neurotransmitter and other neuroactive substances to increase or decrease the transmission of signals between neurons. Astrocytes can communicate with other astrocytes by chemical signaling to control the transmission of information at distant synapses. These functions of synaptic astrocytes involve them in many psychiatric illnesses, neurological disease, information processing, and the formation of memory. Reproduced with permission from Fields RD (2004) The other half of the brain. *Scientific American* 290: 54–61.

morphology, associated with biochemical changes affecting the cytoskeleton, membrane receptors, neurotransmitters, and other substances that astrocytes release. Increasing the number of astrocytes in the cerebral cortex of people suffering from chronic depression or schizophrenia by inducing seizure was proposed by Meduna in 1935 to correct the cellular imbalance. How electroconvulsive shock treatment works is still unclear, but the release of growth factors, neurotransmitters, and stimulation of neurogenesis may be involved. Glia participate in all these processes.

As glia and neurons share many of the same neurotransmitter receptors and ion channels, pharmacological treatments now in use likely act in part through effects on glia. In addition to having membrane receptors for most of the neurotransmitters used by neurons, glia have membrane receptors for many psychoactive compounds, including those in cannabis, heroin, and alcohol, as well as sex hormone receptors. The development of compounds targeted to glia should provide new drugs to treat mental and neurological illnesses.

Astrocytes at synapses also release neurotransmitters and other substances that affect synaptic transmission. Together with their role in taking up neurotransmitters, the release of neurotransmitters and other neuroactive substances allows astrocytes to regulate synaptic transmission to either facilitate or inhibit communication between neurons. This ability implicates astrocytes in epilepsy and many other neurological conditions where excitability is excessive or depressed. This is in keeping with the general homeostatic role of astrocytes in maintaining the environment for neurons and in moderating the general level of nervous activity. Behaviors such as sleep

and chronic pain are examples of astrocytes influencing neuronal excitability.

Oligodendrocytes are also implicated in mental illness by histological studies, analysis of gene expression, and brain imaging. Several genes are expressed at abnormally low levels in the brain tissue of people with schizophrenia and chronic depression, and a number of gene variants have been identified as risk factors for these mental illnesses. Many of these are genes expressed in oligodendrocytes or involved in controlling oligodendrocyte development. The number of oligodendrocytes is reduced in brain regions involved in higher cognitive functions. MRI brain imaging shows that the volume or structure of white matter tracts, which are brain regions where myelinated axons form major bundles connecting different regions of the cerebral cortex, is reduced in cortical regions known to be involved in schizophrenia and depression.

Glial Involvement in Neurological Illness

Astrocytes are involved in every aspect of nervous system injury and disease. Astrocytes and microglia are the 'first responders' to brain injury; they participate in scar formation, immune defense, and clearing and remodeling damaged tissue.

Glia are the major reason that damaged axons in the spinal cord and brain cannot regenerate. Damaged nerve fibers in the peripheral nervous system can regrow and establish proper connections to restore function because Schwann cells do not inhibit the outgrowth of damaged axons. Indeed, Schwann cells assist in the repair process by secreting growth factors and building extracellular matrix scaffolding to guide the

growth of regenerating axons to their proper targets. In contrast, proteins in the myelin sheath formed by oligodendrocytes, such as Nogo-A and others, strongly inhibit the growth and sprouting of damaged axons in the CNS (central nervous system). The normal role of this inhibitory protein may stabilize neural circuits in the brain after they have formed and been remodeled by functional activity that is driven by environmental experience and learning.

Mature neurons cannot divide. In contrast, many types of glia can divide and differentiate into oligodendrocytes, astrocytes, neurons, or other undifferentiated cells with the potential to generate various types of brain cells. This capability involves glia in responding to nervous system injury and disease, and in replacing brain cells lost with age by attrition. However, this 'stem-cell-like' property of glia also implicates them in brain cancer. Nearly all cancers originating in the brain are glial tumors.

Many infectious diseases attack glial cells and the loss of normal glial function results in neuronal degeneration or dysfunction. Dementia resulting from HIV is an example, as the virus does not infect neurons, but rather it infects microglia and astrocytes. Other neurological diseases result from direct effects on glia. Multiple sclerosis, which can impair sensory, motor, and cognitive function, is an autoimmune disorder that attacks oligodendrocytes forming the myelin insulation on nerve fibers, which is essential for normal impulse transmission. Axons that lose their myelin sheath can die, demonstrating the high degree of dependence of neurons on glial function.

Astrocytes release many types of growth factors and antioxidants that protect and stimulate the growth of neurons. Conversely, astrocytes under pathological conditions can release oxidizing compounds, neurotransmitters, inflammatory cytokines, and other toxic substances that damage or kill neurons. These actions involve astrocytes in neurological disorders such as ALS, Parkinson's disease, and Alzheimer's disease. The defensive actions of astrocytes and microglia also implicate them in cognitive decline in aging. Astrocytes can contribute to generating the toxic amyloid plaques that form in Alzheimer's disease, and microglia remove the toxic plaques. Both types of glial cells can be impaired in their normal functions when they become damaged due to Alzheimer's disease. A significant proportion of normal tissue loss in the aging brain results from the loss of white matter formed by oligodendrocytes. The regulation of blood flow by astrocytes implicates these cells in migraine and stroke.

Glia Participate in Information Processing and Memory

Glia are implicated in strengthening and weakening synaptic transmission in the hippocampus in conjunction with memory formation. Both strengthening and weakening of synapses (LTP and LTD; long-term potentiation and long-term depression) can be regulated by hippocampal astrocytes through the release of neurotransmitters, notably glutamate, ATP, and D-serine, but also by the delivery of glucose to neurons and the maintenance of normal concentrations of extracellular ions (notably potassium ions) and glutamate.

Glia communicate slowly compared to neurons. They communicate by broadcasting chemical signals rather than signaling serially as neurons do in communicating through chains of

synapses. A single astrocyte can cover large areas of the brain encompassing thousands of synapses. These features implicate glia in slowly changing nervous system processes having a more general influence on the brain. Examples include astrocyte regulation of hormone secretion regulating thirst, lactation, and maintaining the general levels of excitability in the brain.

Changes in white matter regions of the brain occur after learning complex skills, such as learning to read, play the piano, or juggle. White matter regions are comprised of axons coated with electrical insulation formed by oligodendrocytes. Situated beneath the grey matter cortex, white matter comprises half the volume of the human brain, which is a larger fraction than in any other animal. Changes in the number of myelinated axons or modifications of axons that are already myelinated could improve performance by optimizing the transmission of impulses between cortical regions mediating complex cognitive functions. The same effects on transmission speed and synchrony could involve white matter in cognitive dysfunctions, such as dyslexia, attention deficit hyperactivity disorder (ADHD), and psychiatric illnesses that are associated with disorganized or abnormal processing of cognitive function controlling thoughts, moods, and control of behavior. Electrical impulses in axons can be detected by oligodendrocytes and three cellular and molecular mechanisms for the activity-dependent communication between axons and oligodendrocytes have been identified thus far. These studies in cell culture have shown that action potentials can regulate glial cell proliferation and development, and stimulate myelination of unmyelinated axons.

Thus, the brain's glia and neurons work differently but in a close association that is essential for brain function. Glia perform far more functions in the brain than neurons. Neurons are highly specialized for rapid transmission and integration of information, but most of the brain's functions are carried out by cells that have been comparatively neglected by researchers until recently – glia.

Grandparenthood

B Hayslip Jr. and K S Page, University of North Texas, Denton, TX, USA

© 2012 Elsevier Inc. All rights reserved.

Glossary

Co-parenting A caregiving arrangement in which grandparents and the adult child co-reside and often share responsibility for the care of the grandchild.

Countertransition A life event or role (e.g., becoming a grandparent) whose assumption depends upon the actions of others.

Custodial grandparents Grandparents who assume full-time responsibility for the raising of their grandchildren.

Skipped generation A caregiving arrangement in which the adult child is absent and the grandparents have sole caregiving responsibility for the grandchild.

Tenuous role A role (e.g., grandparenting) whose rights, responsibilities, and boundaries are ill-defined.

Verticalized families A multigenerational family in which the number of generations exceeds the number of persons within a given generation.

Introduction

Being a grandparent is generally viewed as a developmental task of middle or late adulthood; most persons are first-time grandparents in their late 40s. Indeed, grandparenting for some may help compensate for other losses they have experienced and give them a new purpose in life. If life expectancy is increased, the chances of becoming a grandparent are also increased. Seventy-five percent of those born in 2000 can expect to have at least one grandparent still living when they reach age 30. Nearly 60% of older adults have at least one grandchild, and 70% of older adults are grandparents. If we include persons who are in their 40s and 50s, the estimates of the number of grandparents would likely approach 80%.

There is great diversity among grandparents. The once-popular image of the grandparent as a kindly, elderly person in a rocking chair is no longer accurate. Grandparents are more likely to be men and women who are much younger, employed, and even have adult children still at home. This same individual may also be caring for a mother or a father who is quite old. Some people become grandparents in their 30s and 40s, while others do not become grandparents until their 60s or 70s. Because of this variability, it is not surprising to find that grandparenting is a *tenuous* role, having no clear criteria for what constitutes appropriate behavior. It is for this reason that grandparenting is largely an individual experience; while grandparenthood is imposed on persons, they nevertheless assign it meaning, and on that basis, adopt a particular style of grandparenting to reflect this meaning.

Despite the advantages to middle-aged and older persons whose identities centralize the role of grandparent and who see themselves as *self efficacious* grandparents (those who feel that they can exert a significant positive influence on the lives of their grandchildren), to the extent that people do not *choose* to be grandparents, the grandparent role has been termed a *countertransition*. That is, becoming a grandparent depends upon the actions of *others* (i.e., one's son or daughter), and thus, is not a role whose assumption individuals can control. Therefore, the meaning one assigns to being a grandparent and the particular style one assumes are *actively constructed* by each grandparent. In some cases, as grandparents know before they actually become

grandparents that they will be so, the process of actively constructing an assigned meaning and creating a satisfying style of grandparent may begin long before the birth of the grandchild.

While the grandparent–grandchild relationship may extend over 20 years, this is likely to be different when grandchildren are little and grandparents are in good health than when grandchildren are adolescents and grandparents are frail. Ultimately, if the grandparent's health deteriorates significantly, or that person suffers from dementia, the likelihood of that persons' eventual death becomes a loss with which both the adult child and the grandchild must cope. At the same time, for many older adults, becoming a grandparent can buffer fears about isolation, loneliness, feeling not valued, or dying.

Historically, we can expect future cohorts of grandparents to differ from their predecessors in several respects. Relative to previous cohorts of grandparents, today's grandparent is likely to live longer, be more educated, be in better health, have fewer grandchildren (decreasing competition between grandchildren for a grandparent's time), and more likely to be retired. For these reasons, grandparents are more likely to make meaningful investments of time, effort, and resources in their grandchildren's lives. On the other hand, children who are disadvantaged economically, who have single parents, whose grandparents are in poorer health or who have many grandchildren may not realize these advantages via a connection with a grandmother or grandfather. Yet, having a son or daughter who is a single parent can be seen as presenting many opportunities to be involved (again) in childcare and parenting (especially with a first-time mother who is caring for a handicapped/disabled or ill child) with the attendant possibility that the child and parent might disagree on issues regarding child-rearing, discipline, education, peer relationships, or whether the adult child should work or return to school. In this respect, grandparents and grandchildren are best thought of in dyadic terms; their influence on each other is dynamic and bidirectional, and often mediated by the nature of the grandparent's relationship to the grandchild's parent. Indeed, a family systems approach to understanding such relationships is not only beneficial but also indispensable. Thus, understanding grandparents at the level of their relationships with grandchildren as well as in the context of their relationships with

their adult children, spouses, age peers, and friends is key to an effective case conceptualization and clinical work with each member of the dyad.

A Life Course Perspective on Grandparents

The life course perspective is a dynamic approach to the study of change in families, to include the construction of social meaning surrounding life events and the social context in which transitions occur. The social context includes generational time, which refers to events or family transitions that alter interactions within families or change the ways that we view ourselves. Many of these transitions are predictable including adult children moving away from home and forming new partnerships and households. Divorces, births, deaths, and participation in work are other examples of normative life transitions experienced by families. In considering family time, these transitions may be characterized as normative, nonnormative, on-time, or off-time events. All transitions will influence the nature of the connections across the oldest (grandparent), middle (adult child), and youngest (grandchild) generations in a family, which is more likely to be *verticalized* (having more generations than there are persons within a given generation) now.

While the transition of parent to grandparent is normative and begins in middle age, grandparent–grandchild relationships are often mediated by the parent generation. Ties between grandchild and grandparent appear to be stronger when the ties between parent and grandparent are strong, and in some cases, relationships between older adults and their children-in-law are even more influential in determining quality grandparent–grandchild relationships. Often, the adult child's needs for instrumental and emotional support are central and it is these that activate the grandparent support system in times of family stress, where maternal grandmothers are the most involved in this respect. When all is well with their adult children, grandparents in the dominant culture typically adhere to a norm of noninterference, enjoying grandchildren, and engaging in family activities, but not playing an authoritative role with their grandchildren. They leave raising grandchildren and other family decision making to their adult children, and are likely to hold several other meaningful roles that may be more central to their lives and self-concepts than the role of grandparent. When things do not go right for their adult children, they (especially grandmothers) come to the rescue, making their parent and grandparent roles more central to their lives. They provide financial aid, housing, and emotional support to their single children, to children who divorce, and to their widowed children. The response of grandparents to a grandchild's disability or illness affects the ability of parents to adjust; when adult children are unable to take care of their own children, it is often grandmothers who step in and fulfill this role. In such cases, previously established relationships and the perception by family members that they were 'that kind of family,' one in which members helped one another in times of need, are key. Although intergenerational support from family members in times of crisis is common, it is clearly not a universal experience as it applies to remote or distant grandparents; such persons may not be helpful and indeed may cause additional stress to parents in times of need.

Grandparental Meaning

Key to understanding the meaning persons assign to grandparenting is the notion of the centrality of the role; while some middle-aged and older persons consider the role to define them, others consider it peripheral in their lives. Moreover, the grandparent role is not only *symbolic* (reflecting the meaning one assigns to it), but it also has *attitudinal* (beliefs about one's activities as a grandparent), *behavioral* (activities involved in one's interactions with grandchildren), and *emotional* (one's feelings about being a grandparent) dimensions that help define it.

While there is some evidence that more recent cohorts of grandparents construct a role that is either meaningful or not in *global* terms, that is, the role either is or is not, in varying degrees a meaningful one, historically, grandparental meaning has been viewed as multidimensional in nature, for example, being *central* in one's life, being the *valued elder* in the family, representing *immortality through clan* (living on through one's influence on a grandchild after one has died), allowing one to *reinvolvement oneself with one's personal past*, being able to be an *indulgent* (spoiling the grandchild) grandparent. As grandparenthood means different things to different people, how one perceives this role most likely influences one's style of grandparenting.

Meaning is also affected by the quality of one's relationship with the grandchildren. For example, White and minority young adult grandchildren believe their grandparents to be good role models and good sources of advice and support. Indeed, it is common to find that grandparents and grandchildren both give and receive tangible material and emotional support to one another. This type of mutually satisfying, reciprocal relationship strengthens one's convoy of support and enhances the positive meaning attributed to being a grandparent.

Styles of Grandparenting

There are many *styles* of grandparenting, and these are affected by a number of individual, environmental, and socioeconomic factors, especially the authority and control one exercises over the grandchildren. At one end of this continuum is the *surrogate-parent*, who will exercise authority and control over the grandchildren both in the presence and absence of the parent(s). For example, at the dinner table, if the grandchild engages in a behavior that is considered inappropriate, the grandparent will reprimand the grandchild. At the other extreme is the *fun-seeker* grandparent, who does not exercise any authority and control over the grandchildren. In the middle of the continuum are the *Formal*, *Reservoir of family wisdom*, and *Distant figure* styles, who will exercise authority and control over the grandchildren only in the absence of the parent, or on the authority of the parent.

The *Distant-figure* style is very common due to family mobility. It is important to note that although these types of grandparents may be distant in terms of physical proximity to the grandchildren, they may report being close emotionally. Further, when visiting with grandchildren, the distant-figure grandparent may take on characteristics of the other types of grandparenting styles, that is, fun-seeker or surrogate parent. While styles of grandparenting likely vary over time and with one's life situation, there is virtually no longitudinal work to empirically support this assertion. It is safe to say, however, that given the idiosyncratic nature of the meaning assigned to the role, there would be vast individual differences and

diversity regarding grandparenting styles, and that grandparental styles would likely change over time.

Given the above, it is not surprising to find that the role of grandfather is viewed as less salient than that of grandmother, and because of this, there is comparatively little research regarding the significance and function of grandfathers. However, grandfathers make unique contributions to the family network such as being reservoirs of wisdom and role models for those not regularly exposed to male family members.

Race/ethnicity affects grandparenting styles, where grandparents may serve the roles of the family historian or living ancestor, who teaches the grandchildren ethnic traditions, experience, culture, and history. For example, there are differences in grandparenting styles between African Americans and Whites, wherein African American grandparents have almost twice the degree of involvement with their grandchildren as Whites. Compared to Whites, African American grandmothers' parenting involvement is substantial, especially in the areas of control, support, and punishment. Indeed, Mexican Americans belong to larger, more multigenerational families; report higher satisfactions relating to their grandchildren; and have a greater degree of intergenerational contact. In this light, it would not be surprising to observe that cultural and subcultural variations may impact on the functions that accompany the grandparent role. This can include viewing grandparents as mentors for younger parents, as transmitters of cultural values and heritage, as persons who are agents of socialization for and influence over their grandchildren, or as persons who can simply enjoy their grandchildren but not be responsible for their raising. Grandparenthood can therefore be understood in terms of its primacy as a kinship relationship; that is, one becomes a grandparent through the birth of one's grandchildren. Whether one's cultural or ethnic background uniquely defines one's role as a grandparent depends upon whether this role is a valued one. Thus, studying the cultural context in which grandparenting occurs can enhance our understanding of what is likely a normative life transition for most middle-aged and older adults.

Influences on grandparents' contact with their grandchildren

Information on grandparent–grandchildren contact is important, since much contact with, and attitudes toward, older adults is partially influenced by interactions with grandparents. Moreover, contact with grandchildren is a dimension of grandparental style and is therefore influenced by the meaning one assigns to being a grandparent. If one's perceptions of a grandparent are positive, indicating affection and respect for grandparents, it likely enhances contact with that grandparent. Likewise, grandparents who centralize the role are likely to have more and/or desire more contact with their grandchildren. Thus, it is likely that grandchild contact influences and is influenced by the meaning and the style associated with grandparenting.

Race and ethnicity are powerful influences on how the grandparent is viewed by one's grandchildren, influencing contact with them. For example, African Americans see the grandparent role as a more active one in the family than do Whites, reflecting racial and cultural differences in perceptions of the extended family network. Viewed from the perspective of the grandparent, among African American and White grandfathers, it seems to be that (1) the grandfather role is more affectionate than functional among both older African

American and White men; (2) there is a higher centrality of the grandfather role among older African American than older White men (indicating that African Americans tend to be more involved in the lives of their grandchildren than Whites); (3) social and dependency factors, other than proximity, are of little relative importance in the grandfather–grandchild relationship; (4) as a group, African American men show greater variation in both the structural (number of grandchildren) and functional dimensions (association and helping) of the role. This variability appears to be related to (1) the African American family's flexibility in expanding and contracting sources to meet the specialized needs of various extended family members and (2) the flexibility of African American male family roles.

Kinship position is also a salient determinant of grandparents' contact with their grandchildren. Generally, maternal grandmothers and paternal grandfathers tend to display closeness and warmth toward their grandchildren, via the greater likelihood of contact between adult children (especially if they are female) and their mothers. In contrast, and only in a comparative sense, maternal grandfathers and paternal grandmothers manifest more negative attitudes toward their grandchildren, most likely borne of less direct contact with their son's children. As evidence suggests, grandmothers are more satisfied with their role than grandfathers; this may be due to their relative familiarity with intimate family relationships, having been principally responsible for raising their own children. Men who express satisfaction tend to be older, have had active relationships with their young grandchildren, and to have been happy with their involvement in the tasks of child rearing.

Gender also affects contact with grandchildren. Research indicates that grandmothers anticipate the role earlier than grandfathers and get involved sooner. Further, children tend to favor grandmothers over grandfathers, though they nevertheless report that their grandparents are influential in teaching and modeling moral values that are sexual, religious, or political in nature. Also, grandmothers are more likely to have frequent contact with their grandchildren. Grandchildren are therefore more likely to have more contact with maternal grandparents, and such contact with the maternal grandmother generally receives the most favorable evaluations. Not surprisingly, having meaningful frequent contact with a grandparent can buffer the effect of a parent's divorce, mental illness, or death. The age of a grandchild is a significant factor in the activities and roles played by its grandparents; grandparents play specific and different roles at different times in their grandchildren's lives. Specifically, when the grandchildren are young, grandparent roles focus primarily on direct care and involvement, such as play and child care. During the adolescence of grandchildren, grandparent roles revolve around listening, supporting, and serving as the family historian. As grandchildren get older and become more independent, their contact with grandparents likely lessens, though this lessened contact may not necessarily translate into less meaningful contact or perceive less influence of the grandparent on the grandchild.

As mentioned earlier, the number of grandchildren, in addition to age, also plays a significant role in the amount of contact with grandparents. As would be expected, as the number of grandchildren increases, the frequency of contact with each grandchild decreases, due to the fact that one's time and resources are limited.

Geographic distance is the strongest predictor of whether grandparents will have frequent or infrequent contact with grandchildren. The shorter the geographic distance, the more opportunity for interaction, though e-mail and texting may ultimately mitigate the effects of living far from one's grandparent. While geographic distance significantly influences the opportunity for contact between grandparents and grandchildren, most grandparents would like to maintain contact with their grandchildren. Physical proximity facilitates this interaction and distance decreases it.

The age of the grandparent also plays a significant role in contact with grandchildren and the types of activities grandparents engage in with their grandchildren; the age when one becomes a grandparent can greatly influence satisfaction with the role. As the age of the grandparents increase, the less able they are to get involved with active, physical interactions with the grandchildren, that is, active playing, sports, etc. Instead, with increasing age, grandparents provide more emotional support or offer advice to the grandchildren. The health of the grandparent (which may covary with grandparent age) is an obvious factor in determining the contact and types of interactions with grandchildren. It can affect one's vitality, types of activities engaged in, and emotional readiness to be a grandparent.

The quality of the relationship between the grandparent and his/her adult child has a key influence on the grandparent role; also, research consistently demonstrates that the quality of the relationship between a grandparent and his/her child affects the quantity of contact between the grandparent and that set of grandchildren. That is, the adult child serves as a *gatekeeper* for the grandparent–grandchild relationship. Furthermore, the quantity of contact depends on whether grandparents are linked to a set of grandchildren through a daughter or through a son, as maternal grandparents are more likely than paternal grandparents to have frequent contact with grandchildren (see above).

The grandparent's marital status also has an important effect on the frequency of contact with grandchildren, especially in the case of grandfathers. For example, divorced older men have far less contact with their adult children and grandchildren than married ones. Further, widowed grandfathers may have less contact with their grandchildren than married ones because they lack a wife to facilitate the maintenance of family ties. Marital status of grandmothers may also be significant because a lack of a spouse may weaken ties with children and grandchildren, or reduce the resources needed for traveling to visit the grandchildren. Overall, for both grandmothers and grandfathers, the ordering from most to least likely to have frequent contact with grandchildren is married, widowed, remarried, and divorced.

Overall, grandparenthood can indeed be satisfying to those who assign a positive meaning to the role, whose style creates the opportunity to interact with grandchildren, and whose relationships with the adult child are positive. The real value of grandparenthood for many middle-aged and elderly adults is that it can reinforce the sense of family; such persons have been referred to as *significant grandparents*. Such grandparents derive a great deal of satisfaction in knowing that the 'family theme' is being carried on by their grandchildren, even if contact with their adult children and their children's children are minimal.

Grandparents and Grief

Many middle-aged and older persons grieve over the losses that they have experienced in the context of their roles as grandparents. While grandparenting has become a common experience for most younger and older adults in our society, it is important to point out that grandparents, who may be as young as the late 30s, but are more likely to be in their mid-to-late 50s or older, may also be coping with other losses that overlap with the acquisition and maintenance of the grandparent role, which may interact with the death of a grandchild or the loss of contact with a grandchild via the divorce of an adult son or daughter, or affect the adjustment to the raising of one's grandchild via the death or divorce of an adult child. For example, grandparents, as persons who are aging, may be experiencing the loss of their own physical vitality, the loss of a salient work role via retirement or job loss, the loss of a vital relationship with a spouse who has become mentally or physically incapacitated, or the loss of a relationship with the youngest child via that child's departure from home. Such life changes may overlap, leading to what has been termed *bereavement overload*, affecting the nature and frequency of interactions with friends and other grandchildren, and undermining adaptive responses to any single loss. Such losses are not independent of one another. For example, changes in one's physical vitality may influence the nature of the relationship with a younger grandchild, that is, one may grieve over the loss of the ability to play with a school age grandson. Complementarily, grandparents who are ill, physically impaired, retired, or widowed themselves may be viewed differently by grandchildren who associate a relationship with a grandparent with physical activity, having the resources to travel, or with simply having both grandparents available. Thus, changes in the perception of the grandchild–grandparent relationship by both older and younger persons may be a source of grief to both.

We know virtually nothing about the normative dimensions of grief as they relate to grandparenting. Yet they are likely to affect a grandparent's particular response to other more primary losses through death or divorce. In the context of bereavement overload, the death of an adult child or grandchild may therefore symbolize the latest in a series of losses to which the grandparent has yet to adjust, complicating the grandparent's ability to function on an everyday basis, and negatively impacting on their mental and physical health. The death of a grandchild or the divorce of an adult child may coincide with the death of an older parent for some grandparents. While such topics have not been the subject of empirical research, they are not so obvious, but real, losses with which some grandparents may cope. While they may be secondary in nature, they are often co-experienced in concert with the death or divorce of one's adult child or grandchild.

More obviously, some grandparents may grieve the death of a grandchild, the death of an adult child, or the loss of contact with their grandchildren via disruptions in relationships with an adult son or daughter via the latter's divorce or separation. As the adult child helps mediate the degree of contact between grandparents and grandchildren, disagreements between adult children and their parents about child-rearing issues can undermine opportunities for and the quality of relationships with grandchildren. In this respect, 'token' grandparents report

feeling emotionally isolated from their grandchildren. Likewise, relationships with surviving grandchildren, or with an adult child (in the event of a divorce or death of a grandchild), may deteriorate.

Underscoring the salience of such losses in the lives of grandparents is the fact that grandparents play an important role in a grandchild's emotional, cognitive, and social development. Emotionally, grandchildren who benefit from a positive relationship with a grandparent will be better equipped to handle psychosocial conflicts throughout their lives. In addition, through the provision of unconditional love, grandparents aid in their grandchildren's developing self-esteem. Through the transmission of values and in serving as a support system in times of crisis, grandparents can play a significant role in the life of their grandchildren. In this context, it is important to point out that the importance of grandparents does not necessarily diminish as grandchildren reach adulthood, as adult grandchildren list knowing their grandparents and feeling close to them as important qualities in their relationship with a grandparent. Adult grandchildren also expect grandparents to be a buffer between their parents, in addition to being a role model and financial advisor. Thus, it is not surprising that grief is a shared emotional response to the divorce or death of an adult child on the part of the grandparent and grandchild.

As is grandparenthood itself, becoming a grandparent caring for a grandchild, adjusting to the death or incapacitation of a grandchild, or to the death, divorce, or separation of an adult child are all events that also are *countertransitions*. Thus, in terms of understanding grandparents' responses to such losses, it is helpful to see them as analogous to the experience of acute grief, that is, the reaction to sudden death, commonly believed to be more problematic than grief that is anticipatory in nature.

In contrast to the central role that grandparents can play in the lives of their grandchildren, the grief that they experience can best be understood in the context of what is termed *disenfranchised grief*. Such grief is deemed unimportant by others, and thus, survivors are 'not accorded a right to grieve.' This leads to a lack of support from family, friends, or coworkers, and therefore leads to diminished opportunities to reach out emotionally to others who, ironically, often not only do not (and sometimes, cannot) offer sympathy, physical, and instrumental support, but also cannot understand or empathize with what the grandparent may be going through emotionally.

Five characteristics define disenfranchised grief, each of which is relevant to grandparents: (1) *the relationship is not recognized*, wherein among grandparents who may not be seen as central to the family system, feelings and needs may be put on hold or ignored all together at the expense of those of the adult child/parent; (2) *the loss itself is not acknowledged*, as when a grandchild dies shortly after birth, or when the adult child has experienced an abortion or miscarriage; (3) *the griever is excluded*, as when a grandparent who is cognitively impaired via stroke or Alzheimer's disease is denied information about the death of a grandchild, is not permitted to ask questions or attend the funeral, on the assumption that they can no longer comprehend the nature of death; (4) *the circumstances of the death*, as when an adult child or a grandchild dies of AIDS or via suicide, or when grandparents assume caregiving responsibilities under stigmatizing social circumstances, such as in the

case of the incarceration of an adult child, unemployment, divorce, parental drug use, or sexual abuse of the grandchild (see below); and (5) *the ways individuals grieve*, referring to whether displays of emotion are appropriate versus grief that is expressed physically, cognitively, or instrumentally (e.g., involving oneself at work), where the former are encouraged shortly after a death, and the latter are not. In contrast, crying months or years after a death might be considered to be inappropriate as might going back to work too soon after a death. Grandfathers, for example, may be especially handicapped in this respect, in that they are more likely to express their grief instrumentally.

In the event of a grandchild's death, grandparents are often seen as 'forgotten grievers' to the extent that attention is focused upon the impact of the child's death on the parents. It is often presumed that because they have had more experience with death, grandparents will need less support and education in their adjustment to their grandchild's death. While the scientific literature is just emerging as it relates to grandparents' emotional needs when a grandchild dies, it has been observed that although their grief is likely to be twofold: they grieve for their adult child as well as for themselves. Family customs and rituals may not meet a grandparent's needs, and grandparents are put in a delicate position of attempting to support their adult child as well as meet their own needs for support from others. In many respects then, such grandparents' grief is indeed disenfranchised.

While published *empirical* research specific to grandparent bereavement following the death of a child is rare, we know from the writings of bereaved grandparents and those who provide support that grandparents are deeply affected by their loss, provide extensive support to their adult children, and may receive little attention or support from others. Compared to bereaved parents, grandparents are often focused on meeting the needs of their adult children, presumably to the exclusion of their own needs of support and understanding.

Published literature also suggests that although parents and grandparents have had different role relationships with the child who has died, grandparents tend to have shared many of the same responses as the parents to the death of the child. Yet parents express these feelings more often than grandparents and parents exhibit greater distress than grandparents. In some cases, grandparents report that they had not formed attachments to deceased grandchildren, usually those who were stillborn or died very early in infancy. Based on what we know at present, it is clear that grandparents experience much trauma in witnessing the pain and sorrow of their adult children and their own sense of helplessness in alleviating that pain, regardless of their level of closeness to the adult child. This appears to compound their own grief at the loss of their grandchild. Support offered by grandparents is at the cost of putting aside their own grief to attend to the needs of their children and their surviving grandchildren. On the other hand, grandparents identify being included by their adult children and being able to express their own feelings and emotions with their adult children as important sources of personal support they received from their bereaved children. In some cases, offering such support may bring them closer to their children. In other cases, a history of no relationship or a strained relationship with the child would explain a lack of support. Grandmothers are more likely than grandfathers to express a desire to

talk about the child who has died, and are more likely to turn to daughters than to sons for support. Grandfathers, more than grandmothers, offer instrumental support to their children through performing tasks and offering financial assistance, and engaging in work as a means to help with their recovery is more common among grandfathers than grandmothers.

While we know very little about the coping skills used by grandparents following their grandchild's death, they may use such coping skills as reminiscing, spiritual reappraisal, focusing on others, work activities, and moving on with previously made plans. For grandparents, *meaning making*, influenced by factors associated with the death, time since death, gender, generation, and lineage can be understood in terms of *making sense* and *finding benefit*, where the former refers to talking about their efforts to understand why these babies died, drawing on both rational (i.e., medical, physiological) and spiritual or philosophical reasons, and the latter refers to seeing greater closeness in family relationships, changed perspectives or worldviews, and personal growth. Important for grandparents are continuing bonds with the infant who has died, that is, funerals or memorial services, sharing memories of the child; rituals associated with holidays, birth, and death dates; spiritual connections; and symbolic representations (photographs and objects representing the child).

Grandparents and Divorce

Grandparents also grieve when they lose contact with their grandchildren because of the divorce of their adult child. Contact with grandchildren can diminish after divorce, but this depends on the physical proximity to the grandchild, the grandchild's age, and the gender and lineage of the grandparent. Importantly, divorce, separation, or remarriage for granddaughters can be seen as *opportunities* to reconnect with a grandmother.

The grandparent role has been described as a *double bind*, where grandparents must be ready to assume child care duties when asked by a son or daughter, and they cannot express their disagreement over the adult child's parenting practices lest they be prevented from interacting with their grandchildren. If there have been previous disagreements with the mother about child-rearing, when the mother has custody and moves away, both maternal grandmothers' and paternal grandparents' access to their grandchild may be limited. Indeed, the impact of the loss of contact with the grandchild depends upon whether the grandparent is viewed as an *agent* in the lives of a grandchild (by providing support and serving as a role model), or whether the grandparent is viewed as a *victim* (grandparenting is viewed as a compensation for the lack of other sources of life satisfaction). Relationships with grandchildren are most satisfying when visits with both a daughter and a grandchild are maintained.

Grandparents grieve over the failure of a child's marriage, worry about a grandchild's safety and well-being, fear never having contact with the grandchild ever again, and report intense feelings of depression, sadness, feeling useless and unfulfilled. Not surprisingly, in the event of divorce, less physical and emotional contact with grandchildren is associated with poorer physical health and emotional well-being. In most cases, it has become necessary for states to enact laws to

guarantee grandparents' visitation rights in the event of divorce, wherein some grandparents are able to successfully acquire court-ordered visitation if it is perceived to be in the best interests of the child and does not intrude on the rights of the newly adoptive parent. Complimentarily, when grandparents divorce, they report feeling less close to their grandchildren, less likely to play a friend role, and more conflicts with grandchildren, though such effects are moderated by the quality of the relationship with the adult child.

Step Grandparenting and Great Grandparenting

There is a limited literature on step grandparenting and great grandparenting. With regard to becoming a step grandparent, what exists suggests this to be a particularly ambiguous role, wherein positive relationships with step grandchildren are facilitated by (step) parental support, and often have much to do with the age of the step grandchild when the remarriage occurred and the quality of that child's relationship with the step parent. Regarding great grandparents, who are becoming more numerous as persons live well into their 80s, the little we know suggests that this role can have positive consequences in terms of contributing to one's self-esteem if the great grandparent role in the extended family is well defined and internalized as important by the great grandparent. Being a great grandparent may also help one cope with widowhood, and there are incidences of great grandparents raising their great grandchildren.

Custodial Grandparenting

It has been observed that custodial grandparents, adults who are caring for their grandchildren on a full-time basis, are becoming more prevalent. In 2000, 5.7 million grandparents lived with their grand children, and ~2.4 million of such persons were raising their grandchildren. Since 1990, there has been a 30% increase in the number of children (half of whom are under the age of 6) living in households maintained by grandparents. While the absolute incidence of grandparent caregiving is greater for Whites, the odds of becoming so are greater for Hispanics and African Americans.

That grandparent caregivers are both ethnically and culturally diverse is perhaps what is most notable about them. In this respect, the most recent (2000) Census data found that the incidence of grandparents living with their grandchildren varies greatly by race/ethnicity, with Whites considerably less likely to do so (2%) than Asians (6%), American Indians and Alaska Natives (8%), African Americans (8%), Hispanics (8%), and Pacific Islanders (10%). Of such persons, Asians (20%) were least likely to be solely responsible for their grandchildren, relative to Whites (41%), Hispanics (35%), African Americans (52%), American Indians and Alaska Natives (56%), and Pacific Islanders (39%).

Custodial grandparents tend to be younger, more likely to be the mother's parents, have poorer health and fewer social and economic resources, are less highly educated, and are more likely to be raising boys, all relative to traditional, noncaregiving grandparents. The common difficulties reported by custodial grandparents are less satisfaction with grandparenting, less meaningful grandparenting, impaired or strained relationships with their grandchildren, isolation from other

grandchildren and friends because of their parental responsibilities, feeling overloaded and confused about their roles as parents and grandparents, and caring for children (often boys, whose behavioral/emotional problems are more likely to be externalizing) who have behavioral or school difficulties, for which these grandparents are less likely to seek help.

Some grandparent caregivers, whose cultural traditions help define the caregiving experience by virtue of their exposure to insensitive or unskilled service providers, or as influenced by their negative feelings about seeking help from 'outsiders,' may be less likely to ask for assistance for themselves or their grandchildren. Thus, service providers who are sensitive to cultural traditions may be not only more effective in facilitating such grandparent caregivers' access to services, but also more sensitive in dealing with grandparent caregivers. Such interactions can go a long way toward helping grandparent caregivers feel that they are not alone in facing the challenges of raising a grandchild.

Many children being raised by their grandparents live in poverty, the percentage of grandparent caregivers living below the poverty line (19%) being greater versus other types of families with children (14%). Many such children have difficulty registering for school and while 20% of children in homes headed by their parents have no health insurance, 33% of children in grandparent-headed homes lack such insurance. Such difficulties are greatest for grandparents who are caring for their grandchildren 'informally,' lacking a formal legal basis (e.g., adoption, legal custody, guardianship) for doing so. In some cases, they care for grandchildren in a 'skipped generation' household, where the adult parent is absent, and in other cases, they have a 'co-parenting' household, wherein the grandparent and the adult child co-reside, even though the grandparent may have assumed primary responsibility for caring for the grandchild. These family constellations vary with ethnicity, that is, co-parenting is more common among Hispanics and African Americans, and skipped generation households grandparents tend to fare worse physically and emotionally. Unfortunately, grandparent caregiving usually comes about for reasons linked to the divorce, drug use, incarceration, job loss, or death of the adult child, as well as when the parents abandon or abuse their child. These circumstances are stigmatizing and isolate grandparents from needed sources of social and emotional support as well as make it difficult to be treated equitably by social service providers.

Most custodial grandparents, who are in their mid-to-late 50s, would likely endorse the notion that raising a grandchild is the most important task before them. Relative to parents who are raising their children, however, custodial grandparents often have little time to prepare for this tremendous responsibility, assume it under socially stigmatizing and oftentimes negative family circumstances, and frequently have had little direct and/or ongoing responsibility for raising a child for many years.

Underscoring the emotional and physical toll that caregiving takes, the incidence of such illnesses as depression, diabetes, hypertension, and insomnia is greater among grandparent caregivers, who often report more difficulty than their age peers in performing activities of daily living, and over time are more likely to experience poorer physical and mental health than noncaregivers. Such illnesses may cause custodial grandparents to fear for their grandchildren's well being in the event of their

own disability or death. Indeed, 'high levels' of caring for grandchildren (i.e., 9 h per week) increases women's risk of coronary heart disease over time. Taking on the parenting role can also strain grandparents' marriages and disrupt their life plans. Many custodial grandparents come to resent their children for creating the situation leading to the care of the grandchild, and yet, they may feel guilty over having failed as parents in raising such a child. To the extent to which the relationship with the adult child is ambivalent or the relationship between the grandparent and grandchild/adult child is poorly defined, the demands on the grandparent caregiver are more debilitating. Despite these demands, many grandparents put their own needs behind those of their grandchild, and feel a strong sense of love and commitment to their grandchildren to ensure that their lives turn out for the best.

Grief and Bereavement

M Stroebe and W Stroebe, Utrecht University, Utrecht, The Netherlands

© 2012 Elsevier Inc. All rights reserved.

Glossary

Bereavement The situation of having recently lost a significant person through death. Bereavement is the cause of both grief and mourning.

Grief The primarily emotional reaction to bereavement, incorporating diverse psychological (cognitive, social/behavioral) and physical (physiological/somatic) reactions. Grief is a normal reaction to loss, not an illness or psychiatric disorder, although it is associated with higher risk of these disorders.

Grief counseling The helping of people through counseling to facilitate uncomplicated, or normal, grief to alleviate suffering and to reach healthy completion within a reasonable time frame.

Grief therapy Specialized techniques of intervention for bereaved individuals with an abnormal or

prolonged grief reaction to guide them toward a normal coping process.

Grief work The cognitive process of confronting the reality of a loss through death by going over the events surrounding the death, and of focusing on memories and working toward a detachment from the deceased.

Mourning Refers to the acts expressive of grief. These acts are shaped by the mourning practices of a given society or cultural group, which serve as guidelines for how bereaved persons are expected to behave.

Prolonged or complicated grief A deviation from the normal (in cultural and societal terms) grief experience in either time course or intensity of specific or general symptoms of grief.

Introduction

Bereavement is defined as the situation of having recently lost a significant person through death. Although comparatively rare in childhood, bereavement is a stressful life event that, sooner or later, becomes part of nearly everyone's experience. According to some estimates, of children younger than 18 years, 3.4% have experienced the death of a parent, whereas in elderly populations, spousal bereavement is most frequent, with ~45% of women and 15% of men older than 65 years becoming widowed. Thus, bereavement can be viewed as a normal, natural human experience. Even though suffering can be acute and the loss experience extremely painful, most people manage to come to terms with their bereavement – without the need for professional help – over the course of time. Nevertheless, it is associated with an increase in mental and physical health problems, and for some, these difficulties are extreme and persistent. Adjustment can also take months or even years, and there is substantial variation between individuals and across cultures. As such, bereavement is a concern not only for preventive care, but also for clinical practice.

Grief is understood to be a mainly emotional reaction to bereavement, incorporating diverse psychological and physical reactions, while a related term, mourning, denotes the social expressions or acts expressive of grief, which are shaped by the practices of a given society or cultural group. A minority of bereaved persons suffer from complications in the grieving process itself. Complicated grief has been defined as a deviation from the normal (in cultural and societal terms) grief experience in either time course or intensity, or both, entailing a chronic and more intense emotional experience, or an absent or inhibited response, which either lacks the usual symptoms or in which there is a delay in the onset of symptoms. Complicated

grief has not yet been classified as a category of mental disorder in the Diagnostic and Statistical Manual of Mental Disorders, although efforts are being made to have it included as a separate category in forthcoming editions (see section 'Forms of Intervention: Counseling and Therapy').

Over the past few decades, scientific study of phenomena relating to bereavement, grief, and mourning has expanded rapidly: reactions and symptoms, mental and physical health outcomes, risk factors, and efficacy of intervention have all been documented in increasingly sophisticated research investigations. Alongside such developments, theoretical models have been suggested to increase understanding of the manifestations relating to bereavement, grief, and mourning. Taken together, such research seeks to develop ways to identify and provide preventive care for individuals at risk for bereavement-related health problems.

The purpose of this article is to provide an overview of the current state of knowledge with respect to grief and bereavement. Several basic issues are addressed. First, the range of reactions and symptoms that constitute the syndrome of grief are described and changes in grief and grieving over the duration of bereavement are considered. Then the psychological and physical effects of the loss of a loved person on survivors are reviewed: Is the risk of succumbing to health disorders – even to mortality – greater in bereaved than nonbereaved counterparts, and what is the prevalence of health outcomes? Identification of especially vulnerable subgroups and risk factors are the focus of the following section. This leads to an overview of psychological intervention programs and evaluation of their effectiveness in reducing the risk of negative health consequences in bereaved individuals: Can counselors and therapists help to reduce the health problems of bereaved people? Finally, major psychological theories that have

contributed to understanding the health consequences of bereavement and how people go about coming to terms with their loss are outlined.

Symptoms and Course of Grief

In 1944, Lindemann published a systematic analysis of the range of symptoms associated with bereavement. Current understanding still owes much to this early formulation. Patterns of normal grief responses typically cover the following dimensions: affective manifestations include depression, despair and dejection, anxiety, guilt, anger and hostility, anhedonia, yearning, longing and pining, and loneliness; behavioral manifestations include agitation, fatigue, crying, and social withdrawal; cognitive manifestations include preoccupation with thoughts of the deceased, lowered self-esteem, self-reproach, helplessness and hopelessness, suicidal ideation, a sense of unreality, and problems with memory and concentration; physiological and somatic manifestations include loss of appetite (or appetite gain), sleep disturbances, energy loss and exhaustion, somatic complaints, physical complaints similar to those that the deceased had endured, changes in drug intake, immunologic and endocrine changes, and susceptibility to illness and disease. There is lack of evidence specifically on cross-cultural differences in these dimensions. However, studies from related areas, such as depression research, and clinical experience lead one to expect cultural differences in the relative frequency of symptoms across these different dimensions. It is also important to note that, while it has become familiar to talk about the 'symptoms' or 'symptomatology' of grief and grieving following early writers in the field, the above reactions are normal to bereavement and not necessarily a sign of physical illness or psychiatric disorder, even though bereavement is associated with a higher risk of these disorders.

The symptoms outlined above are more or less frequently found across different durations of bereavement. A milestone in the development of understanding the nature of grief and grieving over time was provided by John Bowlby in his three-volume monograph, *Attachment and Loss*. Bowlby documented his own observations with respect to the close relationship between manifestations of grief and time since death, which led him to suggest 'phases' or 'stages' of grief, linking many of the symptoms to different durations of bereavement. Bowlby postulated a succession of phases from an initial stage of shock, with associated symptoms of numbness and denial, through yearning and protest, as realization of the loss develops, to despair, accompanied by somatic and emotional upset and social withdrawal, until gradual recovery occurs, which is marked by increasing well-being and acceptance of the loss. Durations vary, but generally the first two phases are suggested to last up to a number of weeks, and the third, intense grieving phase may last several months or even years. There is considerable cross-cultural variation in the duration of the phases across time (or even with respect to their presence at all), which has to do with mourning customs and cultural norms.

There has been wide acceptance in the scientific as well as in applied fields of such phasal descriptions. However, it cannot

be assumed that a bereaved person will go through these phases in a set order, or even that they are necessarily conducive to good adjustment. Almost without exception, and certainly in the case of Bowlby's original formulation, the phases were introduced as descriptive guidelines, to aid understanding of loss and separation phenomena. They should not be regarded as set rules or 'prescriptions' regarding where the bereaved person ought to be in the 'normal' grieving process. Care must also be observed in speaking of 'resolution' or 'completion' of grief. Most bereaved people would confirm that one does not 'get over it and back to normal life' but rather, that one adapts and adjusts in the course of time to the changed situation and generally that one succeeds in reaching a new equilibrium.

A second influential scientific contribution to understanding the course of grief and the difficulties that are entailed at different periods has been William Worden's so-called task model, described in his monograph *Grief Counselling and Grief Therapy*, much used in counseling and therapy. This approach takes more account of the richness of idiosyncratic manifestations of grief than do phase models. Here, the grief process is taken to encompass four tasks, namely, acceptance of the reality of the loss; processing the pain of grief; adjusting to a world without the deceased; and finding an enduring connection with the deceased in the midst of embarking on a new life. Again, it needs to be emphasized that not all grieving individuals undertake these tasks and that they will be dependent on cultural factors (e.g., in societies where reverence of ancestors is customary, 'an enduring connection' takes place in a very different way: the deceased is, in a sense, still present). Further discussion of these duration-related models will be included in section 'Forms of Intervention: Counseling and Therapy' on theoretical approaches to grief and grieving.

Health Consequences

The majority of bereaved individuals undergo tolerable levels of the above symptoms, and research has shown that over the long term, most bereaved people are resilient, recovering with time from their loss, both emotionally and physically. However, the bereaved are indeed at greater risk than the nonbereaved of suffering from a variety of mental and physical ailments and disorders. These include depression, anxiety disorders, somatic complaints, and infections. In cases where the loss of life has been massive, or the nature of death horrific, bereaved persons are at risk of developing posttraumatic stress disorder. A minority are also vulnerable to complications in the grieving process itself, and sometimes this is related to other preexisting mental-health difficulties. While some of these ailments are most closely associated with recent bereavement, others extend over a longer time span. In line with these patterns, bereaved persons also have higher rates of disability, medication use, and hospitalization than nonbereaved counterparts. The former also consult with doctors more frequently than the latter, although there is also evidence that many of those with intense grief might fail to consult with doctors when they need to.

How prevalent are health problems following bereavement? Estimates vary considerably, depending not only on

the type of debility (and its precise measurement) but also across cultures and according to sample characteristics (e.g., the type of loss: whether death was of a spouse, child, or more distant relative; the nature of loss: whether it occurred in a timely or traumatic manner). Nevertheless, a few general patterns are evident. Most importantly, in general one can conclude that, across a range of debilities such as physical health difficulties, psychiatric disorders (such as posttraumatic stress disorder and clinical depression) and complicated grief, reasonably substantial minorities of bereaved individuals do suffer from severe and lasting consequences following the loss of a loved one, with a rough estimate of around 20–30% prevalence emerging from the different health vulnerability areas. For example, in one study of young widowed compared with matched married persons, 20% of the widowed compared with 3% of the married suffered from severe physical symptoms at 4–6 months post-loss. After 2 years, the rate among the widowed declined to 12%. Given the large number of people who are bereaved at any one point in time, this entails large numbers of persons at risk.

Not only are there a variety of ailments and disorders, but in extreme cases, there is also a higher risk of mortality following bereavement. An increasing body of scientific evidence testifies to the fact that bereaved persons can die of a 'broken heart,' either in the narrow medical sense, in which death occurs (excessively, compared with nonbereaved counterparts) as a result of heart disease, or in a broader metaphorical sense, when death occurs from a variety of causes such as suicide and alcohol-related causes, lung cancer, accidents and violent deaths, causes which are thought to bring about death indirectly, as a result of extreme suffering and pain following the death of a loved one. Most research indicates an early excess risk of mortality for bereaved persons, although excesses have been shown to persist for longer than 6 months after bereavement. It is noteworthy that sex difference patterns vary across types of loss. Whereas partner loss appears to affect men relatively more than it does women, the death of a child seems to have an even greater excessive mortality risk for mothers than for fathers, with relatively more bereaved mothers dying compared to nonbereaved counterparts than was the case for fathers. A study in Denmark showed that excess risk of dying for bereaved mothers extended at least across the first 18 years (the period of the study), whereas for fathers, greater risk was found early on in bereavement, particularly from unnatural causes such as suicide. Nevertheless, it is important to remember that the risk of mortality only affects a very small proportion of bereaved people. For example, in one sample of middle- to old-aged widowers, a mortality rate of 4.8% was observed, as compared with 3.2% for a comparable sample of married men.

Risk Factors

Given the physical and mental-health complications described above, as well as additional difficulties that bereaved persons experience in their ongoing lives (e.g., problems with continuing to work during their bereavement; difficulties in relationships with other persons; memory and concentration problems), research has been directed toward identifying risk

factors, that is, the situational, intrapersonal, and interpersonal characteristics associated with increased vulnerability to the range of debilitating bereavement outcomes. Some researchers have also examined protective factors that appear to promote resilience and to lower risk of adverse health outcomes. Research has also incorporated analyses of the coping process, which can impede or facilitate adjustment, looking at whether there are healthy and unhealthy ways of going about grieving.

The situation and circumstances of death contribute to adjustment, in complex ways. It is important to take the broader circumstances of death, including such factors as cause of death and caregiver strain, into account and to realize that a combination of situational factors (combined with other types, e.g., personal factors) can jointly account for the impact on adjustment. It has frequently been concluded that sudden unexpected death leads to worse bereavement outcome. However, caring for a very sick, terminally ill spouse over a long period has also been found to increase the likelihood of health difficulties subsequent to death.

Characteristics intrinsic to the bereaved individual and/or of the relationship to the deceased also play a part. Research on attachment strongly suggests that the quality and nature of the lost relationship has much impact on outcome. Robust individuals also adjust better to bereavement than people who are fragile. These patterns are probably related to attributional and emotional regulation processes; current research is beginning to look further into such underlying cognitive processes (see below). Childhood loss of a parent is one of the better-researched areas, indicating various long-term effects. Importantly, evidence suggests that the adequacy of remaining parental care (e.g., warmth combined with discipline) after the death of one parent, and personal characteristics of the child (i.e., factors contributing to resilience) are more powerful predictors of later adjustment than the loss of the parent *per se*.

Turning to interpersonal factors, inadequate social support (i.e., informal help provided by family, friends, and neighborhood networks) has generally been regarded as a major variable, protecting individuals from the negative health consequences of bereavement. However, research has shown social support to be a general risk factor, one that affects the health and well-being of nonbereaved as much as bereaved persons. It seems that others cannot easily take the place of the deceased individual or make up for the loneliness experienced on the loved one's death. Use of professional support can also be regarded as an interpersonal resource factor, one that for some, but by no means all bereaved people, can help adjustment to bereavement. We consider this factor in the next section on intervention for the bereaved.

The way that individuals go about dealing with the loss of a loved one, their coping with loss, is important because, unlike many other risk factor variables, it can be changed. For example, it may be amenable to brief interventions. Following older theorizing in the bereavement area, it was generally accepted that bereaved persons had to do their 'grief work' in order to overcome the loss of a loved one. Grief work was understood to entail confronting the reality of the loss and relinquishing the bond to the deceased person. More recently, doubts have been expressed about the adequacy of this postulated form of healthy coping. Empirical research has shown that people who do not work through grief frequently recover as well as, if not

better than, those who do so. Findings on emotional disclosure or social sharing, or on negative effects of avoidance or repression, also provided little support for the grief work notion.

Finer-grained examinations of maladaptive processes are beginning to provide useful leads. They suggest the importance of positive as well as negative cognitions and the regulation of emotion in the grieving process, both of which have been integrated into the dual process model (DPM) (see also section 'Forms of Intervention: Counseling and Therapy'). This model addresses shortcomings of the grief work model and posits an oscillation process, whereby the bereaved individual both confronts and avoids different stressors associated with bereavement. Adaptive grieving thus entails processes of both confrontation and avoidance.

As mentioned earlier, the situational, intrapersonal, interpersonal, and coping risk factors illustrated above affect the bereavement outcome in complex ways. We have noted the likelihood of interactions between factors such as personality and circumstances of death. Many potential risk factors have been under-researched, which makes it difficult for scientists to develop valid screening instruments for use by practitioners. Furthermore, the ways that risk factors relate precisely to the different health outcomes also remain to be seen, such as, for example, why one person may succumb to mental-health disorders while another might die prematurely after bereavement.

Measurement: Normal and Complicated Grief

A number of self-report questionnaires have been developed for the measurement of reactions to bereavement. Most of these inventories have been developed to enable categorization of the range of symptoms of grief in adults, to enable estimates of the intensity of grief and its various components. Frequently used batteries currently include Prigerson and colleagues' Inventory of Complicated Grief-Revised; Hogan, Greenfield, and Schmidt's Hogan Grief Reaction Checklist; and Faschingbauer, Zisook, and De Vul's (Revised) Inventory of Grief. Over the years, more specific measures have also been developed, including Toedter, Lasker, and Alhadeff's Perinatal Grief Scale; the Hogan Sibling Inventory of Bereavement; and Barrett and Scott's Grief Experience Inventory, which focuses on reactions characteristic of suicide bereavement, including feelings of disgrace or guilt.

It is important to realize that there are limitations with respect to applying such instruments for the assessment of grief reactions, and that they are generally more appropriate for research purposes than for clinical use. Individual assessment needs to take account of variables beyond those evaluated through psychometric instruments that are based on self-reports. Such inventories are also unlikely to be comprehensive. Furthermore, difficulties may have to do with just one or a few aspects of the total response (such as disgrace or guilt – but may be not loneliness, depression, or any other symptoms listed – following suicide bereavement). In such cases, calculating a score for the total symptom intensity would clearly not give an accurate picture of the difficulties associated with the loss. Psychometric properties and establishment of norms still need further investigation in the case of many of the developed questionnaires. It must also be remembered that grief itself is a

complex process; it cannot be assessed according to normality versus deviation without taking the length of time since bereavement into account.

Over the past decade, increasing effort has been made, most notably by Holly Prigerson and her colleagues, to develop criteria for the diagnosis of *complicated* or – as currently labeled by Prigerson – *prolonged grief*, for potential inclusion as a diagnostic category in the forthcoming edition of the *Diagnostic and Statistical Manual of Mental Disorders*, which is published by the American Psychiatric Association (bereavement is currently only considered among the V-Codes). These criteria are still being subjected to empirical testing and need to be applied and validated among wider subgroups of bereaved persons.

Given the arguments illustrated above regarding the limitations of self-report measurement and the complexity of the grief experience, there are good reasons to argue that both researchers and professionals in clinical practice must include diagnostic interviews in assessing the (maladaptive) course that grieving takes. A further possibility, sometimes followed by researchers and practitioners, is to use general diagnostic instruments such as the Symptoms Check List (SCL-90), the General Health Questionnaire (GHQ-28), and/or depression lists such as the Beck Depression Inventory or the Zung. In the context of traumatic bereavement, Horowitz, Wilner, and Alvarez's Impact of Event Scale (note its revised form by Weiss & Marmar) is frequently used for the assessment of posttraumatic stress symptomatology.

Forms of Intervention: Counseling and Therapy

A useful distinction between grief counseling and grief therapy was made by William Worden. This distinction helps clarify the range of support programs that are available to bereaved persons, although in practice, the division between the two types of intervention may be hard to judge. *Grief counseling* was defined by Worden as 'helping people facilitate uncomplicated, or normal, grief to a healthy completion of the tasks of grieving within a reasonable time frame.' Emphasis is thus on general support, the offering of comfort and care, helping with secondary stresses that occur as a result of the loss, and encouragement of appropriate grief and mourning. The informal support network is increasingly supplemented in contemporary (western) society by voluntary bereavement organizations such as the Widow-to-Widow program or Cruse (with those who have themselves suffered a loss being involved in the counseling of more recently bereaved persons). Other sources include pastoral care workers and doctors, and health care professionals such as social workers and psychologists. Within the last decade too, an increasing number of possibilities for the type of support that would fall into this category have emerged on the Internet, with many websites providing links to specific sources of bereavement support, including access to internet forums, e-mail groups, chat rooms, and online memorial websites. In both face-to-face and Internet support, it is important to have trained volunteers and the availability of advice and guidance of a skilled and experienced professional to back up voluntary aid. These days, such assistance is typically planned and organized within voluntary programs.

A major question concerns the helpfulness of such sources of support. Most participants report beneficial effects, but this does not mean that such programs would benefit all bereaved persons (those who found no use for them would probably drop out and be lost to impact assessment figures). Nor does satisfaction alone mean that the program actually succeeded in reducing negative health consequences or promoting adjustment. To assess the latter, carefully controlled trials including nonintervention bereaved persons for comparison are necessary. We return to the evaluation of the efficacy of intervention later.

Grief therapy, also defined by Worden, refers to “those specialized techniques . . . which are used to help people with abnormal or complicated grief reactions.” Most experts see grief therapy as appropriate when the grief process has become ‘derailed’ or gone wrong in some way. Ramsay described it as occurring when “the ‘normal’ reactions of shock, despair, and recovery are . . . distorted, exaggerated, prolonged, inhibited, or delayed.” Thus, put simply (and at the risk of oversimplification), while grief counseling would be appropriate for normal grief, grief therapy would be indicated for more pathological variants, which we call complicated grief. It is important to note that expert knowledge is necessary to evaluate whether the special techniques of therapy are needed in any particular case. Nevertheless, a number of indicators can be identified. These include an inability to face up to or process the reality of the death. Avoidance of some aspect of the loss itself or of one’s emotional reaction to it lies at the heart of problematic adjustment. For example, some bereaved persons continue to cling to and talk about the deceased person in order to remain closely bonded to him or her (again, the duration of bereavement needs to be taken into account: such reactions would be typical for most bereaved people early after loss). This too can be interpreted as avoidance: over time, the continued presence of such preoccupation serves the purpose that one does not have to face the reality of the loss. Systematic dealing with avoidance reactions is a common feature in psychotherapy programs for complicated grief.

What types of therapy are available to the bereaved who are suffering complications in their grieving process? In line with the above indicators, a variety of different programs has been developed, all of which, in one way or another, basically stimulate confrontation with the painful associations to do with grief. These differ with respect to the directiveness with which confrontation is forced. For example, within behavior therapy, techniques of systematic desensitization or ‘flooding’ have been used to break down defense mechanisms and release intense emotional reactions. Currently, (probably more) popular cognitive behavior therapy and rational emotive therapy techniques are directed toward certain ideas or assumptions that the bereaved have, for example, that one had not done enough during the terminal phase of the loved one’s life. Part of therapy might then be aimed at disputing the impossible demands that the person had placed on himself or herself during that period. When a client accepts such a reinterpretation, it should be possible to move on in the grieving process. Psychodynamic therapy focuses on conflicts within the grieving individual; for example, concentration might be on working through conflicts in the previous relationship, including both positive and negative aspects. It can also focus on

strengthening aspects having to do with the ego, by facilitating emotions such as anger or guilt.

Within the past couple of decades, grief therapy techniques have expanded to include creative therapy (in combination with other types of therapy), such as drawing, painting, or working with clay, and using music and photos. This technique is particularly useful when the bereaved person is unable to express his or her grief well in words. A different type of technique, hypnotherapy, has most frequently been used in cases of traumatic loss, oriented toward treating posttraumatic stress disorder, and focusing on the dissociation between the traumatic experience from normal consciousness, which has been assumed to inhibit normal grieving. A somewhat similar technique, known as guided imagery, involves reliving, revising, and revisiting the loss experience, with the aim to break down barriers to confronting the reality of the loss. Finally, given the recent popularity of mindfulness training in psychotherapy in general, it seems likely that grief therapy programs will increasingly incorporate mindfulness techniques into their intervention programs in the future, whereby there is mindful awareness of and attention to sensations, thoughts, or feelings associated with grief, and where these are experienced for what they are.

Certain therapeutic procedures are common to different therapeutic interventions. For example, leave-taking or ‘saying goodbye’ ceremonies are frequently used in directive types of therapy. Another is bibliotherapy, in which the bereaved person reads selected publications such as (auto)biographies, which help to make clear that certain grief reactions are common to bereavement. All forms of therapy assume that the bereaved person will ultimately come to the realization, both cognitively and emotionally, that the deceased person has gone, never to return, that leave must be taken from him or her, and finally, that he or she needs to be displaced and a new place found for him or her in the bereaved person’s ongoing life.

Like grief counseling, grief therapy programs are also becoming available on the Internet. For example, Alfred Lange and his colleagues have produced an Internet technique they call *Interapy*, an online standardized treatment for post-traumatic stress and complicated grief that includes a number of elements including psychoeducation and protocol-driven treatment (incorporating exposure to bereavement cues, cognitive reappraisal, and integration and restoration). The effectiveness of such programs specifically for bereaved persons and over long-term bereavement need further evaluation.

The Efficacy of Intervention

Since bereavement is associated with mental and physical health problems, it needs to be established whether intervention is to be recommended, and whether it is actually effective. In considering these matters, review is restricted to psychological, and not medical or pharmacological intervention; that is, it is limited to discussion of effectiveness studies of psychosocial counseling and therapy programs. To our knowledge, very little research exists on the effectiveness of pharmacological and medical interventions for bereaved people. The quality of research into the efficacy of bereavement intervention varies considerably across investigations. Only those studies that

conform to high standards, observing strict methodological criteria (presence of control groups, nonsystematic assignment to the experimental and control condition, an appropriate design with valid and reliable assessment instruments, correct statistical analyses, etc.), have been used to form the basis of conclusions.

Too few studies are available to permit comparison of the relative efficacy of the different types of counseling and therapy or their specific therapeutic techniques described above. However, it is possible to compare efficacy of bereavement intervention programs in terms of the *target group* of bereaved persons for the intervention. Grief interventions can be divided into primary, secondary, and tertiary preventive interventions. Primary preventive interventions are those in which professional help is available to all bereaved individuals irrespective of whether intervention is indicated. Secondary preventive interventions are designed for bereaved individuals who, through screening or assessment, can be regarded as more vulnerable to the risks of bereavement (e.g., high levels of distress, traumatic circumstances of loss, etc.). Tertiary preventive interventions denote those providing therapy for complicated grief, grief-related depression, or posttraumatic stress disorders, usually evident longer after bereavement (since pathological processes usually take time to develop). The efficacy of each of these three types is considered next.

Most primary intervention studies have failed to find positive effects, although more positive results have been reported in more recent studies. There are suggestions that better results occur among females (adults and young girls) than in young males. Within these studies too, better results have been found for people with mental-health problems at baseline, for both adults and children. One likely reason for the lack of effects is that nearly all the studies used outreaching recruitment procedures, in which help was offered rather than asked for. Where positive results were found, the design of the intervention was more often based on inreaching, whereby bereaved persons requested help.

Secondary interventions have generally, though not unequivocally, proven to be more effective than primary interventions, although effects were typically modest and improvements temporary. Recently, for example, improvements have been found among children bereaved by suicide in group intervention (compared to community care). Families at high risk have been found to have slightly more improvement after family-focused grief therapy in terms of general distress (but not with respect to family functioning). Emotion-focused interventions have been found to be most effective for distressed widowers, while problem-focused interventions were most effective for distressed widows. With respect to parents, fathers, in general, and mothers with low baseline values of grief and distress did not benefit from group intervention focused on problems and emotions; highly distressed mothers improved most through intervention. Taken together, the patterns for secondary intervention indicate that effectiveness is associated with strict use of risk criteria and that tailoring intervention toward high-risk subgroups is called for.

Tertiary intervention programs – including both individual and group programs, and across the range from analytically oriented dynamic psychotherapy to cognitive and behavioral therapy – have evidenced lasting positive effects on symptoms

of pathology and grief. For example, strong effects on levels of symptoms of intrusion and avoidance, grief, depression, and anxiety have been reported. A combination of medication (nortriptyline) and psychotherapy gave the best results in a study of elderly bereaved persons. In general, therapy for complicated grief or bereavement-related depression and stress disorders has led to quite substantial and lasting results.

In conclusion, as Colin Murray Parkes noted in 1998, there is “no evidence that all bereaved people will benefit from counseling and research has shown no benefits to arise from the routine referral to counseling for no other reason than that they have suffered a bereavement.” Primary intervention may indeed be helpful when the initiative is left to the bereaved individual. Secondary interventions for high-risk group are an important provision, but, as noted earlier, improvements in assessment of empirically based risk factors are essential to achieve better results. Finally, with respect to tertiary interventions, a reasonably wide variety of treatments for complicated grief is available, and these are generally quite effective.

Theoretical Approaches

Theoretical approaches to bereavement provide explanations for the phenomena and manifestations of grief and grieving. They provide insights into (mal)adaptive coping, that can potentially be used for the planning of empirical research to validate the theoretical principles, and, ultimately, for applied use in helping the bereaved. A wide variety of theories have been proposed and different principles of adjustment have been derived, at different levels of analysis (e.g., individual vs. interpersonal) and with differing degrees of specificity (e.g., from grief work to identification of specific coping mechanisms). Theories range from general psychological theories, such as psychoanalytic and attachment theories, to theories of loss, trauma, and bereavement, such as stress theory, to the bereavement-specific DPM of coping with bereavement. These different types of theories are briefly outlined next, to illustrate the nature of theorizing in the bereavement area.

Theoretical explanations of the psychological reactions and ways of coping with grief have been greatly influenced by Freud's 1917 paper ‘Mourning and Melancholia,’ its impact being evident in the later work of major figures in the bereavement field, including Bowlby, Parkes, Raphael, and Jacobs. According to psychoanalytic theory, when a loved one dies, the bereaved person is faced with the struggle to sever the ties and detach the energy invested in the deceased person. The psychological function of grief is to free the individual from his or her ties to the deceased, achieving the gradual detachment by means of the process of grief work. As noted in section ‘Risk Factors,’ this implies a cognitive process of confronting the reality of loss, of going over events that occurred before and at the time of death, and focusing on memories and working toward a detachment from the deceased. Since Freud, the notion that one has to work through one's grief was for a long time central in the major theoretical formulations on grief and in principles of counseling and therapy. The major cause of pathological grief, according to Freud, was the existence of ambivalence in the relationship with the deceased preventing the normal transference of libido

from that person to a new object. In section 'Risk Factors,' we noted lack of empirical confirmation for the grief work notion.

A second general theory, namely, attachment theory, grew from the psychoanalytic tradition but provided a new and different perspective on the nature of grief. Bowlby's attachment theory emphasized the biological rather than the psychological function of grieving. The biological function of grief is to regain proximity to the attachment figure, separation from which has caused anxiety. In the case of permanent loss, this is not possible, and such a response is dysfunctional, in the sense that reunion cannot be achieved. However, Bowlby, like Freud, also argued for an active working through of the loss. Like Freud, Bowlby sees the proximal cause of pathological grief in the relationship with the lost person. However, the distal cause is childhood experiences with attachment figures, leading the individual toward either a secure or an insecure style of attachment or bonding with the caregiver. These experiences are assumed to have a lasting influence on later relationships. For example, frequent separation from attachment figures in childhood can lead to anxious attachment in later relationships, which results in chronic grief, a complicated reaction consisting of an indefinite prolongation of grief over the death of a loved one. Attachment theory is still enormously influential in the bereavement field, with leading investigators such as Mikulincer and Shaver conducting sophisticated empirical research, which has confirmed the importance of attachment styles in the prediction of adjustment to bereavement.

Stress theory, like attachment theory, has had and still has an enormous impact on bereavement research. One line within this approach is represented by the influential work of Horowitz and his colleagues, whose interest and analysis spans not only bereavement but also traumatic life events in general (see, e.g., his classic 1986 volume *Stress Response Syndromes*). The basic assumption of stress theory is that stressful life events play an important role in the etiology of various somatic and psychiatric disorders. This approach has also received much impetus through the work of Lazarus and Folkman, whose volume *Stress, Appraisal, and Coping* appeared in 1984. According to this theoretical perspective, a stressful life event may precipitate the onset of a physical or mental disorder, particularly if a predisposition to that disorder already exists. The intensity of stress created by a life event depends on the extent to which the perceived demands of the situation tax or exceed an individual's coping resources, given that failure to cope leads to important negative outcomes. Coping may either be directed at managing and altering the problem that is causing the distress (problem-focused coping) or it may be directed at managing the emotional response in order to reduce emotional distress and to help maintain one's emotional equilibrium (emotion-focused coping). Stress theory provides the theoretical underpinning for the so-called 'buffering model,' which suggests that high levels of social support (a coping resource) protect the individual from the deleterious impact of stress on health (see also section 'Risk Factors'). Research has identified neurophysiological mechanisms linking stress with various detrimental consequences to the immune, gastrointestinal, and cardiovascular systems.

The DPM of coping with bereavement was developed by Stroebe and Schut in 1999, to overcome shortcomings of earlier models in describing adaptive coping with

bereavement, in particular, the grief work notion. The DPM grew from cognitive stress theory. It postulates two types of stressors, namely, those relating to the deceased person himself or herself (known as loss-oriented coping, e.g., ruminating about the death), and those having to do with secondary stressors that come about indirectly but as a result of the loss (known as restoration-oriented coping, e.g., actively dealing with a new financial burden). The pattern changes over time, with more loss orientation early in bereavement, and more restoration-orientation as time goes on. Rather than assuming phases or tasks, the DPM includes an emotion regulation process, labeled oscillation. Adaptive coping entails oscillation between both the loss- and restoration-oriented domains, and 'time out,' giving a necessary respite from the arduous process of dealing with these different types of stressors. As such, the DPM is compatible with, but extends beyond, earlier coping models.

Conclusions

Loss of a loved person causes deep suffering and brings with it the risk of mental and physical health consequences. It is not surprising, then, that bereavement and grief have become the subject of considerable scientific investigation. At the same time, it is important to remember that grief is a normal, natural process after bereavement. Most reactions are not complicated, and for most bereaved persons, family and friends, religious and community groups, and various societal resources will provide the necessary support. Professional psychological intervention is generally neither justified nor effective for uncomplicated forms of grief.

Much is now known about the health consequences, risk factors, and forms of complications following loss. Intervention programming has made major advances. Although improvements in research across all the above areas are evident in recent years, methodological shortcomings are still present in some investigations. Furthermore, even though statements about general occurrences and manifestations associated with bereavement could be made, considerable gaps in knowledge still remain. For example, we need to learn more about mortality patterns following different types of loss, or about co-determinants of the poorer outcomes of bereavement. Finally, there is scope for improvement in the design of intervention studies and for strict assessment of their effectiveness following evidence-based criteria.

Glossary

Additive task A group task in which the contributions of individual members are added together to form a group product.

Compensatory task A group task in which the contributions of individuals are averaged to form a group product.

Conjunctive task A group task in which all of the group members must complete a specific action before it is finished. The worst performing group member determines group performance.

Deindividuation A state of decreased self-awareness and a lowering of self-control that can occur when individuals are actively, and typically anonymously, involved in groups or crowds.

Disjunctive task A group task in which there is one correct solution. As soon as it is discovered by one member and accepted by the group, the task is solved. The best performing group member determines group performance.

Group Two or more individuals having some common bond, goal, or task, and exerting influence on one another.

Group brainstorming Generating as many ideas in groups as possible without concern for quality or evaluation.

Group norms Consensual expectations for what is correct or appropriate group behavior.

Group polarization The tendency of group members to become more extreme in their attitudes or opinions after

discussions with individuals who have similar attitudes or opinions.

Group socialization The process by which individuals become full-fledged members of groups.

Groupthink Defective decision-making in groups that results from in-group pressure to reach consensus.

In-group identification The degree to which group members self-identify with and place subjective value on membership social group or category.

Intellective task Verbal or mathematical tasks for which there is a demonstrably correct solution.

Judgmental task Tasks for which demonstrably correct answers do not exist.

Media richness The extent to which the means of communication involves multiple channels such as video and audio.

Mixed motive Situations in which group members are confronted with the choice of whether to cooperate or compete with other group members or other groups.

Social comparison The tendency to compare our opinions and abilities with those of others when we are uncertain about them.

Social facilitation A term describing the tendency for easy or dominant tasks to be enhanced in the presence of others.

Social loafing Reduction in effort by individuals in groups when their individual performances are not easily identified or evaluated.

Group dynamics is the study of the forces or processes that are responsible for various group phenomena (e.g., the formation, development, interaction processes, social influence, and performance of groups). Groups influence individual behavior in many ways, but individuals can also have an impact on groups. Groups appear to satisfy many needs, but they often lead to performance or decision-making that is less than optimal. Several processes that underlie group behavior and ways of improving group functioning are discussed.

Major Characteristics of Groups

Groups come in many forms and have many different reasons for existing. Some groups are merely short-term aggregations of people with no strong interrelationship, such as groups at spectator events, at bus stations, and in elevators. Other groups such as clubs, churches, peers, friends, and families have strong bonds and maintain long-term relationships. Some groups develop simply to have a good time, while others are concerned with accomplishing specific tasks. Other groups are based on large-scale identities, such as gender, ethnicity, or

nationality. It is difficult to use a single description for all types of groups, but most would agree that groups consist of two or more individuals who have some similarity, common bond, goal, or task and who exert influence on one another.

Reasons for Joining Groups

There are many different reasons (i.e., instrumental, personal-emotional, identity, group's resources, and knowledge-related reasons) why people join groups. Instrumental reasons refer to choosing a group because one shares with other members a desire to reach a certain goal (e.g., a political party), to perform a particular task (e.g., play basketball), or to have social connections. The decision to join a particular group may also be motivated by a variety of personal or emotional needs, such as needs for belonging, self-esteem, attention, affection, approval, support, and the reduction of uncertainty about the social world. Individuals who are motivated by such needs are likely to seek groups that consist of individuals who have similar values and beliefs. By involvement in groups, individuals can also establish an identity as in the case of joining a fraternity, sorority, or a political activist group. Individuals may join

groups for other needs such as achievement and influence, to make money, to obtain information, or to learn a skill. They may also join groups for resources such as power, status, and personal recognition. Finally, they may join groups because they want to learn new ideas or perspectives that they cannot obtain by themselves alone.

Group Socialization

Groups differ greatly in the process by which individuals join and become full-fledged members of the group. Some groups have stringent entrance requirements while others have few if any (e.g., political parties). Most individuals who join groups appear to go through some sort of socialization process. At first, the prospective member and the group will investigate each other to determine whether group membership should be considered. Once someone joins a group, groups typically have various procedures and programs to help the newcomer learn group norms and fill social roles. Once this socialization process is complete, full acceptance as a member of the group occurs. At this point, the new member typically feels a strong commitment to and identification with the group. This commitment may wane over time because of conflicts, boredom, or competing interests. The group may attempt to resocialize the individual, but if these efforts are not successful, the individual may exit the group.

Group Development

Groups go through various stages during their existence. In the forming or inclusion stage, individuals get to know each other and the various group rules. At this stage, behavioral patterns in groups lead to the formation of expectations about task, group rules, and interaction processes. Expectation states theory suggests that interactions in groups may follow expectations group members have about other group members on the basis of their personal characteristics, such as gender or age, and relevant skills or experiences. As a result of such expectations, this stage is often followed by a storming or control stage in which members compete for positions, roles, and leadership. Some members tend to take on mostly task related roles whereas others may focus more on socioemotional issues. If the conflicts associated with this stage are resolved effectively, the group enters the norming or affection stage in which there is the development of a deeper emotional bond and common perspective about how the group should function. At this point, the group can focus on the achievement of its goals and tasks in the performing stage. As long as groups function satisfactorily in pursuit of various goals or tasks, they should be able to maintain their existence rather easily. However, if the major goals for tasks are achieved or if the group is having difficulties in achieving its goals, the group may adjourn or disband.

Influence Processes in Groups

Arousal

Although groups differ along many dimensions, there are certain forces that play an important role in most groups. One of

the most basic impacts is that of degree of arousal. When others are observing us or working with us and we do know how they will react to us, we may experience a state of heightened arousal or motivation. This may be in part because of a concern with how others might react to or judge our behavior. This enhanced arousal may increase our ability to do simple tasks or behaviors but it may hinder the performance of more difficult tasks or behaviors. When the presence of audiences or coworkers enhances performance, it is termed social facilitation. By contrast, when the presence of others hinders performance, it is called social inhibition. However, when group members face some external stress, the presence of group members can have a calming effect.

Diffusion of Responsibility

When one becomes immersed in group activities in which one's individual actions or unique contributions are difficult to separate from those of the other group members, group members may experience a diffusion of responsibility. That is individuals may not feel personally accountable for their actions. In extreme cases, this may take the form of deindividuation in which the person loses a sense of self-awareness or experiences a lowering of self-control. In this state, the individual may be very susceptible to the influence of others in the group. Therefore, if others are exhibiting antisocial behaviors or behave ambiguously in a helping situation, the individual may be prone to act in similar ways. However, prosocial norms in groups can increase individual prosocial behavior as well. Diffusion of responsibility can also take its toll on group task performance. When individuals work on a task as a group, especially if the task is an additive or compensatory one (see section 'Working in Groups'), they may not feel individually accountable for their performance. The larger the group, the less is the accountability and it is more likely that individuals will demonstrate social loafing or reduced efforts. By contrast, group members tend to increase their collective effort when they feel accountable or responsible to the overall group product and value the group task. Diffusion of responsibility in groups is not inevitable. It is most likely to occur when it is difficult to identify individual group members, there is no individual or external evaluation of performance, the task being performed is easy or boring, and members of the group are all doing the same task. Alternatively, it can be reduced or eliminated by increasing individual evaluation or identifiability, by using tasks that are difficult or interesting, and by having individuals in the group doing different tasks.

Social Comparison

Comparison of opinions

Groups perform a variety of activities. They make decisions, solve problems, perform tasks, set goals, make plans, or engage in social activities. Each of these activities provides opportunities for individuals in groups to compare themselves with others. This tendency or drive toward social comparison is seen as one of the basic social influence processes in group situations. It is motivated by one's uncertainty about the accuracy of one's beliefs or opinions and a desire to evaluate one's adequacy or ability along a variety of dimensions. Individuals can

use this social comparison process to evaluate their opinions, attitudes, personal characteristics, and abilities. For opinions and attitudes, the tendency is to compare oneself with individuals who are generally similar to oneself in a variety of characteristics that are salient to the group members such as age, gender, religion, values, and other opinions or attitudes. This implies that individuals will seek out groups consisting of individuals who already appear to be similar to them on a number of dimensions. As a result, many groups form on the basis of similarity of interests, attitudes, and characteristics. Such formation or homogeneity, then, creates a pressure for an individual or newcomer to conform to the majority of group or group norm. Moreover, interaction among such group members should increase the extent to which the members receive support for their existing opinions or ideas. Thus, groups should increase the confidence of individual group members in their collectively shared ideas, opinions, and values.

Comparison of abilities

Comparison of abilities among group members involves a slightly different type of process. Comparing one's ability or characteristics with those of others has potential implications for one's self-esteem. If one compares favorably, one's self-esteem is likely to be enhanced. If one compares unfavorably, one's self-esteem may be reduced. One way to increase the probability of a favorable outcome is to use someone who is slightly superior to oneself as a basis of comparison. If as a result of this upward comparison process (e.g., a game of tennis, a sales contest) this other person is indeed superior to oneself, the negative impact on one's self-esteem should be minimal. That outcome should have been expected. Yet if one actually performs in a way superior to that of the comparison person, one's self-esteem should receive a strong boost. Group members can engage in upward comparison processes if there is a strong tendency for competition among group members and incentives to show a high performance.

Sometimes, individuals engage in downward comparison. This involves comparing with someone of less ability, or lower status, or who is less fortunate than oneself. This is most likely among people of low self-esteem or people who have low expectations or self-confidence. Because these people do not expect to compare favorably with others of superior ability or status, this can be seen as a way in which they can ensure maintenance of their self-esteem or positive perceptions of their performance or situation. In group situations, group members tend to display downward comparison even in performance if contribution to the overall group product is costly, motivation of group members is low, and proportion of least productive individuals in groups is high.

Comparison processes often occur between groups as well as within them. Intergroup comparisons can produce higher in-group identification among group members, and consequently greater cooperation and group performance, in an effort to compare favorably to another group.

Conformity and Independence

Individuals in groups have a variety of social needs. Most have a need to be accepted by others and to be seen in a favorable light. People also have a strong desire to have certainty about

different aspects of their social world. Although certain physical features of our world are subject to little disagreement (e.g., color, shape, and size of objects), there is potential for significant disagreement about issues for which there are no objective or commonly accepted answers (e.g., religion, values, and politics).

Our social needs are often met in groups. Other group members can provide acceptance and approval or help increase one's certainty about subjective issues. This fact is the basis for power of group members over the behavior of other members. This power may be exerted to make group members adhere to social norms of the group. Norms are strong expectations for behavior that develop and exist in groups. Groups may expect certain types of dress, manners, and beliefs. Individuals who do not adhere to the group norms may face disapproval or possible rejection. To the extent that individuals are concerned with maintaining positive acceptance by other group members, the group has normative influence over the individual. The degree to which the individual depends on the group as a basis for deciding subjective or social issues (e.g., how to vote) is the extent to which the group has informational influence. As a result of the social and informational influence processes, group members often adhere closely to arbitrary social norms and share a high degree of similarity in opinions and attitudes. When individuals deviate from the group norms, other group members may exert pressure to have the individuals change their behavior or opinions to match those of the group more closely. The degree to which individuals match the standards of the group as a result of such pressure is known as conformity. If they do not change their behavior, they may be rejected or ignored by the group. Ostracism or exclusion from groups may have serious detrimental individual consequences, such as low self-esteem, embarrassment, sadness, anxiety, and helplessness.

Communication in Groups

Communication involves the exchange of information in groups. Most groups or organizations have both formal and informal means of communication. Formal communication networks can vary in degree of centralization. In centralized networks, information from all group members goes through one individual. This is an effective structure when transmission of information is the primary group task. These networks are associated with less satisfaction for peripheral members but may be very efficient for relatively simple tasks. In decentralized networks group members freely communicate with one another. Decentralized networks are best when the group is confronted with complex problems that require full exchange of information. Downward communication in an organization or group goes from the top to the bottom of the organizational hierarchy and typically involves directives and information related to performance of tasks. Upward communication goes from the lower levels of the hierarchy to higher ones and often is used to provide feedback about performance and effectiveness of procedures or policies. Lateral communication is the exchange of information among members or subgroups at a similar level of the hierarchy. Effective functioning of groups requires accurate and efficient communication throughout the organization using all available channels.

Groups also have various informal means of communication. For example, grapevines are informal communication networks based on interpersonal relationships. They are often involved in the transmission of rumors. Informal communication can take various forms such as verbal, nonverbal, written, or electronic. Communication appears to be most effective if multiple channels are employed. Verbal messages followed up by written ones may optimize both impact and clarity. When messages are delivered in person, the receivers have access to nonverbal cues such as facial expressions, eye contact, and bodily movements. These may allow individuals to look for hidden meanings in the verbal message. For example, bodily cues may be helpful in assessing whether someone's verbal message reflects this person's true feelings. Electronic communication is becoming increasingly important in many organizations. It can be very efficient and may facilitate high levels of communication across different levels of the group hierarchy. Such communication can vary in media richness, which is the extent to which it involves multiple channels (e.g., audio only vs. audio and visual). As tasks become more complex or subject to differing interpretations, richer media may be required.

Working in Groups

Types of Group Tasks

Many of our daily tasks are done in group situations. We may prepare meals at home with family members, fix a car with a friend, play basketball with our neighbors, and work in an office with our coworkers. While some tasks can be done only with groups, in other cases individuals can do them in isolation. One interest has been to determine to what extent groups are a help or hindrance to the solution of problems or performance of various tasks. This, of course, depends on the type of task or activity. Much research has investigated tasks that simply involve the addition of individual products such as counting money or generating ideas. These are additive tasks. Although groups obviously will produce more than any single individual, they may not out-produce a similar number of individuals performing alone. On the other hand, if the group members are in competition with one another or there is evaluation of individual performance, individuals in groups may outperform solitary individuals. These patterns of results hold only for relatively simple tasks in which motivation is closely related to performance level. On relatively complex, learning, or conjunctive tasks, the individuals in groups may perform more poorly than solitary individuals because of increased anxiety associated with accountability or evaluation in groups.

Some tasks involve averaging the contributions of group members, such as estimating the number of beans in a jar. These are called compensatory tasks because the biases in judgment of a specific member can compensate for the biases of the other members. Disjunctive tasks require members of a group to discover a correct solution to a problem. As soon as one member comes up with a correct solution that is accepted by the group, the task is complete. However, unless the solution is fairly obvious, groups may sometimes not accept correct solutions and therefore function more poorly than comparable groups of individuals working alone. On a conjunctive task, all

of the members must complete a certain action before that task is completed. This is exemplified by a mountain-climbing team. Here, the performance of the group is determined by its least able member.

Group tasks can also vary in the extent to which it is possible to demonstrate that there is a correct answer. There are no demonstrably correct answers for judgmental tasks that involve evaluations such as the attractiveness of art or the appropriateness of social positions. Intellective tasks involve verbal or mathematical problems for which demonstrably correct solutions do exist. On judgmental tasks, group consensus is the main determinant of the group judgment. For intellective tasks, the correct answer will be chosen if it is recognized by one or more of the group members. In fact, groups appear to be quite good at detecting errors or wrong solutions in the process of determining the correct answers on such problems.

Group Brainstorming

Perception of group performance

Although groups may excel in some situations, they often perform below expectations. Individuals seem to believe that groups will be quite productive, as in the case of group brainstorming. This involves the generation of ideas in groups under a set of rules designed to encourage free exchange of novel ideas. Group members are encouraged to generate as many ideas as possible and instructed not to criticize or evaluate the ideas of others in the group. While most individuals expect this to be an effective procedure, brainstorming groups actually generate fewer ideas than do a comparable group of solitary individuals (nominal groups).

Processes in group brainstorming

The relatively poor performance of brainstorming groups is caused in part by the blocking or interfering effects of the activity of other group members that occurs when one is trying to generate ideas in a group. In addition, group members may be concerned about others' reactions and inhibit the number of ideas they contribute. Because the task is additive, group members may also reduce their efforts or loaf in the group because they typically are not held accountable for individual ideas. All of these factors tend to inhibit performance of individuals in groups. Furthermore, group members may be inclined to match their level of performance to that of the less productive members.

Procedures for effective brainstorming

Various techniques may help counteract and overcome some of the problems of brainstorming groups. Group brainstorming should be used only with individuals who are comfortable working in groups. The group should be given a challenging goal and held accountable for it. Moreover, some procedural techniques can greatly facilitate performance. When groups exchange ideas on pieces of paper without talking (brainwriting) or by means of computers, the performance of groups can exceed the performance of nominal groups. It is also useful to have an incubation session immediately after group brainstorming in which participants can reflect on the shared ideas and build on those ideas.

Group Decision-Making

The Nature of the Process

Much decision-making occurs in groups. Committees, task forces, legislatures, and social organizations are just a few examples of groups that often have to make group decisions. The advantage of group decisions is the opportunity for input from a wide variety of members. This also helps distribute responsibility for the decision among the group members. Unless formal procedures are in place, groups often do not effectively organize their decision-making process. For example, groups tend to go along with the first plausible idea. Also, when the majority of the group has accepted a particular idea or solution, the group consensus rarely changes. The direction of the group decision in juries and other similar groups can be predicted quite well from a knowledge of the prior support for a position among group members. The direction of influence typically goes in the direction of the largest faction. So, if a plurality of a group initially favors a particular position, the final group decision is likely to be consistent with that position. This strength-in-numbers effect may reflect both normative and informational influence processes. Of course, this effect is most likely to occur on judgmental tasks where there is no objective right or wrong decision.

Group Polarization

Groups often come together to discuss issues or opinions. Although there is typically a wide range of opinions among individuals, sometimes group members have similar attitudes or opinions about a topic. This is particularly true in the case of groups that form on the basis of that agreement (special interest groups, political groups). When groups of individuals who are biased to a particular side of an issue discuss the issue, they tend to move their opinions further in the already-favored direction after the group discussion. This shift toward more extreme opinions in groups is termed group polarization. It appears to be caused by three different processes – social comparison, information exchange, and intergroup social categorization.

Individuals in a group who perceive themselves as favoring a particular side of an issue may discover during the group discussion that others more strongly endorse that position than they do. As a result, they may feel some pressure to change their opinions to more strongly reflect the valued direction. In addition, most of the ideas exchanged in such a group would tend to support the favored direction, especially in the absence of input from outsiders. Moreover, polarization can be due to group members' conforming to in-group norms in contrast to out-group norms. When an out-group or intergroup relationship is made salient, in-group members are likely to take more extreme positions as to be more clearly differentiated from out-group norms, which provides additional support for the individual taking a more extreme position.

The group polarization phenomenon applies to groups that have a fair degree of homogeneity of opinions, attitudes, or values. Because people tend to select groups on the basis of similarity of interests and beliefs, many groups are fairly homogeneous. The social comparison, information exchange, and categorization processes in such a group tend to move the

group's attitudes in more extreme directions. It is therefore not surprising that there is so much conflict between groups that are divided along political, religious, and ethnic lines or any other dimension that is related to strong differences in values (e.g., management vs. labor, environmentalist vs. developer). To minimize such polarization tendencies, it may be useful to increase interaction in cooperative activities among members of the different groups.

Groupthink

The nature of groupthink

Even if members in a group have a broad range of opinions, it does not guarantee that these will be carefully examined in a group discussion. Sometimes decision-making groups have strong pressures to come to agreement. This pressure may come from competitors, from crises that demand quick solutions, or from arbitrary deadlines. Groups that are under such pressures may come to decisions without carefully evaluating alternative courses of actions. The processes related to such defective decision-making are known as groupthink.

Characteristics of groupthink

There are a number of features that appear to facilitate the occurrence of groupthink. Consistent with the polarization effect, groupthink is most likely to occur if the group is fairly homogeneous in member characteristics and is insulated from other groups. In addition, a directive leader who champions a particular point of view and exerts pressures for consensus is likely to lead to groupthink.

Moreover, groupthink is most likely to occur in groups where conformity to group norms are desired or expected. In groups that are prone to groupthink there is pressure toward uniformity of opinion, with direct pressure being applied on dissenters. Group members may also rationalize away information inconsistent with their decision. In such groups, members are unlikely to make well-informed decisions and to carefully examine a broad range of alternatives or information. They will tend to overlook the risks of the favored alternative or fail to develop contingency plans. Information in support of the impending decision will be given more weight than information inconsistent with it. Decisions approached in this fashion may be disastrous for businesses and governments. The Bay of Pigs invasion under the direction of president Kennedy, the decision to escalate the war in Vietnam, and the Challenger disaster are among some of the highly publicized instances of groupthink. Detailed analyses of the decision-making involved in these events have revealed much evidence for symptoms of groupthink and the related defective decision-making process. Both experimental and field studies have demonstrated that leadership style is one of the strongest predictors of groupthink.

Preventing groupthink

A number of procedures may minimize or eliminate the occurrence of groupthink. The group should set a goal of making the best possible decision rather than simply developing consensus quickly with a minimum of conflict. Group leaders can play an important role by promoting this goal and not pressuring the group in a particular direction or plan early in

discussion. They may make their groups and their members more openly accountable or responsible for their role (e.g., devil's advocate) in the decision. Procedures should be developed to assure a wide-ranging and full discussion of the alternatives. Breaking the group into small subgroups at various points in the decision-making process may increase the chances of diverse perspectives being carefully considered. If these groups come to similar decisions, confidence in the correctness of the decision is increased. Groups should have 'second chance' meetings in order to reconsider the wisdom of the initial decision. Input from knowledgeable outsiders or experts who are not subject to the pressures of the groups may also be helpful in providing some assessment of the reasonableness of the decision.

Influence of Individuals on Groups

Minority Influence

There are many forces within the group that constrain or limit the behavior of its members. Groups generally do not respond favorably to those who disagree with the majority consensus or position. This fact often inhibits individuals from expressing deviant opinions. When individuals have the courage to deviate, other group members typically attempt to persuade them that they are wrong and to move them in the direction of the majority. If these attempts are unsuccessful, opinion deviants are often rejected or ignored. While opinion deviants are not liked, they do have some potential positive impact on groups. Because of their distinctive position, they gain the attention of group members and may stimulate them to rethink the issue, if not publicly. The fact that someone is willing to dissent may give them some additional credibility and influence because of their low perceived self-interest in the issue. This is particularly true if this person persists forcefully and consistently in the face of attempts by the majority faction to produce compliance with their position. As a result, majority members may actually change their opinion on the main issue or related ones in the direction of the minority position. This change tends to be genuine, in the sense that it is an actual change in their personal opinions that may not be expressed during group interaction but is evident in anonymous measures of beliefs taken after exposure to minority influence. In contrast, individuals who change their position in response to majority influence typically are only complying publicly with the group norm. Assessments of private beliefs often indicate little personal change. The ability of minority factions to stimulate cognitive reevaluation on the part of members of the majority may be one reason that exposure to minority positions in groups can produce subsequent increased creativity in individual problem solving. Exposure to minority perspectives can also increase the subsequent generation of novel ideas or divergent thinking in groups, especially if group members are able to fully participate in the group interaction process.

Leadership in Groups

Characteristics of leaders

Most groups have leaders. As discussed earlier, these are individuals who have the capability or responsibility of directing

the group's activities. They may be informal or temporary leaders who derive their status from actively contributing to the welfare of the group. Those who dominate the discussion in a group are often seen as leaders. Leaders may also attain more formal positions of leadership by means of election or appointment.

The types of skills, traits, and interpersonal styles required of leaders will depend greatly on the type of group. Certainly, military units and research teams require different types of leaders. However, there are some characteristics that appear to be generally important for successful leadership. Leaders must desire to have influence over others, need to be motivated to achieve goals, and should have the determination to persist in this process. Successful leaders tend to be self-confident, honest, and flexible. Intelligence, creativity, and relevant knowledge are also important. Although it makes a great deal of sense that leaders should be motivated and capable, these characteristics do not ensure attainment of positions of leadership or leadership effectiveness. The behavioral style of leaders and situational factors often appear to be more influential than personal characteristics.

Behavioral style

Analyses of leadership behavior have revealed the existence of two distinct styles. Some leaders are consideration- or person-oriented. They are concerned primarily with maintaining good relationships among group members. Their approach to group members is one of interpersonal warmth and trust and involves open communication between leader and followers. A second type of leader is known as production or structure oriented. Their main concern is structuring the situation so that the task is done well and efficiently. This involves developing ways for the group members to function more effectively without concern for developing positive interpersonal relationships. It is possible for leaders to exhibit a wide variety of combinations of degree of concern for people and concern for productivity. A hybrid leader or team manager who is able to exhibit both a concern for people and who has the ability to structure the work environment for productivity may be ideal.

Situational factors

The effectiveness of a particular style of leadership appears to depend on characteristics of the situation such as follower support of the leader, degree of task structure or clarity, and leader power over followers. These features influence the degree of control the leader has over the situation. With low degrees of situational control, production-oriented leadership may be required for effective group performance. Under these conditions, group members need direction and structure, and attempts at improving interpersonal relations may have little impact. With moderate degrees of situational control, a person-oriented style may yield more positive group relations and motivation to perform. A task-oriented leader may alienate group members by using a directive or autocratic approach and as a result further weaken the situational control. With high degrees of interpersonal control, a person-oriented style is not necessary and the group may respond positively to the task- or production-oriented behaviors of the leader. Group member satisfaction and performance tend to be highest in groups with the appropriate match of situation with leadership style.

Transformational leaders

Sometimes, leaders excite the imaginations of their followers and are able to motivate them to perform at high levels or make extreme sacrifices. Franklin Roosevelt, Winston Churchill, and Martin Luther King, Jr. are examples of leaders who fall into this category. These types of leaders have a vision, act in a confident manner, and are good communicators who have a dynamic personal style. They are also skilled in judging others and manipulating their own attractiveness and appeal to their followers. Transformational leaders tend to emerge when groups face crisis situations and need both a strong and visionary leadership and an emotional commitment to a cause by the followers. These types of leaders are not necessary and probably not useful when groups are focused primarily on routine activities.

Summary

We have learned much about group dynamics. Groups are subject to a wide range of processes as they go about their various tasks. Our present state of knowledge can aid us in getting the most out of these groups. However, there is still much to learn and there are many interesting new issues on the horizon. Electronic technology allows for new ways of organizing group interaction and structuring group tasks. These interactions and tasks will be mostly cognitive or informational in nature. New developments in cognitive psychology may allow for the development of more sophisticated understanding of such cognitive interactions among group members. However, it seems likely that many of the principles of group dynamics discovered with face to face interacting groups will be applicable to understanding the interactions of electronic groups.

Glossary

Association cortex Areas of the cerebral cortex that are responsible for sensory processing, so that primary sensory input. For example, when a person looks at another person, the light reflected from that person travels to the eye, and information is then sent back to the primary visual cortex, which then sends signals to the association cortex where it is interpreted and understood to be the image of a person.

Charles Bonnet syndrome A syndrome in which visual hallucinations occur after loss of normal visual function.

Lewy body disease A form of dementia that affects both the cerebral cortex and subcortical nuclei.

Phantom limb syndrome A syndrome in which an individual feels abnormal sensations or pain in a limb (arm or leg) that has been amputated.

Subcortical nuclei Collections of gray matter containing neurons deep in the brain, above the brainstem and below the superficial gray matter, that play a role in transmitting, receiving, and integrating information from other parts of the nervous system.

The psychological history of man does not offer a more curious question than that of hallucinations. To see what no eye perceives, to hear what no ear hears, to be convinced of the reality of sensations to which all are incredulous – does not this present matter for research full of interest?

Brierre de Boismont

The word *hallucination* has its roots in the Latin *hallucinari* or *allucinari*, which means ‘to wander in mind.’ A contemporary definition of hallucinations was suggested by David in 2004:

A sensory experience which occurs in the absence of corresponding external stimulation of the relevant sensory organ, has sufficient sense of reality as to resemble a veridical perception, over which the subject does not feel direct and voluntary control, and which occurs in the awake state.

Introduction

We become aware of the outside world through our senses. As information enters and moves through the various centers of the brain, it is parceled, filtered, and analyzed by an orderly sequence of events, which culminates in conscious awareness. The processing starts in the peripheral sensory organs, moves through the thalamic nuclei, and ends in the primary sensory regions of the cerebral cortex. Lastly, the information moves downstream to a variety of unimodal and multimodal sensory association areas. Dysfunction of this orderly sensory system caused by any one of the many neurological or psychiatric insults may clinically manifest as hallucinations.

The full spectrum of hallucinations is beyond adequate description in a book chapter or even an entire volume devoted to the subject. Hallucinations may occur in both pathological and nonpathological contexts. Normal people without neurologic disease who experience sensory deprivation, starvation, or extreme pain may experience vivid hallucinations. In contrast, hallucinations may occur in people crippled by a severe neurologic illness such as viral encephalitis, stroke, epilepsy, or dementia. Hallucinations may occur as undesirable symptoms of many disease states such as schizophrenia and become the focus of treatment. Hallucinatory states may also be induced by ingesting naturally occurring or artificially created substances. Hallucinations may arise in any sensory modality. They may occur in the visual modality and appear in the form of ballerinas dancing next to a person’s bed. They may occur in the somatosensory modality and manifest as the feeling of a persistent limb following amputation of the extremity. Some may hear people speaking when alone, while others perceive smells.

David makes several important points in his definition. First, hallucinations are fundamentally a *subjective* sensory experience and thus are somewhat resistant to objective analysis using the scientific method. Second, the degree of insight that the person experiencing the hallucination has into the reality of the experience is variable. For instance, patients with schizophrenia may be convinced that the voices that they hear are arising from a tape recorder playing in the room though the device, if present, is inactivated. In contrast, a patient with Charles Bonnet syndrome (CBS) often realizes that the visual hallucinations are artificial. Third, although people with hallucinations may, to some degree, influence the context of the hallucination, they generally do not have any control over them. Lastly, dreams are not true hallucinations as they do not occur in the wakeful state.

In antiquity, a strikingly modern categorization of hallucinations existed. The Hippocratic School considered the experience of visions and voices to be associated with *paranoia* which was differentiated from *epilepsy*, *mania*, and *melancholia*. The experience of visions and voices was therefore classified as a medical entity. Hippocrates believed that the source of hallucinations was a special ability to experience phenomena which were not apparent to normal individuals. This type of ‘gain of function’ explanation for hallucinations has a common theme in antiquity. For instance, the oracle and high priestess Pythia in eighth century BC experienced hallucinations which were interpreted as prophecies (see [Figure 1](#)). The mathematician Pythagoras was thought to be guided by voices. Even Socrates marveled at a perceived voice which he believed to be exterior to his own mind, which has been referred to as the Demon of Socrates.

Figure 1 Priestess of Delphi by John Collier, 1891. The oracle was inspired by vapors rising from a crack in the rock below.

In medieval Europe, visions and voices were categorized instead as possessions by external forces, such as the devil or an angel. The person who experienced hallucinations might be thought to have absence of all rational thought, might be deemed insane, and was referred to religious courts for trial and punishment. For instance, in fifteenth century France, Joan of Arc proclaimed that she had visions from God that told her to fight to recover her homeland from English domination (see [Figure 2](#)). She was eventually captured by the English and burned at the stake at the age of 19.

The mid-nineteenth century European scientists brought fundamental changes to the understanding of hallucinations. In 1845, a French physician from the Pitié-Salpêtrière in Paris, named Jean-Étienne Esquirol, published a work titled *Mental Maladies: A Treatise on Insanity*. In this treatise, Esquirol first used the word *hallucination* to refer to visual or auditory experiences which were considered real by the person experiencing them but not real to observers. Esquirol unified hallucinatory experiences occurring in various sensory modalities as fundamentally similar. He postulated that all hallucinations are autonomous activations of memory traces which have an influence on primary sensory systems. Eight years later in 1853, another French physician named Brierre de Boismont championed the position that hallucinations are not necessarily an accompaniment of insanity, and posited that they may occur as purely isolated phenomena. In the 1890s, Augusto Tamburini, an Italian neuroscientist, first proposed that hallucinatory experiences arise due to ‘irritative activation of regions of the brain which are active in processing of information in the modality of the hallucination’ ([Ireland, 1893](#)).

Figure 2 Jeanne d'Arc, by Eugene Thirion, 1876. Joan of Arc receives divine inspiration from visions.

Classification of Hallucinations by Proposed Mechanism

Contemporary understanding of the neurophysiology of hallucinations comes from several lines of both clinical and experimental evidence. The largest contribution comes from clinical descriptions of patients with hallucinations due to either destructive or activating lesions of the nervous system. From clinical accounts, it has become clear that vivid hallucinatory experiences can arise in patients without comorbid cognitive or psychiatric disease. Clinical accounts of vivid hallucinations in patients with isolated dysfunction of peripheral sensory organs have demonstrated that without access to the outside world, the primary sensory networks can function in an autonomous manner, producing vivid hallucinations. Clinical accounts of hallucinations in patients with lesions of the subcortical structures have demonstrated that the sensory systems are modulated by neural structures in the brain stem and the thalamus. Reports of hallucinatory experiences by patients undergoing cortical electroencephalographic (EEG) recording during evaluation for epilepsy surgery have provided evidence for hallucination arising either as a consequence of seizures or electrical brain stimulation; these reports demonstrate specific anatomic-clinical correlations depending upon the location of the involved cortex ([Table 1](#)).

In addition to clinical accounts, current understanding of hallucinations has been enriched by structured experiments using functional brain imaging. This line of evidence has strengthened correlation between hallucinatory modality and the regions of the brain involved. Functional experiments using PET and functional MRI in patients actively hallucinating have outlined primary and participating regions in the generation of the hallucination.

In the following sections, the most frequent causes of hallucinatory experiences are described and defined on the basis of the proposed mechanism or underlying pathological

Table 1 Classification of hallucinations by proposed mechanism

Hallucinations arising from direct cortical activation or inhibition
1. Epilepsy
2. Migraine
Hallucinations consequent to peripheral sensory organ dysfunction
1. Charles Bonnet syndrome
2. Musical hallucinosis
3. Phantom limb syndrome
Hallucinations arising from dysfunctional subcortical processing
1. Peduncular hallucinosis
2. Hypnagogic and hypnopompic hallucinations of narcolepsy
3. Lewy body disease
4. LSD intoxication
Hallucination due to impaired reality monitoring
1. Schizophrenia and other psychiatric diseases

Proposed mechanisms for hallucinations may be well characterized or may only be theoretical. The mechanism in each case may be mixed and the hallucination is classified by the most likely mechanism to be contributing to the hallucinations.

condition. However, the mechanism of production of hallucinations is often not definitively established.

Hallucinations Due to Pathological Cortical Activation or Inhibition

Tamburini postulated that hallucinations may arise from direct activation of the cortex which was involved in processing this modality. Current evidence suggests that both pathological cortical activation and pathological cortical inhibition may generate hallucinatory experiences. The strongest evidence for this comes from intracranial EEG. In addition, functional imaging experiments in patients experiencing migraine attacks have provided evidence that cortical inhibition may generate hallucinatory experiences.

Hallucinations associated with epilepsy

Seizures may arise from any region of the cerebral cortex with some predilection for the limbic system. The modality and complexity of the hallucination which is experienced by the patient is determined by the type and amount of cortex that undergoes regional activation or regional inhibition during the course of a seizure. Elementary sensory phenomena such as hearing an auditory tone, seeing phosphenes, or feeling unilateral somatosensory paresthesias occur if a seizure arises from the primary sensory cortex. For instance, a patient may hear buzzing when seizures arise close to Heschl's gyrus of the temporal lobe and are a strong localizing feature. In addition, elementary positive visual phenomena such as simply shaped flashes and negative phenomena such as scotomas strongly localize to the occipital cortex.

Seizures arising from sensory association areas of the occipital, temporal, parietal, or frontal lobes may produce more complex hallucinatory phenomena. Seizures arising near the temporal-occipital junction may produce complex, formed visual illusions such as animals, people, and flowers as in pallinopsia; images may appear in duplicate, have altered size with macropsia and micropsia (similar to Alice in Wonderland syndrome of migraine), or autoscopia where the patient may see himself as though outside his body. Seizures arising from association areas of the temporal lobes may produce

vivid auditory hallucinations of voices, singing, or music. Complex auditory hallucinations in epilepsy tend to be stereotyped. For instance, a patient with temporal lobe epilepsy reported that she heard the song *Smoke Gets in Your Eyes* at the beginning of every seizure. This is contrary to musical hallucinosis resulting from progressive hearing loss where a large repertoire of childhood or popular songs may be heard. Vivid multimodal hallucinatory experiences resembling actual memories may be seen in patients with seizures arising from the hippocampus or other limbic areas. For instance, patients may feel that at seizure onset, they are reliving an experience from early on in life, including seeing, feeling, and hearing the events of the experience. This type of multimodal complexity is generally not seen in seizures arising from isolated association regions of the cortex and suggests that involvement of the limbic structures is likely.

Hallucinations and migraine

The hallucinations of migraine auras encompass a wide spectrum of phenomena, from simple elementary visual disturbances in the migraine scotomas to complex visual illusions. The most common elementary visual hallucination of migraine is the scintillating scotoma. Patients report bright, jagged, shimmering, and moving zigzags which start at the visual fixation point and move outward toward the periphery of one side of vision. The scotoma frequently takes the shape of a horseshoe and moves through the visual field over a period of 20 min (see [Figure 3](#)). In addition to the typical aura, a large variety of hallucinations have been reported to occur prior to a migraine headache. For instance, some patients report the feeling of a presence next to themselves, hallucinations of physical duality, or simple auditory hallucinations such as static or beeping. Rare reports of multimodal hallucinations in the visual and auditory modalities also exist. For instance, one patient reports seeing a pulsating colored ball which would ring with each movement.

A small subgroup of patients who experience the typical aura of migraine will experience more complex visual disturbances which typically start following the initial scintillating scotoma. Patients may describe complex disturbances of body perception referred to as Alice in Wonderland syndrome. In this syndrome, patients describe the sensation of their body getting larger until it fills up the entire room or their head growing to twice its size. In addition, hallucinations of little people or animals performing complex acts have been well described as an aura migraine and have been termed Lilliputian vision.

Hallucinations Secondary to Dysfunctional Subcortical Processing

Multiple lines of both clinical and experimental evidence suggest that vivid hallucinations can be generated by isolated dysfunction of specific neuronal systems located in the upper brain stem and in the thalamus. The implicated nuclei include the serotonergic nuclei of the dorsal raphe, the aminergic nucleus coeruleus, the GABAergic nuclei of substantia nigra pars reticulata, and several nuclei of the thalamus. In general, these nuclear groups project a variety of cortical and subcortical targets and have wide-ranging effects in control of state functions ([Mesulam, 2000](#)).

Figure 3 Evolution of the scintillating scotoma over time. Reproduced from Lashley KS (1941) Patterns of cerebral integration indicated by scotoma of migraine. *Archives of Neurology and Psychiatry* 46: 333. Copyright 1941.

Multiple clinically distinct yet neurophysiologically similar hallucinatory syndromes arise from postulated dysfunction of the nuclear groups in the upper brainstem. These include peduncular hallucinosis, hallucinations of narcolepsy, hallucinations of Lewy body disease (LBD), and intoxications with certain hallucinogenic substances. Why hallucination may occur with dysfunction of these nuclear groups is not clear. However, it is likely that normal thalamic function is modulated by regulatory activity of these brainstem nuclei. Altered synaptic input to the thalamus might then be postulated to cause disturbed processing of sensory information in the thalamus, leading to hallucinations. A fascinating potential explanation for well-formed hallucinations proposes that these arise from abnormal entry of the patient into a state similar to dreaming. In fact, hallucinations of peduncular hallucinosis (see below for further detail) have significant dream-like qualities, that is, they involve the entire visual field and frequently have a story associated with them.

Further experimental support for the idea that hallucinations in these disorders result from inappropriate entrance into the dream states comes from the discovery of the ponto-geniculate-occipital (PGO) waves. PGO waves are bursts of synchronous neuronal activity which start in the pons, propagate to the lateral geniculate nucleus, and then reach the striate cortex of the occipital lobe. A lesion affecting the dorsal nuclei of the raphe causes transient increase in the PGO spikes, recorded on EEG during the paradoxical sleep, and evokes potential dreams, namely, hallucinosis. These hallucinatory syndromes may occur when inhibitory control of the PGO system is suspended.

Peduncular hallucinosis

The syndrome of peduncular hallucinosis refers to the occurrence of vivid visual hallucinations in the context of an acute lesion in the midbrain or other subcortical region. It was first described by Jacques Jean Lhermitte in 1922 and was later refined by Van Bogaert in 1927. The term 'peduncular' was not intended as a reference solely to the cerebral peduncles but to the whole midbrain and its surrounds. De Morsier extended the syndrome to include thalamic lesions. The syndrome has been reported with a variety of lesions in the upper brain stem and pulvinar nucleus of the thalamus, isolated lesions of the substantia nigra pars reticulata, right paramedian

thalamic infarction, following infarction of left cerebral peduncle, and mass lesions in the posterior fossa and pineal region. In addition, a similar syndrome with lesions of the cerebellum has been reported.

Descriptions of the hallucinations experienced by patients with peduncular hallucinosis are largely limited to case reports and small case series. Benke et al. provided detailed descriptions of hallucinations in five patients diagnosed with peduncular hallucinosis. All patients had acute brainstem lesions such as stroke or hemorrhage. The hallucinations were highly complex with scenes of familiar places and people performing stereotyped behavior and encompassed the whole visual field. The hallucinations appeared realistic, with few fantastic qualities to them. Frequently, the same hallucination lasting several minutes occurred over a period of weeks. The hallucinations might become more vivid with eye closure. This is opposite to CBS in which hallucinations disappear after eye closure.

Patients with peduncular hallucinosis may have a variety of associated signs and symptoms. Neurological examination frequently reveals the presence of upper brain stem dysfunction, such as vertical eye movement abnormalities, hemiparesis, dysarthria, or ataxia. In addition, patients have frequently been reported to have difficulties with arousal and suffer significant hypersomnolence. Neuropsychological evaluation of patients with peduncular hallucinosis has revealed significant cognitive disturbances, including deficits of memory and frontal network function. It is not clear if cognitive dysfunction is necessary for the development of this syndrome or is merely an associated factor.

Hypnopompic and hypnagogic hallucinations of narcolepsy

Jean-Baptiste-Édouard Gélinau first coined the term 'narcolepsy' from Greek to mean 'seized by somnolence.' He described patients with excessive daytime sleepiness, sleep attacks, and episodes of muscle weakness triggered by emotions. Later, Gélinau added that patients with narcolepsy may report hallucinatory experiences wither while falling asleep or while waking up from sleep. Patients with narcolepsy report vivid visual, auditory, or tactile hallucinations, which occur shortly after the person feels the characteristic urge to go to sleep or when waking up. As the hallucinations start, the patient is generally aware of his surroundings and is awake. Patients report seeing vivid images or complex scenes, hearing voices, feeling a presence, or feeling someone brushing against them. EEG studies of hypnopompic hallucinations have shown that they may occur as the patient inappropriately enters rapid eye movement (REM) sleep from wakefulness or stage I sleep. The hallucinations typically occur in the first REM cycle and are characteristically absent during subsequent REM cycles later in the night. The specificity of hypnagogic and hypnopompic hallucinations for diagnosis of narcolepsy has come under scrutiny. Ohayon et al. determined that both types of hallucinations frequently occur in normal healthy adults, though hallucinations upon waking from sleep may be more specific for narcolepsy.

Hallucinations of LBD

LBD was first described by Woodard in 1962 with additional features and improved diagnostic criteria provided by McKeith

in 1992. Patients present with a history of chronic, progressive cognitive decline and have prominent deficits of working memory and visuospatial function. They then soon develop an extrapyramidal syndrome which is somewhat different from Parkinson's disease. Hallucinations are a common early feature of LBD and occur in ~80% of patients over the course of illness. Patients frequently describe vivid, nonthreatening, hallucinations, primarily visual, consisting of seeing people and animals which are usually superimposed onto a normal background of the environment. For instance, a patient may report seeing a group of children playing on the floor in his bedroom. Insight into the artificial nature of the hallucinations is frequently fully preserved.

Research into the mechanism of hallucinations in LBD generally refutes the claim that they must arise from widespread cortical atrophy or focal atrophy of the occipital regions. As summarized by Nestor, there are several lines of evidence which suggest that a cholinergic deficit is responsible for hallucinatory experiences in LBD. This is supported by the observation that visual hallucinations generally improve with cholinergic augmentation in LBD. In addition, the hypometabolism seen on PET in patients with LBD is reversed by cholinergic augmentation. This is further supported by studies of neurohistochemical markers of muscarinic receptors in patients diagnosed with LBD.

Lysergic acid diethylamide, mescaline, and psilocybin intoxication

Lysergic acid diethylamide (LSD) was first synthesized in 1938 by Albert Hofmann as a derivative from the rye fungus *Claviceps purpurea*. Its psychoactive properties were discovered in 1943 by accidental ingestion of the drug by Dr. Hoffman. LSD causes euphoria, a perceived enhanced capacity for introspection, vivid visual hallucinations, synesthesias, and alterations of thinking and time experience. The hallucinogenic action of LSD is likely secondary to specific effects of the drug on serotonergic receptors of the raphe nuclei of the midbrain and the locus coeruleus. In fact, the affinity for serotonergic receptors is a common property of other hallucinogenic substances, including mescaline and psilocybin. Mescaline occurs naturally in the peyote cactus *Lophophora williamsii*. The hallucinations experienced during the intoxication are similar to LSD. Psilocybin is produced by many species of fungi and has hallucinogenic properties similar to LSD and mescaline.

Hallucinations due to Cortical Deafferentiation

Abundant clinical evidence suggests that patients who lose the function of peripheral sensory systems, such as vision or hearing, can experience vivid hallucinations in the same modality as the sensory loss. Reports of such hallucinations date back to the 1700s with descriptions of CBS. CBS is the prototypical cortical deafferentiation syndrome which occurs in situations when afferent input of the primary visual cortex is lost, often from eye disease. Musical hallucinosis and phantom limb syndrome may have similar causes. The hallucinations experienced by patients with these symptoms suggest that if central sensory systems are deprived of adequate peripheral input, they may start to function in a semiautonomous manner.

Charles Bonnet syndrome

CBS is defined to be vivid visual hallucinations which occur in the setting of worsening vision (Fernandez et al., 1997). The Swiss naturalist Charles Bonnet first described such hallucinations in his grandfather. The visual hallucinations may not occur as part of another entity, such as LBD, although this approach has been questioned. Hallucinations have most frequently been described in the presence of macular degeneration, cytomegalovirus (CMV) retinitis, or other causes of acute and chronically progressive blindness. The hallucinations have most frequently been described in adults, but it is likely that the full syndrome can occur at any age, including childhood. Patients report vivid and well-formed images of people which occur in the setting of poor lighting. The hallucinations are nonthreatening, are exclusively in the visual modality, and they characteristically disappear upon eye closure.

Functional imaging studies done on patients with CBS demonstrate that during the course of the hallucination, the primary visual cortex is in fact not active. During the hallucination, visual association areas which lie downstream from the primary visual cortex demonstrate BOLD signal activation on functional MRI. Areas include the lateral temporal cortex, striatum, and thalamus. Further functional MRI experiments in patients with CBS found activation in areas corresponding to the content of the hallucination. Patients who hallucinated in color activated the V4 color area of the cortex, and patients who hallucinated in black and white did not.

Treatment of CBS focuses on improvement of lighting in the residence of the person. A variety of antiepileptic and antipsychotic medications have been tried with variable efficacy (usually lacking effect) in CBS.

Musical hallucinosis

Exclusively auditory musical hallucinations in the absence of psychiatric disease have been described since the 1950s (Ross, 1978). Patients typically report hearing loud and well-formed instrumental music with or without singing. The music is typically something they know well from childhood. Berrios found that ~70% of cases of musical hallucinosis are associated with hearing loss and typically occur in the presence of otosclerosis. The syndrome has also been reported following traumatic brain injury, brain stem strokes, and epilepsy. The neural mechanism of musical hallucinosis, at least in cases of peripheral hearing loss, may be similar to the visual hallucinosis of CBS and includes autologous activation of downstream association areas. The syndrome occurs with static lesions of the temporal lobes and may also occur in the course of temporal lobe epilepsy, which in the authors' experience at times produces tunes that cannot be readily identified by the patient. Treatment usually is aimed at removal of the underlying cause. Use of hearing aids and cochlear implants has been associated with decrease of musical hallucinosis when peripheral hearing loss underlies the condition, and neuroleptics usually fail in this circumstance. Attempts at treatment using an antiepileptic typically fail if the auditory hallucinations are not produced by seizures.

Phantom limb syndrome

In 1872, Weir Mitchell reported that a patient may continue to feel the presence of the limb after it has been amputated. Amputation of other body parts, such as the nose or genitals, may also

produce similar sensations. Following an amputation, the patient reports a conscious presence of the limb, which he may be able to move at will. Often, the limb is stuck in an awkward position or is dramatically misshapen, being the wrong length or thickness. The phantom limb may be painful with burning, aching, prickling, or crushing sensations.

A variety of peripheral and central neural mechanisms have been proposed to explain the appearance of phantom limbs. Initially, the syndrome was thought to arise peripherally from enlargements of nerve stubs which grew at the site of the amputation. However, removal of these seldom produced significant relief from phantom limb pain and did not affect perception of the limb. Other largely unsuccessful methods for eliminating the pain of phantom limbs included injection of procaine into stump, dorsal rhizotomy, and spinal anesthesia.

More recently, central causes of phantom limb syndrome have been proposed, based on clinical observations of patients following limb amputations. Ramachandran et al. recognized that full somatotopic representations of the amputated extremity may exist on the face ipsilateral to the amputation. Stimulation of the face produced modality-specific sensations on the phantom limb of the patient. Subsequent studies of patients with upper extremity amputation using MEG functional mapping showed that sensory stimulation of the face produced activation in the primary sensory cortex of the hand. From the aforementioned experiments, it seems that phantom limbs may be generated by activation of peripheral somatosensory endings of the face which activate regions of the primary sensory cortex, which previously was attributed to the hand. He further demonstrated that use of a mirror box, which provides the patient with the perception of the missing limb, can alleviate phantom limb pain, further supporting the concept that a disturbance of central mechanisms of perception generates the symptoms. The phantom limb syndrome therefore shares fundamentally similar features with CBS. How the mechanism of reorganization occurs, and the extent to which the thalamus and cortex interact, is not known, though clinical features suggest the importance of the cortex in these syndromes.

Hallucinations Due to Deficits Top-Down Processing in the Idiopathic Psychiatric Disorders

Clinical phenomenology of hallucinations in idiopathic psychiatric disorders has been well studied. Hallucinations characteristically occur in schizophrenia, but are also common in major depression, bipolar disorder, and schizoaffective disorder. Auditory hallucinations occur in 60% of patients with schizophrenia; visual, olfactory, and somatosensory hallucinations likewise occur but are far less prominent. Patients with schizophrenia may describe hearing a clear voice like a tape playing in their head. Frequently, these take the form of conversations between people. The voices may issue commands, compliments, or insults addressed to the person. Schizophrenics often lack control over the voices and feel powerless to stop them. Sometimes, they may exert full control over the voices and can summon or quiet them at will.

Hallucinations experienced in psychiatric disorders may have several characteristics that distinguish them from hallucinations that appear in neurologic disease. Strong emotional reactions to hallucinations are common when they occur in

neurologic diseases. For instance, patients with peduncular hallucinosis often fear the hallucinatory experience but rarely report strong emotional content in the hallucination itself. Conversely, strong emotional content is frequent in hallucinations caused by psychiatric disorders. For instance, voices that criticize and threaten are common in schizophrenia (see Table 2). In addition, the content of hallucinations in psychiatric disease may be influenced by the personal ideas, preferences, or previous experiences of the patient. For instance, hallucinations associated with posttraumatic stress disorder may include the vivid experience of reliving the trauma. In contrast, hallucinations in neurological disease are generally not influenced by past experience, personality characteristics, or expectations of the patient.

Although hallucinations in psychiatric disease have been well characterized, the neural mechanisms underlying their formation remain poorly understood. Among the more influential cognitive models is the concept that psychiatric disease alters a patient's ability to distinguish between internally and externally generated events; it creates deficits in reality monitoring. Internally generated events include imagination and reasoning, whereas externally generated events are limited to the perceptual process. The model therefore suggests that patients with schizophrenia have hallucinations because they incorrectly perceive internally generated ideas as externally occurring perceptions. Neuroimaging studies provide some support for this model. For instance, hallucinations in schizophrenia are associated with inappropriate activation of the anterior cingulate region of the frontal lobe; this area is important for distinguishing between internally generated thoughts and externally generated percepts. Other imaging studies in patients with schizophrenia show a decrease in the size of the superior temporal gyrus, cerebellum, insula, temporal pole, and the thalamus, though how these might influence propensity for hallucinations is unclear. Functional imaging studies find superior temporal gyrus activation during the presence of auditory hallucination. Successful treatment with antipsychotic agents that block dopamine receptors in basal ganglia provides another anatomic locus that plays a role in generating

Table 2 Hallucinations and clinical disorders: dominating modality, emotional content of hallucinations, and emotional reaction

<i>Disorder</i>	<i>Dominant modality</i>	<i>Emotional content</i>	<i>Emotional reaction</i>
Schizophrenia	Auditory, visual	Yes	Yes
Affective disorders	Auditory, visual	Yes	Yes
Posttraumatic stress disorder	Auditory, visual	Yes	Yes
Postpartum psychosis	Auditory	Yes	Yes
Borderline personality disorder	Auditory	Yes	Yes
Lewy body disease	Visual	No	Possible
Parkinson disease	Visual	No	No
Alzheimer's disease	Visual	No	No
Charles Bonnet syndrome	Visual	No	Possible

hallucinations. A clear cognitive model of hallucinations in psychiatric disease still needs to be elucidated.

Conclusion

Hallucinatory experiences have been woven into the fabric of history and have provided the impetus for brain research. Present understanding of the mechanisms comes from several sources: clinical description with neuroanatomical correlations from MRI, clinical descriptions correlated with EEG, functional imaging during the experience of hallucinations, and assessment of functional consequences of therapy. These have provided at least four distinct mechanisms of generation of hallucinations: cortical deafferentiation, direct cortical stimulation or inhibition, subcortical release, and top-down dysfunction. Despite these observations, no single neuroanatomical model likely explains the whole spectrum of hallucinatory experiences. The approach to a patient who is experiencing hallucinations should include detailed history of time of onset, spectrum, modality type, and inciting phenomena. Examination of a patient should focus on cognitive testing, examination of peripheral sensory organs such as eye and ear, and a history of psychiatric disease. The patient should get structural imaging such as an MRI, and an EEG if seizures are suspected. Treatment depends on the syndrome in which the hallucinations appear and ranges from dopamine antagonism,

cholinergic augmentation, antiepileptic medication, or modulation of the function of preserved sensory organs.

Handedness

S D Christman, University of Toledo, Toledo, OH, USA

© 2012 Elsevier Inc. All rights reserved.

Glossary

Ambidexterity The ability to use both hands equally well; can take two forms: doing 50% of things with the left hand and 50% with the right, or doing all things equally well with either hand.

Aphasia Disordered processing of grammatical and/or semantic aspect of speech and language after left hemisphere damage.

Carotid artery (left and right) Large blood vessels that form the brain's principal blood supply.

Corpus callosum A brain structure consisting of hundreds of millions of nerve fibers (axons) that serves as

the primary connection between the left and right cerebral hemispheres.

Episodic memory Our memory for specific episodes from our lives, as opposed to semantic memory (our general world knowledge).

Median The middle value in a series of data points; the value for which 50% of the data points are larger and 50% are smaller.

Testosterone A hormone responsible for the development of masculine traits, in contrast to estrogen, a feminizing hormone.

Historical and Sociological Overview

The term 'handedness' in psychology refers to the related facts that (a) humans generally display a preference for the use of one hand over the other when performing tasks that require agility and fine motor control and (b) the majority of humans specifically display a right-hand preference. This right-handed predominance has been part of our species' nature for a long time, as evidence from ancient tools and drawings suggests that the majority of humans have been right-handed for at least the past 100 000 years.

Although the left and right hands of humans are anatomically equivalent, human societies have long noted (and puzzled over) the fact that roughly 90% of all humans exhibit a preference, particularly when writing, for the right hand, with only about 10% preferring the use of the left hand. The exact proportion of left-handedness remains a matter of dispute, with estimates based on North American and European samples ranging from 8% to 15%, with males being slightly more likely to be left-handed. In contrast, many non-Western cultures appear to have lower rates of left-handedness ranging from 2% to 8%. However, this applies only to left-handedness for the socially relevant activities of writing and eating. Evidence suggests that when less socially relevant activities, such as throwing a ball or combing hair, are examined, the rates of left-handedness in non-Western societies approach those found in the West.

The right-handed majorities' reaction to the left-handed minority has ranged from the negative to the positive. Aristotle thought that left-handedness and ambidexterity posed a serious problem for the prevailing view of his time on the inherent superiority of the right side of the body. In contrast, the Bible speaks approvingly of the 700 left-handed sling shooters from the tribe of Benjamin, who were renowned for their accuracy; on the other hand, the Bible also states that sinners on the Day of Judgment will sit at the Lord's left hand before being cast into everlasting fire (while the righteous await at the Lord's right hand). In total, negative associations of left-handedness outweigh positive ones.

This prejudice against the left hand (and left-handers) extends beyond the Judeo-Christian tradition. In Buddhism, the path to Nirvana forks, with the left-hand path representing the wrong way of life. In Hinduism, the right hand is used for many civil and reverent activities, including eating, giving, receiving, and worshipful offering. In Islam, ritual washing of the hands involves pleas that, on the Day of Judgment, the book of one's actions in life be placed on the right hand, representing salvation, not the left hand, which represents damnation. Among Gypsies, it is believed that if your right palm itches, you will receive money, while if your left palm itches, you will lose money. In many African cultures, twitching of the right eye signifies that something pleasant is about to happen, while left eye twitching may foretell a death in the family. In Morocco and among Eskimos, left-handers are viewed as potential sorcerers or cursed persons. The list is virtually endless.

This bias against the left hand is amply reflected in human languages. The English word *left* derives from the Anglo-Saxon term *lyft*, meaning 'weak' or 'broken.' The French word for left, *gauche*, means 'awkward' or 'tactless' in English. The German word for left is *linkisch*, which also means 'clumsy.' The Spanish word for left, *zurdo*, is used in phrases like *no ser zurdo*, meaning 'to be very clever' but is literally translated as 'not to be left-handed.' The Italian word for left, *mancino*, also means 'dishonest.' Finally, the English word *sinister* comes directly from the Latin term for 'left,' *sinister*, while the English word *dexterity* derives from the Latin term for 'right,' *dexter*.

The late nineteenth century saw the rise of an ambidexterity movement that encouraged people to become proficient with both hands, yet standard educational practices in the early and mid-twentieth century advised teachers to strongly discourage left-hand use among schoolchildren. Not surprisingly, the actual nature of human handedness is more complicated and nuanced than any simple view that 'left-handedness is good' or 'left-handedness is bad.'

Given the anatomical similarity between the left and right hands, the human tendency toward right-handedness does not

reside in or arise from the hands themselves. For millennia, human societies viewed right-handedness as essentially a moral choice: since most people are right-handed (e.g., because of what sacred traditions prescribe), everybody should choose to be right-handed.

It is worth noting that this bias against the left may have more to do with the left hand of right-handers than it did with left-handers themselves. As is discussed below, research into manual skill and dexterity shows that the left and right hands of left-handers perform at comparable levels as the right hand of right-handers: it is the right-handers' left hands that turn out to be weaker and slower and are the 'odd hand out.' Presumably, right-handers assumed that everybody had weaker left hands, leading them to wonder why anybody would choose to use their left hands.

Not surprisingly, the right-handed predominance in human hand use has led to systematic biases favoring the right hand in our environment and tools: most buttons and controls are on the right side of objects, virtually all scissors and can openers are designed for right-hand use, and so on. This is not necessarily that big a problem, however, because, as just mentioned, left-handers are generally better at using their right hands than right-handers are at using their left (right-handers would likely have problems, however, if confronted with a world full of left-handed tools).

Interestingly, there is one common tool that has been specifically designed to favor the left hand over the right hand: the typing keyboard. In the early days of mechanical typewriters, typing at too fast a rate would cause the typewriter to jam up and stop working. As a result, the layout of the keyboard (the so-called QWERTY keyboard, named after the initial set of letters on the top row) was set up so that the most common letters (e.g., 'E,' 'R,' 'S') were put on the left side of the keyboard in an intentional effort to slow down the typing of the right-handed majority. A more efficient keyboard layout (at least for right-handers), the DVORAK layout, has been shown to significantly increase typing speeds for right-handers, but has been unable to overcome the preexisting dominance and popularity of the QWERTY layout.

Another common object that, while originally designed to favor the right hand, has ended up possibly favoring the left hand is the guitar. When the guitar was first developed, guitars were tuned to an open chord, meaning that the left hand's role consisted primarily of fretting one string at a time to create the melody. The more demanding job of finger picking was given to the right hand. As the guitar evolved, however, the left-hand role became more challenging (e.g., fingering chords that required three or four strings to be fretted) while the right hand's role typically switched to strumming, a task requiring less dexterity than finger picking. It has thus been suggested that what is currently called a 'right-handed' guitar may be better characterized as a left-handed guitar, and vice versa. This line of reasoning has been applied to the guitar-playing talent of Jimi Hendrix, a right-hander who plays a left-handed guitar.

Early Research on Handedness

The modern era of handedness research can be dated back to the French physician Paul Broca's landmark 1865 paper on the

localization of language in the brain, showing a link between damage to the left hemisphere and aphasia. Although Broca originally set out to simply demonstrate that language functions were localized to the frontal lobes of the brain, he and his contemporaries were surprised to learn that language was lateralized to the *left* frontal lobe in particular. This finding that the brain was not characterized by the same bilateral symmetry found in other paired organs of the body (e.g., lungs, kidneys, eyes, etc.) helped shed light on the nature of handedness: since the left hemisphere of the brain (a) is in charge of language and (b) controls the *right* side of the body, then it made sense that humans would be right-hand dominant for writing. It was thus reasoned that left-handedness was associated with right hemisphere dominance for language. Broca's findings presented one of the first hints that handedness may not be a simple personal choice, but instead may be grounded in human physiology.

The prevailing assumption at the time was that left-handers were mirror images of right-handers, such that left-handedness was presumed to be associated with *right* hemisphere localization of language. In turn, this led to a widespread view of left-handedness being somehow pathological and/or inferior, since left-handers had language in the 'wrong' side of the brain. Much of the research on handedness during the first half of the twentieth century tested claims that left-handedness was associated with various negative conditions, such as low IQ, neurosis, speech defects, psychopathology, bed wetting, and poor muscular coordination. As a result, it was common educational practice to force left-handers to learn to use their right hand for writing, in the belief that this would benefit their educational development. As it turned out, evidence began emerging showing that forcing schoolchildren to switch from left-handed to right-handed writing led to an *increased* risk for developing various learning disabilities. As a result, the practice of forced switching of writing hand has gradually disappeared.

Another important focus of research on handedness during the first half of the twentieth century was the measurement and classification of handedness. One of the most important insights to emerge was that the hand preferences of left-handers differed markedly from those of right-handers. For example, while most right-handers prefer their right hand for most everyday activities, left-handers display a much more variable pattern of hand preference, being more likely than right-handers to use their nondominant hand for various activities. More generally, strong and consistent hand preferences are more likely to be found for skilled activities (e.g., writing, eating) than unskilled activities (e.g., grip strength, picking up objects).

Of particular importance were studies of language lateralization in left- versus right-handers. The development of a new technique, the Wada Test, provided conclusive determination of which side of the brain contained language areas by allowing researchers to put one or the other side of the brain to sleep (via injection of an anesthetic into the left or right carotid artery) and then testing the language capacity of the remaining hemisphere. This research confirmed what had been assumed about right-handers: 96% had language solely in the left hemisphere (the remaining 4% had right hemisphere language). The picture for left-handers was somewhat surprising, as the majority of left-handers (70%) also had language solely in the

left hemisphere. However, left-handers were more likely than right-handers to have right hemisphere language (15%) or language in both sides of the brain (15%). This confirmed the growing realization that left-handers were not simply mirror images of right-handers. Instead, a new view began emerging: brain asymmetry was roughly similar in left- and right-handers, but was more variable in left-handers.

An interesting foreshadowing of a new approach to handedness that is described at the end of this article can be found in related research which argues that the relation between left-handedness and language lateralization was qualified by variations in the strength of left-handers: pure left-handers were thought to be more likely to have right hemisphere language, while language in both hemispheres was thought to be associated with left-handers whose overall hand preference was mixed (e.g., they used their nondominant hand for at least a few activities). At the very least, it had become clear that the relationship between hand dominance and language lateralization was not a straightforward one.

Modern Research on Handedness

Behavioral and Physiological Research

Interest in handedness saw a marked increase in the 1960s as a result of Roger Sperry's groundbreaking (and Nobel Prize winning) work on the so-called 'split-brain' patients, who had their corpus callosum surgically severed to control the spread of epileptic seizures. While Sperry's own research primarily focused on differences between the left and right hemispheres, it sparked renewed interest in the differences between left- and right-handers.

As mentioned above, early research assumed that left-versus right-handers were right- versus left-hemisphere dominant, respectively. Accordingly, right-handers were thought to be better at left-hemisphere functions such as language and logical thinking, while left-handers were thought to excel at right-hemisphere functions such as spatial processing and intuition. This notion is reflected in the bumper sticker slogan: "If the left brain controls the right side of the body and the right brain controls the left side of the body, then only left-handers are in their right mind." In hindsight, this research was flawed because of incorrect understandings of both the relationship of handedness with cerebral dominance and the precise nature of what mental functions the left versus right hemispheres are specialized for.

By the 1980s, a more nuanced view of handedness began emerging, featuring three new developments. First and foremost, it started becoming clear that the vast majority of humans, left- and right-handed, have left-hemisphere dominance for speech and language functions. Although the majority of left-handers do have left-hemisphere dominance for language, a sizable minority of left-, but not right-, handers have either right hemisphere language or have language functions represented in *both* sides of the brain. It is worth noting that left-handedness is associated with a slightly increased risk of stuttering, which in turn is thought to be associated with having speech ability in both sides of the brain: we have a single mouth, so when both sides of the brain are trying to talk at the same time, there can be interference if the two sides of the brain are not working together.

Second, the notion that left-handers are 'right-brained' was replaced by the idea that the majority of all humans, regardless of handedness, have the same functions lateralized to the left and right hemispheres, but the brains of right-handers are more strongly lateralized. That is, the division of labor between the two sides of the brain in right-handers is relatively 'all-or-none,' while in left-handers it is 'most-or-some.' For example, a common method to determine which side of the brain handles which types of tasks is to present information to a single side of the brain. This can be accomplished by presenting that information to the left versus right visual fields or the left versus right ears, which project to the right versus left hemispheres, respectively. Such studies show, for example, that while just about everyone shows right visual field advantages and right ear advantages for linguistic materials, the size of these advantages is significantly larger in right-handers. In other words, the brains of right-handers are more lateralized than those of left-handers.

A nice example of this principle can be found in studies of fine motor control. In general, the left hemisphere is better at fine motor control than the right. Thus, right-handers are much better at tasks requiring fine motor control (such as speeded finger tapping or placing small pegs into small holes) when using their right hand than when using their left hand. Left-handers, in contrast, show much smaller differences between left- and right-hand performance, as fine motor control is more evenly distributed across both hemispheres. Thus, as mentioned earlier, it is the left hands of right-handers, not left-handers themselves, that are relatively weak and clumsy.

The third new development involved a rethinking of exactly how the two sides of the brain differed in their functions. Through the 1970s, the prevailing view was that most types of tasks and stimuli were always handled by one hemisphere; for example, all verbal tasks were presumed to be processed exclusively by the left hemisphere and all visuospatial tasks exclusively by the right hemisphere. This has been replaced by a componential approach, emphasizing that both sides of the brain work together in dealing with most tasks and stimuli, dividing up the labor so that one hemisphere handles some components of the task and the other hemisphere handles the remaining components. To illustrate, in the verbal domain, when we are listening to another person talk, the left hemisphere processes the phonology (i.e., specific speech sounds), while the right hemisphere processes the prosody (i.e., the varying intonation of speech that carries emotional information). Similarly, in the visuospatial domain, the left hemisphere processes the 'trees' (i.e., local details) and the right hemisphere processes the 'forest' (i.e., the global configuration).

These developments led to a switch from the prior emphasis on 'cerebral dominance' (e.g., each side of the brain being dominant for different tasks) to a new emphasis on inter-hemispheric interaction (e.g., how the two sides of the brain divide up the labor of ongoing tasks). There was also emerging evidence that the corpus callosum, the bundle of nerve fibers that constitutes the primary connection between the left and right cerebral hemispheres, is larger in non-right-handers. Taken together, this suggested that left-handers may exhibit greater amounts of interhemispheric interaction than right-handers, a theme that is revisited in the final section of this article.

In conclusion, brain asymmetry in left-handers is more variable in both magnitude and direction than in right-handers. Interestingly, this increased variability in left-handers is mirrored in other domains. For example, while there are no overall differences in intelligence with respect to handedness, left-handedness is associated with increased variability in intelligence: left-handedness is overrepresented among both mentally impaired and mentally gifted populations.

Development and Genetics of Handedness

The exact origins of right- versus left-handedness, both in terms of the evolution of our species and the development of the individual, remain somewhat mysterious. From an evolutionary standpoint, many conjectures have been offered. From a male-based perspective, it has been argued that our species became right-handed because of the practice of carrying shields in the left hand (to protect our left-sided hearts), thus freeing the right hand to become specialized in the fine motor control required by weapon use. From a female-based perspective, it has been argued that we became right-handed because of the practice of mothers carrying their babies in their left hand (to keep the baby close to the comforting sound of the mother's left-sided heart), thus freeing the right hand to become specialized in the fine motor control required by foraging for food. Others have argued that the fact of right-handedness was arbitrary; what was important was that, for the purposes of efficiency when working together in groups, we all used the same hand (think of a left-handed violinist in the string section of an orchestra) and it just happened to end up being the right hand.

While the precise evolutionary history of handedness remains unknown, perhaps the most plausible account is based on the notion that our earliest ancestors may initially have been right hemisphere (and left hand) dominant for basic communication and postural control functions. As our ancestors started developing linguistic and tool-making ability, the previously underused left hemisphere was 'available' and hence language and fine motor control functions ended up being lateralized to the left side of our brains.

A little more is known about the development of handedness within an individual. First and foremost, it is clear that handedness has a hereditary basis, as it does tend to run in families. That said, handedness does not appear to have the simple genetic basis that traits such as hair and eye color have. For example, 20–25% of identical twins are discordant for handedness (i.e., one is left-handed and the other is right-handed). Intriguingly, modern genetic models of handedness get around this puzzle by arguing that there is no gene for left-handedness *per se*.

Rather, such models argue for a genetic spectrum ranging from strong right-handedness to random or mixed-handedness. It is assumed that there is a gene that predisposes us to be right-handed (the so-called 'right shift' gene). If we get two copies of that gene, we will be strongly right-handed. If we get only one copy, we will be weakly to moderately right-handed. And if we get no copies of that gene, our handedness will be the random outcome of chance environmental factors, with about half of people with no copies of that gene ending up right-handed and the other half ending up left-handed.

Specifically, this model suggests that about 25% of the human population lacks both copies of the right shift gene; hence, roughly 12.5% of these individuals will end up being right-handed and about 12.5% being left-handed, very close to the actual population percentages. This model suggests that the optimal pattern involves inheriting a single copy of the right shift gene. People with both copies may end up being so left hemisphere and right-hand dominant that they experience difficulties with right hemisphere nonverbal functions and left-hand use, while people with zero copies may end up with insufficient left hemisphere-based verbal abilities.

Other nongenetic bases for handedness have also been proposed. First, there appears to be an association between left-handedness and birth trauma and stress. The idea is that birth complications, such as hypoxia (reduced oxygen to the brain), can lead to left hemisphere damage and hence non-right-handedness. Moreover, this model suggests that a predisposition to birth complications may be genetic, thus accounting for the heritability of left-handedness. While birth stress may indeed be a factor in left-handedness, it cannot be the whole story, as many left-handers have no history whatsoever of birth trauma or stress.

Another potential, nongenetic cause of left-handedness involves the effects of testosterone on fetal development. A curious association between left-handedness, autoimmune disorders (e.g., allergies, eczema, asthma, Crohn's Disease) and pigmentation anomalies (e.g., albinism, premature graying, blond hair) has been explained by the effects of testosterone on the fetal development of the neural crest, an embryological feature that eventually matures into the central nervous system, the pigmented cells of the body, and important components of the immune system. It has been proposed that increased exposure to (and/or increased sensitivity to) testosterone slows the development of the left hemisphere, allowing the right hemisphere to become more dominant and thereby increasing the likelihood of left-handedness.

These three accounts (genetic, birth stress, testosterone) are not necessarily mutually exclusive. For example, perhaps what runs in families is not a handedness gene, but a genetic predisposition to increased exposure to testosterone, which then leads to left-handedness. Similarly, increased fetal exposure to testosterone in females can result in masculine characteristics such as slimmer hips, which in turn could be a factor in producing birth stress. It is quite possible that all three accounts have merit, and human handedness is the result of a complex interaction between genetic, environmental, and hormonal factors.

Measurement of Handedness

A few words are in order concerning the measurement and classification of handedness. Because humans vary in both direction (left vs. right) and degree (strong vs. mixed) of handedness, defining handedness solely in terms of 'the writing hand' is insufficient. A better inventory of hand use and preference is required. The most commonly used measure of handedness in contemporary research is the Edinburgh Handedness Inventory. It asks about hand use for ten common activities: writing, drawing, throwing, using a spoon, using a knife without a fork, using scissors, opening a jar, brushing teeth, upper hand on a

broom, and lighting a match. For each activity, there are five possible responses: always left, usually left, no preference, usually right, and always right (worth -10 , -5 , 0 , $+5$, and $+10$ points, respectively). Total scores range from -100 (indicating pure left-handedness) to $+100$ (pure right-handedness).

This measure allows one to classify handedness in terms of both direction and degree. In terms of direction, positive versus negative scores reflect left- versus right-handedness, respectively. In terms of degree of handedness, the picture is a bit more complicated, as there is no obvious criterion for distinguishing between strong- and mixed-handedness. However, current convention uses a median split: at the population level, about half of all humans score above 80 (indicating a right-hand preference for all ten activities, leading to classification as strong-handed) and the other half score 80 or below (indicating that they use their nondominant hand for at least one activity, leading to classification as mixed-handers). This distinction between strong- versus mixed-handedness, instead of the usual right- versus left-handedness, is discussed further below. The frequency distribution of handedness scores for a large sample is shown in Figure 1.

Another way to measure handedness involves the use of performance-based tasks, instead of simple self-report. Tasks requiring fine motor control (such as the pegboard task described earlier) are typically used. Although performance-based measures yield the same overall picture (e.g., most humans are better with their right hand), performance and self-report measure do not always agree entirely with one another. The reasons for this discrepancy remains unclear, although it does suggest that hand preference reflects a complex interaction between innate, physiological hand differences and various social, personal, and environmental factors.

Figure 1 Frequency distribution of handedness scores for a large sample.

Handedness and Other Lateral Preferences

In addition to showing systematic hand preferences, humans are also characterized by related preferences for foot, eye, and ear use. Foot preference refers to the foot used for tasks such as kicking a ball or trying to pick up a small object with the toes. Eye preference refers to the eye used for things like sighting down a telescope. Ear preference refers to the ear used for listening to a phone or pressing an ear against a watch to hear its ticking. Research indicates that all four preferences (hand, foot, eye, and ear) are positively correlated: right-handers are more likely to be right-footed, right-eyed, and right-eared. The strongest relation is between handedness and footedness. However, none of these correlations are very strong, as it is quite common to find instances of crossed dominance (e.g., being right-handed but left-eyed). There is a suggestion in the research literature that crossed dominance for hand and eye may be associated with various psychological disorders and cognitive impairments; however, the evidence for this association remains weak at best.

Handedness in Nonhumans

No overview of handedness would be complete without at least a brief consideration of handedness and lateral preferences in nonhuman species. While individual animals often display strong and consistent preferences for use of one side of the body over the other, it is rare to find population-level asymmetries comparable to human's overall right-hand preference. When such population-level asymmetries are observed, they can involve either left- or right-sided preferences: for instance, parrots are left-footed for manipulating objects, some species of bears are left-pawed for killing prey, and blue gourami fish are left-finned for initiating social contacts, while rats are right-pawed for food reaching, the common European toad is right-footed for various manual activities, and many birds are right-eyed for looking for food and use their right foot to initiate ground scratching while looking for food. Interestingly, pawedness in dogs and cats is dependent on sex: male dogs and cats tend to be left-pawed, while females tend to be right-pawed, suggestively echoing the increased left-hand preference among human males.

Handedness in nonhuman primates is most likely to be directly related to human handedness. Studies of chimpanzees indicate that they possess a similar pattern of hand preferences to humans, using their left hands for reaching and catching and their right hands for tasks requiring finer motor control such as throwing and gesturing. However, these preferences are not as strong at the population level as those in humans, as the ratio of right- to left-handedness in chimpanzees is about 2:1 or 3:1, compared to the 8:1 or 9:1 ratio found in humans.

Animal research allows the running of genetic breeding studies that would be unethical in humans. A landmark study involved an attempt to breed for a right-pawed strain of mice. Although individual mice typically display strong paw preferences, there is no population-level paw preference (half prefer the left paw and half the right). Hypothesizing that perhaps mice had never encountered an evolutionary pressure favoring right-pawedness, researchers set about trying to breed for a

right-pawed strain of mice. For multiple generations, the most strongly right-pawed mice were bred together, the most strongly left-pawed mice were bred together, and the mice without clear paw preferences were bred together. In the end, this attempt was a failure: even when breeding two strongly right-pawed mice, whose parents, grandparents, great grandparents, etc. had all been strongly right-pawed, their litter of baby mice were equally divided between being left- and right-pawed. Unexpectedly, however, all the baby mice were strongly pawed (left or right). The researchers had inadvertently discovered that while direction (left vs. right) of paw preference was not heritable, degree (strong vs. mixed) of preference was heritable. By the end of the experiment, they had established two distinct genetic strains of mice: one was very strongly pawed (half left and half right), while the other strain consisted of mice with weaker and more balanced paw preferences.

A New Approach to Handedness: Degree, Not Direction

Findings such as those from the breeding study just discussed have prompted a new approach to the classification of handedness. In contrast to the traditional approach of comparing left- versus right-handers, a growing body of evidence suggests that degree of handedness (e.g., having a *strong* preference for use of a single hand vs. having a *mixed* pattern of hand preferences) may be a more powerful and appropriate way of approaching the nature of handedness.

Rather than the usual classification of ~90% right-handed and ~10% left-handed, this approach argues that ~50% of humans display a strong and consistent preference for the same hand across most activities, while the other 50% display a mixed-hand preference. As mentioned above, the median score on the Edinburgh Handedness Inventory is 80: scores above 80 indicate that a person uses the dominant hand for all ten activities listed on the inventory, while scores below 80 indicate use of the nondominant hand for at least one activity. In other words, 'mixed-handedness' does not refer to ambidexterity, but simply to the use of the nondominant hand for at least one or two things.

This new way of classifying handedness helps address a number of lingering puzzles about handedness. First, it explains an evolutionary mystery: given that left-handedness does not appear to be either beneficial or deleterious relative to right-handedness, the proportion of left- and right-handers should gradually drift toward a 50–50 equilibrium, instead of remaining at the stable 90–10 ratio. The strong versus mixed approach is more consistent with a stable and balanced equilibrium. Second, it maps more directly onto the existing genetic models which postulate a continuum between random (mixed) handedness versus strong right-handedness, not left- versus right-handedness. Third, it maps more directly onto studies in both humans and non-humans showing that *degree* of laterality, but not *direction* of laterality, is heritable.

From a theoretical perspective, this new approach to handedness focuses on interhemispheric interaction and, specifically, functional access to right hemisphere processing: given the evidence described above that stronger degrees of

handedness are associated with a smaller corpus callosum size, it is assumed that strong right-handers have decreased access to right hemisphere processes. For example, the right hemisphere is responsible for the retrieval of episodic memories, and strong right-handers perform more poorly than mixed-handers when remembering both real-world and lab-based memories. Strong right-handers are also more prone to false memories. Similarly, the right hemisphere is responsible for accurate representations of our body image, and strong right-handers are more prone to significant distortions of their body image. Also, the right hemisphere is responsible for the updating of currently held beliefs in response to new information, and strong right-handers are less open to persuasion. Finally, the right hemisphere is involved in divergent thinking, an important component of creativity, and mixed-handers are better at divergent thinking.

Importantly, in the majority of these studies, strongly left-handed people tend to be more similar to strongly right-handed people than either are to mixed-handers. Accordingly, these studies routinely fail to find differences between left- and right-handers; the handedness differences are confined to mixed–strong comparisons. That said, the totality of the evidence currently indicates the existence of three distinct handedness groups: strong left, mixed, and strong right.

Summary

Along with sex and age, handedness constitutes one of the primary biological dimensions of human individual differences. And just as most human societies display various prejudices and biases concerning sex and age, handedness, and specifically the left hand and left-handers, has also been the subject of many biased beliefs.

Research into the traditional classification of left- versus right-handedness has shown that left-handers are not the mirror image of right-handers; rather, all humans possess the same basic pattern of brain asymmetry, but that asymmetry is more variable in left-handers. Although handedness clearly has a hereditary basis, there is no evidence for a 'left-handed' gene per se; rather, genes appear to simply code for strength of right-handedness. Birth stress and hormonal factors have also been implicated in the development of left-handedness.

Lateral preferences for use of one side of the body over the other have been found in many nonhuman species. However, the strengths of such preferences at the population level are rarely as strong as those seen in humans. Hand preferences in Great Apes appear to be closely analogous to those found in humans.

Recently, there has been a growing shift from thinking about handedness in terms of direction (left vs. right) to thinking in terms of degree (mixed vs. strong). About half of all humans have strong handedness, using the same hand for virtually all skilled activities, while the other half uses their nondominant hand for at least one or two activities. Mixed-handedness is associated with increased access to right hemisphere processing, and has been shown to be associated with, among other things, superior memory, more accurate body image, and increased tendency to update beliefs.

Hippocampal Formation

H J Spiers, University College London, London, UK

© 2012 Elsevier Inc. All rights reserved.

Glossary

Action potential A nerve impulse, comprising a brief rising and falling of a cell's membrane potential.

Episodic memory Memory for events and episodes that were personally experienced.

Local field potential Local voltage changes in a brain region due to the combined electrical effects of a synchronously active population of neurons.

Medial Toward the midline of the brain.

Neurogenesis The birth of new neurons.

Pyramidal cell The main excitatory cell type in the neocortex and hippocampal formation, the cell bodies of which appear pyramidal in shape.

Introduction

The undulating, twisted, interlocking brain structure called the hippocampal formation has fascinated anatomists from the dawn of dissection in ancient Egypt. Over the centuries, its physical appearance has been likened to seahorses, silkworms, and the horns of a ram. The seahorse stuck, and we know it today from the Latin for seahorse: hippocampus. The hippocampal formation is composed of the hippocampus, subicular complex, and entorhinal cortex. It is unparalleled in terms of its unique circuitry and physiology. Housed within it are some of the most morphologically spectacular cells in the brain. Decoding their activity patterns has opened a window into some of the brain's fundamental operating characteristics and uncovered the existence of a map and compass within the brain. Unlike most of the brain, new neurons are born within it during adulthood, which must strive to integrate themselves into an intricate network of existing cells. With the discovery of dense amnesia following the surgical removal of the hippocampal formation in the famous patient HM, this brain region has been firmly wedded to memory. But just what 'type' of memory it supports and how it functions remains contentious. This article aims to distil the key concepts surrounding the hippocampal formation into a digestible form and provide a brief overview of its anatomy, physiology, pathology, and theorized functions.

A Seahorse in the Brain: Anatomy

Like many of the world's international borders, the borders of the hippocampal formation are disputed. One view, adopted in this article, is that the hippocampal formation is composed of six regions. These are the hippocampus proper, dentate gyrus, subiculum, presubiculum, parasubiculum, and entorhinal cortex. In other nomenclatures the entorhinal cortex, presubiculum, and parasubiculum are separated from the hippocampal formation and are gathered under the term 'parahippocampal region.' When the term 'hippocampus' is used it often refers to the hippocampus proper and the dentate gyrus collectively.

A cross-sectional cut through the hippocampal formation reveals a snugly curled up snaking shape in which the dentate

gyrus appears to be 'biting' the hippocampus proper (see [Figure 1](#)). The hippocampus proper is divided into three main subdivisions: CA1, CA2, and CA3. CA stands for 'Cornu Ammonis,' which refers to Amun's horns, named after the ancient Egyptian god of the hidden world whose symbol was ram's horn. The pyramidal cells in the Cornu Ammonis occupy a single packed layer, quite unlike the neocortex where pyramidal cells are spread over several layers. By contrast the dentate gyrus contains no pyramidal cells, but is densely packed with smaller granule cells, ~18 million in the human brain. In addition to these cells, a variety of interneurons are found in the different structures of the hippocampal formation.

From mouse to man the hippocampus is highly homologous across all mammals. In primates, the hippocampal formation is curled inside the medial temporal lobe ([Figure 1\(a\)](#)), alongside the amygdala, perirhinal cortex, and parahippocampal cortex. The entorhinal cortex has been viewed as the neocortical gate-keeper, sending projections into the structure, receiving its output and communicating with other neocortical structures. The other major source of communication with the rest of the brain is the fornix, the white matter pathway connecting the hippocampal formation to various subcortical structures and providing some output to prefrontal cortex. Via this pathway and other routes the hippocampal formation receives modulatory input from dopamine, norepinephrine (adrenaline), serotonin, and acetylcholine systems.

Theories of hippocampal function were influenced by several features of its connectivity. Four important ones are: (1) information arriving at the hippocampal formation has been highly processed through various unimodal and multimodal neocortical pathways, (2) there are largely unidirectional connections between its regions, (3) there are dense projections from the dentate to CA3, and (4) there are highly self-connected network pyramidal cells in CA3. Unidirectional connectivity is unusual in the cortex, where pyramidal cells are usually characterized by dense reciprocal connections to other cells. A full characterization of connections is beyond the scope of this article (see [Further Reading](#)).

The main flow of information follows four fiber pathways (see [Figure 1\(b\)](#)). Two arise from the entorhinal cortex. The first is the perforant path, bringing input from its layer II to the dentate and CA2/CA3, the second (less dense) is the

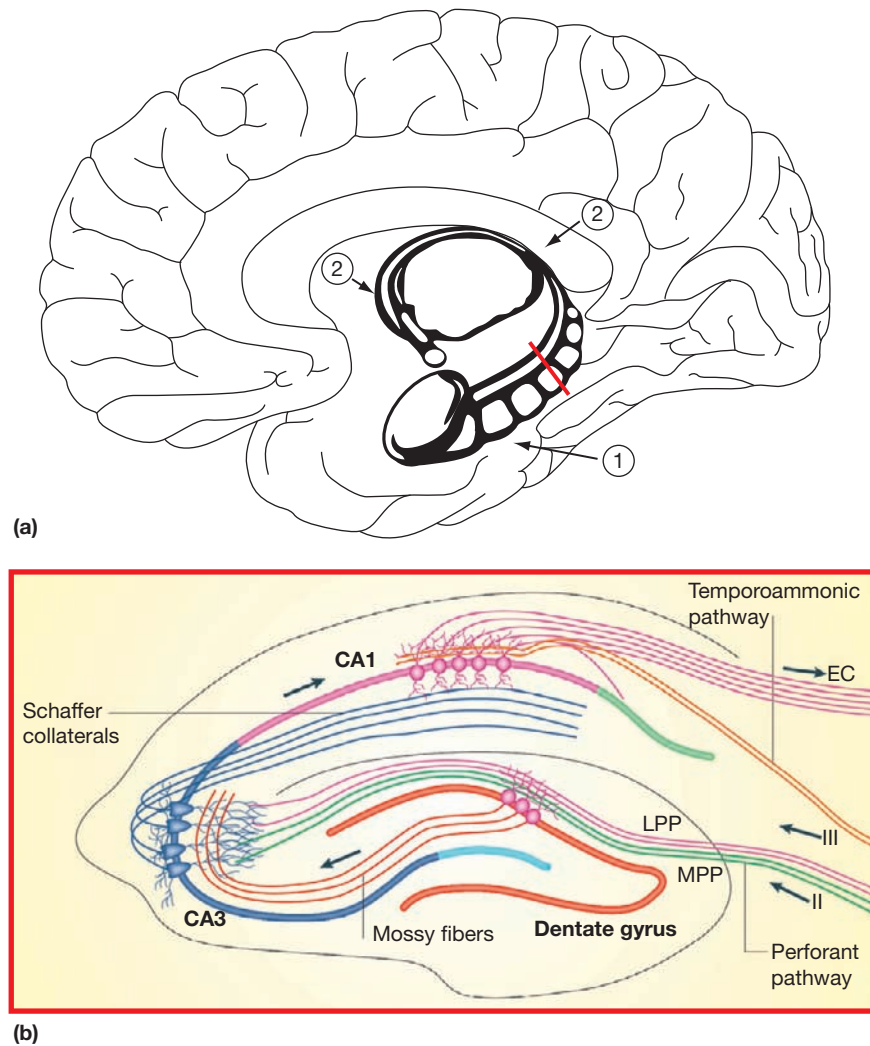

Figure 1 Anatomy of the hippocampal formation. (a) An illustration of the medial surface of the human brain. The front of the brain is to the left. The position of the hippocampal formation in the medial temporal lobe is highlighted by darker lines, (1) hippocampal formation and (2) fornix. Reprinted from Amaral DG (1994) Hippocampal formation. Solid arrows depict the main ‘trisynaptic’ excitatory pathway. MPP, medial perforant path; LPP, lateral perforant path. II, III refer to layers II and III of the entorhinal cortex (EC). The fornix output pathway (not shown) arises from the CA1 collaterals and subiculum. Adapted from Figure 1 in Deng W, Amoni JB, and Gage FH (2010) New neurons and new memories: How does adult hippocampal neurogenesis affect learning and memory? *Nature Reviews Neuroscience* 11: 339–350, with permission from Macmillan Publishers Ltd.

temporoammonic pathway from layer III to CA1. From the dentate arises the dense ‘mossy fiber pathway’ which projects exclusively to CA3. The synapses from this pathway are referred to as ‘detonator synapses,’ because of their strength in driving CA3 cell activity. The CA3 cells project to CA1 via Schaffer collaterals, and to many other CA3 cells via recurrent collaterals. CA1 cells project to the subiculum and the deep layer neurons of the entorhinal cortex and via the fornix to other structures. The subiculum, presubiculum, and parasubiculum have interconnections with the entorhinal cortex and with various other structures.

Spikes and Waves: Physiology

The physiology of the hippocampal formation has played an important role in providing evidence for its function. A central

idea in neuroscience is that memories are stored in the brain by the strengthening or weakening of synaptic efficacy between cells in regions responsible for memory storage. Evidence for this was first provided by Bliss and Lømo in 1973 with their discovery of long-term potentiation (LTP) in the hippocampus. LTP refers to a persistent enhancement in signal transmission between two neurons resulting from synchronous activity of the neurons. It has been traditionally studied either ‘in vitro’ (literally: ‘in glass’) by cutting a living slice from the hippocampus, stimulating fiber pathways within it and recording cells, or ‘in vivo’ by stimulating and recording in awake, behaving animals using chronic indwelling electrodes. Since its discovery, it has been studied extensively and observed in many brain structures. Mounting evidence indicates that memory storage requires LTP. Research focused on its induction, maintenance, and expression and a wealth of knowledge has been gained about the molecular cascades underlying it.

Our understanding of hippocampal physiology has been advanced considerably by the use of extracellular microelectrodes to record the local field potential (LFP) and individual cell activity in awake, active, and sleeping animals, typically rats or mice. The LFP is generated by local voltage changes in the brain region due to the combined electrical effects of a synchronously active population of neurons. Two predominant LFP states have been observed during awake behavior: theta state and large irregular activity. When a rat is either alert or moving, a prominent regular 4–12 Hz ‘theta rhythm,’ oscillation is observed throughout the hippocampal formation; when resting or eating the LFP is instead dominated by large irregular activity. Several interesting aspects of theta are worth considering. Theta is modulated by the speed of running and influences the temporal pattern of pyramidal cell activity in hippocampus proper. The ability to induce LTP varies with the theta cycle, which has led to the suggestion that encoding and retrieval may be separated temporally by theta cycles. The theta oscillations are thought to reflect the combination of subthreshold membrane potentials and spiking activity, and appear to synchronize across the hippocampus to create a traveling wave across its axis. Large irregular activity has also been associated with synchronization in the bursting activity of the cells, particularly with the occurrence of sharp wave-ripples of 150–200 Hz. Evidence indicates that the ripples are generated by CA3, and during these events, brief near synchronous activity of many hippocampal neurons occurs. This reactivation of recently active cells may be important for the strengthening of connections between cells and for transfer of information to other regions. Sharp wave-ripple events are common in sleep and their disruption impedes spatial learning.

In addition to studying the LFP, remarkable insights into the function of the hippocampal formation have been found

by decoding the activity of individual neurons during awake behavior. This is discussed in greater detail below.

Maps and Compasses: Neural Coding

Each of us carries in our head an internal map of our world and a compass to orient within it. These appear to be located within or near the hippocampal formation. This was discovered by implanting microwires into the hippocampal formation of rodents and recording the extracellular activity while the animal explores an environment. By continually recording the animal’s position together with the neuronal activity it is possible to map the activity of cells to the surface of the environment and to the momentary orientation of the animal within it. This approach revealed an elegant system dedicated to spatial mapping and orientation.

Because of their distinctive properties, cells in different regions of the hippocampal formation have been labeled with names such as ‘place cells,’ ‘head-direction cells,’ ‘grid cells,’ and ‘border cells.’ The first to be discovered were place cells by O’Keefe and Dostrovsky in 1971. These exist in the hippocampus proper and fire action potentials (a rapid depolarization in the membrane potential) when an animal is in a particular location in the environment, but are typically silent otherwise (see [Figure 2\(b\)](#)). The location in an environment where a cell fires is called its place field. In a given environment, only a subset of place cells will be active, with each cell’s place field occupying a slightly different location, such that their collective, overlapping place fields carpet the whole environment. Place cells express different activity patterns in different environments, a phenomenon known as remapping. By recording a large ensemble of cells it has been possible to decode a rat’s

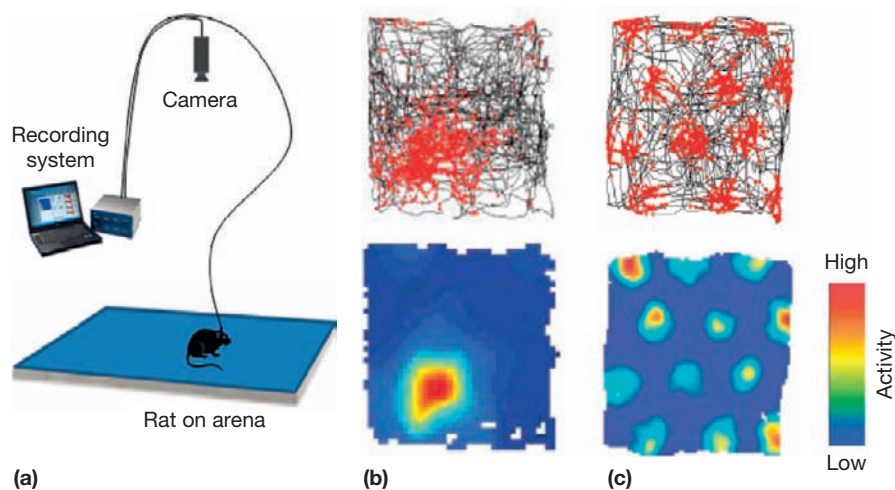

Figure 2 Single-unit recording in the hippocampal formation. (a) A diagram of a set up used for in vivo single unit electrophysiology, courtesy of Kathryn J. Jeffery. A rat is shown in a rectangular flat arena. A cable connects the implanted microwires in the rat’s hippocampal formation to a recording system. The recording system also receives information about the location of the rat via a camera. (b, c) Top, plots of a rat’s trajectory in the arena (black lines). Overlaid red dots are the locations at which action potentials were fired by a single place cell in CA3 (b), and a single grid cell in the dorsomedial entorhinal cortex (c). Below each is shown a false color plot of the spatially smoothed firing rate of each cell, showing the Gaussian peaked fields of activity. Note that, in this example, the place cell field is large than the grid cell field, but field size can vary substantially along the dorso–ventral axis. Adapted from Figure 1 in Fyhn M, Hafting T, Treves A, Moser MB, and Moser EI (2007) Hippocampal remapping and grid realignment in entorhinal cortex. *Nature* 446(7132): 190–194, with permission from Macmillan Publishers Ltd; Figure 2 in Hafting T, Fyhn M, Molden S, Moser MB, Moser EI (2005) Microstructure of a spatial map in the entorhinal cortex. *Nature* 436(7052): 801–806, with permission from Macmillan Publishers Ltd.

location in an environment to within 1 cm. Unlike the topographic maps in the visual, somatosensory, and motor cortices, the place cell map is not topographically organized within the hippocampus. Cells with place fields next to each other in an environment are not located next to each other in the hippocampus. However, the size of the place field varies from small in the dorsal hippocampus to large in the ventral hippocampus. Place cells have several interesting properties. Their response appears to be a high-level, multimodal conjunction of inputs that includes information about self-motion. They respond by remapping predominantly to changes in the boundaries, distant landmarks, and large-scale sensory aspects of the environment, such as the floor and wall colors. They can learn incidentally (without reward) over several trials to discriminate very similar environments.

The cells in a number of peri-hippocampal areas such as the mammillary bodies, anterior thalamus, dorsal presubiculum, and retrosplenial cortex also produce a spatially tuned response, but it is not place related. Instead, these cells offer something akin to an internal compass by expressing activity tuned to certain head-directions in the current environment. Thus, one cell might fire maximally when an animal's head is facing Northeast, another when facing Southeast, another Northwest, etc. Collectively the population covers all possible heading orientations. These cells are referred to as 'head-direction cells.' The cells can be modulated both by self-motion information (such as vestibular or motor signals) and visual information. When prominent landmarks in an environment are rotated between visits to an environment, these cells will tend to follow the rotation, with all cells rotating by the same amount.

'Grid cells' and 'Border cells' have both been discovered in the medial entorhinal cortex and more recently in other regions of the subicular complex. They are similar to place cells in that they show spatially localized patterns of activity in an environment, but they each differ from place cells in intriguing ways. Grid cells generate multiple place fields arranged in a tessellating grid-like pattern across the environment (see [Figure 2\(c\)](#)). If lines are drawn between all fields, their pattern appears somewhat like a sheet of graph paper imposed on the environment, but rather than graph lines being at 90° right angles forming squares, the grid lines are at 60° to each other forming triangles. Simultaneously recorded grid cells show the same orientation of their grid pattern within an environment, but may show different spacing between fields. Mirroring the dorsal ventral scaling of place field size, cells in the dorsal region have a small spacing between fields, whereas those in the ventral region have large spacing between fields. It is thought that grid cells provide inputs to place cells about the distance traveled in the environment.

Border cells, referred to as boundary vector cells, likely provide inputs about the environment, and as their name suggests, they signal the location of borders in a given environment. Border cells will typically fire along, or just slightly offset to, a border placed in an orientation matching its preferred orientation, for example, Northwest. An important facet of the system is that in addition to the cells described, conjunctive cells which combine grid or place properties with head-direction tuning, exist. These cells will only fire in a given place or set of places and only when an animal is facing a particular direction. These have been found in the medial entorhinal cortex and

presubiculum, but not the hippocampus proper. Cells in dentate gyrus can express spatially localized patterns of activity, but in any given environment very few cells are active.

It seems humans too have place cells and grid cells. Evidence for place cells has come from recordings made from electrodes implanted in patients with drug-resistant epilepsy while they navigated a virtual reality (VR) environment. Indirect evidence for grid cells has been provided by using functional magnetic imaging (fMRI) to examine brain activity patterns during VR navigation. Because a proportion of conjunctive head-direction modulated grid cells align to the 60° triangular grid orientations it was predicted that the activity of such cells might produce a sixfold symmetry of activity patterns. This proved to be true for activity in the right entorhinal cortex, indicating that this region in humans may contain grid cells.

Combining human neuroimaging and VR has provided a number of other insights into the response dynamics of the hippocampal formation. For example, people who are better navigators produce more activity in their hippocampus; activity in the right entorhinal cortex increases with the Euclidean distance to a goal, and hippocampal activity is maximal during the initial learning of a network of streets. In summary, while analyses of neural activity have taught us much about the information processed in the hippocampus, combining such work with other approaches can help uncover the functions of the hippocampal formation.

Mapping, Declaring, Relating, Binding, Constructing: Theories of Function

What is the function of the hippocampal formation? Does it serve a unique function or multiple functions and does it operate as part of a wider system? Undoubtedly, it does not work alone and its contributions to cognition are likely varied. A full characterization of its function will arguably require understanding the computational contributions of each subregion in its structure and their interrelations. This is a significant challenge far beyond current knowledge. However, some constraints on what it may, or may not, be involved in have been gleaned over the years, but not without considerable debate and disagreement.

Historically, the hippocampal formation was linked to olfaction through a supposed strong relationship to the olfactory bulb and later tied to emotion because of its connections to other brain regions. These views are generally no longer held. However, there is evidence that the hippocampal formation forms part of a circuit involved in anxiety and this idea was developed into a theory by Gray. There is expanding interest in the role the hippocampus plays in stress disorders and depression (see section '[Dying Cells: Pathology](#)'). However, it was the discovery of dense amnesia following the surgical bilateral removal of the hippocampal formation in patient HM in 1953 that firmly cemented its role in memory processing. Patient HM, now known as Henry Molaison, was reported (along with several other cases) in a seminal paper by Scoville and Milner in 1957. He underwent the surgery for the treatment of drug-resistant epilepsy (see section '[Dying Cells: Pathology](#)'). The surgery removed the hippocampal formation,

parahippocampal gyrus and amygdala. From the time he awoke from the surgery until the time of his death in 2008 he was unable to remember any new events he experienced – a severe anterograde amnesia. He also suffered a temporally graded retrograde amnesia, such that he could not remember events or information from a period just before the surgery, but the further back in time he was probed, the better he was able to recall memories. This gradient of retrograde amnesia has been observed across a large number of amnesic cases.

Despite HM's dense amnesia he (and other similar patients) showed a remarkable capacity for short-term memory, procedural memory and priming (the speeded response to a repeated stimulus). This led to the argument that the hippocampus is necessary for a 'special type' of memory. While numerous theories have been proposed over the past 60 years, this article will highlight six current and influential theories. The focus of many of these theories has been on the role played by the hippocampus, as opposed to the hippocampal formation more broadly. These theories are:

1. *Cognitive map*: Hippocampus stores a map of the environment supporting flexible navigation and spatial memory retrieval, and in humans, remembering events.
2. *Declarative memory*: Hippocampal formation is part of a medial temporal lobe system which supports memory for facts and events for a limited time period.
3. *Relational memory*: The hippocampus is necessary for storing and representing flexible relationships between stimuli disjointed over space and/or time.
4. *Multiple trace*: The hippocampus is permanently needed to support rich detailed episodic memory, but not semantic memory.
5. *Episodic memory* (binding – what/where/when): The hippocampal formation is necessary to bind together information about what happened, where and when, and later retrieving this memory for such episodes. It plays a time-limited role in representing these memories.
6. *Construction*: The hippocampal formation is part of a system supporting the reconstruction of the past or construction of possible future events.

Cognitive map theory was developed by O'Keefe and Nadel. It argues that the hippocampus forms a flexible cognitive map of the environment to support the recall of what is located or happened in different places and navigation to unseen goals. This theory evolved primarily from the idea of a cognitive map put forward by Tolman in the 1940s, together with an analysis of the effect of lesions to the hippocampus and the discovery of place cells. An important aspect of the cognitive map is that information is learnt rapidly and incidentally, that is, without explicit reward. A criticism leveled at the theory is that in humans the hippocampus appears to be in need of remembering nonspatial information, and that spatial information is just one type of information stored by the hippocampus. However, it was proposed that the map may store information about what objects are located in different places and that for humans the map may have evolved with the addition of linguistic and temporal inputs to support an episodic memory system. One aspect of cognitive map theory that is disputed is that it puts no time limit on the involvement of the hippocampus. Thus, once a map of an environment is

formed in the hippocampus, the brain is dependent on the hippocampus indefinitely for the retrieval of the information in the map or the episodic memory.

Declarative theory, proposed by Cohen and Squire, and developed by Squire thereafter, contrasts with cognitive map theory by arguing that: (1) the hippocampus has a time-limited role in memory retrieval and (2) the hippocampal formation is part of a unitary medial temporal lobe memory system (which includes the perirhinal and parahippocampal cortices) for the conscious encoding and memory for facts and events. The term 'declarative' is used because both memory for facts (semantic memory) and events (episodic memory) can be declared as either true or false, for example, 'Socrates was a man,' 'I ate eggs for breakfast today.' A central idea in the theory is that the declarative memory system is distinct from several nondeclarative memory systems, which are responsible for procedural memory, priming, conditioning, and stimulus adaption. Information in these systems is not veridical. For example, knowing how to move your body to ride a bicycle (a form of procedural memory) cannot be said to be true or false. Unlike other theories, declarative theory makes no specific claims about the contribution of different medial temporal lobe regions to memory function. Based on the temporal gradient of amnesia, declarative theory argues for a time-limited role in long-term memory. Building on a model by Marr, initially declarative memories are stored in the connections within medial temporal lobe and between it and the neocortex. Gradually, over time a 'systems-level consolidation' occurs such that connections form and strengthen between neocortical regions and eventually the neocortex rather than the hippocampus is needed to recall the memories. This view has also been referred to as the standard model of memory consolidation.

Multiple trace theory (MTT), proposed by Moscovitch and Nadel disputes the idea that the medial temporal lobe is a unitary long-term memory system in which all information is consolidated in the neocortex. MTT agrees with the standard view with regard to semantic information, but argues that the rich, vivid reexperiencing of events or episodes always relies on the hippocampal region. This is based predominately on the observation that amnesic patients with medial temporal lobe damage typically report few episodic memories from any time point before their lesion and those they do are rarely vivid and detailed. This view is disputed by declarative memory proponents who argue amnesics can recall detailed episodic memories from time points in their remote past.

Relational theory, proposed by Cohen and Eichenbaum, builds on the idea of a declarative memory system and a time-limited role in memory. It argues that the specific role of the hippocampus is in processing the relationships between stimuli disjointed in space or time and that other regions of the medial temporal lobe are involved in processing information about items or contexts. In this view, the hippocampal formation can be used to compare and contrast information held in the system to extract relationships and apply this information flexibly to new situations. The focus on processing relationships and flexibility is somewhat similar to the concept of a cognitive map, since a map is a very good example of this. However, the key difference is that in relational theory space is viewed as only one of the many types of relationship that can be coded by the hippocampal formation.

The episodic memory theory has multiple proponents and has evolved from a range of findings. According to this view, the main purpose of the hippocampal formation is to encode and store episodic (or episodic-like) memories for weeks, months, or possibly years. Episodic-like is used to refer to the fact that while animals can show something like episodic memory, it may be qualitatively different from the sense of mental time travel that accompanies episodic retrieval in humans. This view is similar to the MTT view, with the exception that episodic memories are consolidated in the neocortex. Evidence that hippocampal formation might be especially crucial for episodic, but not semantic memory came from the study by Vargha-Khadem and colleagues in 1997 of several patients with amnesia due to bilateral hippocampal damage that occurred in childhood. They all had profound episodic memory problems. Despite this they had all gained a remarkable amount of semantic knowledge. This was surprising because amnesics with damage in adulthood do not show such levels of semantic learning. This led to the view that the neocortex may be able to slowly incrementally learn about information, and that the hippocampus normally facilitates this process by providing information stored in episodic memory. Like many other cases of amnesia due to relatively selective damage within the hippocampal formation, children were unable to recall past events, but were unimpaired in their capacity to recognize previously seen stimuli on some recognition tests. This and results from lesion studies in primates and rats led to the view, proposed by Aggleton and Brown, that the hippocampus supports the episodic or episodic-like abilities, and that the perirhinal cortex imbues the brain with the capacity to determine whether a stimulus is familiar or not. Evidence for the latter comes from lesions and single unit recording of perirhinal neurons which signal whether a stimulus has been encountered before or not. In addition, some models argue that the parahippocampal cortex is important for representing context. These 'binding into context' models argue that the role of the hippocampus is to bind together perirhinal object representations with parahippocampal background context representation, allowing a rich reexperiencing of the whole event when information is later recalled. The idea of vivid recollection of the past emphasized by MTT, has led several researchers recently to argue that the hippocampal formation does more than store and retrieve memories; it reconstructs the past and even constructs possible future events.

The 'construction' theory is relatively new and based predominantly on neuroimaging and neuropsychological observations. It argues that the hippocampal formation is part of a 'core network' required to support episodic memory and navigation, and also imagination. Increased activity in the hippocampus has been observed during periods when subjects were thinking about the future and amnesic patients with hippocampal damage has been found to struggle to describe new, imagined situations. Such patients appear to be able to imagine individual objects and colors, suggesting that their problem lies in creating a rich and coherent mental construction of a scene. This view also accords with other evidence indicating that the hippocampus is needed to solve odd-one-out or working memory tasks, which involve holding a mental representation of a room or scene in working memory. Thus, it has been

argued that a function of the hippocampal formation is to construct rapid online mental representations of scenes and places. This view offers an alternative explanation for why the hippocampus may be critical for remembering rich, vivid events from all time periods of one's life in that they need to be reconstructed. It would seem hard to imagine that constructing future scenarios is a function of the rodent or other nonhuman animal hippocampi. However, recent evidence suggests that hippocampal place cells can show activity that might be akin to 'simulating possible future paths.' During some sharp-wave-ripples (see section '[Spikes and Waves: Physiology](#)'), a set of cells can briefly fire action potentials in the order that they would be activated if an animal ran along a path in the environment. While this 'sequence replay and preplay' might be related to future thinking, an alternative possibility is that during evolution humans adapted a spatial memory system to support not only the reconstruction of episodic memories, but also the construction of fictitious events and places.

Undoubtedly, pinning the theory on the tail and body of the hippocampal formation will continue for decades to come. The study of hippocampal formation has, and will continue to be, influenced by research conducted with patients who have suffered some form of pathological damage to the hippocampus. Such pathological states are considered in the next section.

Dying Cells: Pathology

The hippocampal formation appears to be particularly prone to disruption from a variety of causes. In this section, the effects of dementia, stress, epilepsy, and schizophrenia are considered. Before we consider these various aberrant states, it is worth considering the healthy aging. Analysis of the human brain has revealed mixed results as to whether cell loss occurs substantially in the hippocampus. In rats, healthy aging is not associated with significant cell loss, but rather with disrupted synaptic plasticity, such that LTP is short lasting. Place cells (see section '[Maps and Compasses: Neural Coding](#)') in aged rats show reduced remapping responses to changes in the environment, suggesting that these cells are less capable of detecting environment novelty. The place cells can also fail to reestablish old patterns of activity in familiar environments, suggesting that they are not capable of detecting a previously visited place with the same accuracy.

Common causes of substantial cell damage in the hippocampal formation include Alzheimer's dementia, ischemia/hypoxia (loss of oxygen supplied by the blood), trauma, hypoglycemia (low blood glucose), and epilepsy. Hippocampal damage is also associated with rare conditions such as herpes encephalitis, where an acute infection from the herpes simplex virus spreads through the hippocampus, amygdala, and associated structures. Due to the relative sparing of other brain structures that can occur in this disease and in cases of hypoxia, patients with these pathologies have proved highly important for the study of hippocampal amnesia.

Epilepsy and Alzheimer's disease are among the most common of neurological diseases and are both strongly associated with the dysfunction of the hippocampal formation.

Alzheimer's disease is a hugely debilitating disease that typically manifests as an inability to acquire new memories and disorientation. It has been associated with cell loss, originating in the entorhinal cortex and spreading to the rest of the hippocampal formation and beyond as the disease progresses. Epilepsy is commonly linked to hippocampal pathology, in the form of hippocampal sclerosis. It is unknown whether the seizures arising in epilepsy are the result of hippocampal damage or whether they are the cause of the damage. In cases of hippocampal sclerosis, evidence indicates that the seizures originate from the hippocampus. Links have been made between its unique anatomy and the origin of the seizures. Increased connectivity, neurogenesis, loss of inhibitory inputs and increased excitatory drive, among other factors, have all been suggested to contribute to the development of epilepsy.

Stress can also have a damaging affect on the hippocampal formation. Stress produces glucocorticoids which then bind to the dense glucocorticoid receptors inside the hippocampal formation. They have been found to inhibit neurogenesis (see section '[New Birth: Adult Neurogenesis and Morphological Change](#)'), alter gene expression and reduce the excitability of some classes of cell, and prune the dendrites of CA3 pyramidal cells. Patients suffering posttraumatic stress disorder and who have experienced extreme stress over long time periods can show hippocampal atrophy.

Schizophrenia is another disease associated with hippocampal damage in the form of reductions of its volume. It has been argued this may be the cause of the long-term memory problems many patients show with the disease. Because of the lack of cell damage markers at autopsy and the presence of abnormal cytoarchitecture, established prenatally, it has been suggested that the changes are likely the result of altered developmental processes rather than due to damage. Also, altered dopamine levels, central to the syndrome, may be partly caused by the reduction of hippocampal formation input.

New Birth: Adult Neurogenesis and Morphological Change

While the hippocampal formation seems particularly fragile, prone to decay and disease, it is also one of the few brain regions where the birth of new neurons (neurogenesis) occurs in adulthood occurs. From the time of the renowned neuro-anatomist Ramon y Cajal, a central tenet in the brain was that no new neurons grow in adulthood. It took many decades before this view was overturned and the growth of new neurons was identified in two brain areas, the olfactory bulb and part of the hippocampal formation: the dentate gyrus. This neurogenesis may help support new learning and memory, possibly by reducing interference, increased capacity, and tagging memories with temporal information. Despite initial mixed results, this research is continuing to weigh in favor of neurogenesis being important for memory.

Does size matter? It would appear to for the hippocampal formation. In several nonhuman species, its size varies depending on the demands placed on spatial memory. Furthermore, in some species the volume may change as a function of

the seasonal demands. In humans, some jobs place greater demands on spatial memory than others. An extreme case of this is the licensed London taxi driver, who must learn the labyrinth of London's (UK) ~25 000 streets in order to obtain a license, and navigate to hundreds of destinations on a daily basis. By examining magnetic resonance imaging scans of London taxi driver brains, Maguire and colleagues found greater gray matter volume in the posterior hippocampi and reduced gray matter volume in their anterior hippocampi compared with an age-matched control group. In addition, the longer taxi drivers had navigated in London the greater the posterior gray matter volume and the more reduced the anterior gray matter. Thus, suggesting that healthy adult humans have the capacity to change the structure of their hippocampus when accruing knowledge of complex environments. The same changes do not appear to occur in London bus drivers who were matched for driving experience, indicating that this change is unlikely to be driven by stress, driving experience, or daily self-motion. Whether the change in structure is related to neurogenesis, changes in cell morphology, or other factors remains to be explored in future research.

Summary

From the ancient Egyptian era to present day, people have written about the hippocampal formation and pondered over its anatomy and function. In the last 40 years, our knowledge has leapt forward. Crucial discoveries have been made in understanding its unique circuitry, physiology, neural code, and functional properties. This has been made possible by the development of a wide range of technical innovations and a creative approach to experimentation. There is a general consensus that the hippocampal formation is crucial for episodic memory, but how best to characterize its involvement in this and other functions remains an issue to be resolved.

Glossary

EEG (electroencephalogram) Electrodes attached to the scalp to record the electrical activity in the brain.

fMRI (functional magnetic resonance imaging) An imaging technology used to examine changes in the brain, including blood flow.

Hippocampus A structure in the brain involved in the processing of memories.

Lateral prefrontal region A region located in the frontal lobes of the brain; it has been implicated that this region is related to personality, and cognitive and social behavior.

Skin conductance (measure) A measure of change in the electrical conductivity of the skin that occurs through the activity of the sweat glands, causing an increase in level of perspiration.

Somatic (measure) A measure of body movement through the skeletal muscles.

Introduction

Empirical research on the psychology of film music examines how people respond to film and music on a number of different psychological levels using a variety of methodological approaches. Experimental investigators have conducted these studies in order to demonstrate how people perceive both auditory and visual elements. Many of the early experiments used simplistic examples. The experiments are categorized into the following sections: visual information; auditory versus visual information; music, film, and association; music, film, and structure; music, film, and emotion; music, film, and memory; music, film, and closure; music, film, and plot continuation; music, film, and sound quality; physiological affect; music, film, and affect; and music, film, and meaning.

Research on the psychology of film music began in the 1950s with the work of Tannenbaum. Osgood, Suci, and Tannenbaum and Gerrero were among the first to use the semantic differential method. Freeman and Neidt conducted a film music and education experiment to examine the effect of familiar and unfamiliar film music on the perception of visual elements. In the 1970s much of this research employed simple audio and visual clips. For example, Massaro and Warner conducted an experiment to study the relationship between audio and visual elements using simple tones and letters, and Berg and Infante examined the impact of musical modes on visuals. Marshall and Cohen examined the relationship between music and visual elements using animation. Some experiments focused strictly on the visual elements, while others examined audiences' physiological responses to disturbing stimuli accompanied by different types of audio material.

There were few studies on the perception and cognition of film music in the fields of both musicology and psychology prior to the 1990s. Cohen suggested that the cognitive framework for exploring film music should focus on meaning, structure, memory, awareness, and experimental aesthetics. A special volume of the journal *Psychomusicology*, on the psychology of film music, presented a range of empirical studies that examined the relationship between music soundtracks and different types of images, film, and television. Following these groundbreaking studies, scholars have conducted a

variety of experiments on film music, broadening our understanding of how audiences respond to both music and film using different techniques, methods, models, and theories.

Semantic Differential

Osgood, Suci, and Tannenbaum used the semantic differential method to examine the effects of music on three different interpretations of a film. This technique was used in several of the following studies, measuring participants' reactions using bipolar scales with contrasting adjectives at each end. These adjectives are organized through 'evaluation,' 'potency,' and 'activity' (EPA). For example, evaluation may include the adjectives, 'good-bad'; potency, 'strong-weak'; and activity, 'active-passive.' The bipolar scales used in EPA studies are usually numbered 3-2-1-0-1-2-3, where 0 is labeled 'neutral,' 1 'slightly,' 2 'quite,' and 3 'extremely.' In studies that involve the semantic differential, researchers may assess subjects' confidence in particular choices by means of a 5-point scale, from 1 (I have no idea) to 5 (I am sure that it is). Some scholars ask subjects to rate music on scales that have extreme values of 'low-high liking,' 'very strong disagreement-agreement,' 'highly displeasing-pleasing,' and 'not familiar at all-extremely familiar.' Others require subjects to rank emotions according to certain adjectives from 1 (not at all) to 5 (very much).

Visual Information

Film music cognition experiments are often conducted with examples featuring the film alone to determine how viewers perceive visual material. An early experiment conducted by Zadny and Gerard focused on audiences' interpretations of visual elements. This study focused strictly on the visual images to find if viewers presented with certain scenarios, would remember objects onscreen connected to the scenarios. In this experiment, the participants were divided into three groups and then presented with a video clip of a man and woman looking around an apartment and picking up certain objects. Each group was presented with a different scenario:

the man and woman were searching for drugs; they were burglars searching for valuables; or they were waiting for their friend. The participants in the 'burglar' condition remembered the objects (credit cards and diamond ring) related to this scenario. These items were more easily remembered than other items, such as the drug paraphernalia. Zadny and Gerard found that viewers remembered objects connected to specific story lines, suggesting that film genres and scenarios define how audiences perceive film.

Auditory Versus Visual Information

Perceptual psychologists focus on auditory and visual sensory modalities (sensations originating from the sensory systems). Experiments by Massaro and Warner on auditory versus visual perception created a foundation for later empirical research. These types of studies were valuable in determining how sound and image interacted before scholars later examined motion pictures and film scores. They provided a basic understanding of how listeners perceive audiovisual material through a simple task of pairing tones with letters. The experimenters required participants to identify tones of higher or lower pitch while their attention was focused on a letter. These experiments were designed to test the degree to which selective attention can affect auditory or visual perception. Massaro and Warner found that tone recognition decreased when a participant's attention was divided between tones and letters.

In a more recent study, Repp and Penel conducted an experiment using tones, letters, and shapes to find out how listeners perceive audio and visual information. Their goal was to determine whether auditory information dominates visual information in perception and in a coordinated action (finger tapping). The audio material consisted of identical high-pitched piano tones. They were presented with two visual sequences, including a black 'X' and two squares, and a circular green flashing light. The audio and visual examples were shown separately and together. Participants were asked to view the images on a computer monitor, and were required to tap their finger with the sequence of events. The results demonstrated that in the audio alone and visual alone conditions, there was greater variability of taps in the results for the visuals. Their overall finding was that audio material provides more temporal information (where people were able to stay in synchrony with a sequence) than visual material.

Koelsch et al. wanted to determine if music activates certain neural (brain) mechanisms related to the processing of semantic meaning using EEG, a method of recording the electrical activity of the brain. Participants were presented with target words on a screen after listening to either a spoken sentence or a musical clip. The results suggested that both music and language can prime or set up the meaning of a word. They maintained that it is possible for music to activate neural mechanisms related to the processing of affective meaning.

Music, Film, and Association

In the 1970s and 1980s, a number of scholars began to examine the interaction between music and moving images. The early work of Berg and Infante focused on the impact of

the major and minor modes of music on the perception of film. Participants were required to view examples that showed a man with either a happy, neutral, or sad facial expression followed with clips that relayed a 'favorable' or 'unfavorable' situation. The music accompanying each clip consisted of a major or minor melody. They suggested that the modes affected participants' responses where the major mode elicited favorable responses and the minor mode elicited unfavorable responses.

Marshall and Cohen hypothesized that music and visuals that match in meaning, direct a viewer's attention to certain visual features in film. In their initial experiment, participants were assigned to one of five conditions, including 'adagio-film,' 'allegro-film,' 'film only,' 'adagio only,' and 'allegro only.' They were asked to describe what had occurred in the film and provide adjectives to describe the visual elements, which included large and small triangles, a circle, and music. They were then required to assess each figure on a bipolar scale. One of their findings suggested that music influences the meaning of film characters.

Sirius and Clarke wanted to determine how individuals would respond to music and moving images that were precisely composed for one another. They used a series of examples, utilizing computer-generated geometric shapes without sound, specifically composed music sequences without animation, and animation with music. They stated that these examples were more characteristic of film music (less abstract) than those used in Marshall and Cohen's study. Participants were required to view film alone and film with soundtrack examples and rate them on bipolar scales. They found that the soundtrack increased the rated 'pleasingness' (music was rated high on the evaluative dimension) of the film images, and lowered the activity ratings. The results of the aforementioned studies suggest that music impacts the audience's perception of film, creating an association between the two elements.

Cohen conducted an experiment to follow up on the results of her earlier work. She suggested that the audience's perception of film and music can be described through the concept of 'associationism.' This occurs when the meaning of the music is then transferred to the film. Cohen further elaborated on the Congruence-Association Model (CAM) to demonstrate the functions of film music. Structural congruence allows the audience to focus on specific details of the visuals. This framework suggests that when viewing a film, the audience member becomes engaged in creating a working narrative (i.e., the viewer's interpretation of the story), and the film music helps to create greater awareness and attention to the story.

Music, Film, and Structure

Cohen later conducted an analytical study revealing that there were similarities in mental processes employed by film and music for different types of structure (e.g., rhythm and direction). Scholars in film music cognition have wondered whether audiences feel the music and film is congruent. In the 1990s, empirical studies on film music cognition began to address this question. Lipscomb and Kendall examined audiences' perception of commercial film music, and hypothesized that the majority of participants would choose the

composer's intended score as best fit or most suitable for a particular film. They wanted to determine how Hollywood film composers and audiences understand films in relation to the soundtrack. Participants were required to view five scenes from Hollywood films combined with five different soundtracks, and were asked to select the version that was most suitable. The majority chose the composer's original version as best fit for the film.

Lipscomb proceeded with this research for his dissertation and then a study. He maintained that current empirical studies investigated 'association' and film music. However, Lipscomb and Kendall found that there was another judgment made while viewing a film with music-accent structures, meaning the points at which important events in the film score are aligned with important events in the images. He utilized music combined with different types of visual material to determine whether individuals can detect the matching of music and visuals. In the first experiment, he employed sound files and computer animations with three degrees of alignment, including 'consonant' (i.e., perfect synchronization), 'out-of-phase' (i.e., share a common temporal interval, but perceived as out of synchronization), and 'dissonant' (i.e., out of synchronization). In the second, he used clips that consisted of abstract geometric shapes with the same degrees of audiovisual alignment as the first experiment. In the third experiment, three short clips were selected from a motion picture accompanied by the soundtrack. The overall finding was that participants were able to distinguish between the different levels of synchronization more easily in a simple film (e.g., music with geometric shapes) than in a major motion picture.

Bolivar, Cohen, and Fentress designed an experiment to show how soundtracks and temporal relationships influence the meaning of film. The participants viewed a series of audiovisual clips and were required to rate them for 'friendliness' or 'aggressiveness.' The visual examples were taken from a series that examined the social interactions between pairs of wolves, and the soundtracks consisted of instrumental passages that were extracted from commercial recordings. The examples included 'friendly audio with friendly video,' 'friendly audio with aggressive video,' 'aggressive audio with friendly video,' and 'aggressive audio with aggressive video.' Participants were required to view the clips and then rate them for matching, including 'do not match,' 'cannot tell,' and 'they match.' When the mood of the soundtrack matched with the visual action, the majority of participants stated that the meaning was congruent or matched. In addition, participants were able to determine whether an example temporally matched.

The next experiment focused on a different type of audiovisual relationship. Krumhansl and Schenck examined the structural properties between music and dance using Balanchine's choreography for Mozart's *Divertimento No. 15*. Participants were assigned to one of three conditions, including 'music only,' 'dance only,' and 'music and dance.' They were required to view the music and dance examples, indicating where new ideas in the music and dance began in addition to the ends of sections. During this test, they were asked to judge the amount of tension and emotion, and found that the new ideas corresponded with low levels. These ratings increased before the ends of sections, suggesting that there is temporal organization between music and dance.

In a recent study, Tan et al. set out to determine if music needs to be presented concurrently with visual images in order to influence viewers' interpretation of film. Participants were required to view film clips focusing on a single character. The music was presented before or after each clip. The characters displayed emotionally neutral facial expressions, and the music conveyed happiness, sadness, fear, or anger. Tan et al. demonstrated that music does not need to be presented in relation to the film in order to influence audiences' interpretation of the content.

Music, Film, and Emotion

Cohen stated that music is one of the strongest sources of emotion in film. However, it is difficult to determine how audiences respond to stimuli on an emotional level. The scholars in the following study measured participants' neural (brain) activity to understand what occurs in the brain when listening to and viewing film. Elder et al. conducted a study to find out whether film music would increase activity in certain brain regions. Participants were required to view short film and music examples. The music examples were rich in emotion and poor in concrete content (i.e., information about the concrete world). The film examples were poor in emotion but rich in concrete content. The music examples were negative, positive, or neutral in emotional character, and the film clips were all emotionally neutral. They used functional magnetic resonance imaging (fMRI) to measure participants' neural activity. The results demonstrated that combining the music and film examples caused an increase in activity in the amygdala; these are groups of nuclei located in the medial temporal lobes of the brain that perform primary roles in the storage of memories associated with emotion. This combination also caused an increase in the hippocampus and lateral prefrontal regions of the brain. The emotional music on its own did not increase participants' neural activity. Edler et al. suggested that the amygdala responds to an emotional stimulus when associated with visual images that are rich in concrete content.

Music, Film, and Memory

Empirical studies on film music cognition began to examine whether music would aid in the memory of film. Boltz, Schulkind, and Kantra conducted an experiment to determine if music matched to the subject matter of a film, helped the listener in the memory of the visual action. The participants viewed a series of visual examples taken from network television. The music consisted of a number of unaccompanied instrumental melodies that either matched or did not match with the film. Watching the examples participants were required to estimate the time between the beginning and end of each example, and indicate whether they had viewed the episode before. They were then required to provide unexpected memory responses. The results demonstrated that the visual examples were more easily remembered when cued by the music.

Boltz is known for her film music cognition experiments incorporating the schema theory. This theory of knowledge organization suggests that individuals hold a web of mental

structures related to certain words or concepts. For example, individuals may associate 'feathers,' 'wings,' and 'beak' with the word 'bird.' She suggested that schemas are often incorporated into film, and may be activated when listening to the soundtrack and viewing the film. Boltz conducted a study to determine whether music can contribute to the understanding of a story. Participants were required to view film clips accompanied by positive (major, tonality, and regular rhythm), negative (minor, atonality, and irregular rhythm), and no music. After viewing the clips, they were required to determine the ending of the film, and the motivations and personalities of the main characters. They were also asked to rate the film's actions on bipolar scales. Some of the participants returned a week later, and were asked to remember certain objects from each film. Her main finding was that positive and negative music influenced the participants' interpretation and memory of the film in relation to its mood.

Boltz then designed another experiment to determine whether music that matches the subject matter of a film aids in its memory. In the first experiment, participants were asked to view a series of music and film clips that matched or did not match in emotional content, and were asked to remember the music and film. When the mood of the music matched the mood of the film, the music and film were more easily remembered. When the music and film did not match, participants remembered only one of the elements. In the second experiment, the matched examples were remembered when cued by the original scenes. The examples that did not match were more easily remembered when there was no information about the scene. Her results suggested that music paired with film examples of a similar mood were recognized more often than those from pairs that were not matched. Recently, Boltz et al. continued these types of experiments and found that the affect (positive and negative) and format (e.g., video, montage) of the visual material was also influential in how participants perceived the music.

Music, Film, and Closure

Film composers usually compose closed music in order to create a sense of closure for the audience. In music, a sense of closure is created when music comes to a final point, and in film, closure is created when the events taking place in the story line are resolved. Thompson, Russo, and Sinclair examined closure in film with three experiments featuring closed music, open and closed music, and closed music with visuals. They wanted to find out whether musical closure influences closure in film. The first experiment was designed to determine whether musical closure in underscoring or background music would affect the participants' sense of closure in a short animated film. In the first condition, participants were presented with examples of strongly closed underscoring, and in the second condition a different group of participants was presented with music that did not convey a sense of closure. The results indicated that individuals were more likely to relate their experience to visual cues than audio, since only five subjects mentioned the music. Thompson et al. found that listeners felt musical underscoring alone created a sense of closure, but when combined with images, the visual elements were more effective in its portrayal.

Music, Film, and Plot Continuation

Scholars have conducted studies to determine how music affects audiences' perception of the story line or plot of a film. The following studies employ different techniques in order to determine the influence of the music. Bullerjahn and G ldenring conducted an experiment to demonstrate how the soundtrack influences the interpretation of film. The participants viewed a film produced by drama professors and students, and were presented with five contrasting soundtracks. Three professional film composers wrote different film scores, including two crime versions, a thriller, a melodrama, and an 'indefinite' version. The music differed in style, orchestration, use of motifs, and place and length of music. Participants were required to provide information about the film through rating scales and open-ended questions about the relationships between the characters, the history, and the film events. The overall results suggested that the soundtrack plays a role in determining the mood of a film, the film genre, and how the film progresses. They maintained that each soundtrack created its own type of film and plot.

In the next study, Magliano et al. examined a number of elements that make up film productions. They wanted to determine whether certain film elements would enable participants to predict future events in the story line. In the first experiment, participants were instructed to write predictions while watching the film, and in the second, they were asked to provide think-aloud statements at different points in the film. Magliano et al. determined that music was one of the factors influencing participants' predictions of the visuals. Film composers call the prediction of the visuals, 'telegraphing.' The music can telegraph before certain events occur, thereby affecting audience expectations.

Vitouch conducted a study to determine if film music influences the reality of film. The participants were required to view two identical film clips accompanied by the original score and a 'fake' score. They were then asked to write a continuation of the plot, and these were analyzed with a focus on emotional content. Vitouch found that differing scores influenced how participants interpreted the plot.

Music, Film, and Sound Quality

The results of the experiments outlined so far have demonstrated that music is extremely important in how audiences perceive film. However, the visual elements play a very important role as well. To explore this interaction, Iwamiya examined the relationship between audio and visual elements with two different experiments in order to examine the quality of film and music, and if film compensates for degraded music (poor sound quality). Participants were presented with examples where the audio and visual materials matched or did not match. In the first experiment, participants were required to rate the audio and visual meaning, and degree of matching. He found that auditory meaning influenced the visual meaning for certain congruent examples. In the second experiment, the music was presented with and without visuals, and with degraded sound as well as the original fidelity. Iwamiya maintained that the visuals compensated for the effects of the audio degradation, suggesting that there are varying levels of auditory-visual interaction.

Physiological Affect

Empirical studies on physiological responses to film music span from the early 1970s to the late 2000s. These studies use a variety of methods to demonstrate how the human body responds to film and music while viewing accident scenes. Koriat et al. conducted one of the first studies in this area to measure the self-control of emotional reactions to a stressful film using dialog instead of music. The participants were asked to view an industrial safety film, showing accident scenes with a dialog soundtrack. Before viewing the film, they were required to listen to sets of instructions, including 'neutral,' 'increased involvement,' and 'increased detachment.' They found the participants' heart rates and skin conductance levels increased while viewing the film in the increased involvement condition, and the arousal levels of participants in the increased detachment condition were lowered.

Thayer and Levenson then conducted an experiment to measure participants' psychophysiological responses. The participants were presented with a film on industrial safety using two different musical conditions while their physiological responses, including cardiovascular, skin conductance, and somatic were monitored. The 'horror music' condition employed music that increased the stressfulness of the film and the 'documentary music' condition used music that decreased the stressfulness. They were then required to report on their perceived level of anxiety. Thayer and Levenson's results showed that when participants viewed the accident scenes with the horror music soundtrack, their level of anxiety and perspiration increased, demonstrating that film scores affect the body through skin conductance levels. More recently, Khalfa et al. conducted an experiment to demonstrate that skin conductance levels are affected when listening to emotional music. The emotions of fear, happiness, sadness, and peacefulness were tested. Similar to the results of the previous studies, they found that skin conductance levels increased with examples that induced fear. They also found that the levels increased for music that created happiness.

Heuer and Reisberg used disturbing and neutral pictures in their study, but instead of music, the images were presented in combination with spoken dialog. This experiment was designed to show the effect of arousal on an individual's memory. They hypothesized that participants would better remember the information if the subject matter caused physiological arousal. The participants were divided into four groups, including 'arousal,' 'neutral,' 'memorizing,' and 'problem-solving' (participants in this group were told that the experiment was about the relationship between physiological responses and problem solving). They attended one session and were instructed to return 2 weeks later. The arousal group watched a story with 12 slides accompanied by a simple taped sentence. The slides were shown for 6 s, relaying the story of a surgeon father operating on an accident victim. The neutral, memorizing, and problem solving groups watched 12 slides that relayed the story of an auto mechanic father fixing a car. The participants witnessed accident scenes on slides while their heart rate and arousal levels were monitored. Following the slide presentations, they were required to rate the emotion of the story. They were also given a questionnaire to fill out at home, and in the second session, they were asked to write as much as they could about the presentation. One of their main

findings was that the participants in the arousal group recalled more from the story than the other groups.

In a more recent study, Sokhadze examined the effects of music on recovery after viewing stressful stimuli. Participants' physiological responses were monitored while viewing film clips that displayed elements of disgust followed with pleasant and sad music, and white noise. Sokhadze stated that the stimuli caused participants' heart rates to decelerate in addition to increased heart period variability, increased skin conductance levels and response frequency, decreased facial blood flow and velocity, and variations in brain wave patterns. He found that the pleasant and sad music restored the physiological measures to their normal baseline levels.

Music, Film, and Affect

Scholars have focused on the relationship between audio and visual elements in empirical studies by presenting participants with music and soundtrack clips, and then the music alone. Participants are then required to respond to the clips through a variety of written responses, including cognitive tests, scale ratings, and open-ended questions as well as writing down whatever comes to mind when listening to the music. Gerringer, Cassidy, and Byo used some of these methods, and conducted an experiment on the effects of film music and video on nonmusic majors. Participants were divided into groups and presented with abstract and programmatic musical examples. Half of the participants viewed film and music examples and the other half listened to music alone examples. One of their main findings was that participants in the music alone group were more analytical in their responses for both musical examples.

Many of the empirical film music studies focus on music in general, but not on the music of specific film composers. Recently, Force conducted eight different experiments for her dissertation to determine how audiences affectively respond to music of the film composer, Philip Glass. He composes film scores that are minimalist or repetitive in nature. This study examined a variety of different methods inspired by many of the previously mentioned experimental investigations. The film and soundtrack examples were selected from a wide range of films from 1982 to 2004. The experiments tested whether audiences liked Glass's music, and if it matched the films, in addition to the mood that it created, the themes that it portrayed, the perceptions of the characters, and the emotion and anxiety created. Participants were required to respond to the examples through a number of forced-choice responses (scale ratings and descriptive words) as well as open-ended written responses. Similar to Gerringer et al.'s results, one major finding was that when participants were given the opportunity to freely write about the music, they provided very detailed and descriptive responses.

Music, Film, and Meaning

Experimental investigations have explored how audiences perceive the meaning of film music, and recently, cross examined music within scientific, cross-cultural, and evolutionary

perspectives. He focused on the meaning of music and how listeners engage with it. In this more theoretical study, he maintained that the meaning of music is often shared, and can be used to relay visual information.

In the following two studies, investigators have developed new types of methodology to examine meaning in film music. Tagg and Clarida explored the response to music accompanying the credits for ten television series to determine the relationship between music as structure and as meaning, identifiable and repeatable by members of a community. In this highly descriptive book, they hypothesized that it is possible to establish links between the two, and their goal was to determine what constitutes a musical structure. Tagg presented the examples to students at the beginning of a lecture with instructions varying in each session. He introduced the lecture topic and stated that they would be examining the audience's experience of music. He then asked the students to participate in a short experiment. The participants were required to listen to the clips and then instructed to write down anything that could be happening on an imaginary film or television screen. They analyzed the listeners' written responses by means of a visual-verbal taxonomy where words were extracted from full sentences provided by the participants. The response sheets were collected and filed according to a number for each respondent, and the results for each tune were displayed in numerous tables. After analyzing the responses using the taxonomy, they found that certain visual examples had a large number of visual-verbal associations related to certain themes, for example 'love' or 'kindness.' Tagg and Clarida revealed that audiences respond to film based on attitudes formed by their social and cultural environments.

Kendall conducted a study on the perception of musical meaning in music and film after creating a one-dimensional 'continuum of referentiality' model to measure musical meanings that range from pure sound events that are considered 'areferential' to iconic associations, and then to arbitrary associations, considered 'referential.' His goal was to determine if participants would use the entire continuum in response to film with soundtrack examples. Participants were presented with six short film clips in random order that were hypothesized to span the full length of the continuum. He found that participants were able to use the entire scale when judging the audiovisual clips. Kendall's finding suggested that the continuum would be an effective method to use in future film music studies.

Summary

The experiments outlined in this entry examined how music and visual elements interact to create a film-watching experience for audiences. The studies focused on the role of the visual elements, the audio elements, and a combination of the two. The early studies explored the perception of audio and visual elements, and used simplistic examples for testing. For example, Massaro and Warner's research demonstrated that audiences are able to perceive music and film at the same time. Many of the experiments over the years focused on how music influences the perception of visual elements. This research began with Marshall and Cohen's groundbreaking experiment

that demonstrated that the meaning of background music has a direct effect on the meaning of film. In addition, Boltz, Schulkind, and Kantra's research indicated that music aids a listener in remembering visual elements. Some studies examined the role of music separate from the visuals. For example, Bullerjahn and G ldenring's results indicated that soundtracks conjure up certain types of film and plot for listeners. The majority of the studies in recent years have focused on the congruency between music and visuals. In Boltz's study, she found that when the mood of the music matched the visuals, the majority of participants felt that the meaning matched as well. In addition, Lipscomb and Kendall found that participants chose the composer's original score as most suited to the film. Scholars have shown that the audio and visual elements can work together to create the film experience. Thompson, Russo, and Sinclair's study found that certain music created a sense of closure for audiences, but it was further strengthened with the visuals. A few experiments showed how the visual elements effect the perception of the music. For example, Iwamiya demonstrated that the visuals compensated for degradation in the audio material. Other scholars examined physiological responses to audio and visual elements. Thayer and Levenson's study demonstrated that when disturbing scenes were presented with disturbing music, the human body responded to this through an increase in anxiety and perspiration. Scholars have also approached this research from a more theoretical level, and have examined how shared meanings and associations of film and music help to relay certain ideas in the film. For example, Cross's research showed that if the meaning of the music is shared, it can be used to relay certain ideas about the visuals. In addition, Tagg and Clarida's research demonstrated that audiences respond to film based on attitudes formed by their environment.

Experiments on the psychology of film music began as early as the 1950s, but most of the research did not begin until the late 1980s and early 1990s. Since then, a very small group of scholars have conducted research in this field. Over the years, film music experiments have evolved from the utilization of simple tones and visuals to complex studies involving whole sections of film and certain genres of music. There are still many unanswered questions about how humans respond psychologically and physiologically to both film and music, but with the increasing number of scholars emerging in this field many of these issues will continue to be explored.

Glossary

Axis II disorder One of the five axes of the multiaxial system of the Diagnostic and Statistical Manual. Axis II contains information about personality disorders and mental retardation.

Borderline personality disorder Personality disorder that overlaps substantially with histrionic personality disorder; it is characterized by marked instability in mood, interpersonal relationships, impulse control, and identity.

Histrionic From the Latin word *histrionicus*, meaning of or pertaining to actors, acting, or theater.

Hysteria A historically common medical diagnosis in women, marked by excessive emotionality and unexplained physical symptoms. HPD traces its roots to this condition.

Hysterical personality disorder A precursor to histrionic personality disorder described briefly in the DSM-II in 1968. This diagnosis emphasized seductiveness, impressionistic speech, dramatic and emotional displays, and clinging and demanding relationships.

Impressionistic speech Also known as hyperbolic speech. A term used to describe speech lacking in detail and emphasizing emotion.

Description

Histrionic personality disorder (HPD) manifests itself by early adulthood. Like other personality disorders, HPD is associated with enduring abnormalities in emotion, cognition, and interpersonal behavior. According to the most recent version of the American Psychiatric Association's Diagnostic and Statistical Manual (DSM), the DSM-IV-Text Revision (DSM-IV-TR), published in 2000, individuals with HPD are characterized by excessive displays of emotionality and need for attention. They are often flamboyant and dramatic, frequently earning the reputation of the 'life of the party.' Indeed, this theatrical behavior inspired the name 'histrionic,' after the Latin 'histrionicus,' meaning pertaining to an actor.

Not surprisingly, people with HPD often experience discomfort when not the focus of interest. Their attention-seeking behavior, which often expresses itself as enthusiasm and flirtatiousness, may initially charm a new friend or love interest. Nevertheless, this behavior quickly becomes frustrating once it becomes evident that these dramatic behaviors serve largely as attention-grabbing gestures. Individuals with HPD may also attempt to attract others through inappropriately seductive and sexual behavior. Because they tend to use their physical appearance to draw attention to themselves, they often expend an inordinate amount of resources on fashion and grooming. In addition, they may 'fish' for compliments and become distraught by an unflattering photograph or trivial criticism of their physical appearance.

Individuals with HPD are characterized by exaggerated expressions of emotion that typically strike others as overblown or insincere. Their language often seems vague and generalized (sometimes termed as 'hyperbolic speech'), and is marked by black-and-white opinions lacking in detail or supporting evidence (e.g., "That movie was just wonderful," "He was a horrible, terrible boyfriend"). Individuals with HPD are easily influenced by people and fleeting trends, and may be overly trusting of others. Additionally, people with HPD tend to believe their interpersonal relationships to be more intimate

than they actually are, and may refer to a casual acquaintance as a cherished friend.

Some of the associated features of the disorder, which are not listed as formal diagnostic criteria in the DSM-IV-TR, include persistent difficulties with romantic and sexual relationships. The relationships and friendships of individuals with HPD often lack genuine emotional intimacy, and their sexual seductiveness may coexist with a tendency to find sexual relationships consistently unsatisfying. People with HPD may be manipulative, a tendency that often coexists with pronounced dependency on their romantic partners. Their friendships are often unsuccessful, largely because friends are often alienated by their incessant demands for attention and sexually provocative behavior. Individuals with HPD usually expect immediate satisfaction and may become excessively frustrated when forced to wait for desired rewards, such as a return call from a friend. They frequently seek excitement and novelty, although their interest in new things wanes quickly. Finally, individuals with HPD may make manipulative suicidal gestures and threats to gain attention, although they rarely commit suicide.

History

HPD traces its roots to the broad and poorly delineated condition once known as 'hysteria,' a state of excessive emotionality traditionally linked to females. The origins of hysteria extend at least as far back as 1900 BC to the writings of ancient Egypt and Greece. At that time, hysteria was said to be brought on by a misplaced uterus or 'wandering womb'; indeed, the prefix 'hyster' means 'womb' in Latin. In Hellenic Greece, people often thought of the uterus as akin to a wild animal, free to roam around a woman's body. This wandering occurred when the womb remained barren for an extended period of time. Thus, women with unsatisfactory sex lives, such as virgins and widows, were especially considered prone to hysterical outbursts. In fact, in ancient Greece, sexual behavior was often prescribed as a remedy for hysteria.

By the Middle Ages, theories regarding the causes of hysteria had shifted considerably. Hysteria was then viewed as the result of wanton sexuality, which supposedly predisposed women to the disorder. Hysteria also became increasingly associated with witchcraft and demonic possession. As early as the seventeenth century, doctors began to see what they called 'disorders' in the personality traits of patients with hysteria. These traits included mental dullness, lethargy, egocentricity, and unexplained physical ailments, most of which are not considered relevant when diagnosing HPD today. Other features, such as suggestibility and outbursts of emotion, evolved from the idea of theatricality, and are commonly associated with HPD today.

Following the Middle Ages, hysteria was increasingly recognized as a natural and physical disorder. Eventually, the idea of hysteria as a disease of the brain and mind emerged. Viennese neurologist Sigmund Freud, whose work with hysterical patients in the late nineteenth and early twentieth centuries laid the groundwork for later theories concerning the unconscious, believed that women possessed innate characteristics, most importantly the absence of the penis, which predisposed them to hysteria.

Following World War II, the American Psychiatric Association developed the DSM to standardize the vast array of diagnostic systems used to diagnose mental disorders. Neither HPD nor hysterical personality was listed in the first edition, DSM-I, which was published in 1952. Nevertheless, both conditions resemble the DSM-I entry for 'emotionally unstable personality.' In 1968, 'hysterical personality' was described briefly in DSM-II, with an emphasis on seductiveness, impressionistic speech, histrionic and emotional displays, and clinging and demanding relationships. Finally, HPD, now referred to by the somewhat less pejorative term histrionic personality disorder, appeared in full-fledged form in DSM-III in 1980, with a substantial focus on dramatic and attention-seeking behavior that persists in today's diagnostic descriptions.

Prevalence and Demographics

Studies using standardized interviews suggest that the prevalence of HPD is about 2–3% of the general population. Much higher rates of HPD occur in clinical settings, with rates typically ranging between 10 and 15%. The differences in prevalence across studies are probably due in part to differences in the measures used to diagnose HPD.

DSM-IV warns readers that cultural factors may influence the manifestation of HPD. However, the manual does not delineate these factors or their specific effects on the manifestation of the disorder. In fact, scant research has examined cultural differences in the prevalence or expression of HPD. Some researchers suspect that differing cultural norms affect the rate of HPD across various populations. For example, HPD may be diagnosed less frequently in Asian cultures than North American cultures due to the discouragement of overt sexuality in the former cultures. In contrast, in Hispanic cultures, where overt displays of sexuality are less stigmatized, HPD may be more prevalent. Nevertheless, there is little systematic research on these conjectures.

Historically, HPD has been viewed as a predominantly female disorder, and DSM-IV notes that HPD may occur

more often in females than in males. Psychologist Paula Kaplan has speculated that HPD is a collection of exaggerated behaviors traditionally perceived as feminine. Some authors, like George Washington University psychiatrist Paul Chodoff, have even argued that merely behaving in a highly traditional 'feminine' manner may lead to a diagnosis of HPD, although research evidence for this claim is wanting. Notably, in non-clinical samples, HPD is equally prevalent in males and females. This finding suggests that the apparent sex difference in HPD may be due to a selection bias. Specifically, women with HPD may be more likely than men with HPD to seek treatment, perhaps because they are more likely to suffer from co-occurring conditions, including depression.

Several researchers have examined the potential for sex-bias in the diagnosis of HPD. In 1989, University of Kentucky psychologists Maureen Ford and Thomas Widiger examined psychologists' ratings of a case vignette describing an individual with either HPD, antisocial personality disorder (APD) – a condition marked by manipulateness, dishonesty, and irresponsible behaviors – or an equal number of features of both disorders. The sex of the individual was listed as male, female, or unspecified. For the APD vignette, clinicians diagnosed the disorder more frequently in men than in women, or in those of an unspecified gender. Clinicians tended to diagnose females who exhibited APD features with HPD. When the vignette described an individual with HPD, clinicians diagnosed it at high rates in women and low rates in men. In contrast, when clinicians rated individual diagnostic criteria in the DSM, sex differences disappeared, suggesting that sex bias for HPD exists at the level of the overall diagnosis, but not at the level of individual diagnostic criteria.

Although HPD may be associated with traditional manifestations of femininity, David Klonsky, then at the University of Virginia, and his colleagues also found associations between the disorder and masculinity in a 2002 study. Specifically, people who behaved in a traditional fashion consistent with their biological sex, such as a stereotypically 'masculine' male or a stereotypically 'feminine' female, displayed more histrionic features. Some authors have conjectured that traditionally 'masculine' manifestations of HPD, such as the 'macho' male, may exist, but due to biased diagnostic criteria these people may be overlooked or underdiagnosed.

Co-occurrence and Comorbidity

HPD frequently co-occurs with other personality disorders, which are listed in Axis II of the DSM. This co-occurrence is especially marked for Cluster B ('dramatic, emotional') personality disorders, which in addition to HPD are borderline personality disorder (BPD), APD, and narcissistic personality disorder (NPD). This overlap of HPD with BPD, which is especially pronounced, may be due in part to similarity in the diagnostic criteria of these conditions, including attention seeking and manipulateness. Nevertheless, individuals with BPD tend to be more marked by self-destructiveness, feelings of emptiness, and anger-filled relationships than individuals with HPD. DSM-IV attempted to reduce the overlap between these two conditions by removing the criteria of angry outbursts and manipulative suicidal gestures from the diagnosis of

HPD. Some researchers, such as Emory University psychologists Drew Westen and Christine Heim, have even proposed the existence of a subtype of BPD with prominent histrionic features.

Both HPD and APD are characterized by manipulative behaviors, impulsiveness, and recklessness. However, HPD lacks the pervasive involvement with antisocial and criminal behavior associated with APD. Individuals with HPD or NPD are both known to crave attention; however, those with NPD are more likely to use this attention for validation rather than satisfaction of sexual or interpersonal needs.

HPD also overlaps highly with dependent personality disorder (DPD). Individuals with DPD and HPD are similar in their reliance on others for approval and guidance; however, individuals with DPD typically lack the theatrical quality of those with HPD.

Finally, HPD exhibits moderate to high rates of co-occurrence with Axis I conditions (major mental disorders), such as somatization disorder, dissociative disorders (e.g., dissociative identity disorder, known formerly as 'multiple personality disorder'), major depression, and dysthymic disorder, a form of chronic and low-level depression. Still other Axis I conditions can be confused with HPD. In particular, bipolar disorder, formerly known as 'manic depression,' may superficially resemble HPD because of its high levels of impulsivity, self-centeredness, and extraversion, especially during manic and hypomanic (mild manic) states.

Assessment

There are no published diagnostic instruments for the assessment of HPD per se. As a consequence, clinicians typically use 'omnibus' or broadband measures of personality disorders to diagnose HPD. These measures include the Structured Interview for DSM-IV Axis II (SCID-II) and the Personality Diagnostic Questionnaire, DSM-IV version (PDQ-4), both of which contain subscales for HPD. In the SCID-II, a clinician rates one item per HPD diagnostic criterion on a scale of one to three. A rating of one indicates the criterion is absent, whereas three indicates the criterion reaches threshold or is true. In contrast, the PDQ-4 is a True or False self-report questionnaire. Other broadband measures such as the Minnesota Multiphasic Personality Inventory-2 (MMPI-2) and Million Clinical Inventory, 3rd edition (MCMI-III), may be helpful in detecting HPD. For example, on the MMPI-2, individuals with HPD will often display a Hysteria-Psychopathic deviate profile or a Psychopathic Deviate-Hypomania profile. Elevations on the Hysteria scale of the MMPI-2 reflect a Pollyannaish view of the world, along with a propensity toward physical complaints; elevations on the Psychopathic deviate scale reflect a propensity toward antisocial behavior, including dishonesty, manipulateness, and elevations on the Hypomania scale, reflecting a propensity toward high levels of energy, poor impulse control, and grandiosity. Individuals with HPD sometimes also exhibit high scores on the MMPI-2 Psychasthenia scale, reflecting self-doubt and worry.

Most diagnostic measures for HPD rely largely or entirely on self-report. Nevertheless, some authors have questioned the utility of self-report in the assessment of HPD given that people with this condition tend to lack insight into the nature and

extent of their symptoms. As a consequence, the use of informants, such as coworkers or friends, may offer fresh opportunities for the assessment of HPD and related personality disorders. In a pioneering study of the effects of maladaptive personality traits on military discharge, University of Virginia psychologist Thomas Oltmanns found that peer nominations of HPD were substantially superior to self-reports of HPD in predicting early separation from active duty. This study suggests that informant reports can not only provide meaningful information about the maladaptive traits associated with HPD, but also help to circumvent some of the limitations of self-reports in detecting this condition.

Another potentially fruitful avenue for the assessment of HPD stems from rapid perceptions of small pieces of interpersonal behavior, sometimes termed 'thin slicing.' In another study by Oltmanns' team, participants viewed the initial 30 s of a videotaped interview of individuals diagnosed with personality disorders, including HPD. Even from this brief clip of behavior, observers blind to participants' diagnoses judged people with HPD as more extraverted and likeable than other people. These findings suggest that relatively little interpersonal information may be required to detect at least some of the hallmark interpersonal features of HPD.

Etiology

The etiology (causation) of HPD remains poorly understood. Comparisons of monozygotic (identical) and dizygotic (fraternal) twins suggest that HPD is moderately heritable, but as yet unknown environmental factors also play a role in its development. Some authors have argued that early parenting factors play a role in HPD; for example, some have contended that HPD stems from an anxious attachment style. Nevertheless, it is not clear whether the deficits in interpersonal attachment observed in individuals with HPD are causes of the disorder, or merely manifestations of it.

From a personality trait perspective, individuals with HPD differ from other individuals on the dimensions of the five-factor model of personality. In particular, studies show that HPD is associated with elevated scores on some facets of extraversion, such as gregariousness and excitement-seeking; neuroticism, such as impulsivity; openness to experience; and fantasy, and decreased scores on some facets of conscientiousness, such as self-discipline and deliberation. Nevertheless, the extent to which these trait differences shed light on the causes of HPD, as opposed to merely describing its personality features, is unclear.

Treatment

Psychologists and psychiatrists have implemented a variety of interventions with HPD, none of which has been systematically investigated in controlled studies. No studies have examined the potential utility of medications with HPD patients, so most of the attention has been focused on psychotherapies.

Cognitive and cognitive-behavioral treatments are designed largely to alter the underlying assumptions of HPD patients. University of Pennsylvania psychiatrist Aaron Beck and other cognitive therapists have argued that HPD is associated with a

set of core and often unspoken beliefs, such as “I need others to admire me to be happy” or “Unless I am consistently entertaining, people close to me will abandon me.” Their treatment for HPD is centered on challenging this and other core beliefs using cognitive restructuring and behavioral experiments (‘homework’) intended to disprove these beliefs. For example, a cognitive therapist might set up a behavioral experiment in which an HPD person remains quiet at several parties and determines whether her friends actually abandon her.

Other commonly used therapies for HPD include (a) behavioral therapy, which attempts to extinguish maladaptive behaviors, such as manipulateness or excessive seductiveness, and to reinforce adaptive behaviors, such as efforts to achieve attention in socially healthy ways (e.g., appropriate assertiveness); (b) interpersonal therapy, which attempts to improve the social skills of individuals with HPD; and (c) psychodynamic therapies, which attempt to use the therapeutic relationship to resolve childhood conflicts and parenting deficiencies (e.g., insufficient attention from one’s mother, father, or both) that ostensibly contribute to HPD. Without controlled scientific data, however, it is difficult to recommend any of these psychotherapies with confidence. Research is needed to compare the efficacy of competing therapeutic approaches for HPD, and to ascertain whether attempting to alter HPD individuals’ deep-seated personality traits is more fruitful than accepting these traits and attempting to alter their problematic behavioral manifestations.

HIV/AIDS: The Role of Behavior and the Social Environment in a Global Pandemic

J B F de Wit and P C G Adam, The University of New South Wales, Sydney, NSW, Australia

© 2012 Elsevier Inc. All rights reserved.

Glossary

Antiretroviral treatment (ART) Treatment of retroviruses with genome in the form of RNA rather than DNA; mostly used to refer to the treatment of HIV with a combination of drugs. Also known as Highly Active Antiretroviral Treatment (HAART), which refers to increased efficacy compared to early treatments.

Empowerment Strengthening individuals and communities by building confidence, capacity, and resources.

HIV surveillance The regular and comprehensive monitoring of the spread of HIV in a population. Second-generation surveillance also includes the monitoring of risk behaviors to signal and explain changes in infection rates.

Magic bullet A perfect drug to cure disease or, more generally, a simple solution for a complex problem.

Opportunistic infections Infections that are mostly present when someone has a compromised immune system, for example, because of HIV.

Pandemic An epidemic that has spread across a large region, such as a continent.

Risk compensation Adjustment in behavior in response to perceived changes in risk; individuals may behave less cautiously when risk, for example, for HIV infection is perceived as lower.

Social cognition The study of how people make sense of their social world and process social information, including its encoding, storage, and retrieval in memory.

Social drivers Social, political, and economic factors that may contribute to ill health and impaired well-being in a population; mostly used to explain health inequities between population groups. Social factors also shape the behaviors of individuals and communities and their access to health services.

Social stigma Social disapproval of individuals and communities because of specific characteristics, beliefs, or practices; often rooted in stereotypes and prejudice; contributes to ostracism and discrimination.

Viral load Amount of virus in a person's body fluid, such as blood; measure of the severity of a viral infection.

Introduction

Since AIDS was first noted in the early 1980s, the epidemic of HIV, the virus that causes it, has become one of the major health crises humanity has ever seen. Today's pandemic affects millions of people across the globe. As an unprecedented public health crisis, the HIV epidemic also undermines the social fabric and the economic development of entire communities and nations. Ensuring appropriate, adequate, and continued engagement of individuals, communities, leaders, and funders in the HIV response continues to be a major challenge, often augmented by the stigmatized nature of the practices involved in HIV transmission and the marginalized position of many of the affected communities. An important lesson learned over the past decades is that there is no easy and simple prevention 'magic bullet,' nor is there one for treatment. However, a significant body of research in the behavioral and social sciences has revealed some of the factors that shape sexual and drug use behaviors.

As the remainder of this article will discuss in more detail, the multiple behavioral practices that are implicated in effective HIV prevention, diagnosis, and treatment are not only shaped by individuals' awareness, preferences, and skills but also by the barriers and opportunities in their wider social environment. The next sections focus on the primary prevention of HIV, and, in particular, highlight the role of sexual practices and sexual health promotion. Following a brief

outline of the history, evolution, and status of the global HIV epidemic, social cognition approaches to understanding and changing sexual risk-taking will be discussed. This is followed by a consideration of the limitations of conceptual frameworks that focus on individuals' decision-making, and an exploration of the ways in which social processes shape sexual practices and vulnerability to HIV. Against this background, the subsequent section addresses the evolution of prevention models that have emerged. Continuing innovations in medical research promise a new approach to HIV prevention, and these biomedical HIV prevention approaches are also discussed.

History and Epidemiology of HIV

An excellent, detailed overview of the history of the HIV epidemic has been collated by Avert, an international HIV and AIDS charity (see websites listed below). This reminds us that awareness of AIDS began in the United States in mid 1981, when a number of reports in medical journals documented the occurrence of unusual numbers of a rare form of aggressive cancer and a rare lung disease in young gay men in New York City and California. Experts at the US Centers for Disease Control and Prevention quickly suspected that this outbreak of co-occurring life threatening opportunistic infections possibly signaled a new disease caused by an infectious agent that

might be sexually transmissible. It was however unclear what the cause was, how many people were affected or at risk and what might be done. Following the alarming first reports, public health concerns rapidly increased as AIDS was also diagnosed in other communities in the United States, in particular people who inject drugs, people with hemophilia and Haitian migrants; very soon AIDS had also been reported in many other countries and in every continent. In these times of fear of an unknown, lethal disease that could possibly affect entire populations, the discovery, in 1983, of HIV, the virus that causes AIDS, was of critical importance. Once the etiological agent was known, diagnostic tests could be developed and epidemiological studies could be conducted to assess prevalence, incidence and risk factors.

Today, we know that there are three main ways in which HIV is transmitted: contact with blood, mother-to-child transmission, and sexual intercourse. Sexual transmission is by far the most important route for the spread of HIV globally. Sexual risk of HIV mainly results from vaginal–penile and anal–penile intercourse, and can be prevented by the consistent use of male or female condoms. Antiretroviral drugs provided to HIV-positive pregnant women can substantially reduce the likelihood of their children being infected. In many parts of the world, infection through blood and blood products is now effectively prevented. The main risk related to contact with blood involves the sharing of needles, syringes, and other equipment for injecting drug use. Transmission via this route is preventable through the use of sterile equipment; disinfecting equipment reduces the likelihood of transmission but does not eliminate it. Programs that provide sterile needles and syringes are effective harm reduction measures to prevent the spread of HIV and other infectious agents, notably the hepatitis C virus, among people who inject drugs.

In its 2010 report on the global epidemic, the Joint United Nations Program on AIDS (UNAIDS) estimated that by the end of 2009 a total of 33.3 million people were living with HIV worldwide, of whom 2.5 million were children younger than 15 years. Since 2001, the estimated number of people living with HIV (PLHIV) has increased by 16%, which is in part explained by the successful expansion of access to antiretroviral treatment (ART) that is saving lives. Worldwide, 5.2 million people received ART in 2009, a 30% increase compared to only 12 months earlier. As a result of increasing numbers of people receiving treatment, AIDS-related deaths declined from a peak of 2.1 million in 2004 to an estimated 1.8 million in 2009. Also, while HIV infections still occur at high rates, with an estimated 2.6 million new infections diagnosed in 2009, this number is down by 21% compared to 1997, when the annual number of new infections is thought to have peaked. Substantial prevention success has in particular been achieved in Sub-Saharan Africa. Although it is difficult to establish the factors that underlie this prevention success at the global level, it is thought to at least in part reflect the effectiveness of ART, particularly for the prevention of mother-to-child-transmission (PMTCT). It is also clear that other prevention programs have been strengthened, including the availability of free, anonymous, and voluntary counseling and testing for HIV (VCT), as well as the promotion and distribution of condoms. Despite some prevention success and the rapid increase in

access to ART in developing countries, numbers of people newly infected remain high. Stemming the HIV epidemic upstream, by strengthening prevention of new infections, continues to be critical.

Understanding the Role of Behavior

Mapping Risk Behaviors

The recognition that HIV is in particular transmitted via sexual and drug use practices has sparked an unprecedented amount of research into these behaviors. This research addresses three major, interrelated, questions: what is the association between behavior and HIV infection, how do risk behaviors differ between individuals and communities and how do they evolve over time, and which factors can explain risk behaviors and offer points of entry for prevention through behavior change. Behavioral risk factors for HIV infection have mainly been addressed through case-control studies that compare individuals with and without HIV, and through cohort studies that follow individuals over time and assess the potential risk factors of individuals who become newly infected during the course of the study. This type of behavioral epidemiology has provided a strong evidence-base that unprotected vaginal and anal intercourse and the sharing of needles and syringes are the main behavioral risk factors for the transmission of HIV. It has also established that the consistent, correct use of condoms and lubricants effectively prevents transmission, as does the use of sterile injecting equipment. An important focus of behavioral epidemiology is to more precisely establish the likelihood of transmission of HIV under different conditions. This work has shown that in heterosexual intercourse, HIV is more easily transmitted from an infected man to a woman than vice versa, and is more easily transmitted through anal than vaginal intercourse. In homosexual anal intercourse, the risk of HIV transmission is higher for the receptive than the insertive partner. The risk of HIV infection also increases with the number of sexual partners that individuals have, in particular when these partnerships are concurrent.

Knowledge of behavioral risk factors has contributed to understanding that specific communities are more vulnerable to HIV infection, and has enabled behavioral surveillance to track changes over time in most-at-risk-populations. Worldwide, behavioral risk for HIV is particularly high among gay and other men who have sex with men, including transgender men, and this increased risk extends to the female partners of bisexually active men. Sex workers and their clients are also at behavioral risk for HIV, in particular in developing countries where sex workers are less empowered, and condom use is less established and less normative than in many parts of the developed world. The risk for HIV in people who inject drugs is reduced in countries that have put in place effective harm reduction approaches, but in many countries coverage of such services remains absent or limited. Moreover, sexual partners of drug users are at risk of HIV infection, and there frequently is overlap between communities of people who inject drugs, sex workers, and men who have sex with men. In most societies, young people are considered vulnerable to HIV because of their developing

sexual relationships, and their higher number of sexual partners compared to many adults. In countries where the HIV epidemic has generalized, and is mostly transmitted through heterosexual contact, all sexually active individuals are considered at risk.

Social Cognition Theories

Second-generation surveillance of HIV that not only gathers information regarding the occurrence of infections but also monitors risk behaviors, has become an important tool to guide the allocation of resources for prevention, and to track its impact over time. However, this behavioral monitoring in itself is insufficient to guide the development of approaches that effectively promote preventive behaviors, notably the use of condoms. Theory-based research into the factors that shape behaviors is critical for the development of effective prevention programs. Much of this research is informed by theories derived from a social cognition perspective of social behavior. Broadly, this perspective acknowledges that individuals' behaviors are shaped by a wide range of factors extrinsic and intrinsic to the individual. Individuals' cognitions, or thoughts, about their behavior are seen as important proximal factors, which mediate the effects of other factors. Cognitions are also assumed to be more open to change than other factors (e.g., a person's social environment), which makes them attractive targets for behavior change programs. Over time, a range of social cognition theories of behavior have been developed, some of which have been specifically designed to explain health behaviors more generally or HIV-related behaviors in particular. These theories have in common a concern about how individuals make sense of social situations, and are based on the assumption that the way in which people perceive reality offers a more important explanation of their behavior than an objective description of the environment in which they live and act. In a social cognition perspective of behavior, beliefs are more important than factual knowledge, although beliefs at least in part reflect knowledge and can be changed through direct experience, modeling, or the provision of information.

The social cognition approach to health behavior encompasses a range of well-known and frequently used theories, such as the Health Belief Model, Protection Motivation Theory, the Theory of Reasoned Action, the Theory of Planned Behavior, and Social Cognitive Theory. These theories differ substantially in the precise variables they propose as explanations of behavior and the relationship between these variables, but, across theories, several key concepts can nevertheless be identified that are thought to influence people's behaviors. These include a notion of perceived threat that is thought to motivate individuals to change their behavior. Perceived outcomes of the behavior and perceived social norms are thought to further guide behavioral decision-making. The likelihood that people enact their behavior of choice is thought to be also influenced by their perception of self-efficacy, that is, their sense of ability to enact the behavior. The relationship between these variables and behavior is often assumed to be mediated by people's intentions, a reasoned plan that captures individuals' motivation and reflects their salient beliefs about the behavior. Based on the recognition of overlap between theories, several integrated

models have been proposed to explain HIV-related behaviors. These include the Information–Motivation–Behavioral skills model that sees HIV preventive behavior as a reflection of individuals being well informed, motivated to act, and having the skills and confidence to take action. This model also delineates implications for HIV prevention, which should focus on providing effective, relevant, and targeted health information; increasing personal motivation (e.g., by influencing perceived threat and the consequences or outcomes of behavioral alternatives) and social support; and skills training to strengthen self-efficacy.

Enacting Motivation

For a long time, the extensively researched social cognition models have been considered to offer a good explanation of health behavior. However, more recently, they have come under substantial scrutiny and it is acknowledged that, while they may explain more variance in behavior than alternative approaches, they usually only explain one-quarter to one-third of the variance in behavior. Social cognition models have also been criticized on several conceptual grounds. One longstanding criticism notes that individual theories are incomplete and focus only on some factors while ignoring others, as illustrated by the diversity of factors that different theories highlight and the many studies that have proposed additional factors. An influential version of this criticism underscores that social cognition models highlight factors that contribute to individuals' motivation, but fail to explain how motivation is translated into action. In part, this is addressed by the important role of the self-efficacy concept in many theories. Furthermore, the reasoned approach to behavior, which encompasses the Theories of Reasoned Action and Planned Behavior, acknowledges the importance of environmental constraints and individuals' skills and abilities in acting on behavioral intentions. In addition, stage theories in the social cognition tradition, in particular the Transtheoretical Model (also known as the Stages of Change Model), underscore that behavioral change is a process that involves a progression from being essentially unengaged to successfully maintaining change. Stage theories differ in the number of phases they distinguish. The AIDS Risk Reduction Model, for instance, distinguishes three stages, whereas the Transtheoretical Model proposes five stages. Nevertheless, two broad stages are commonly proposed: a motivational stage and a behavioral enactment stage. The motivational stage involves deliberating alternatives and setting a goal, while the behavioral enactment stage involves planning and acting to achieve the set goal. Stage models hypothesize that different types of cognitions are influential at different stages of the change process, and that progression through stages of change is supported by a range of evolving, experiential and behavioral, self-regulation processes.

A body of theory and research, which also draws on traditions in clinical psychology, underscores the importance of self-regulation skills and strategies in translating intentions into behavior, such as the setting of goals, cognitive and behavioral preparations, and the ongoing monitoring and evaluation of goal-directed activities. This research has in particular demonstrated the role of preparatory behaviors, such as buying, carrying, and talking about condoms, and highlights the importance of planning when and how to act on one's good

intentions (action plans) and how to deal with potentially difficult situations and setbacks (coping plans). One specific form of planning, the formation of implementation intentions that specify more precisely when, where, and how to perform a specific behavior, has been found especially effective in strengthening the link between intentions and behavior in many health behavior domains. Despite substantial promise for HIV prevention, the application of planning strategies to condom use remains limited, perhaps because of the complexity of the multiple (preparatory) behaviors, and the need for their repeated enactment to achieve the goal of consistent condom use.

Behavior in Context

A second criticism leveled at social cognition models holds that these models overemphasize the role and importance of individuals' decisions. It is argued that many behaviors occur in complex and evolving social interactions, and social cognition models are seen as failing to take into account the influence of the situation, context, and social environment on behavioral practices. At least in part, this criticism may, however, reflect theoretical misunderstandings. Social cognition models, in particular the reasoned action approach, underscore that individuals' behaviors reflect beliefs that are salient in a specific situation and time. Nevertheless, alternative theoretical approaches have also emerged that more generally question the role of decision-making in social behavior. These approaches build on theory and research in experimental social psychology, which has shown that individuals' goals can be activated automatically by cues in the environment, and guide behavior without much deliberate thought. Furthermore, these automatically activated goals often provide alternative courses of actions, such as habits, that pose barriers to acting on 'good intentions.'

Recently, so-called dual systems theories have been proposed, such as the Reflective-Impulsive Model, which see behavior as resulting jointly from two action systems: one reflective or reasoned, and one impulsive or reactive. According to these models, whichever action system is most influential in guiding behavior depends on a range of factors, such as the motivation and ability to devote thought to deciding on a course of action, and the strength of action tendencies in the impulsive system. Impulsive action tendencies tend to be stronger when they reflect habits, social concerns, and personal needs, especially when these have been deprived. This type of theory can well explain why individuals are more likely to engage in sexual risk-taking when they are sexually aroused or in love, as these affective states result in behavioral responses that originate in the impulsive system. Furthermore, the influence of the use of alcohol and drugs on sexual risk-taking can be explained by a reduction of behavioral guidance provided by the reflective system.

The concern that social cognition models overemphasize individual decision-making and largely ignore the importance of social interactions and the influence of the situation, context, and social environment is also acknowledged and addressed in these theories themselves. Importantly, building on the Major Theorists' Model of Behavior that integrates concepts from prominent social cognition models, the reasoned action approach now identifies environmental constraints and

individuals' skills and abilities as factors that affect the translation of intentions into behavior. However, although social cognition models increasingly address the role of the environment in which individuals enact their intentions in more explicit ways, and specify mechanisms through which the environment affects behaviors, we note that their primary focus remains on the proximal factors that affect individuals' behavioral decisions.

Environmental Constraints

It is increasingly recognized that individuals' health and behaviors are shaped by factors in their environment. The main conceptual tenet of a resulting social-ecological approach is that health behaviors are functions of the reciprocal relationships between an individual and the environment. In this perspective, the environment controls and sets limits on behavior, which implies that changing aspects of the environment will result in the modification of behavior. At the same time, individuals' behaviors shape their environment, and changes that promote health can be achieved through empowering individuals and communities. The environment in which individuals live is multilayered and multidimensional, and a distinction is often made between the physical, the sociocultural, and the socioeconomic environment, at the macro-, meso-, and microlevel. Commonly distinguished environmental influences encompass regulations, policies, services, and practices that are located in the broader society, more delineated communities, specific organizations, and close social relationships, such as peers and families.

Empirical support for a social-ecological approach to health comes from epidemiological studies that document social inequalities in health and from social science research to understand these social drivers. Social drivers refer to the social processes and arrangements that operate around an individual and that reflect prevailing norms, values, networks, structures, and institutions. Research into the social drivers of the HIV epidemic reflects the recognition that the developing world is much more strongly affected than the developed world. Moreover, in developing and developed countries alike, the more socially vulnerable or marginalized, notably women, young people, men who have sex with men, and people who inject drugs, are more likely to become affected, as are ethnic/racial minorities, in particular African-Americans in the United States. Research into the way these social factors affect the HIV epidemic is still limited and fraught with difficult challenges. Importantly, social drivers are complex, interactive phenomena that need to be understood within a specific context. This requires sophisticated methods and conceptual frameworks. Nevertheless, evidence is accumulating that illustrates that preventive practices can be undermined by cultural myths and misconceptions regarding the transmission and prevention of HIV. Also, religious teachings, such as those that prohibit sex outside of marriage and ban the use of condoms in most if not all instances of sexual intercourse, may increase the vulnerability of individuals and communities. Gender inequality and traditional masculine values disempower women to insist on sexual faithfulness or condom use, in particular when their opportunities for economic independence are limited. Armed conflict, political instability, displacement, and economic hardship may promote sex work, and, to the extent that this source of revenue

is critical for survival, sex workers' ability to insist on condom use is compromised. Furthermore, social stigma and taboo underlie the denial of the existence of specific communities, such as men who have sex with men, and result in a lack of services or make services difficult to access because of real or expected discrimination. The increasing recognition of the importance of these and other social factors in the health and behavior of individuals and communities supports a focus on creating an enabling environment as an indispensable health promotion strategy for the prevention of HIV infection.

Evolving Prevention Responses

Behavior Change Approach to Promote Condom Use

HIV prevention encompasses a range of strategies that broadly comprise behavioral change programs and the provision of health services. The promotion of behavior change, in particular condom use and HIV testing, is the earliest response to prevent HIV. Importantly, behavior change was initiated by affected communities, in particular gay men, before being promoted by governmental and nongovernmental agencies. There is now a large body of evidence that has been synthesized in numerous reviews and meta-analyses of original studies that show that significant effects of behavioral prevention of sexual risk can be found in a range of population groups, including adolescents, heterosexual adults, gay and other men who have sex with men, people who use drugs, PLHIV, ethnic minority groups, sexually transmitted infections (STI) clinic patients, and people with mental illness. Significant effects of behavioral prevention have been obtained using a range of outcome measures, in particular increased condom use, reducing unprotected sex, and reducing numbers of partners. Effects on the acquisition of HIV and STI infections have been assessed less often than effects on behaviors. Evidence is now also growing that a range of behavioral prevention strategies can be effective in promoting risk reduction behaviors, including mass media campaigns, computer-delivered interventions, individual counseling, small-group programs, peer education, and community social influence and empowerment approaches. Curriculum-based sex and HIV education has also been found to improve sexual behaviors. Importantly, while it is sometimes thought that frank, comprehensive sex education may hasten sexual initiation or increase sexual behavior in young people, there is strong evidence that it may in fact delay sexual initiation and reduce sexual behavior. Abstinence-only education for young people, in contrast, is generally not effective and has been criticized for misrepresenting information and withholding life-saving options.

HIV behavioral prevention programs are highly diverse, and not only target a range of communities in different countries, but typically also encompass multiple components, use a range of delivery strategies, and differ in intensity and composition of the target audience. Consequently, much remains to be learned regarding the features that are most likely to contribute to program efficacy, but it is clear that well-targeted and well-designed behavioral prevention programs can be cost-effective. What has been learned is that, irrespective of target audience and delivery strategy, programs that are most effective are informed by behavioral theory, based on appropriate formative

behavioral research, and address the real needs of the individuals and communities they target. These needs may well change as the HIV epidemic evolves, as may preferred (electronic) delivery channels. What is required is a continuing adaptation of HIV prevention that reflects these and other changes, as well as evolving behavioral theory.

VCT and Other Health Services

The availability and accessibility of health services also is a cornerstone of HIV prevention. HIV prevention health services that have proven to be effective include VCT, the prophylactic use of ART to prevent HIV infection from mother-to-child, and, depending on laws and policy acceptance, harm reduction measures for people who inject drugs. Evidence is also available now from studies in high prevalence countries in sub-Saharan Africa, which suggests that male circumcision reduces the likelihood of men becoming infected with HIV through heterosexual intercourse. Over time, male circumcision may also benefit women, as it reduces the likelihood that their male partner is HIV positive. VCT in many ways is seen as a key element of HIV prevention, and is therefore also often offered outside of the health care system (e.g., in community venues), anonymously, and free of charge. Testing for HIV has important advantages for individuals' health and well-being, as well as for public health. It can give concerned individuals who test HIV negative peace of mind and link people who test HIV positive to treatment and support services. Early detection of HIV infection enables the timely initiation of ART, with substantial benefits for individuals' health. Furthermore, there is a considerable body of evidence that shows that people who test positive for HIV change their sexual behavior in ways that reduce the likelihood of infecting their partners.

The health and prevention benefits of HIV testing are well recognized, and a range of health agencies, including the US Centers for Disease Control and Prevention and the World Health Organization, have provided recommendations and guidelines to scale-up provider-initiated testing in a wider range of health care settings. To be optimally effective, this routine offering of HIV testing needs to be accompanied by adequate referral and access to prevention, treatment, care, and support services. As HIV infection remains a serious condition that in many contexts is highly stigmatized, it is argued that obtaining informed consent for provider-initiated HIV testing remains important, even though this may pose a burden on the health care system and reduce uptake. Testing HIV-negative typically has no effect on individuals' behaviors, and behavioral counseling is often not appreciated by people who test HIV negative. In our view, these are, however, insufficient reasons to abandon counseling for individuals who test HIV negative. Rather, this suggests that more acceptable and effective counseling models need to be developed. There is some research that shows that enhanced or more tailored counseling can be acceptable and have beneficial effects on sexual risk-taking of individuals who test negative. Furthermore, while the uptake of HIV testing can be increased when this is more frequently and routinely initiated by providers, it remains important to also promote client-initiated testing through communication approaches. This requires understanding and addressing barriers to and facilitators of client-initiated HIV

testing. In addition to easy access to services and timely provision of test results, these include an awareness of personal risk, and, perhaps most importantly, perceived stigma of HIV and fears of social rejection by partners, family, and the wider community.

Biomedical Prevention: Promises and Challenges

VCT, PMTCT, and male circumcision make explicit use of medical technologies for the prevention of HIV, and as such are part of what has become known as biomedical HIV prevention. This also includes the diagnosis and treatment of STIs that increase the likelihood of HIV infection, in particular those that can cause genital ulcers, such as syphilis and genital herpes. Evidence of the efficacy of community interventions to treat STIs on HIV infection rates is, however, mixed, at best. Ideally, biomedical prevention also includes vaccination, but it is unlikely that an effective and safe vaccine against HIV will become available in the near future, due to the complexities of the virus. A biomedical HIV prevention approach that is seen as particularly promising is ‘treatment for prevention,’ which refers to the use of ART to reduce the likelihood of HIV transmission. PMTCT is a currently used form of treatment for prevention, with a robust evidence-base to support its efficacy. Other forms of treatment for prevention, for which there is some evidence, include the initiation of ART for the prevention of HIV infection shortly after accidental exposure to HIV, known as postexposure prophylaxis. Preexposure prophylaxis is a novel use of ART for prevention that is being investigated for efficacy. Preexposure prophylaxis involves providing people who are not infected with HIV with antiretroviral drugs to reduce the likelihood that they become infected upon possible exposure to the virus. These drugs can be provided orally or in the form of topical microbicides. The treatment-for-prevention approach rests on the notion that the likelihood of HIV transmission is associated with the viral load of an infected person, and should hence be reduced when this viral load is reduced, as a result of effective treatment. The available evidence has led the Swiss Federal AIDS Commission to take the position, known as the ‘Swiss statement,’ that an HIV-infected individual, who has no other STIs and successfully adheres to ART that has reduced the presence of HIV in the persons’ blood below detection thresholds, is not infectious during heterosexual intercourse. Advocates argue that a way to address the global HIV epidemic would be to regularly test everyone at risk for HIV, and immediately start treating all infected individuals, regardless of the status of their immune system as is currently the case. This would result in a reduction in HIV viral load at the population level and reduce the likelihood of HIV transmission in most-affected communities.

Biomedical prevention offers a range of benefits, but also holds major challenges. In particular, while PMTCT is widely supported, other forms of treatment for prevention have proven to be particularly controversial, as has male circumcision. A major benefit of biomedical prevention is that it (potentially) increases the range of options to reduce the sexual transmission of HIV. This is particularly important when condom use remains inconsistent because of limited availability or acceptability. Alternative options that can (also) be

controlled by women and girls are particularly important in social and cultural contexts in which their ability to negotiate condom use is restricted, because of sociocultural, socioeconomic, and gender inequity. Furthermore, many men and women prefer not to use condoms, and numerous studies show that some gay men in particular have developed a range of noncondom risk reduction strategies, on the basis of shared understandings of the mechanisms of HIV transmission and prevention. These community understandings have produced two broad risk reduction strategies based in particular on HIV testing practices, such that some gay men, in some relationship contexts and under some conditions, are willing to engage in unprotected anal sex with a partner who has a similar (i.e., concordant) HIV status (a strategy known as serosorting), or adjust their sexual role to minimize the risk of transmission when engaging in anal sex with a partner who has a different (i.e., discordant) HIV status (a strategy known as strategic or seropositioning; HIV-positive partner takes receptive role, HIV-negative partner takes insertive role).

It is thought that gay men who engage in noncondom risk reduction strategies are aware that these reduce but not eliminate the risk of HIV transmission, and accept this risk to balance protection with pleasure and intimacy. This balance may have substantially shifted for many (gay men), as a result of effective ART that changed HIV infection from a once lethal to a now chronic, challenging condition that has much less impact on people’s health, well-being, and life-expectancy. Incorporating regular viral load testing and knowledge and communication of results may contribute to further reducing the risk of HIV transmission, in particular when viral load is undetectable. However, substantial resources are required for a roll-out of biomedical prevention, which may detract from less costly alternatives. Concerns have also been raised regarding the use of treatment for prevention in countries where availability and accessibility of treatment remains limited. Additionally, biomedical prevention is generally less protective than condom use, and it is possible that a reduced risk of transmission resulting from biomedical prevention can be offset by increased risk behavior. Some evidence of such risk compensation is found among gay men, with increasing trends in unprotected sex and HIV diagnoses observed after the introduction of antiretroviral therapy, which have been linked to optimistic perceptions of treatment efficacy. Furthermore, biomedical prevention may well increase the range of options under the control of women, girls, and others in vulnerable positions, but it leaves unaddressed the social, cultural, and economic factors that shape and perpetuate the structural inequities between individuals, communities, and nations.

HIV Prevention Through Structural Change

Structural approaches constitute the third cornerstone of HIV prevention, which have gained substantial traction, in particular in response to the HIV epidemic in developing countries. Structural approaches aim to address the social drivers of the HIV epidemic that shape the vulnerability of individuals and communities to HIV. This structural approach to HIV prevention is an integral component of health promotion and the new public health approach. Health promotion and new public health approaches go beyond biomedical disease

eradication aims and health education to change behavior, by recognizing the wider social influences on health, and emphasizing the experience of positive health and well-being, rather than the mere absence of illness and disability. Health promotion is a comprehensive approach that, in addition to the development of personal skills and a reorientation of health services, highlights the importance of the development of healthy public policies, the creation of supportive environments, and the strengthening of community action. The community is seen as central to health promotion and should be supported, enabled, and empowered to advocate, inform, and lead holistic programs of action in specific settings, such as neighborhoods, workplaces, schools, and cities. Some communities are organized around shared interest rather than geography, and the prevention of HIV among gay men is a prime example of community-led health promotion.

Renowned examples of a structural approach to HIV prevention include needle and syringe programs. Since the first programs were implemented in the early 1980s, a large body of evidence has accumulated that strongly supports the efficacy of this approach, and shows that, conversely, they do not promote (injecting) drug use. An example of structural prevention for the general population is the national response of Uganda, where the government provided the supportive environment and leadership for a multitude of activities. Other structural approaches to HIV prevention are also supported by evidence, such as the 100% condom use programs in brothels in Thailand, in which managers and police played a key role, or the fostering of empowerment and capacity-building of sex workers and their organizations. Beneficial effects have also been found for structural approaches to mitigate the vulnerability of women and girls, through programs that aim to transform masculine norms or reduce gender-based violence by providing women with microcredits to attain economic independence. A more structural approach focusing on life skills has also been adopted for HIV prevention in young people. Life-skills education addresses a number of topics, such as human rights, citizenship, and social issues, rather than narrowly focusing on health-related skills. Human rights, in particular sexual and reproductive health rights, inform a range of activities of family planning organizations, including sexuality education, service provision, and advocacy for policy and legal reform. Although life-skills and life-skills education are fuzzy concepts, there is evidence to suggest this approach has positive effects on young people's knowledge, attitudes, intentions, skills, and abilities. Effects on sexual behavior and infection rates are less often found.

Structural approaches are promising because of the substantial contribution they can make to the HIV response. To date, however, the implementation and evidence-base for structural interventions remain limited. Structural factors operate in context-specific ways, and the implementation of structural approaches therefore requires a clear conceptual analysis and understanding of this context, and programs may not be directly transferrable to other contexts. Also, multiple structural factors operate in a specific context and can be addressed in various ways, requiring sophisticated analysis and prioritizing. Furthermore, health promotion agencies and practitioners may consider structural interventions beyond their expertise and remit. To date, the number of structural interventions that

have been rigorously evaluated remains limited. Building the evidence-base for structural approaches has proven challenging because of their focus on distal factors that are indirectly related to health behaviors and outcomes, the multiple and dynamic activities that make up structural interventions, and their context specificity.

Conclusion

The HIV pandemic is intricately linked to human behavior, in particular sexual practices, which account for the vast majority of infections globally. Since the early days of the epidemic, a range of effective behavior change approaches have been developed, but there is agreement that these alone are insufficient to curb the epidemic, as is treatment of HIV infection. An important lesson learned is that health behaviors are not only shaped by individual factors but are also patterned by social, economic, and political factors that play-out in structural inequities at the level of relationships, organizations, communities, and nations. A structural approach to HIV prevention is nascent, and much remains to be done to advance conceptual understanding, develop practical guidance, and build the evidence-base. Furthermore, structural approaches target distal factors, and mostly work toward longer term goals. There is no prevention 'magic bullet,' and it is increasingly recognized that the global HIV epidemic can only be effectively addressed by a combination of responses. This combination prevention includes treatment, biomedical prevention and behavior change programs, as well as structural approaches. However logical this may seem, the challenge is to find the right programmatic 'mix' that adequately reflects the epidemic in a country or region, and appropriately addresses the needs of most-affected individuals and communities. Thus far, unfortunately, history has illustrated that much remains to be done to develop, adapt, implement, and bring to scale prevention programs that are known to be effective.

Glossary

Allostatic load The progressive pathological state that occurs when regulation is constantly challenged in a way that chronically activates the autonomic nervous system, neuroendocrine stress axis, or immune system.

Control In the context of physiological regulation, variables that are altered so as to maintain the constancy of another (regulated) variable are controlled variables.

Control system A physical or biological system that is affected by its own behavior.

Homeostasis The state of relative constancy of numerous bodily variables that is achieved by active physiological processes.

Milieu intérieur The internal environment of the body, including the blood, extracellular fluid, various tissues, etc.; the French term is used in homage to the great physiologist Claude Bernard, who began the science of homeostasis.

Negative feedback A signal based on the output of a system that leads to a reduction in that output; negative-feedback control is the basis of many homeostatic regulations.

Osmolality The concentration of a solute in bodily fluids, that is, the total amount of solute in moles per kg water; for bodily fluids, usually given as mOsm kg⁻¹ water.

Regulation In the context of physiology, the maintenance of some variable in a homeostatic state, that is, in a state of relative constancy.

Rheostasis The regulation of a changing state rather than a constant state, for example, the regulation of body temperature during sleep or fever.

Setpoint A reference value to which feedbacks can be compared in order to generate compensatory control signals.

Settling point In a system that is regulated in the absence of a setpoint, the level that the regulated variable reaches when feedback and other influences reach equilibrium.

Introduction

Homeostasis denotes the maintenance, or regulation, of a number of internal bodily variables in a state of relative constancy. Homeostasis is a characteristic of all organisms that have internal environments, from the cytoplasm of individual cells (which for unicellular organisms is all there is) to the multiple 'systemic' internal environments of mammals. Homeostasis is a fundamental organizing principle of physiology, similar in importance to the principle of adaptation in evolutionary biology or the principle of gene regulation in cell biology. In their classic *Textbook of Medical Physiology*, Guyton and Hall write that "essentially all organs and tissues of the body perform functions that help maintain ... constant conditions" and therefore, a large part of physiology is concerned "with the manner in which each organ or tissue contributes to homeostasis" (p. 4). In general, the number of variables regulated, the precision with which they are regulated, and the complexity of the systems regulating them increase with increasing complexity of the organism. Nevertheless, although the number of regulated variables is quite large in more advanced organisms, it is still only a fraction of the total number possible.

Key to the definition of homeostasis is that homeostatic variables are maintained in a state of *relative* constancy. That is, they are maintained within a certain range, or envelope, not at an exact value. The ranges vary considerably. In each case, however, the variable is held within a range that is small in comparison to the range that would occur in the absence of regulation.

Cellular Homeostasis

At the cellular level, crucial regulated variables include the membrane potential, the concentrations of several ions, pH, and volume. The membrane potential, usually between -30 and -70 mV in mammalian cells, is a characteristic of all cells and is regulated mainly by the arrangement of ion-specific membrane channels and transport mechanisms, especially the 'sodium-potassium pump' (Na^+/K^+ ATPase, one of the major energy users of the body). Most cells maintain a cytoplasmic pH of 7.0–7.3, corresponding to an H^+ concentration of 50–100 nmol. This is the optimal range for many enzymatically controlled metabolic processes, gene expression, etc. Intracellular pH is regulated both by ion-transport mechanisms and the buffering action of various molecules, especially proteins that vary the amount of bound H. Cellular volume is regulated under powerful regulatory influences. Mild cell shrinkage itself is not harmful to cellular function, but the increase in intracellular osmolality that it reflects is very harmful. As explained below, thirst is the most powerful defense against cell shrinkage. This is a good example of how cellular homeostasis can be directly related to the highest levels of bodily function.

Systemic Homeostasis

The internal or systemic environment consists of a number of separate organs and fluid compartments, such as blood, extracellular fluid, cerebral-spinal fluid, etc. The concentrations of many molecules are separately regulated in different

compartments. Glucose, a crucial source of metabolic energy, is a good example. In the plasma (i.e., the noncellular fraction of the blood), glucose concentration is regulated between 4–8 mmol l⁻¹ (as described in detail below), whereas glucose concentration in the extracellular fluid of the brain is regulated at much lower values, ~0.1–2.5 mmol l⁻¹. The reduction in concentration is due to specialized tight junctions and astrocytic foot processes found in the cerebral microvessels (i.e., the blood–brain barrier). Given that the brain is normally wholly dependent on glucose as an energy source and utilizes about one-fourth of the body's glucose supply, it may seem paradoxical that such a barrier impedes passage of glucose from the blood into the extracellular fluid and subsequently into the neurons. The explanation is that neuronal glucose supply is in the end determined by the influx of glucose into the neuron and that molecular concentrations do not reflect molecular fluxes, or rates of movement. Glucose influx into the neurons is controlled differently than glucose influx into most tissues, and proceeds at levels more than sufficient to supply the neurons with energy until extracellular glucose concentration reaches levels well below 1 mmol l⁻¹. In contrast, as described below, glucose influx into muscle, adipose tissue, and most other peripheral tissues is reduced to almost nothing when plasma glucose falls toward 4 mmol l⁻¹.

History of Homeostasis

Homeostasis has a long history. Present concepts represent the crystallization of the thinking of a long line of people of great genius, beginning well before the advent of an empirical science of physiology. In his history of physiological regulation, Adolf describes Hippocrates, who lived about 2500 years ago, as teaching that the healthy body is characterized by equilibria among 'constituent qualities,' that disease disrupts this balance, that the body attempts to heal itself by reinstating it, and that the goal of medicine is to aid this process. Galen, about 1800 years ago, speculated about the contributions of specific bodily mechanisms to these processes and was even able to demonstrate some examples, such as the control of breathing by the central nervous system, which he showed in animal vivisection experiments. Many similar examples of the contributions of physiological controls of vital functions slowly accrued over the centuries. The next conceptual advances, however, were quantum leaps. These are associated with four great scientists, Bernard, Cannon, Richter, and Wiener.

Claude Bernard (1813–1878)

Bernard, a professor at the Collège de France in Paris, made many groundbreaking discoveries in physiology. Some of these are (1) that pancreatic secretions are required for fat digestion, (2) that the liver produces glucose, (3) that the liver and other tissues store glucose in the form of glycogen, (4) that the brain contributes to the control of hepatic glucose metabolism, (5) that the nervous system controls peripheral vasodilation and vasoconstriction, (6) that changes in blood flow to various tissues contribute to maintenance of proper body temperature, and (7) that water intake and loss are equated so as to maintain blood volume, one of the first demonstrations of a

physiological balance. Equally important, however, were two of Bernard's theoretical legacies. The first of these (1865) was his codification of the scientific method as it applies to physiology and medicine. The second was arguing the central physiological importance of homeostasis, which he described in other words, for advanced life forms. In his final work, published just after his death in 1878, he wrote the famous sentence: "The constancy of the internal environment is the condition for a free and independent life." In homage to the importance of this idea to physiology, the key phrase, 'la fixité du milieu intérieur,' is still often given in the original French. The external environment changes dramatically, but the internal environment is maintained constant.

Walter B. Cannon (1871–1936)

Cannon, a professor at Harvard Medical School, Boston, MA, USA, also pursued a wide range of physiological investigations. These included, in addition to vegetative functions, the physiological bases of emotions, such as fear and rage, and of motivational states, including hunger and thirst. Cannon coined the term homeostasis in publications in 1926 and 1929. He recognized that Bernard's work was his starting point, but extended it in important ways. First, he emphasized that the body is not able to maintain the internal environment perfectly constant, but maintains it in a more or less narrow range. This is evident in his choosing to combine the prefix *homeo*, or similar, rather than *homo*, or same, with *stasis*, or standing still. Second, Cannon emphasized the coordinated and dynamic operation of homeostatic mechanisms. Central to his view was the existence of mutually antagonistic control mechanisms, so the regulated variable could be simultaneously pushed and pulled into place. In addition, he emphasized how individual controls could be either stimulated or inhibited, depending on the environmental challenges at hand. Finally, Cannon brought homeostasis into the public eye with his 1932 classic, *The Wisdom of the Body*.

Curt Richter (1894–1988)

Richter was a professor at the Johns Hopkins University School of Medicine, Baltimore, MD, USA. His special contribution was the documentation of numerous examples of how motivated behavior contributed to homeostasis. Sodium appetite was an early example. He discovered that removal of the adrenal glands, which causes uncontrolled excretion of sodium in the urine, elicits a dramatic appetite for sodium. The rats maintained themselves in good health by ingesting large amounts of sodium chloride solutions, even if the solutions were so concentrated that they were shunned almost entirely by intact rats. Furthermore, the appetite was highly selective – ingestion of magnesium chloride, for example, was not increased. Richter subsequently demonstrated the existence of a large number of appetites for nutrients that are elicited during deficiency states. In most cases, however, the animal did not appear to innately recognize the taste of the depleted nutrient, but had to learn which foods contained it. Nonnutritive homeostatic regulations, for example thermoregulation, were also shown to include behavioral components, such as nest building.

Homeostasis was, in Richter's words, the product of 'total self-regulatory functions' of the body.

Norbert Wiener (1894–1964)

Wiener, a professor at the Massachusetts Institute of Technology, Cambridge, MA, USA, made fundamental contributions to mathematical information theory, especially as applied to the use of feedback to govern dynamic systems. Wiener called this cybernetics; control theory is the more current term. The most general definition of a cybernetic system is a system that affects its own behavior. Two types of classical closed-loop negative-feedback control systems are diagrammed in **Figure 1**. Note the terminology: the variable that is held constant is said to be *regulated*, and the various effectors or response variables that are varied in order to achieve such regulation are said to be *controlled*. A powerful tool developed during this early period was mathematical analyses of the dynamics of positive- and negative-feedback control systems; particularly useful are the 'control transfer functions,' which allow calculation of the time courses and final levels of the controlled and regulated variables if the system characteristics are known. On a very different level, Wiener and others recognized at the outset that cybernetic principles have implications spanning mathematics, engineering, biology, computer science, and even philosophy. For example, they provide potential explanations for apparently purposeful,

goal-directed behavior without resort to volition, intention, or teleology. Wiener's connection to homeostasis was direct: one of Cannon's last students, Arturo Rosenblueth (1900–1970), also worked with Wiener and in 1943 published with Wiener a seminal paper that included a description of the application of control theory to homeostasis.

Current Concepts in Homeostasis

A number of new perspectives about homeostatic regulation have developed in recent decades. This section outlines some of these.

Settling Points

The mathematics of control theory indicates that dynamic control systems can achieve impressive stability even in the absence of a reference value or set point. The regulation of blood glucose, described below, is an example. Essentially, if compensatory feedback mechanisms are activated when the regulated variable reaches a certain threshold, then the system will achieve constancy. The lower schematic shown in **Figure 1** diagrams this. In such a system, negative-feedback control will return the regulated variable to the original level following a temporary challenge, so that the system is indistinguishable

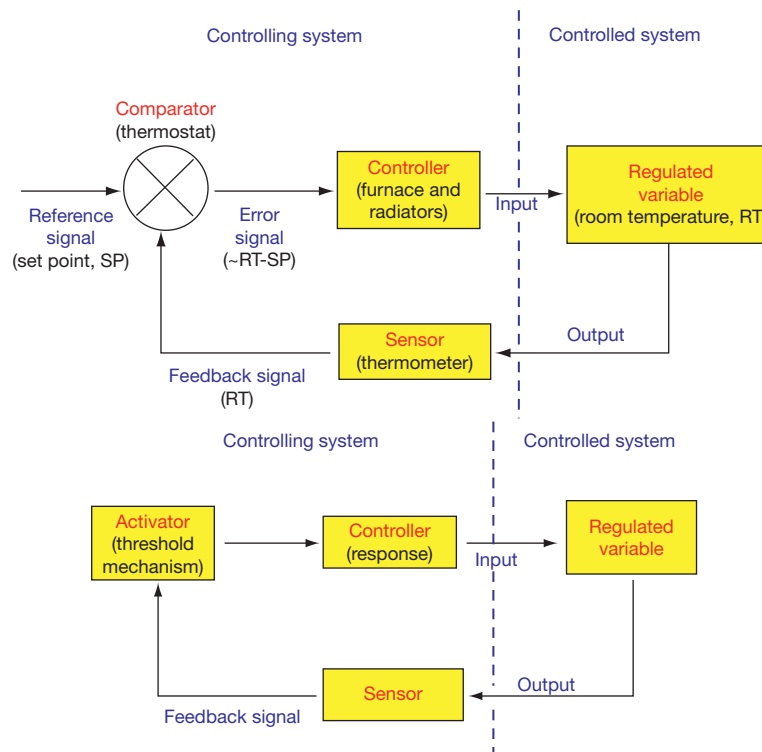

Figure 1 Upper panel: the organization of a negative-feedback regulatory system with a setpoint. The regulated variable, or some surrogate of it, is sensed (negative feedback) and compared to a reference signal (setpoint), and discrepancies (error signals) activate a controller mechanism that changes the regulated variable in a way that reduces the feedback. The system components of a thermostatically controlled central-heating system are labeled in black. Lower panel: the organization of a negative-feedback regulatory system without a setpoint. Instead of a comparator mechanism, the feedback signal elicits a response in the controller mechanism when a certain threshold is reached. Most neural and endocrine regulations are organized in this way. The two systems produce equivalent regulation under many circumstances, but the latter is more susceptible to partial failures when chronically challenged; that is, the regulated variable is held at a different level than that originally held. See text for details.

from a setpoint system. During a chronic challenge, however, the constant level might be altered, so that regulation occurs as if the setpoint were increased. The new level is called a settling point. The difference between the original level and the new one is determined by the magnitude of the challenge in relation to the number, strength, and dynamics of the various feedback mechanisms involved. The majority of physiological regulations appear to operate in this way.

Rheostasis

Many regulated variables change in the absence of changes in the challenges they experience. Body temperature, for example, changes regularly through the course of the day, changes for long periods in animals that undergo seasonal periods of dormancy or hibernation, and changes as a result of activation of the immune system during many illnesses (i.e., fever). All of these alterations display the characteristics of active regulation. Thus, as the organism enters such situations, regulation does not promote constancy, but change. This is called rheostasis or variable-state regulation.

Allostasis and Allostatic Load

The simplest regulatory situation involves temporary responses to occasional, transient challenges. Sometimes, however, homeostatic challenges are frequent, long-lasting, or even permanent. In these cases, regulation requires frequent or long-maintained responses. Allostasis, meaning constancy of change, refers to the idea that regulatory control systems are often not at a state of rest, but are operating frequently or for long periods. Central heating exemplifies this – in cold climates furnaces run all winter to maintain room temperature. Unlike furnaces, however, physiological systems often appear to be adapted to operate for only relatively brief periods (i.e., phasically). Furthermore, if they are required to operate for long periods (i.e., tonically), there are often deleterious side effects. The neuroendocrinologist Bruce McEwen coined the term ‘allostatic load’ to describe the progressive increase in risk of such pathophysiological consequences when homeostasis is continually challenged. The immune system and the stress axis (described below) are both powerful homeostatic effectors, but both produce deleterious side effects if forced to operate tonically. For example, arousal caused by physical or psychological stress includes elevations in blood pressure and cortisol secretion (described below). Both of these prepare the body for impending action. However, if such events occur frequently or if recovery is slow, as is the case in some individuals, pathologies can develop. For example, blood pressure surges accelerate atherosclerosis and increase the risk of cardiovascular disease, and chronic, mild increases in blood cortisol concentrations inhibit bone formation. Other examples of allostatic load are the disruptions of rheostatic regulations of sleep and metabolism suffered by people who work during the night.

Anticipatory Controllers

Negative-feedback control requires that a perturbation occurs in order for the system to react. This introduces a time lag into the system, which can reduce the efficiency of regulation or,

depending on the dynamics of the relevant effectors, lead the system into unstable oscillations. The simplest way to avoid these problems is for the system to detect changes that typically occur before the regulated variable changes appreciably. For example, the heating systems of some houses are connected to outdoor thermometers; when the temperature falls outdoors, the furnace starts to heat the house so that an increase in heat delivery averts cooling in the interior. In higher organisms, anticipatory controllers help maintain many regulated variables in narrower envelopes than would otherwise be possible. The mechanisms generally depend on nervous or endocrine reflexes, as described below for the regulations of body temperature and blood glucose.

Homeostatic Control Systems

Endocrine Mechanisms

Hormones, defined as chemical messengers that are secreted into the bloodstream by glands, carried in the circulation to target tissues, and elicit biological responses by acting on specialized receptors in the target cells, play numerous vital roles in homeostasis. Several such endocrine mechanisms are described in the following sections. The secretion of many hormones is controlled by the action of circulating factors, often including other hormones, on the gland cells. Most are also controlled by neural inputs. The secretion of the pancreatic hormone insulin, which, as described below, is crucial for blood-glucose regulation, exemplifies these types of controls: blood glucose, other hormones, and neural inputs all affect insulin secretion.

A number of hormones that are important for homeostasis are part of the *neuroendocrine system*, which links the hypothalamus, the pituitary gland at the base of the brain, and the peripheral glands. This system is outlined in the section on the hypothalamus below. The *immune system* is another homeostatic system that depends on chemical messengers, although these are not classically described as hormones. The immune system also affects the brain, and many immune responses, such as fever, are generated by the brain.

Neural Mechanisms

There is no single set of brain structures devoted to homeostatic regulation. Rather, as is also the case for other brain functions, the neural controls of homeostatic functions depend on neural networks that are defined functionally more than anatomically, that are spread diffusely through large portions of the brain, and that overlap with other functional neural networks. Furthermore, these networks are both redundantly and hierarchically organized. That is, the neural control systems include several semiautonomous subnetworks (or representations), typically in increasingly more rostral brain areas, with each representation (or partial representation) contributing increasingly sophisticated aspects of homeostatic control. This leads to increasingly flexible responses in more complex organisms, arming them with a variety of different homeostatic responses which can be adapted to fit very different situations, thereby enabling them to pursue the ‘free and independent’ life described by Bernard.

Autonomic Nervous System

Direct neural control of internal homeostatic functions is mediated mainly by the autonomic nervous system, which innervates most glands and smooth muscle, that is, vascular and gastrointestinal muscle. The autonomic nervous system consists of two sub-systems, which generally have opposite effects on the tissues that they innervate. (1) The 'sympathetic' system consists of (a) 'preganglionic' neurons with cell bodies in the intermediolateral column of the thoracic and lumbar spinal cord, which project to (b) 'postganglionic' neurons in the sympathetic chain ganglia just outside the thoracic and lumbar vertebral column; the postganglionic axons project to the target tissues. The primary neurotransmitter of the sympathetic nervous system is norepinephrine. (2) The 'parasympathetic' nervous system consists of (a) 'preganglionic' neurons with cell bodies in the dorsal vagal complex of the caudal brainstem (the sources of motor neurons of the tenth cranial nerve, the vagus) or in the sacral spinal cord, which project to (b) 'postganglionic' neurons located in various peripheral ganglia; again, the postganglionic axons project to the target tissues. The primary neurotransmitter of parasympathetic postganglionic neurons is acetylcholine. Strong sympathetic activation, as occurs in anger or fear, leads to physiological arousal – increased vigilance, heart rate, and blood flow to the skeletal muscles, and decreased blood flow to the gastrointestinal system and skin (which is why arousal leads to cold hands and feet). In contrast, when the parasympathetic nervous system is more active, one relaxes, the heart rate slows, and more blood is directed into the digestive organs.

Caudal Brainstem

A number of small regions in the caudal brainstem are involved in the motor control of many homeostatic functions. Blessing refers to these areas as 'groups' of neurons rather than 'centers' in order to emphasize, first, that they are important points in widely distributed neural networks, not the areas in which function is 'localized,' and, second, that their properties remain incompletely understood. The medullary respiratory groups are good examples. Lesion, stimulation, and recording studies indicate that a 'dorsal respiratory group' of neurons in and adjacent to the nucleus tractus solitarius as well as a more ventrally located 'rostral ventrolateral respiratory group' project to and usually control the activity of lower motor neurons in the brainstem and spinal cord that mediate inspiration. More caudal to the latter is the 'caudal ventrolateral respiratory group,' which projects to and controls lower motor neurons that mediate expiration. These groups also connect with each other and with further medullary groups, including groups that appear to generate the rhythms of respiration as well as a different network of neural groups that participate in the control of vasodilation and vasoconstriction, thus coordinating oxygenation of the blood via respiration and delivery of oxygenated blood to the tissues. All these groups of neurons are on the output side of the neural control of respiration. They receive afferent information from a variety of sources, including, for example, chemoreceptors sensitive to the concentrations of O_2 , CO_2 , and H^+ in the blood and mechanoreceptors in the upper and lower respiratory tract and in the lungs.

Hypothalamus

The hypothalamus is a second brain area intimately involved with homeostasis. There are three types of contributions. (1) *Neuroendocrine controls*: 'Magnocellular' neurons in the supraoptic (SON) and paraventricular (PVN) nuclei of the hypothalamus project to the posterior lobe of the pituitary gland, and 'parvocellular' neurons in the PVN project to the median eminence, where they secrete 'releasing hormones' into the portal capillaries that carry them to the anterior lobe of the pituitary gland. The pituitary responds by releasing hormones that either have direct regulatory functions (e.g., growth hormone) or regulate the activity of peripheral glands involved in homeostasis (e.g., adrenocorticotrophic hormone, or ACTH, which causes the adrenal cortex to release cortisol and other glucocorticoid hormones). Typically, both pituitary and peripherally released hormones also act as negative feedbacks in the hypothalamus. **Figure 2** summarizes the organization of hypothalamic – anterior pituitary – endocrine controls. (2) *Autonomic controls*: Neural projections from various hypothalamic areas to autonomic cell groups in the medulla (e.g., the dorsal motor nucleus of the vagus nerve, a principal parasympathetic nerve) and the spinal cord (e.g., the intermediolateral column of the thoracic and lumbar spinal cord, the source of sympathetic preganglionic neurons). (3) *Behavioral controls*: The hypothalamus contributes to the generation of motivational states leading to behaviors that contribute to homeostasis, such as thermoregulatory behavior, drinking, and eating.

Cerebrum

Brainstem and hypothalamic homeostatic mechanisms are linked to the highest levels of neuronal control, the neural networks in the cerebral hemispheres. This is also the least well understood level of control. One example is illuminating. In all mammals, a cerebral brain area known as the amygdala receives quite direct inputs from several sensory systems and appears to integrate them to produce a signal essentially representing how good or how aversive something feels, whether it be the temperature of water on the skin or a taste in the mouth. In primates, a particular area of the cerebral cortex that does not exist in lower mammals, the orbitofrontal cortex (OFC), has similar connectivity and functions in concert with the amygdala. Presumably, the OFC representation of hedonics allows more sophisticated, plastic, and useful judgments than achieved by the amygdala alone. An apparent function of the OFC is probably familiar: during hypothermia, for example after cold exposure, a shower that normally is felt to be aversively hot is felt to be pleasant. Pleasure and aversion, therefore, can serve homeostasis in an adaptable way. At the same time, it is also clear that modern life presents many circumstances in which the influence of pleasure can overwhelm other homeostatic control mechanisms.

Examples of Homeostasis

Regulation of Cell Volume

Cell membranes are highly permeable to water, but impermeable to most solutes, so that these are trapped inside or outside the cell. Thus, loss of water in the systemic compartments

Figure 2 The neuroendocrine system of the anterior pituitary. A variety of hypothalamic neuroendocrine cells (top) project to the median eminence and secrete releasing hormones into the local portal circulation, which delivers them to the secretory cells of the anterior pituitary (middle); these cells then secrete hormones that either control the activity of peripheral glands or act directly on target tissue (bottom). See text for details. Abbreviations: adrenocorticotropic hormone (ACTH); corticotropin-releasing hormone (CRH); dopamine (DA); follicle-stimulating hormone (FSH); growth hormone-releasing hormone (GHRH); gonadotropin-releasing hormone (GnRH); insulin-like growth factor-1 (IGF-1); luteinizing hormone (LH); pro-opiomelanocortin (POMC); thyrotropin-stimulating hormone (TSH); T3, T4, thyroid hormone 3 and 4; thyroid-stimulating hormone (TSH). (blood and extracellular fluid) increases systemic osmolality, creating an osmotic force that causes water to leave the cells until an equilibrium is reached. Thus, the cell shrinks and intracellular osmolality increases in proportion to the amount of water lost. The first line of defense against cell shrinkage is secretion of the hormone arginine vasopressin (AVP, formerly called antidiuretic hormone) from the posterior pituitary. AVP causes the kidney to excrete higher osmolality urine, thus effectively decreasing systemic osmolality, allowing water to move back into the cells, and restoring cell volume. AVP secretion and the kidney response are proportional to the amount by which plasma osmolality increases over the normal value of 280 mOsm kg^{-1} water. The second, and more powerful, line of defense against cell shrinkage is thirst. Increases of only a few percent osmolality elicit a strong desire to drink water, which causes people and animals to interrupt other activities and seek water. Both responses to cellular dehydration originate from neurons in the anterior hypothalamus and an adjacent area

(the vascular organ of the lamina terminalis), which increase activity upon shrinkage. Some of these neurons project to the magnocellular neurons of the SON and PVN, whose axons project to the posterior pituitary and release AVP. The neural circuitry for thirst is less well understood. The increase in renal sodium excretion and inhibition of ingestion of sodium and other solutes also contribute to cell-volume homeostasis. Finally, note that both the hormonal and the behavioral controls of cell volume appear to correspond to the type of negative-feedback control system depicted in the lower panel of [Figure 1](#), in which regulation is achieved by a variety of threshold mechanisms without a setpoint.

Regulation of Body Temperature

Humans live, work, and play in ambient temperatures that range from below freezing (0°C) to over 40°C , yet maintain deep or core body temperature with a few tenths of a degree.

This regulation is asymmetric: we defend against hyperthermia more vigorously than against hypothermia. This is probably because the regulated temperature, although near optimal for many enzymatic metabolic reactions, is only a few degrees from the upper limit of survival.

The regulation of body temperature is achieved by a neural mechanism that appears to closely match the classical negative-feedback control system that includes a setpoint, as described in the upper panel of [Figure 1](#). The most important temperature-sensitive neurons are in the preoptic and anterior hypothalamic areas (POA/AH). About 20% of the neurons in these areas are intrinsically warm-sensitive: they increase the rate of activity upon local warming. A small percentage of POA/AH neurons are cold-sensitive, but in this case it appears that the sensitivity is indirect; that is, these neurons receive synaptic inputs from distantly located cold-sensitive neurons in the skin or in spinal cord (POA/AH warm-sensitive neurons also receive inputs from extra-hypothalamic temperature-sensitive neurons). The skin receptors, of course, exemplify the anticipatory homeostatic mechanisms discussed above. Finally, the POA/AH also includes neurons with constant spontaneous rates, which are thought to provide the setpoint signal. The comparator is a neural computation based on antagonistic synaptic connections between the temperature-sensitive and setpoint neurons and the effector neurons that initiate thermoregulatory responses. Thus, when the temperature-sensitive neurons and the setpoint neurons are equally active, their postsynaptic effects cancel out and the system is quiescent. Finally, the setpoint is variable: factors such as immune system activation and state of arousal change the setpoint to produce fever and the changes in core body temperature during sleep, hibernation, etc.

Behavioral thermoregulatory responses are organized by neural networks in the forebrain. Little is known about them. The most important vegetative cooling mechanism is vasodilation in the skin, which can increase heat transfer out of the body several fold. Vasodilation is controlled by inhibitory neural projections from the POA/AH to cell groups in the posterior hypothalamus that control sympathetic projections to the peripheral vasculature. Sweating, which increases evaporative heat loss, is controlled by different POA/AH outputs to various cell groups in the caudal brainstem that control parasympathetic projections to the sweat glands. When the body is too cold, the opposite responses occur. In addition, a projection from the POA/AH to the 'cell group for shivering' in the posterior hypothalamus is stimulated, leading via several synapses to the skeletal muscles. The resultant shivering can increase bodily heat production several fold. The various thermoregulatory controllers appear to be driven by separate assemblies of temperature-sensitive and setpoint neurons in the POA/AH.

Regulation of Blood Glucose Concentration

Glucose is the major energy-yielding molecule in nonruminant mammals and normally is the only metabolic fuel used by the brain and kidney. The supply of glucose is assured by regulation of blood glucose levels. As shown in the upper panel of [Figure 3](#), glucose enters the blood from exogenous (i.e., intestinal absorption) and endogenous (i.e., metabolic production) sources and normally leaves the blood only via uptake into

the cells (during pathological hyperglycemia some glucose is also excreted via the kidneys). The rates of both influx of glucose into the blood and efflux from the blood vary considerably according to the cell type and physiological state. Net blood glucose flux is held in balance, so that plasma glucose is maintained between ~ 4 and 8 mmol l^{-1} (plasma is the noncellular component of blood, normally about 45% of blood volume; plasma glucose is often expressed as mg dl^{-1} ; $0.0555 \text{ mg dl}^{-1} = 1 \text{ mmol l}^{-1}$).

Plasma glucose is usually highest soon after a carbohydrate-rich meal and lowest in the morning, that is, during the 'post-absorptive state,' when no glucose is being absorbed. The upper panel of [Figure 4](#) shows typical fluctuations in blood glucose across the day. At first glance, these fluctuations may seem large. In fact, however, they are small in comparison to what would occur without regulation. This can be appreciated by consideration of glucose flux in the postabsorptive state. In this state, endogenous glucose production and utilization are each $\sim 2.2 \text{ mg kg}^{-1} \text{ min}^{-1}$, which in a 70-kg person represents $\sim 150 \text{ mg min}^{-1}$. The amount of glucose in the plasma at any moment in the same person is $\sim 2 \text{ g}$. Thus, if utilization were not actively balanced by production, the entire amount of glucose in the plasma would be used up in $< 15 \text{ min}$! The postabsorptive state is the simplest steady-state situation, when glucose utilization is minimal and the physiological systems affecting blood glucose are not changing. After carbohydrate-containing meals, influx is greater than efflux. If glucose were not cleared from the plasma efficiently in this situation, plasma glucose levels would rise to $> 30 \text{ mmol l}^{-1}$. This occurs in uncontrolled type 1 diabetes mellitus, a disease in which the pancreas makes no insulin.

Three levels of control contribute to blood glucose regulation. The first, known as autoregulatory mechanisms, consists of fixed metabolic arrangement that facilitates regulation. The second set of mechanisms consists of neural and endocrine responses that are elicited by increases or decreases of blood glucose beyond fixed thresholds. Finally, a behavioral mechanism – hunger – is an emergency response elicited by very low levels of blood glucose. The latter two mechanisms proceed via negative feedback, but with threshold-activated responses rather than a setpoint and comparator.

The most important metabolic mechanisms occur in the liver. Ingested carbohydrates are absorbed into the hepatic portal vein and pass through the liver before reaching the systemic circulation. Glucose enters the hepatocytes by facilitated diffusion and is transformed into glucose-6-phosphate (glucose-6-P) by a class of enzymes known as hexokinases. Hexokinases exist in most cells, and the resulting glucose-6-P enters a variety of metabolic pathways. In the liver, most of it is transformed into glycogen; in most other cell types, it is oxidized. When glucose levels are low, glycogen is converted back to glucose. In addition, the liver is the main site of gluconeogenesis, that is, the production of glucose from lactate, amino acids, and fatty acids. Although the muscles also contain glycogen and the kidney is also capable of gluconeogenesis, there is little glucose efflux from these tissues into the blood. That is because the muscles (and most other tissues) do not express glucose-6-phosphatase, so cannot convert glucose-6-P back to glucose, and because the kidney oxidizes glucose for energy, whereas the liver oxidizes mainly fat. In addition, the particular

Figure 3 Upper panel: how glucose enters (influx) and leaves (efflux) the bloodstream, emphasizing the normal zero net flux in the postabsorptive state, as described in the text. Lower panel: the normal regulatory envelope of blood glucose (euglycemia) together with the endocrine responses to increases or decreases in blood glucose. The number of plus signs (+) indicates the relative regulatory potency of the hormone; only insulin is indispensable.

hexokinase expressed in the liver, glucokinase, or type IV hexokinase, contributes to maintenance of blood glucose in two other ways. First, whereas the rate of production of glucose-6-P is maximal at quite low glucose concentrations for other hexokinases, glucokinase enables high rates of glucose-6-P synthesis only when intracellular concentrations are relatively high. As a result, when blood glucose concentrations are low, the enzyme is inactive, free glucose levels in the hepatocyte remain relatively high and little glucose diffuses in. In contrast, when glucose levels increase toward hyperglycemia, glucokinase is more active, leading to rapid formation of glucose-6-P and helping the liver to clear glucose from the blood. Second, whereas the buildup of glucose-6-P inhibits other hexokinases, it does not inhibit glucokinase. This further facilitates hepatic glucose uptake when glucose levels are high.

Endocrine mechanisms make crucial contributions to the regulation of blood glucose (Figure 3, lower panel). The contribution of insulin is indispensable. Indeed, because of its unique role, insulin is known as the glucose-regulatory hormone, and the hormones discussed below that have opposite effects to that of insulin are known as 'counter-regulatory' hormones. Insulin is secreted by the pancreatic beta cells in proportion to blood glucose levels, as shown in Figure 3.

Insulin facilitates the uptake of glucose by muscle, adipose tissue, and other tissues, thus preventing hyperglycemia during periods of high influx of glucose from the intestines. Insulin also inhibits hepatic glucose production. Chronic hyperglycemia is toxic; thus, the absence of insulin, that is, type 1 diabetes mellitus, is a deadly disease. Insulin secretion drops to basal levels during the postabsorptive state, thus reducing glucose uptake into the muscle and adipose tissue toward zero. These tissues switch to fat and protein as energy sources. This spares glucose for brain and kidney, which utilize glucose preferentially and in which glucose uptake is not insulin-dependent.

Decreases of blood glucose toward the normal lower limit of regulation elicit secretion of several other hormones. Glucagon is the most important under normal conditions. Glucagon stimulates hepatic glycogenolysis and gluconeogenesis, both of which occur at high rates in the postabsorptive state. As glycogen is depleted, after about 8 h of fasting, gluconeogenesis predominates. During longer fasts, the brain begins to utilize fat, in the form of ketone bodies, so that the rate of gluconeogenesis can decrease and body protein is not consumed more rapidly than necessary. Epinephrine, secreted from the adrenal medulla, also stimulates hepatic glucose production. Unlike glucagon, however, epinephrine also acts in

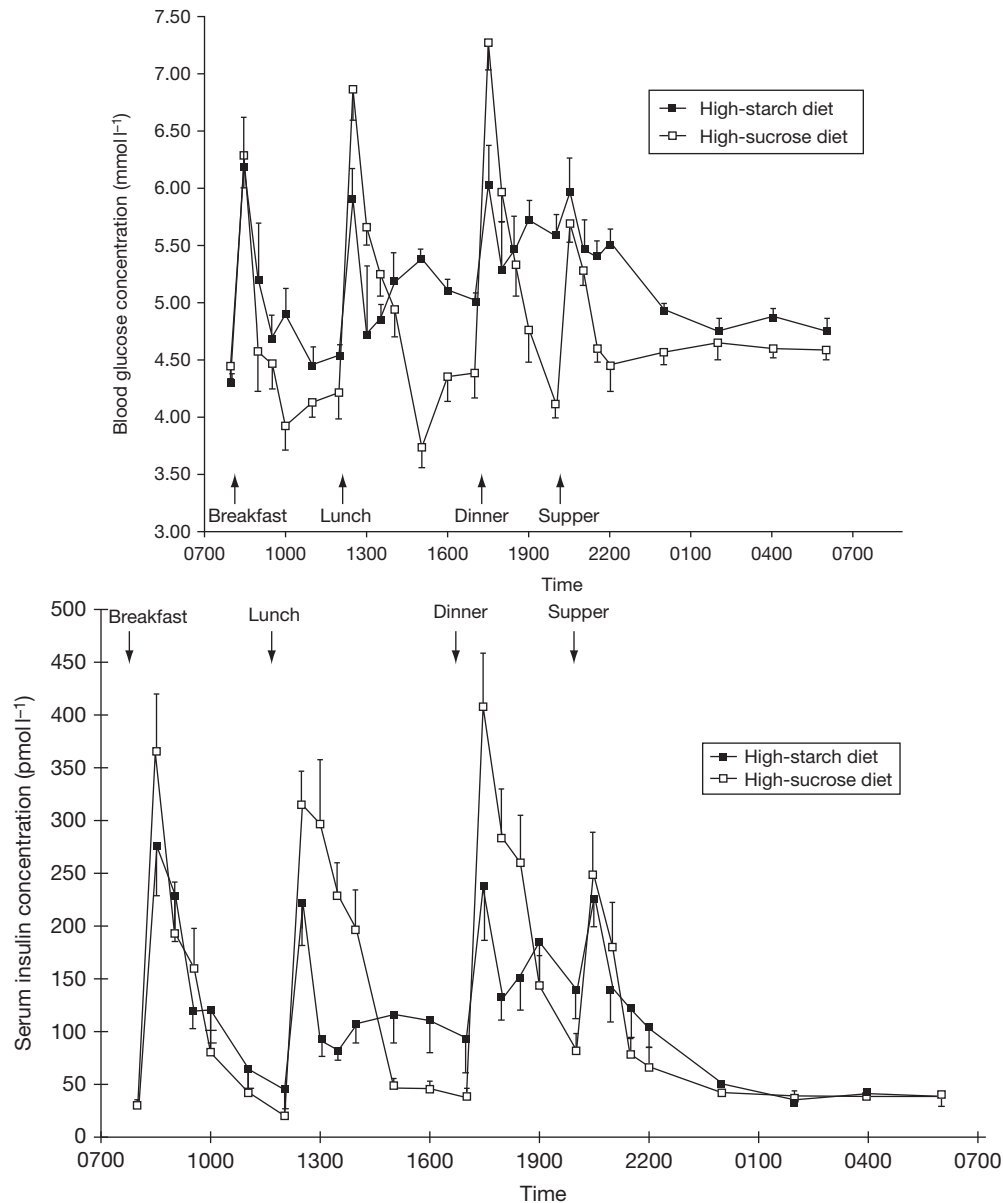

Figure 4 Normal patterns of blood glucose (upper panel) and insulin (lower panel) in healthy normal-weight individuals (four men, four women) who ate four daily meals. Each meal consisted of a variety of normal foods that were matched in protein, fat, and energy contents and contained 50% of energy as either sucrose or starch; dietary fiber was also higher in the starchy foods (14 vs. 6 g day⁻¹). Note how insulin levels closely track glucose levels and how rapidly blood glucose is brought back to near the basal level after meals. Reprinted with permission from Daly ME, Vale C, Walker M, Littlefield A, Alberti KGMM, Mathers JC (1998) Acute effects on insulin sensitivity and diurnal metabolic profiles of a high-sucrose compared with a high-starch diet. *American Journal of Clinical Nutrition* 67: 1186–1196.

insulin-sensitive tissues to decrease glucose utilization and to increase the production of gluconeogenic substrates, which are transported to the liver via the blood. When glucose levels are low for still longer periods, growth hormone and cortisol contribute to the inhibition of glucose utilization and stimulation of glucose production. Cortisol also appears to increase the actions of glucagon and epinephrine.

The behavioral regulation of blood glucose is a last defense against lethal degrees of hypoglycemia. Hunger is elicited when plasma glucose falls to $\sim 3 \text{ mmol l}^{-1}$. Prompt carbohydrate ingestion can act within minutes to increase plasma glucose.

Unfortunately, if plasma glucose falls just a little more, to $\sim 2.8 \text{ mmol l}^{-1}$, neural function is compromised, and people may no longer have sufficient cognitive function and motor coordination to eat. To make matters worse, with repeated episodes of hypoglycemia, the system eliciting hunger becomes less sensitive.

Eating is linked to glucose regulation in another unfortunate way. The abundance of highly palatable, energy-dense foods in affluent societies has led to chronic overeating and an obesity epidemic. Chronic overeating and obesity lead to chronic increases in insulin secretion, which has the

unfortunate consequence of reducing the sensitivity of most tissues to insulin. Thus, more and more insulin must be secreted to control blood glucose. In time, the control is faulty, leading to elevations in both blood glucose and insulin, or type 2 diabetes mellitus. Other pathogenic consequences also occur, for example, a chronic state of systemic inflammation; this is a type of allostatic load. Finally, the pancreatic beta cells become exhausted and die, leading to type 1 diabetes mellitus.

Anticipatory controls are also important in the normal regulation of blood glucose. Sweet taste and, after experience with food, just the smell, sight, or thought of food elicit secretion of insulin via neural reflexes. This is known as the cephalic phase of insulin secretion because the receptors are cephalad, that is, in the head. In addition, the entry of food into the intestines elicits secretion of the gut hormones GLP-1 (glucagon-like peptide-1) and GIP (gastric-inhibitory polypeptide or glucose-dependent insulinotropic polypeptide), which act in the pancreas to stimulate insulin secretion. This is known as the incretin effect or the intestinal phase of insulin secretion. Under normal conditions, this anticipatory mechanism accounts for ~40% of meal-stimulated insulin secretion.

Glossary

Adaptation An evolved trait in all or most individuals in a population that functions to solve an adaptive problem.

Adaptationist Explaining the evolution of traits in terms of their adaptive function.

Adaptive problem A problem hindering survival and reproduction that was recurrently faced during the evolutionary history of a species.

Ancestral benefits Benefits to the survival and reproduction of the ancestors of a species.

Coevolution When two (or more) species or sets of strategies in the same species reciprocally affect each other's evolution.

Coevolutionary arms race The back-and-forth evolution of defense and offense between opposing evolutionary

strategies (e.g., strategies of predators and prey; strategies of exploiters and victims).

Conspecific Another individual of the same species.

Intrasexual rival A member of the same sex with whom an individual is in conflict over some limited resource(s).

Lethal raids Short duration, often surprise attacks made by a small group of warriors against another group to obtain resources or exact revenge.

Metatheory A set of principles that both describes and prescribes what is acceptable and unacceptable as the means of conceptual exploration of the foundations, structure, properties, methods, or results of some theory in a scientific discipline.

Homicide may be defined as the killing of one human being by another. There are different legal categories of homicide that vary from one jurisdiction to another. In general, legal systems view some homicides to be justifiable or excusable, while others are not. Justifiable homicide is limited to the killing of a felon by a law enforcement officer in the line of duty or the killing of a felon by a private citizen during the commission of a felony. First-degree murder, in contrast, is unlawful killing that is willful, deliberate, and premeditated. The term homicide typically is used by government agencies to explain causes of mortality, while murder and manslaughter are used by criminal justice agencies.

The Epidemiology of Homicide

A total of 13 636 people were victims of homicide in the United States in 2009. This converts to a homicide rate of 4.5 out of 100 000 people for that year. With an average life span of 78 years in the United States in 2009, the lifetime risk of being a homicide victim is 1 in 287. According to homicide data from the Federal Bureau of Investigation, at least 78.5% of homicide victims in 2009 were male. Forty-nine percent were African American. Homicide rates were highest in the South and lowest in the Northeast region of the United States. These homicide statistics do not include members of the US military who were killed in warfare.

Historically, the homicide rate in the United States remained quite steady during the 1980s, decreased markedly in the 1990s, and has remained steady through the early 2000s. Researchers in the United States have argued that faster ambulances and better emergency room care, much of which was developed during the first Gulf War between the United States and Iraq from 1990 to 1991, are partly responsible for the decrease in homicide rates during the 1990s in the

United States. They have estimated that there would be 30 000–50 000 additional killings in the United States every year—at least tripling or quadrupling the current homicide rate—without the advances in emergency care technology that have occurred during the last 30 years.

In 2007, homicide ranked fifteenth among the leading causes of death for men and women of all ages. Women and men, however, did not have the same likelihood of being killed by someone else. For men, homicide was the thirteenth leading cause of death. For women, homicide did not crack the top twenty. The likelihood of being killed also differed as a function of age and ethnicity. For all men between the ages of 15 and 24 years, homicide was the second leading cause of death, but for black men in the same age group, it was the number one cause of death.

It is more likely that a killer will be someone the victim knows than someone the victim does not know. However, Dr. Martin Daly and Dr. Margo Wilson from McMaster University have noted that the killing of genetic relatives is significantly less common than the killing of unrelated individuals, suggesting that proximity alone is not a satisfactory explanation for why people kill. Across cultures, 65% of homicides involve males killing other males, 22% involve males killing females, 10% involve females killing males, and only 3% involve females killing other females.

The most common method for homicide in the United States in 2009 was firearms (67.1%), followed by knives or cutting instruments (13.4%), unknown or other dangerous weapons (13.7%), and hands, fists, feet, etc. (5.9%). Homicide rates do not vary significantly with the season or lunar cycle. Less than a third of those who commit homicide are intoxicated when they kill.

Regional differences in homicide rates have been well documented. In the United States, the rates of killing are much higher than in many industrialized nations, exceeding those

in the United Kingdom and Japan by a factor of ten; exceeding those in France, Austria, Sweden, and Germany by a factor of nine; and exceeding the rates in Canada, Italy, Portugal, Korea, and Belgium by a factor of five. But, the homicide rates in many other countries are equivalent to or exceed those in the United States. The lifetime probability of being a homicide victim in Venezuela and Moldova is 1 in 90, twice that of the United States. In Estonia and Puerto Rico, the likelihood is 1 in 60, three times that of the United States. And in Colombia and South Africa, the likelihood is greater than 1 in 20 that a person will die at the hands of a killer, more than ten times the lifetime homicide risk in the United States. Even among those nations that currently exhibit low homicide rates, much higher frequencies of conspecific killing were a consistent part of their histories. Historical evidence suggests that the relatively low homicide rates in many modern societies are a recent phenomenon. It should also be noted that the rates of homicide recorded by nations typically do not include casualties of warfare or genocide.

The homicide rates in industrialized nations pale in comparison to the risk of being killed by a competitor in many preindustrial cultures. Including deaths resulting from lethal raids and tribal warfare, homicides account for roughly one in ten deaths of adult men among the Huli, one in four deaths among the Mae Enga, and one in three deaths among the Dugum Dani and Yanomamo. Even among the so-called gentle people or peaceful Kung San of Botswana, there were 22 homicides over a 25-year period in a population of 1500, more than four times the rate of killing in a typical year in the United States.

Theories of Homicide

Despite the fact that tens of thousands of homicides are committed worldwide every year, lethal violence is not well understood. For our understanding of homicide to be complete, we must explain, for example: (1) why men are vastly overrepresented among killers (87%); (2) why men are also overrepresented among murder victims (75%); (3) why women commit some kinds of homicide more than men (e.g., infanticide of own children); (4) why people kill in qualitatively distinct conditions, leading to predictable motives for killing; and (5) why people experience homicidal fantasies in circumstances that correspond closely to the contexts in which people actually kill.

The majority of theories that have been used to explain homicide were not designed specifically for that purpose. They are general theories of behavior, all crimes, or all violent crimes. Different theories of homicide need not be competing. They often address different levels of explanation and are often complementary, capable of contributing unique insights into the explanation of why people kill.

Homicide Adaptation Theory

Dr. David Buss from the University of Texas and Dr. Joshua Duntley from Richard Stockton College have proposed a theory that humans possess adaptations designed for killing conspecifics. Psychological adaptations for homicide are

argued to be the outcome of the process of natural selection. Over human evolutionary history, they were favored by selection when they contributed better solutions to adaptive problems, on average, than competing designs. Information processing adaptations evolved to scrutinize and sometimes produce homicidal behavior in adaptive problem contexts similar to those recurrently solvable by homicide in the ancestral past. Although some have suggested the possibility of adaptations for homicide and others have argued that humans may have an instinct to kill, few other theorists have gone into depth in exploring the evolved design of adaptations for homicide.

Dr. David Buss and Dr. Joshua Duntley hypothesize that homicide was functional in solving a wide variety of adaptive problems. Specifically, the killing of a conspecific could have contributed to: (a) preventing the exploitation, injury, rape, or killing of self, kin, mates, and coalitional allies by conspecifics in the present and future; (b) reputation management against being perceived as easily exploited, injured, raped, or killed by conspecifics; (c) protecting resources, territory, shelter, and food from competitors; (d) eliminating resource-absorbing or costly individuals who are not genetically related (e.g., stepchildren); and (e) eliminating genetic relatives who interfere with investment in other vehicles better able to translate the investment into genetic fitness (e.g., deformed infants, the chronically ill, or infirm).

Homicide is such a unique and potentially powerful strategy with dramatic fitness consequences for both the perpetrator and the victim that it is reasonable to hypothesize that it has been subjected to evolution by natural and sexual selection. Homicide is different from other strategies for inflicting costs because it leads to the absolute end of direct competition between two individuals. The person who is killed can no longer compete with his killer. A dead competitor can no longer directly influence the environment or social context that he shared with his killer. The distinct outcomes of homicide would have created equally unique selection pressures to shape human psychology specifically for contexts of homicide.

Adaptations for homicide would be more likely to evolve when they reliably contributed to the solution of an adaptive problem with a high impact on individual fitness, such as preventing a rival from killing one's child. Adaptations for homicide also would be more likely to evolve when a large number of different adaptive problems could be solved, or at least partially solved, by adopting a homicidal strategy. Consider, for example, the intrasexual rival of a man who was preventing his ascension in a status hierarchy, attempting to poach away the man's mate, monopolizing a scarce and valuable shelter as winter approaches, and who took every opportunity to publicly humiliate the man's brother. Killing the rival has the potential to contribute to the solution of each of these adaptive problems.

Different ancestral problems required different specific solutions. Homicide adaptation theory proposes that there are multiple, different psychological adaptations for homicide, each of which is devoted to the solution of different kinds of adaptive problems. It follows that the psychological design that produces infanticide is distinct from the psychological design for warfare and the psychological design that produces mate homicide in men is distinct from the psychological design for mate killing in women. Some information

processing mechanisms are undoubtedly shared between the different adaptations for homicide and with adaptations for the solution of other adaptive problems. Selection would favor the sharing of subroutines performing the same function over reinventing them anew for each psychological adaptation. However, any given adaptation for homicide has at least one design feature that is distinct from other adaptations. Homicide adaptation theory, in short, proposes that selection has fashioned a number of specialized psychological adaptations that produce conspecific killing in order to solve distinct and historically recurrent adaptive problems.

Homicide adaptation theory is a coevolutionary theory. Just as killers obtained large ancestral benefits from the use of homicide in some contexts, victims and their genetic kin suffered extraordinary costs. The costs of being killed by a conspecific are hypothesized to have created selection pressure for the evolution of defenses against homicide and to adaptations in victims' genetic kin to prevent relatives' untimely deaths or otherwise minimize their costs. The evolution of defenses against lethal aggression would have created new selection pressure on adaptations for homicide, shaping new design features capable of bypassing victims' defenses. This coevolutionary arms race between homicide adaptations and victim defenses is hypothesized to have contributed to rapid evolutionary change and elaborate design in both.

Homicide adaptation theory proposes that there were specific combinations of adaptive problems individuals recurrently faced in the evolutionary past that would have been best solved by killing. Selection would have favored individuals who possessed the psychological adaptations that reliably led to the production of homicidal behavior when they faced such contexts. The best solution to most adaptive problem contexts faced by our ancestors did not involve homicide. However, the potential fitness gains accomplished by the use of killing to solve a small, specific set of adaptive problems would have selected for psychological adaptations that produce conspecific killing.

Homicide adaptation theory argues that the psychological mechanisms that produce homicide steer an individual in the direction of adaptive behaviors that reliably result in the death of another individual. This is accomplished through a variety of affective, motivational, and computational systems that narrow in on homicide as the solution to adaptive problems. The adaptive problems to which we are referring are fluid, changing as they unfold over time. As other individuals pursue their own goals, the nature of adaptive problems changes and the solution to one set of adaptive problems may reliably create others. Rather than evolving in response to a single, static set of circumstances, homicide adaptations were shaped by the ancestrally reliable unfolding of adaptive problems.

Homicide adaptation theory does *not* imply that homicide will be the *preferred* strategy for each or any adaptive problem in all situations. In most circumstances, the high costs of committing homicide would have outweighed its benefits. Instead, the theory proposes that homicidal behavior was the best solution for rare combinations of adaptive problems and circumstances. It is not possible to point to just one feature of a context that will activate a psychology of homicide in every instance, in every person. There are always other, mitigating environmental factors, heritable personality features,

hormonal influences, and the developmental and experiential calibration of psychological mechanisms that influence behavior. Many or all of these features were part of the selection pressures that shaped homicide adaptations. Thus, a combination of external cues to the presence of an adaptive problem ancestrally solvable by conspecific killing and internal psychological states that make lethal violence an adaptive option activate homicide adaptations. The presence of these cues and psychological states, as well as their magnitude, can help us to predict when conspecific killing will be more or less likely to occur. Without complete knowledge of how human psychology produces homicidal behavior, however, it is not possible to make perfect predictions about whether homicide will occur in an individual case. The same is true of making predictions about any behavior.

In sum, homicide adaptation theory proposes a new explanation of homicide: Over the long expanse of human history, there were recurrent sources of conflict between individuals, such as conflict over reputation and social status, conflict over resources, and conflict over romantic partners. Killing is hypothesized to be one among an arsenal of context-contingent strategies shaped by natural selection to win conflicts with others. Homicide differs qualitatively from nonlethal solutions to conflict. Once dead, a person can no longer damage the killer's reputation, steal his resources, prevent the killer from attracting a romantic partner, hurt the killer's genetic relatives, or have sex with the killer's spouse. According to homicide adaptation theory, our evolutionary heritage has endowed all of us with a psychology to kill others. These psychological processes lead us to entertain fantasies of killing and, in rare instances, act on them when we encounter sources of conflict that were successfully won by homicide in the evolutionary past.

Cultural and Social Theories

Cultural and social explanations of homicide rely on the fundamental principles of learning theory. These explanations propose that learning from the social environment is responsible for differences in homicide rates between groups, including differences in men's and women's propensities to kill. The specific environmental source identified as the causal force behind lethal aggression differs from one explanation to another. For example, some theorists suggest disorganized communities lead to crime, others argue that crime is learned through differential association with deviant peers, while others argue that the gap between desires for a better lifestyle and lack of legitimate means to fulfill them creates strain that fuels crime. Each of these theories argues that homicide is the product of learning by normal people.

A core assumption of social theories that lead them to predict men should be more likely to commit homicide than women is that observing violence in the world causes violent behavior. Because humans observe more instances of men perpetrating violent acts in life and in the media, the theories argue men are more likely than women to engage in similar behaviors. The causal arrow linking violence in the world to the violent behavior of individuals, however, need not run in this direction. For example, evidence shows that boys preferentially seek out violent toys and media images. When parents

encourage their boys to be tough and their girls to be gentle, they may be responding to existing predispositions in each sex. Popular media may target boys with more violent programming than girls to exploit desires each sex already has.

The imitation of violence in the media is also limited in its explanatory power as a causative influence of homicide because it cannot explain evidence of killing in the distant past. Evidence of lethal violence appears in the archaeological record as early as the Paleolithic, between 20,000 and 30,000 years ago. Researchers have found skeletal remains in Europe and Egypt that show projectile points embedded in bone and depressed fractures on skulls, indicating blunt force trauma. Most cranial fractures have been found on the left side of the skulls, suggesting they were made by a right-handed attacker in face-to-face combat.

In sum, cultural and social theories of homicide propose that the process of learning from the social environment is responsible for differences in homicide rates between cultures and differences in men's and women's propensity to kill. Cultures of honor valorize violence as a solution to interpersonal disputes, and violence is socially encouraged in male children but discouraged in female children. Learning is undoubtedly important for the adaptive calibration and activation of adaptations that produce lethal violence and the pursuit of homicidal strategies, accounting for some of the variance in why people kill. However, cultural and learning theories in their present form are too general to generate specific hypotheses about how experience affects psychological processes involved in producing homicide differently from psychological processes involved in addressing other domains of human experience, such as mating relationships and food preferences. The addition of an evolutionary perspective to the study of how social and cultural processes affect individuals' psychology of homicide has great potential to suggest fruitful directions for future research and may help to account for many observed patterns of homicide (e.g., infanticide perpetrated primarily by young mothers). This would allow novel, specific predictions to be generated about trends in homicide that may be the function of different social environments and help to explain why people sometimes commit homicide instead of doing something else.

Pathology Theories

Pathology theories of homicide propose that people kill when their thinking is abnormal. The causes of cognitive malfunctions vary, as do the forms of abnormal cognition they produce.

A prospective study of major mental disorders and criminality conducted using a birth cohort in Northern Finland found that violent offenses were most prevalent among males with alcohol-induced psychoses or schizophrenic alcohol users. Those suffering from depression were least likely to kill. Research conducted in Australia found a similar trend in the disorders that are most common among killers, which also include bipolar disorder, psychopathy, dissociative identity disorder, and unipolar mania. In both studies, people with mental illness were found to be more likely than people not suffering from a disorder to kill members of their families. Proximity theory, which argues that people are most likely to

kill those with whom they interact the most, has long been dismissed as an explanation for homicide, but may be somewhat compatible with the trends in homicide apparent among the mentally ill.

Suboptimal arousal theory is based on the observation that some people have a preference for intense environmental stimulation. Those who feel most starved for arousal are presumed to be more likely to engage in highly arousing thrill-seeking and risk-taking activities. Criminal behaviors, including homicide, may be committed more often by those who are suboptimally aroused.

Seizuring theories of crime are based on research into the causes of epilepsy. Not all seizures lead to convulsions. If subconvulsive seizures are located in the limbic system, they may have significant effects on emotions, sometimes resulting in criminal behavior.

Other pathology explanations have argued that failure of the frontal lobes to function properly may disinhibit violent behavior. Frontal lobe damage is associated with increased impulsivity and lack of planning ability that may contribute to some homicides.

Another pathology theory is rooted in the observation that one male out of every 700–1000 is born with an extra Y-chromosome, and one male out of every 500 is born with an extra X-chromosome. Both genetic abnormalities result in males who score lower on standard intelligence tests and show an increased likelihood of criminal behavior, including lethal aggression. However, these genetic abnormalities are likely to explain only a tiny fraction of the homicides committed, since males with an extra chromosome only constitute 1–2% of the total prison population.

The percentage of all homicides that can be attributed to psychopathology in a particular region appears to be linked to the homicide rate. Where homicide is rare, a higher proportion of killings are committed by people suffering from disorders such as schizophrenia. Where homicide is more frequent, a smaller percentage of killers are identified as suffering from major psychopathology. For example, studies of the perpetrators of homicide in Britain found that 39% of killers suffered from a mental disorder. In Sweden, 53% of killers were found to be mentally ill, as were 35% of Canadian killers. Britain, Sweden, and Canada have some of the lowest homicide rates in the world. In contrast, only 19% of killers in New York City, 4.4% of killers in Detroit, and 4.4% of homicidal offenders in Australia were found to suffer from mental illness.

In sum, there is evidence that psychopathology is a contributing factor in some (albeit a minority of) homicides and that these killers are more likely to manifest symptoms of mental disease, such as targeting genetic relatives. This does not mean, however, that psychopathology is the sole cause of such homicides. Psychopathology and probably most individual differences do not add additional information-processing capabilities to human psychological adaptations. Sources of individual differences more likely distort cognitive adaptations, perhaps occasionally affecting the likelihood that a person will kill. An individual with schizophrenia who has delusions that his mother is an extraterrestrial who has plans to eliminate all of humanity, for example, is clearly delusional. Despite errors beliefs and interpreting input from the environment, the activation of psychological mechanisms to produce

homicide may be appropriate and adaptive if indeed his mother were an extraterrestrial. It is difficult to kill someone. The production of a sequence of behaviors capable of successfully ending another person's life requires a large number of calculations that cognitive system errors, by themselves, would be incapable of producing. One reasonable hypothesis is that psychopathology leads to the inappropriate activation of psychological mechanisms capable of producing successful homicidal behavior. A challenge for future research is the identification of how, specifically, different forms of psychopathology influence and activate the psychological processes that produce homicide.

Individual Differences Theories

Individual differences in personality may also lead to the differential activation of cognitive mechanisms that produce homicide in other ways. Personality leads people to experience the same environments differently, seek out different environments, and be excluded from a certain subset of social environments. People with personalities that lead them to occupy environments characterized by high levels of interpersonal conflict may be more likely to encounter contexts that predictably lead to lethal aggression. For example, people who score high on measures of antisocial personality, low in conscientiousness, high in neuroticism, and low in intelligence are more likely to engage in criminal activities, including homicide.

Another group of explanations for killing propose that individual differences may make homicide more adaptive for some people in terms of evolutionary fitness. Cheater theory argues that two, alternative reproductive strategies have evolved in human males. One type of male (Dads) is law-abiding and loyal to women. Male cheaters (Cads), on the other hand, are argued to adopt strategies of criminality, including homicide in order to obtain resources and short-term mates.

Dr. David Rowe's alternative adaptation theory points out that criminals typically devote more effort to mating than they do to parenting. Rowe argues that criminality is a strategy that can only thrive when there are others to exploit. As the number of criminals in a population increases, the effectiveness of criminal strategies like homicide will decrease.

Conditional adaptation theory (CAT) attempts to integrate adaptive individual difference theories and learning theories. It proposes that everyone has the same genetic potential to exhibit criminal behavior at birth. Early life experiences cause individuals' potentials to change. Children who witness poor, unstable relationships between their genetic parents and live in relatively resource-scarce environments are argued to be more likely to adopt short-term, opportunistic mating strategies as adults and riskier strategies for obtaining resources, including theft, violence, and lethal aggression.

Individual difference factors may interact with evolved psychological mechanisms for homicide to produce a decreased threshold for conspecific killing by leading to the inappropriate activation of adaptations for homicide. The mistaken activation of adaptations that lead to lethal aggression may have several sources, including (a) the presence of evolutionarily novel stimuli in modern environments that 'trick' homicide adaptations into recognizing a problem as potentially solvable by killing when it is not; (b) errors in the mechanisms that

weigh the costs and benefits of homicide, leading to the underestimation of costs, the overestimation of benefits, or both; and (c) a failure of some mechanisms that are necessary for the normal functioning of homicide adaptations to activate, leading to incomplete processing and the erroneous motivation of homicidal behaviors. In each of these cases, the majority of evolved mechanisms for homicide continue to function as they were designed. Thus, despite systematic errors at certain levels of cognitive processing, a complete explanation of killing others that is partially the result of inappropriate activation of homicide mechanisms must include an analysis of the evolved mechanisms involved. While the preceding individual difference theories suggest that lethal aggression may have been adaptive for some individuals in the ancestral past, other explanations propose that homicide was never adaptive.

The By-product Hypothesis

Over the past few decades, several evolutionary scientists have offered explanations for homicide. Almost without exception, however, the evolutionary hypotheses posit killing as unnatural and not part of our evolved psychology. The ethologist Eibl-Eibesfeldt, for example, proposed that killing (e.g., in war) is a culturally imposed behavior that overrides an innate human inhibition to kill. Killing, according to this view, is a cultural aberration and in no way part of human evolved psychology. This explanation leads to no detailed predictions about the various forms of homicide or about the contexts in which they occur.

The most comprehensive evolutionary explanation specifically advanced to account for patterns of homicide to date was proposed by Daly and Wilson, who have made pioneering contributions to our understanding of homicide and the contexts in which it occurs. They advance two distinct arguments about homicide. In the first argument, Daly and Wilson are agnostic about whether there are adaptations designed to produce homicide, "...our evolutionary psychological approach in no way depends upon homicide per se being 'an adaptation.' It may or may not be the case that actual killing was a regular component of the selective events that shaped human passions".

Daly & Wilson also advance the view that humans do not have an evolved psychology of homicide. Rather, they propose that homicides can be viewed as "dysfunctionally extreme byproducts," "epiphenomena", or "overreactive mistakes" of evolved mechanisms designed for their non-lethal outcomes. According to this argument, "It is quite possible that actually killing one's antagonist is more often than not an overreactive mistake—an act with negative consequences both for the killer's net hedonic utility and for the actual expected fitness of which that utility is an evolved token." These arguments illustrate that Daly and Wilson explicitly are not proposing that humans have evolved distinct adaptations for homicide, although they do not rule out the possibility completely.

Although Daly, Wilson, and colleagues do not propose that humans have evolved psychological mechanisms specialized for killing, they do emphasize the importance and priority of an evolutionary psychological explanatory account: "...what is needed is a Darwinian psychology that uses evolutionary ideas as a metatheory for the postulation of cognitive/emotional/motivational mechanisms and strategies." Daly and Wilson

must be correct that at least some homicides are byproducts of the operation of evolved mechanisms designed for non-lethal outcomes, such as coercion and control. Homicide Adaptation Theory, in contrast, would argue that these represent a minority of killings. David Buss, Joshua Duntley, and other Homicide Adaptation Theorists argue that most killings are better explained as the designed products of adaptations selected specifically for their lethal outcomes.

In sum, nonadaptationist explanations of homicide may be able to predict some variance in who is likely to become a criminal and to identify some broad features of contexts that may trigger criminal behavior. When considered individually, they all share similar weaknesses, which include (a) a failure to provide a comprehensive explanation of the patterns of homicide; (b) not making predictions about when homicide, instead of some other criminal behavior, is likely to occur; (c) not offering explanations for a large number of the observed patterns of homicide; (d) not specifying whether homicide is a kind of criminal behavior that could have ever been adaptive during our evolutionary history; (e) failure to provide an explanation for why people who are not pursuing a general strategy of criminality would ever commit homicide; (f) an inability to explain why the majority of normal people report experiencing homicidal fantasies; and (g) failure to explain the patterns of people's homicidal fantasies.

Detering Homicide

The two major debates in the problem of deterring lethal aggression today concern the effectiveness of capital punishment and gun control.

The Role of the Death Penalty

Research on the effectiveness of the death penalty at the societal level has been conducted by economists who have applied sophisticated statistical techniques to the problem, both over time (from year to year) and across regions (from state to state). However, the results of the research are conflicting and any conclusion by a reviewer of the research may be colored by the reviewer's own opinion. A cautious conclusion must be that the deterrent effect has not yet been proved.

An alternative methodology has been to explore the number of homicides committed in the days following an execution. A meta-analysis of numerous studies has supported the deterrent effect of executions on subsequent homicide rates. However, the researchers who conducted the meta-analysis cautioned that the effect depended on the type of study carried out and the effects of publicity.

Other researchers conducted a study of the deterrent effect of the death penalty in Texas, where the death penalty is used frequently enough to generate stable estimates of whether homicide rates respond to executions. They found small, short-term reductions in homicides in the first and fourth months following executions, amounting to 2.5 fewer killings. However, the researchers argued that the executions may have functioned merely to displace homicides from one month to another, which reduces the lives saved to 0.5 in the year after an execution.

The Role of Guns

Advocates of gun control often argue that limiting people's access to firearms would prevent violent crime and, in particular, homicide. Testing this assumption in the United States is problematic because gun control is quite weak by the standards of other nations where guns are rarely owned by private citizens. Tests of the effectiveness of the introduction of gun control laws have been conducted in other countries. For example, Australia introduced strict gun laws in 1997 in response to a mass shooting in Port Arthur, Tasmania in 1996, where 35 people were killed. Some researchers have concluded that the law has led to a decrease in homicide rates, while others using the same data have argued that the law did not have any significant effects on reducing firearm homicide. More research is needed on this important topic.

Hope and Optimism

D S Bailis and J G Chipperfield, University of Manitoba, Winnipeg, MB, Canada

© 2012 Elsevier Inc. All rights reserved.

Glossary

Hope A positive feeling and motivational state, which arises from the beliefs that one has the agency (i.e., energy) and pathways (i.e., behavioral means) required to attain one's goals.

Optimism The extent to which individuals expect desired outcomes to happen in the future, and expect undesired outcomes not to happen.

Hope and optimism are hallmarks of psychological health. Both terms have been used in common language for centuries to describe people who hold positive expectations about the future. Modern research shows that such people, in contrast with those who hold negative expectations, engage in a variety of coordinated, adaptive responses to the challenges and opportunities they encounter in life. The study of hope and optimism also reveals key themes in the development of psychology over the past 30 years, including our grasp of (a) the centrality of *goal-strivings* to human behavior, (b) how people's understanding of the *causal structure* of life events is related to their subsequent emotions and motivation, and (c) factors contributing to the *positive* range of human experience, including physical and psychological health beyond the absence of illness.

In this article, our principal aim is to review the definitions, leading standardized measures, and adaptive consequences of hope and optimism. Following these topics, we review ongoing research into the possible risks of hope and optimism, including the misperception of personal risks and failure to disengage from unattainable goals. We conclude with some general observations about the realistic or unrealistic nature and value of positive future expectations. As a caveat, we note that our review is couched in a modern and Western perspective on hope and optimism. In our estimation, the available literature on hope and optimism offers few definite statements about historical or cross-cultural variability in these concepts, but cross-cultural research in this general area of psychology (i.e., including related topics, such as attributions, perceived control, and mindfulness) holds some implications that may be fruitful to pursue with respect to hope and optimism. In particular, it appears likely that people in different cultures and historical eras have used substantially different cognitive mechanisms or strategies in order to attain and maintain positive future expectations. Once attained, however, the adaptive consequences of these expectations may be a universal feature. These consequences, with respect to striving and well-being, have been confirmed in research spanning different cultures and even different species.

Definitions

Hope and optimism both involve positive expectations about the future, but only optimism is defined strictly in these terms.

Optimism is the extent to which individuals expect desired outcomes to happen in the future, and expect undesired outcomes not to happen. As individuals drop in their expectation of desired outcomes and gain in their expectation of undesired ones, they move from the positive pole, optimism, to the negative pole, pessimism. Optimism has most often been conceived as a character trait or strength, which people possess in varying degrees. As such, it is a relatively enduring and beneficial aspect of how individuals approach a wide range of situations. The term 'optimistic' has also been used to describe specific perceptions (e.g., of low risk) or self-evaluations (e.g., of high ability) that are overly positive or inflated in comparison with objective standards. Although such perceptions may be unrealistic, they can soothe people's worries and doubts in a difficult situation, and encourage continued striving toward goals.

Like optimism, hope is a positive feeling and motivational state, but one that intrinsically involves beliefs about the self and one's own actions as they relate to the attainment of desired outcomes. These beliefs, as articulated in Snyder's influential theory of hope, include a successful sense of *agency*, which refers to the energy required to attain goals, and *pathways*, which refers to the means of attaining goals. Hope is also typically regarded as a stable individual difference. People with high hope, as opposed to those with low hope, more often think about different routes to their goals, more fully specify these alternate routes, and more frequently tell themselves that they can and will accomplish their goals.

As with other personality traits, hope and optimism emerge from a combination of genetic and environmental influences, as well as cultural and historical ones, operating over the lifespan. Indeed, each of the broad dimensions of temperament that can be observed in infancy or childhood, and that have a probable biological basis, may set the stage for hope and optimism in adulthood. A child's temperament describes the way he or she notices and reacts to changes in his or her external environment or internal state. The broad dimensions of such reactions include negative affectivity (i.e., fear, anger, sadness, ease of being soothed from distress), effortful control (i.e., planning, capacity to focus or shift attention), and extraversion or surgency (i.e., activity level, excitement, lack of inhibition, affiliation). A child who exhibits a high capacity for effortful control may have an easier time than one with lower capacity in forming the experiential basis for beliefs about high agency and pathways, which are essential to hope. A child who exhibits high negative affectivity may have correspondingly

more frequent experiences of events not working out to his or her liking, and by generalizing these experiences may tend toward pessimism.

An interesting case of temperamental bias is related to extraversion/surgency, or the way infants react to unfamiliar stimuli with either an inhibited or an uninhibited behavioral profile. Infants with the inhibited profile show distress in response to unfamiliar people, places, objects, sensations, or events, whereas infants with the uninhibited profile show a relatively bold or spontaneous approach to the same sort of experiences. Research by Kagan and colleagues has shown the preservation of these inhibited or uninhibited reactions to unfamiliarity from as early as 16 weeks after a normal term birth to the age of 17 years. Although there may be no simple mapping between these infant temperaments and adult traits of hope and optimism, people's reactions to unfamiliarity throughout their childhood and youth will still shape their adult personality development in terms of how they view the future or the unknown. Whereas some hopeful or optimistic adults will have had a high tolerance for unfamiliarity and uncertainty throughout their lives, others will have arrived at being hopeful or optimistic by nurturing self-views or world-views that reduce their fear of the unknown.

Leading Standardized Measures

Research on hope and optimism has benefited from the development of self-report measures that corresponded closely with the theoretical elaboration of each concept. We review three of the leading measures here: that is, the Life Orientation Test (LOT), the Attributional Style Questionnaire (ASQ), and trait and state versions of the Hope Scale.

Dispositional Optimism and the Life Orientation Test

Scheier and Carver developed the LOT to measure dispositional optimism, a concept that figured prominently in their overarching theory of self-control. The theory assumed that most if not all of people's actions are goal-directed, and that people's emotional balance had much to do with the success or failure of their goal pursuits. The role of dispositional optimism could be seen in the self-control theory's formulation of goal strength as the product of two factors: the degree to which an outcome was expected, and the degree to which it was valued or desired. A logical implication was that people with generally higher expectations – that is, optimists – would have generally stronger goals, leading in turn to greater persistence, faster progress, more positive affect, and less negative affect.

In line with this major implication of their theory, Scheier and Carver coined the term *dispositional optimism* and developed the LOT so as to capture individual differences in positive expectations that were tied, not to a specific pursuit, but to the occurrence of good outcomes in general. The LOT, in its revised form, consists of ten self-statements with which respondents can agree or disagree, to varying degrees, using a 0–4 numerical rating scale. Eight of the statements refer to the likelihood of good or bad outcomes and thus contribute directly or inversely to the total score: for example, 'In uncertain times, I usually

expect the best,' or 'If something can go wrong for me, it will.' The remaining two statements are fillers that reduce the salience to respondents of the concept being measured.

This method of scaling lends itself to psychometric testing. Such testing typically examines the agreement or internal consistency of responding across items, temporal stability of the rank-ordering and separation of individuals' total scores, and correlation of these scores with relevant outcomes and other optimism measures. In a noteworthy example, Scheier and colleagues showed that scores on the LOT predicted depression, even in partial correlation analyses that controlled for individual differences in neuroticism, trait anxiety, self-mastery, and self-esteem. This finding suggests that optimism has unique features that are related to psychological adaptation, beyond those that may be shared with these other characteristics, and also that scores on the LOT indeed reflect these unique features of optimism.

Learned Optimism and the Attributional Style Questionnaire

Another approach to the definition and measurement of optimism grew out of research on explanatory style and the learned helplessness model of depression. An individual's explanatory style refers to the way in which he or she usually engages in explaining life events, by attributing them to an underlying cause. Weiner first introduced the idea that these attributions can be arrayed on several dimensions. The first dimension is *internality*: internal causes originate from within oneself or are subject to personal control, whereas external causes originate with other people or circumstances. The second dimension is *stability*: stable causes are durable and unlikely to change, whereas unstable causes are temporary and likely to change. The third dimension is *globality*: global causes influence all or a wide range of personal endeavors, whereas specific causes influence an isolated or narrow range.

Informed by this dimensional analysis, Abramson, Seligman, and Teasdale realized the potency of certain attributions to account for learned helplessness – a phenomenon previously observed in learning experiments, which seemed to provide a model for depression. Learned helplessness is a motivational deficit that occurs as a result of exposure to painful or noxious stimuli that are also inescapable. The deficit becomes apparent at a later time, when escape is possible, but it goes undetected because the individual ceases to try. What Abramson and colleagues realized was the parallel implication of attributing a negative life event to an underlying cause that was internal (i.e., 'it's my fault this happened'), stable (i.e., 'it's something about me that will never change'), and global (i.e., 'it's going to affect everything I try to do'). In the wake of this type of attribution, it is understandable that one might lose motivation. The flipside of this argument, however, is that making an external, unstable, and specific attribution for the same event would tend to curtail or counteract the motivational loss. Seligman coined the term *learned optimism* to describe this route out of depression, whereby setbacks became the occasions for learning that better outcomes lay ahead.

Research on explanatory style produced a self-report measure, the ASQ, which quantifies individuals' proneness to learned helplessness on one hand, or optimism on the other. The ASQ presents respondents with 12 hypothetical events,

such as searching unsuccessfully for a job, or being treated lovingly by a spouse or a significant other. The 12 events are balanced in referring to good or bad outcomes, in either the achievement or affiliation domains. For each event, respondents write down one major cause. They then rate the cause on each of the three attributional dimensions, using 1–7 numerical rating scales. These ratings are summed across good or bad events, such that higher ratings in the direction of greater internality, stability, or globality contribute directly to the total score. In support of the reliability and validity of these scores, Peterson and colleagues demonstrated the internal consistency and temporal stability of dimensional ratings for good and bad events, and discussed additional evidence that ASQ scores predicted respondents' attributions for specific events at a later time, as well as depressive symptoms.

Hope and the Hope Scale

According to Snyder's theory, hope is a two-dimensional concept, which manifests itself in a person's beliefs about successful agency and pathways to attain goals. The Hope Scale reflects this theoretical structure, being composed of four items on successful agency, four items on successful pathways, and four filler items. The agency items refer to goal pursuit in the past, present, and future: for example, 'I've been pretty successful in life,' 'I energetically pursue my goals,' and 'My past experiences have prepared me well for my future.' The pathways items refer to overcoming obstacles to goal pursuit: for example, 'I can think of many ways to get out of a jam,' or 'I can think of many ways to get the things in life that are most important to me.' Each item is answered using a 1–4 rating scale from 'Definitely False' to 'Definitely True.' Snyder and colleagues introduced the Hope Scale with substantial psychometric evidence from diverse samples consisting of college students and patients in a state mental hospital. This evidence consistently supported a two-factor structure and convergent validity with respect to optimism, desire for control, self-esteem, hopelessness as a symptom of depression, and other clinical symptoms.

The Hope Scale, as described above, is a *trait* measure. However, soon after, Snyder and colleagues introduced a 6-item *State* Hope Scale. The state scale was intended to capture the additional variability in hope, around an individual's dispositional set-point, which he or she might experience in connection with current goals and problems. The State Hope Scale consists of three items on successful agency and three on successful pathways, which were formed by modifying the contents of the dispositional scale to refer to the present moment. Thus, the original item, 'I energetically pursue my goals,' was changed to, 'At the present time, I am energetically pursuing my goals.' Snyder and colleagues showed that scores on the State Hope Scale were positively correlated with those on the trait Hope Scale, and with other state measures of mood and self-esteem. In an experimental test, participants completed the State Hope Scale both before and after they had engaged in a relaxation and guided visualization exercise. As part of this exercise, participants were randomly assigned to recall vividly a time when they either succeeded or failed to reach an important goal. Both agency and pathways subscores of the State Hope Scale changed significantly, such that

participants who visualized a past success gained hope, whereas those who visualized a past failure lost hope for their current goals.

Adaptive Consequences

A vast literature now attests to the adaptive consequences of hope and optimism. Indeed, despite carefully reasoned arguments and substantial research effort, it has been hard to find contexts in which these traits do not have adaptive effects. In reviewing this literature, it is useful to note that just two broad categories of adaptive outcomes follow directly from the theory of hope and optimism as positive motivational states. These categories are (a) effort and persistence at goal-directed tasks, and (b) positive and negative feelings that arise from ongoing goal pursuits. Other broad categories, which have emerged as extensions of research on the initial two, include (c) the use of adaptive coping strategies, and (d) positive physical and psychological health outcomes related to the length and quality of people's lives. We review these categories, in turn, in this section. In each case, although we may rely on research illustrations that are specific to hope or optimism, the adaptive consequences are applicable to both concepts.

Effort and Persistence

The willingness to keep trying in the face of problems or setbacks is a defining quality of both hope and optimism. Accordingly, numerous studies of hope and optimism have shown this behavioral outcome, covering a wide range of goal domains and settings. In the case of optimism, we review some relevant examples in the sections on health and risk perception below.

In the case of hope, Snyder and colleagues provided a clear experimental demonstration when they asked college students (all of whom had previously completed the trait Hope Scale) to imagine themselves in an introductory college course, in a field that might eventually be their major, having set the goal of receiving at least a B grade in the course. In one condition, participants imagined only this much, whereas in the other condition they further imagined receiving a poor grade on the first exam. After thus imagining either no feedback or negative feedback, all participants answered questions about the effort they would exert to reach their goal of a B grade. They also listed specific strategies they would use, rating each strategy as to the likelihood that they would use it and the certainty that it would work. Among participants with low pretest scores on the Hope Scale, both indicators of effort and persistence were significantly lower in the negative-grade feedback than in the no-feedback condition. However, among participants with high pretest scores on the trait Hope Scale, there were no significant differences on either indicator of effort and persistence between the two feedback conditions. Thus, these hopeful participants were apparently unfazed by the imagined setback of a negative grade.

Extending this research from a hypothetical scenario to real life, Snyder and colleagues conducted a related study of achievement in an actual college course. Students' performance (final course grade) was used as an indicator of their effort

and persistence after the first exam. Hope scores at the start of the term reliably predicted final course grades, even after statistically controlling for students' grades on the first exam. Thus, the positive effect of hope on final course grades occurred, regardless of the initial feedback, the ability level of the students, and the many other factors that might lead some students to do well and others poorly on a given test. As the results of the earlier study would also imply, it appeared that students with higher hope consistently tried harder than their counterparts with lower hope, and thus attained a better average performance in the remainder of the course.

Positive and Negative Feelings

When people expect positive outcomes, they are apt to feel relatively good about their current situation, even if it is a challenging one. To begin with, negative feelings will be lower: that is, the challenging aspects of a situation will be less frustrating, distressing, and depressing to individuals who expect things to work out alright in the end, as compared with those who hold negative expectations. Furthermore, positive feelings will be higher: that is, by maintaining effort and persistence, hopeful and optimistic individuals will increase their chances of ultimately reaching their goals and will have the positive feelings such as happiness, interest, and enthusiasm that come with each step of progress along the way.

In line with these predictions, numerous studies have linked optimism to the absence of distress and depression in samples facing a variety of stressors: for example, students entering university, caregivers to people with a major illness or disability, terror/trauma survivors, new parents, couples facing infertility, surgical patients, patients with progressive diseases such as cancer or AIDS, or older adults experiencing falls. Hope has also been linked to psychological adjustment in challenging settings or circumstances of academics, physical health, sport, interpersonal relationships, and psychotherapy, among others. Indeed, in one study, trait hope scores were related to the positive and negative feelings participants had about their goals of the next 6 months, when these feelings were summed across the goals that participants had generated for four broad life domains: work and school, primary family life, intimate relationships, and personal changes or development.

Coping with Problems

To say that people who are hopeful and optimistic tend to redouble their efforts and maintain a favorable affective balance when confronted with stressors further suggests that these individuals have effective ways of coping with problems. One aim of Scheier and colleagues' work on the LOT was to clarify the relationship between dispositional optimism and specific coping strategies. Thus, in addition to optimism and depression, this research involving large samples of university undergraduates as respondents concurrently assessed on coping strategies of planning, suppression of competing activities, seeking of social support, positive reinterpretation, using humor, turning to religion, acceptance, denial, venting emotions, behavioral and mental disengagement, and use of drugs or alcohol, among others. Dispositional optimism correlated significantly with the self-reported frequency of use of

all of the strategies that were measured in this research. The direction of these correlations suggested both greater use of effective strategies such as planning or positive reinterpretation, and lesser use of questionable strategies such as denial or drug/alcohol use, by individuals higher as opposed to lower in dispositional optimism.

As the length and variety of the foregoing list implies, coping is complex. People engage in many different behaviors for the purpose of coping with problems, and many typologies and theories have been advanced to explain the coping process. However, two broad dimensions of coping that are commonly agreed upon are (a) whether coping behaviors or strategies are oriented toward solving problems versus soothing distressed emotions, and (b) whether they are oriented toward approaching problems versus escaping from or avoiding them.

Solberg Nes and Segerstrom performed a meta-analytic review of 50 studies on optimism and coping, in which the strategies were cross-classified according to both of these dimensions. A key finding from the meta-analysis was that optimism related positively to both problem- and emotion-focused coping strategies that had an approach orientation, and negatively to both problem- and emotion-focused strategies that had an avoidance orientation. This finding is important, not only because it revises previous thinking about the relationship of optimism to each dimension of coping on its own, but also because it suggests that dispositional optimists are prepared to cope head-on with either a controllable stressor that can be reduced directly by taking action, or an uncontrollable stressor that requires acceptance and accommodation. Approach-oriented coping by dispositional optimists thus appears to be quite flexible and resourceful, according to the demands of the stressor or situation, rather than locked into a certain repertoire that may be better suited to some stressors than to others.

Physical and Psychological Well-Being

If we can add effective coping with problems to a list of adaptive consequences that already includes goal-directed effort and attainment, and more positive and fewer negative emotions, we might next begin to wonder about the accumulation of these benefits of hope and optimism over time. Several lines of research now suggest that hope and optimism have effects on physical as well as psychological health, through which they can extend and improve the quality of people's lives.

Physical well-being

In one of the earliest examples, Peterson and colleagues coded the prevailing explanatory style that was expressed by 99 men in an open-ended questionnaire they completed in 1946 about difficult wartime experiences. These men were all Harvard University graduates, carefully selected for the study on criteria of sound physical and psychological health, who were approximately at the age of 25 when they completed the questionnaire. The coding of a pessimistic explanatory style, in terms of the use of internal, stable, and global attributions for bad events, followed the same underlying logic as the ASQ measure we described earlier. Summary ratings of physical health were derived from records of the men's physical exams, which were performed by their physicians every 5 years.

Pessimistic explanatory style at age 25 predicted ill health (including mortality), beginning at age 45 and continuing to the last available record at age 60. The ill effects of pessimism thus spanned over 30 years of these men's lives and occurred despite this study's careful control of their prior health conditions, both in the initial sample selection and afterwards in the intervening physical exams.

Scheier and colleagues examined the effect of dispositional optimism on recovery from coronary artery bypass surgery in 51 men who were assessed the day before their surgery, approximately 1 week afterward, and again 6 months afterward. Recovery after 1 week was assessed using patient and physician ratings and physical markers, which included the length of time before first sitting upright in bed, walking around the room, and walking unassisted for 10 min or more. Recovery after 6 months was assessed in terms of whether the patient had resumed normal activities and the number of domains in which this was so (e.g., working, exercising, having sex, socializing, and doing hobbies). Detailed medical information on each patient was used to evaluate the effects of dispositional optimism on recovery at each time. Independent of medical factors such as the patient's standing on multiple risk factors for coronary disease, severity of existing disease, and extensiveness of surgery that was performed in each individual case, more optimistic patients showed a faster and fuller recovery than their pessimistic counterparts by walking sooner in the first week after surgery, and by resuming more of their normal activities, faster, in the first 6 months after surgery.

Bailis, Chipperfield, and Perry assessed optimistic self-perceptions of physical health and activity level in a sample of 322 older adults, who were mostly women between the ages of 74–86. Optimism in this study was expressed in terms of the difference between where the respondents thought they stood in comparison with the norm for their age, and their normalized scores on comparable objective measures of preinterview hospitalizations, chronic health, and functional ability. Of the various ways to measure optimism that we have reviewed thus far, overestimation of one's health and activity level relative to the age-appropriate norm might seem the least likely to convey an adaptive benefit. Yet in the sample overall, and especially among the subset with low perceptions of control over their health, more optimistic self-evaluations were related to significantly lower odds of being hospitalized in two postinterview years. Moreover, these optimistic self-evaluations had survival implications over the next 2–6 postinterview years. An individual with relatively optimistic self-evaluations (+1 standard deviation above the sample average) had a probability of death that was lower by half from that of an otherwise similar individual with relatively pessimistic self-evaluations (–1 standard deviation below the sample average).

Psychological well-being

Being seriously ill or hospitalized takes a toll on psychological well-being, and it is striking from the standpoint of both physical and psychological health that hope and optimism can allay these negative conditions. Even among people who have these negative conditions, however, hope and optimism lead to differential outcomes in terms of quality of life. For instance, in Scheier and colleagues' study of coronary bypass patients, dispositional optimism was a significant positive

predictor of quality of life judgments taken 6 months postoperatively. This prospective relationship held even after statistically controlling for the extent of the patients' illness, surgery, and risk factors for future coronary health problems. Furthermore, this relationship was due, in part, to the influence of dispositional optimism on coping strategies that were observed in the first postoperative week, such as seeking information about the recovery process and not dwelling on negative emotional aspects of the experience. In this example, the cumulative effect of many small acts of coping is particularly salient.

Recently, however, research on hope, optimism, and well-being has taken another turn by considering hope and optimism, not as incremental predictors, but rather intrinsic properties of psychological well-being. For example, Chipperfield, Perry, and Weiner examined well-being among 353 community-dwelling older adults by asking them to report how often, during the past 2 days, they had experienced a series of discrete positive and negative emotions. One of the main findings of this study, in contrast with the anecdotal view of later life, was of the broadly positive nature of older adults' daily emotional experience. Thus, positive emotions such as happiness, hope, gratitude, and pride occurred much more frequently in this sample than negative emotions such as frustration, sadness, boredom, regret, guilt, shame, or fear. Over 85% of respondents reported at least one instance of feeling hope, in particular, which was also significantly correlated with perceived social support. The emotional side of hope has perhaps been overshadowed by the emphasis on cognitions in previous research and theorizing on hope and optimism. However, as Chipperfield and colleagues point out, there is new reason to be interested in hope as a feeling state, with increasing knowledge of the health-related psychological functions of positive and negative emotions.

Together with positive and negative emotions, another key aspect of psychological well-being is the sense that one is prospering or flourishing in life. In order to develop a brief measure of flourishing, Diener and colleagues reviewed the various philosophical and research traditions that have examined psychological well-being from the perspective of basic human needs, social capital, psychological resources, or existential purpose and meaning. From this enormity, the authors extracted just eight statements to represent flourishing. We find it instructive to note that three of them are devoted to hope and optimism: 'I am engaged and interested in my daily activities,' 'I am competent and capable in the activities that are important to me,' and 'I am optimistic about my future.' Here, again, hope and optimism appear as direct indicators of flourishing, a major component of psychological well-being.

Possible Risks

Modern research on the traits of hope and optimism has been energized as much by questioning their potential downside as by advancing their claim of adaptive effects. To the extent that hope and optimism stand for rigidly positive thinking, individuals who strongly express these traits should be relatively vulnerable to misperceiving personal risks. Such individuals also should find it especially difficult to disengage from goals that cannot be attained. To foreshadow our main conclusion,

it is probably the case that hope and optimism stand for positive thinking that is flexible rather than rigid, and therefore more beneficial than costly, even in situations that are marked by high risks or near-impossible goals. However, research into these kinds of situations is ongoing, and this part of the story of hope and optimism is continuing to unfold.

Misperception of Personal Risks

Virtually all models of judgment and decision-making incorporate perceived risk as a variable that influences motivation and action. Such theorizing has been particularly common in the study of health behaviors, where, for example, an individual's motivation to obtain a preventive medical exam for cancer is thought to depend, in part, on the likelihood that he or she perceives of developing the disease. If highly hopeful or optimistic individuals perceive automatically that developing cancer is unlikely to happen to them, they should be correspondingly disinclined to obtain the preventive exam – and therefore vulnerable to missing the benefits of early detection. The danger is most acute to those hopeful or optimistic individuals who may also have a variety of objective risk factors for the disease, in the form of their other health behaviors, age, dwelling, occupation, family history, and so on.

Aspinwall and Brunhart asked the question whether optimism functions like denial in the situation of being confronted with personal health risk information. Participants in their research were vitamin users or tanners who had completed relevant health behavior and optimism measures some months earlier, and were then given the opportunity in experimental sessions to read about the health risks and benefits of vitamin use and ultraviolet exposure. By further measuring the amount of time participants spent reading each type of information, and their recall of it 1 week later, the investigators could determine whether more optimistic participants tended to ignore information about the risks associated with the particular behaviors in which they themselves engaged, as the denial metaphor would suggest. To the contrary, however, both dispositional and health-related optimistic beliefs were associated with greater attention to and recall of personally relevant risk information in this study. This pattern, which is really the mirror image of denial, coincides with the studies reviewed earlier that showed more approach-oriented coping by more optimistic individuals.

As noted above, however, the prediction of danger or negative outcomes relies, not just on the extent of an individual's optimism, but also the extent to which it is unrealistic in comparison with his or her profile of objective risks for those outcomes. Dillard, Midboe, and Klein assessed unrealistic optimism in a large-scale, longitudinal study of alcohol consumption by college students. The classification of unrealistic optimists in this study followed from a comparison of their scores on two standardized measures: one on alcohol-related risk perceptions and the other on alcohol consumption. The students' dispositional optimism was also assessed. Although dispositional optimism did not predict any negative outcomes in this study, unrealistic optimism predicted a greater number of alcohol-related negative events that were reported in four follow-up interviews over the next 18 months. Among others, these negative events included having a hangover, forgetting

places and events, getting behind in schoolwork, engaging in regretted behaviors, damaging property, getting into trouble with security or police, having arguments, getting injured, and requiring medical treatment. Thus, it appears that optimistic risk perception has a downside, when it is both unrealistic and applied to the regulation of risk behaviors. It also appears that dispositional optimism is not fundamentally unrealistic.

Failure to Disengage from Unattainable Goals

Everyone eventually confronts the fact that some personal goals cannot be attained. The reasons for goal-unattainability are manifold, from aging and developmental changes, to social and cultural constraints, negative life events, or even conflict with other goals for the limited time, attention, energy, and material resources that people have available to devote to all of their pursuits. Wrosch and colleagues have proposed and provided evidence for a model of adaptive regulation of unattainable goals. According to the model, thriving or subjective well-being is accomplished by first disengaging from the unattainable and then reengaging in alternate attainable goals.

From the evidence we reviewed previously, it stands to reason that highly hopeful and optimistic individuals should have extra difficulty with the first step of this process, disengagement. Therefore, in comparison with less hopeful or optimistic individuals, they may be less likely to thrive when confronting unattainable goals. To date, however, the evidence for this prediction has been mixed. Aspinwall and Richter gave participants a set of unsolvable anagrams, ostensibly as a measure of verbal intelligence, under conditions in which they either could or could not move on to another set of solvable anagrams. All participants who had no alternative worked on the unsolvable anagrams until they reached the time limit of 20 min. Among participants who had an alternative, however, those higher in dispositional optimism were significantly faster to move on to the next task, and they showed greater persistence and performance on some variants of that task. These results directly counter the prediction that optimism equals blind persistence. They suggest, instead, that optimism predisposes adaptive regulation of unattainable goals, with respect to both the disengagement and reengagement steps in the model by Wrosch and colleagues.

Although it is indisputable that the participants in the foregoing study had a confrontation with goal-unattainability, the confrontation was also brief. Segerstrom has proposed that less adaptive functioning might result from dispositional optimism if or when people are confronted with goal-unattainability on an ongoing basis. One of her studies followed students through the notoriously difficult and competitive first year of law school, comparing those who relocated with those who did not relocate in order to attend. Between these two groups of students, she reasoned that those who remained in their usual social context would encounter more complex or difficult problems in balancing their academic and social goals. The outcome of major interest to Segerstrom's research was a test of the students' immune response (i.e., skin redness or swelling), following injection of a preparation of mumps virus. Suppression of the immune response is potentially mediated by stress-related affect and motivational states, and it presents another pathway by which optimism

could be linked to physical health outcomes. Among students who relocated to attend law school, those higher in dispositional optimism showed a correspondingly stronger immune response, across five relevant testing points throughout the first year. However, among students who did not relocate, and thus found themselves in a more complex and difficult goal-conflict situation, those higher in dispositional optimism showed a weaker immune response. Thus, in these conditions, in which students' current goals were mutually unattainable for an extended period due to time constraints, optimistic students apparently had a harder time managing the conflict and were more predisposed than pessimistic students to physical illness.

Conclusions

In this article, we reviewed the definitions, leading standardized measures, adaptive outcomes, and possible risks of hope and optimism. We conclude with two main points that can be drawn from this review. The first such point is that *small differences in thinking can make a large difference in adaptive outcomes*. Especially when we consider the roots of hope and optimism in the accessible products of cognitive processes – including attribution, social comparison, and recall of previous instances of successful agency and pathways – the difference between hopeful or optimistic individuals and their counterparts seems almost arbitrary. For everyone who tries to evaluate the likelihood and desirability of future events, there is always a multitude of relevant causes, comparison standards, and memories that he or she could bring to bear. Although hope and optimism are frequently conceived as traits, and they are empirically as stable and influential as any aspect of personality, both come down to a matter of emphasis on certain causes, comparison standards, or memories that keep the future looking bright. Set beside the variety and fullness of adaptive outcomes that are related to hope and optimism, this matter of emphasis seems slight.

We have not included the topic of cognitive-behavioral interventions in our review. It is sufficient to say that interventions such as attributional retraining have been effective in shifting individuals' emphasis in the direction of greater hope or optimism. However, the larger point to emerge from consideration of the roots of hope and optimism, and effects of interventions, is that people do not ordinarily have much insight into their own mental processes of evaluating the future. Each person thus arrives at the same perceptions repeatedly, without necessarily realizing the extent of mental processing that has taken place, or the potential to either fine-tune or compensate for individually specific aspects of this processing. Such self-insight could help all of us to make better plans.

The second general point is that *people who feel invested in the future take better care of themselves in the present*. Whether through adaptive goal regulation, risk regulation, emotional management, or coping with problems, as reviewed here, hopeful and optimistic people make the most of their opportunities in life, and the least of their difficulties. Even the apparent exceptions we considered, such as unrealistic optimism or goal conflict, seem only to prove the rule: that is, people who express little concern with the risky behaviors in which they routinely engage, or who find themselves chronically unsure of which

goal to pursue, seem not to be invested in the future so much as in the present moment.

We acknowledge that hopeful and optimistic perceptions can be overly positive, and that hopeful and optimistic people are not always aware of when or how they sustain their positive beliefs. Even so, we wish to end on the note that better self-care in the present is an entirely rational response to the condition of being invested in the future, whether the basis of such investment is objectively wise or foolish. Thus, in our view, the branding of hope and optimism as 'cockeyed' in the vernacular, or 'illusory' and 'irrational' among social scientists, misses the overarching point. That is, hope and optimism are self-fulfilling beliefs about the future. By encouraging better self-care today, they pave the way for better physical and psychological well-being tomorrow – the better, in turn, for people to enjoy the results of their current goal pursuits and to form the goals that they will be pursuing next.

Hormones and Behavior

J B Becker, J A Cummings, A N Perry, and C Westenbroek, Zina Pitcher Place, Ann Arbor, MI, USA

© 2012 Elsevier Inc. All rights reserved.

Glossary

Alloparental behavior The exhibition of parental behavior toward another individual's offspring.

Androgens Hormones (testosterone and dihydrotestosterone) and related compounds (e.g., anabolic steroids) with a chemical structure that will act at the androgen receptor.

Estrogens Hormones (estradiol, estriol, estrone) and related compounds with a chemical structure that will act at the estrogen receptors.

Estrous cycle The ovarian cycle of nonprimate species.

Hormone A substance that is produced in a gland that is carried through the blood stream to produce an effect on a target organ.

Neurohormones Hormones produced in the brain and released into the blood stream as well as directly within the brain. Oxytocin and vasopressin are examples of

neurohormones. Importantly, the peripheral and central release of neurohormones can occur synchronously or independently.

Oocyte The primordial egg, immature ovum, or egg cell that is produced in the female ovary during early stages of development.

Progestins Hormones (progesterone) and related compounds with a chemical structure that will act at the progesterone receptors.

Sexual differentiation The process through which males and females develop from a bipotential individual to individuals with a masculine or feminine phenotype throughout the body.

Stress response The coordinated response of the autonomic nervous system and neuroendocrine systems (primarily the hypothalamic, pituitary, adrenal axis) to a perceived stressor.

Introduction

In the majority of mammalian species, life proceeds in a rather predictable direction. An individual is born, matures, and finally attains sexual maturity. All throughout these processes, hormones have played a role in the behaviors in which an individual engages. When the body lacks the necessary materials for growth and maintenance, the appropriate hormonal signals are sent out that promote ingestive behaviors. When an individual encounters a life-threatening situation, once again hormone signals are issued that mobilize energy resources and allow the individual to mount an appropriate response. Finally, when an individual is fertile and conditions are good for reproduction, hormones shift the individual's behavior into finding and securing a mate. For most male mammals, behavior does not change as a consequence of mating. In females, when mating results in fertilization of eggs, hormones coordinate changes in her physiology and behavior that support pregnancy maintenance, fetal development, and preparation for motherhood. With parturition, the ensuing birth starts the entire cycle again for a brand new individual.

Of course, this is a gross oversimplification of life, intended to highlight how hormones function to coordinate physiology and behavior with the environment. We tend to think about hormones and behavior as unitary concept, but not all hormones act in the same way, nor do all hormones act the same in males and females. The simplest and most direct way hormones act is to have a rapid and direct action on behavior. The increase in heart rate and blood flow that we experience when we slam on the brakes to avoid hitting the car in front of us is an example of the adrenal medulla stress hormones having such an effect. Other hormones can take longer to produce an effect or just set the stage so that if a particular event

happens the appropriate behavior will be triggered. The hormones that the female rat's ovaries release to prepare her to be sexually receptive around the time of ovulation are an example of this type of hormone action. The hormones set the stage or prime the animal to be able to engage in the behavior, but if the male does not mount the receptive female, she does not engage in sexual behavior.

During development one of the things that hormones influence is how the brain develops, resulting in sex differences in brain and behavior of adult animals. The sex differences may be seen independent of hormonal activation, or hormones may be required to see that brains of males and females are different. Hormones secreted during the perinatal period of brain development and again at puberty induce sexual differentiation of the brain that determines whether animals will exhibit masculine or feminine sexual behavior as an adult. These behaviors still require the appropriate male and female hormones to activate the behavior during adulthood, and then the presence of a conspecific of the other sex is needed to actually engage in the behavior.

Finally, it is important to remember that the relations among hormones, behavior, and the environment are not linear and unidirectional, but rather involve complex reciprocal relations. Thus, while it is apparent that physiological or social state can drive changes in hormones that promote certain behaviors, the reverse is also true. Changes in the social or physical environment can induce hormone changes that subsequently modify physiology and behavior. Therefore, when considering a species in which a certain behavior appears to have been liberated from hormones, it is probably more accurate to consider the behavior to have been liberated from a specific physiological state, with either a new set of hormones contributing to the regulation of the behavior, or even more

likely, those original hormones and/or their downstream signaling pathways having become coupled to other environmental stimuli or internal signals. This consideration is especially important in species, such as humans, where behavior has been heavily shaped by learning and cultural influences and therefore oftentimes appears to be beyond hormonal regulation. Books have been written on the topic of hormones and behavior. This overview is not meant to be comprehensive, but rather present a brief picture of how hormones and behavior are related in humans and other species.

Sexual Behavior

Sex is a risky endeavor for both males and females due to the possibility of physical injury, either from the act itself or from intraspecific competition for mates, and the transmission of pathogens that can affect survival and future reproductive potential. Like many dangerous ventures it also has its rewards, it is the ultimate reward in this case, propagation of one's genes into future generations. 'Nothing ventured, nothing gained' is only a profitable strategy when one is sure that there is actually something to be gained. Thus, selection has favored a tight coupling of fertility with the motivation to seek out mates and engage in copulation in both males and females. Therefore, when considering hormonal regulation of sexual behavior, it is essential to consider both the appetitive (or motivational) components, as well as the consummatory phase, which comprises the performance of the sexual act from beginning to end. This distinction is especially critical when examining sexual dysfunctions, as in many instances motivation and ability can become uncoupled.

Male Sexual Behavior

Males and females differ in reproductive strategies that are believed to have evolved from the amount of resources invested in the offspring. Female mammals, birds, and other vertebrates are limited in the number of offspring they can produce, because they put considerable energy into the nurturing and caring for the young. Consequently, females have evolved to be 'choosy' when it comes to selecting a mate. Males, on the other hand, have evolved strategies to attract and mate with as many females as possible in order to pass along the greatest number of their genes to future generations. As such, males have evolved a number of techniques to compete for mates – to gain access to the best territories, or for the best partners. Oftentimes, these techniques will put the males themselves at risk for injury or even death, indicating that the motivation to engage in sexual activity must be sufficiently high to drive the animal to seek out and mate with a partner. Gonadal hormones drive many of these behaviors and exhibitions.

Male sexual behavior can be broadly classified into two distinct phases: the appetitive phase (or motivation to engage in sex) and the consummatory phase (the ability to engage in sexual activity). Hormones affect both phases of sexual behavior, although to differing extents in different species. In order for sexual activity to be fully functional, both components

must be fully functional. Androgens produced by the testes are involved in masculine sexual behavior by affecting the reception, perception, and processing of stimuli associated with the female (making a mating episode more likely to occur), and by facilitating the mechanics of the sexual interaction. Androgens may have their effects directly, by increasing motivation to engage in sexual activity, or indirectly, by enhancing the effects of requisite neural systems. In both cases, androgens are permissive in that a threshold amount of testosterone is usually necessary for a male to engage in sex, but more testosterone does not further increase male sexual ability or motivation.

Sexual experience can modulate sexual behavior in males, as experienced male rats exhibit increased resistance to impairment by stress or castration (removal of the source of the hormones), show greater changes in the brain during sex, and will ejaculate after fewer intromissions with a female compared to sexually naïve animals. The neurotransmitter dopamine plays a large role in aiding male sexual behavior by facilitating genital reflexes and copulation. In fact, female-stimulated dopamine release, which is dependent upon testosterone, is necessary for efficient mating behavior. On the other hand, the neurotransmitter serotonin is inhibitory with respect to sexual behavior – it is released upon ejaculation and is responsible for the refractory period that occurs after ejaculation (this also helps to explain why some patients, both men and women, taking selective serotonin reuptake inhibitors for depression often experience decreased libido and sexual performance).

Peptide hormones also play a role in male sexual behavior. Elevated prolactin levels interfere with male sexual behavior, and may be due in part to its role in bonding and parental care (see section 'Parental Behavior'). Opioids have been shown to inhibit male sexual behavior in humans and nonhuman primates, and may be due to their suppression of testosterone.

Female Sexual Behavior

As mentioned above, males and females differ in their potential rates of reproduction. The female gamete required for reproduction is large and expensive in terms of the resources the body requires to produce mature follicles, and caring for offspring is energy consuming and dangerous. A female is also born with a finite number of primordial eggs (i.e., oocytes) available, so the supply is limited. This, however, is not thought to be a limiting factor for reproduction in most species. In humans, and in some other species where life expectancy exceeds the supply of eggs, menopause is thought to result at least in part due to the loss of available oocytes. Thus, when considering that the ultimate reason for engaging in sexual intercourse is to pass along one's genes to subsequent generations, it is of great benefit to females of most species to increase the chances that her eggs are fertilized when mature. While women have evolved to free themselves from these tight regulations that link receptivity to ovulation, females of many other species are often limited in their ability to engage in sexual activity by hormones. The hormones estradiol and progesterone coordinate both ovulation and sexual receptivity, ensuring that females are receptive to a male's advances at a time when the sexual interaction would have the greatest

chances of yielding a successful pregnancy. At the same time, engaging in sexual activity is risky for females for a number of reasons including: increased vulnerability to predators, exposure to infection or disease, and risk of injury or even death as males are frequently larger than females and can engage in violent behaviors before and during sexual intercourse. It is therefore the greatest benefit to the female to expose herself to these risks only when doing so will have the greatest chances of yielding a successful mating episode and result in pregnancy.

An excellent example of the coupling of ovulation and receptivity can be seen when examining sexual behavior in the rodent. A female rat will not allow a male to mount her for sexual intercourse unless she has been appropriately primed with the steroid hormones estradiol and progesterone. These hormones act on the brain and, in conjunction with hormones that are produced in the brain and pituitary (such as oxytocin, luteinizing hormone, and follicle stimulating hormone), act throughout the body to result in a cascade of events ending in ovulation at a time when the female is behaviorally receptive to a male's advances, or in estrous.

While hormones do not restrict women in terms of ability to engage in sexual activity throughout the menstrual cycle, hormones do affect other aspects of sexual behavior such as interest in and motivation to engage in sexual activity. For example, women's preferences for masculine traits such as facial characteristics, height, and expression of dominant behaviors changes across the menstrual cycle, with the greatest preference for masculinity around the time of ovulation when estradiol is elevated. An increased degree of masculinity is thought to indicate a higher 'quality' of mate with improved genetic fitness – a characteristic that is sought after when the likelihood of conception is high. Sexual motivation also changes across the cycle; women report increased sexual fantasies and self-stimulation, more interest in sex, and a higher number of sexual episodes during their fertile period. These increases in sexual interest can be visually noted as well, as women have been shown to dress more provocatively during their fertile phase compared to other phases of their menstrual cycle.

Sexual Dysfunction

Sexual dysfunction with men is most often the loss of ability to engage in sexual activity due to diabetes, aging, or other illness such as hypertension. For women sexual dysfunction is most frequently due to hypoactive sexual desire disorder (HSDD), or a loss of the desire to engage in sex.

In women the loss of desire does not appear to be mediated only by hormones, as young women with normal levels of hormones can experience decreased sexual desire. The ability to engage in sexual activity is not compromised in women reporting reduced motivation, as genital blood flow is not decreased in the aroused state. Thus, the decrease in sexual motivation is not linked to reduced ability. There do appear to be some differences in brain areas and neurotransmitter systems activated in association with sexual motivation and arousal in women experiencing HSDD compared with women who do not have the disorder, which may interact with hormone levels. HSDD is believed to be a disorder of the brain's reward circuitry, with two general possibilities: women

experiencing HSDD may have overactive (or hyperfunctional) inhibition of sexual reward circuitries, or underactive (or hypo-functional) sexual arousal circuits. Recent neuroimaging studies have pointed to the former as the leading possibility, indicating that hyperfunctional serotonergic systems can inhibit the dopaminergic sexual arousal system, resulting in reduced sexual motivation.

Currently, there are no successful pharmacologic therapies for women experiencing HSDD. Testosterone has been linked to increased sexual motivation and increased self-reported incidents of sexually satisfying experiences in women, but there are a number of unwanted side effects of taking testosterone to increase desire, such as growth of facial hair and increased risk for breast cancer with prolonged use. More research is needed in order to identify exactly how and where the disorder manifests itself in women experiencing HSDD, and to develop and test potential therapeutics to treat the disorder.

For men, sexual dysfunction is most commonly related to performance, or ability, and not to motivation. One of the causes of erectile dysfunction in men who don't have diabetes or other disease is a reduced level of dihydrotestosterone (DHT), an androgenic product that results from breakdown of testosterone in the testes, which interacts with nitric oxide (NO) to achieve and maintain an erection. The production of NO is dependent upon DHT, levels of which decrease in men over the age of 40. NO stimulates cGMP by activating guanylate cyclase, resulting in smooth muscle relaxation and blood inflow to the penis. Treatments that have been effective in many men with erectile dysfunction act by potentiating the action of NO by inhibiting PDE5, the enzyme that breaks down cGMP.

Insulin resistance is present in many patients with endocrine-metabolic disorders like type 2 diabetes and obesity, and produces attenuated synthesis and release of NO and higher NO consumption in tissues. The reduced NO impairs vasodilation in patients, often resulting in erectile dysfunction. Patients with erectile dysfunction have a higher body mass index and obesity prevalence compared to men with normal erectile function. In fact, many patients learn of their endocrine-metabolic disorder or cardiovascular disease upon presentation to the doctor with erectile dysfunction. Insulin resistance has also been associated with reduced testosterone levels, which may indirectly affect ability to engage in sexual activity by reducing the available amount of DHT.

Testosterone and Aggression

In male animals, testosterone levels have been related to aggressive behaviors. This is seen most clearly in territorial animals that breed seasonally, such as the red deer or big horn sheep. In these animals, the onset of the breeding season is associated with testicular growth and the production of testosterone, which induces the growth of secondary sex characteristics in the red deer, such as antlers, and also induces these males to establish individual territories and become aggressive toward other males. In many of these species, the social rank of the male is correlated with testosterone and age, and aggressiveness is correlated with testosterone levels.

So while testosterone is only permissive for masculine sexual behavior, it is positively correlated with the level of aggression in many species, including humans. Testosterone has also been correlated with risky behavior in men, but not women, although low testosterone may result in risk aversion in women.

Parental Behavior

Parental care involves a trade-off in which the increased survival of existing offspring is weighed against various costs of parenting. In mammals, parental care is almost the exclusive domain of the female due to the obligations of gestation and lactation. Some species of rodents, canines, and primates, including humans, however, are biparental with males contributing substantial amounts of paternal care. Whatever the species, the expression of parental care is ultimately determined by the interplay of genes, experience, and the environment, and hormones represent one of the primary mechanisms mediating communication among these factors.

In all mammalian species, the changing levels of estradiol and progesterone that occur during gestation are necessary for maintaining pregnancy, mammary gland development, and lactation. Additionally, these ovarian steroids appear to be critical for the subsequent expression of nurturing maternal behaviors, in large part due to the sensitization of the brain to oxytocin and prolactin, two neuropeptides that are essential for parturition and lactation and directly promote the expression of maternal behavior in rodents, sheep, and primates.

In addition to gonadal steroid hormones, corticosterone, or cortisol (CORT; exact hormone varies across species) is secreted from the adrenal glands and elevated during mid- to late gestation to contribute to mobilizing energy reserves, fetal lung maturation and labor induction. First-time mothers with higher CORT levels are also more attracted to and better able to recognize their own infant's body odor. Similar to estradiol and progesterone, CORT also sensitizes oxytocin signaling in the brain, which may underlie the correlation between CORT levels and maternal responsiveness to infant cues.

Even though fathers don't go through the same physiological changes during gestation as their pregnant mates, they do show dramatic changes in hormone levels. In most mammals, fatherhood is generally associated with reduced testosterone levels and elevations in estradiol, CORT, prolactin, and oxytocin. Many of these hormonal changes, such as increased prolactin and CORT levels, are initiated during gestation and may serve to prepare the expectant father for the energetic costs associated with paternal care. These changes may result from programmed neuroendocrine responses following mating or represent direct modulation by cues from the pregnant female.

The reduction in fathers' testosterone levels may be secondary to the rise in prolactin, as hyperprolactinemia results in hypogonadism in males; however, it may also serve an adaptive function by reducing the chances that the male will abandon his offspring in order to seek out additional mating opportunities. In nonhuman primates, infant odors rapidly decrease testosterone secretion and a similar phenomenon may occur in human fathers, as cross-cultural studies reliably demonstrate that married men with young children have lower

testosterone levels than married men without children and single men. Interestingly, mothers of young children also have reduced testosterone levels compared to nonmothers. Conversely, a transient increase in testosterone following infant distress vocalizations occurs in both men and women and may represent an adaptive response to increase protection and attendance to the infant. Thus, one model is that low levels of androgens support soothing and nurturing parental activities in both sexes, whereas acute increases in androgens may promote vigilance, increased attendance to offspring and their defense.

While changes in gonadal and adrenal steroids coordinate reproductive physiology and parental behavior, oxytocin and prolactin mediate the expression of parental responses. In most species, this induction of oxytocin and prolactin signaling is mediated by the changes in estradiol and progesterone that occur during gestation; however, it is also possible to induce oxytocin and prolactin secretion and thereby induce maternal behavior in individuals who haven't been primed with these ovarian hormones. In rodents, the process of pup sensitization induces parental responses in ovariectomized females and in males simply via repeated daily exposure to pups. Since rodents and primates both show increased oxytocin and prolactin secretion following exposure to infants, it appears that these systems can also be activated independent of gonadal steroids. This route of activation may be especially important in primates, including humans, as well as other species that engage in alloparental behavior, in which individuals other than the biological parents contribute parental care.

More research is required to clarify the role played by specific hormones in the regulation of parental behavior, especially in humans. Nevertheless, a common endocrine profile appears to support parental responses in most species. In some species, parental responses are entirely dependent upon the priming of gonadal steroid hormones; in others, infant cues themselves may be sufficient to induce parental responses by directly tapping into the oxytocin and prolactin systems. It has been said that, "There are but two lasting bequests we can give our children. One is roots, the other, wings." In light of emerging research in humans, it is possible that oxytocin provides the roots (i.e., the nurturing dyadic relationship), whereas prolactin provides the wings by encouraging exploratory play and extra-dyadic activities.

Sex Differences in Energy Homeostasis

Males and females differ in the regulation of energy balance and body weight, and at least part of these differences is due to differences in the gonadal hormones secreted – estradiol in women and testosterone in men. Maintaining a positive energy balance requires communication between the adipose tissue and the brain. Insulin from the pancreas, leptin from fat, estradiol from the ovary, and testosterone from the testes are important hormones that allow the brain to keep track of the amount and location of adipose tissue and adjust food intake and metabolism appropriately.

Leptin acts in several brain regions, including the hypothalamus, to regulate metabolic activity. Increased leptin levels are associated with reduced food intake and increased energy

usage. Interestingly, estradiol directs fat to be deposited subcutaneously (i.e., under the skin) rather than viscally (i.e., in the abdominal cavity around the organs), and subcutaneous adipose tissue secretes leptin at a higher rate than does visceral fat. Therefore, the brain may receive more reliable information about subcutaneous fat stores, which could lead to excessive (i.e., 'under-reported') fat accumulation in visceral stores. Leptin synthesis is regulated by sex hormones, with testosterone being negatively correlated with leptin levels, whereas estradiol results in increased leptin levels.

Leptin levels are relatively stable in contrast to insulin levels, which fluctuate rapidly in response to circulating glucose. Because visceral adipose tissue is relatively insensitive to insulin, obese men are at greater risk for metabolic disorders than women. This sex difference disappears if obese women accumulate visceral fat and thus become more insensitive to insulin. In addition to sex differences in insulin sensitivity from differences in fat distribution in the body, there are also indications for differences in central effects of insulin. Intranasal application of insulin, which increases insulin levels in the cerebrospinal fluid, results in a reduction of body fat in men but not women. This indicates a clear sex difference in the central effects of insulin.

Feeding Regulation by Estradiol

Ovarian hormones also regulate food intake. For example, during the proestrous phase of the rat's estrous cycle (following the rise in estradiol) food intake is reduced. Primates, including humans, show a similar pattern, with a reduction in food intake around ovulation. Estradiol is the ovarian hormone responsible for this effect, as shown by studies using estradiol replacement in ovariectomized female rats. This regulatory effect of estradiol appears to take place in the brain and not in the periphery. One possible mechanism by which estradiol can influence food intake is by affecting the satiety signals by interacting with cholecystokinin (CCK). Additionally, estradiol appears to attenuate orexigenic signals in the brain, possibly by affecting neuropeptide Y (NPY) and ghrelin signaling. Estradiol also affects peripheral leptin and insulin signaling, which impact metabolism and food intake as described above. Estradiol and leptin receptors are present in the same brain nuclei, especially in the hypothalamus, allowing for a direct communication between estradiol and leptin levels. Even though leptin levels do not fluctuate over the rat estrous cycle, leptin receptors in the brain are inversely correlated with estradiol levels. This provides a way for estradiol and leptin to communicate about the adipose tissue distribution to the brain and sex-specifically regulate energy homeostasis.

While the effect of estradiol on food intake is mediated in the brain, gonadal hormones also affect peripheral adipose tissue distribution. Subcutaneous fat has higher levels of estradiol and progesterone receptors, whereas visceral adipose tissue has more androgen receptors. The amount of visceral fat is inversely correlated with estradiol levels, hence after menopause in humans or ovariectomy in rats, when estradiol levels drop, the amount of visceral fat is increased.

As estradiol has positive effects in women, the same is true for testosterone in men. Hypogonadism in men is

accompanied by a loss of muscle and an increase in subcutaneous fat, which can be reversed by injections with testosterone. Also in elderly men, who show reduced levels of testosterone, there are indications that supplementing testosterone has positive effects on maintaining lean body mass.

Sex Differences in Eating Disorders

The DSM-IV defines three broad categories of eating disorders: anorexia nervosa, bulimia nervosa, and eating disorder not otherwise specified. Anorexia nervosa is recognized by extremely low body weight and a fear of increase in weight. Bulimia nervosa is characterized by repeated binge eating and measures to counteract the effects of the binge. Variants of these disorders with sub-threshold symptoms are gathered in eating disorder not otherwise specified.

Anorexia nervosa and bulimia nervosa both have a higher prevalence (about 3 times) in women, whereas sub-threshold binge eating is more common in men. Anorexia nervosa mainly occurs in young women around puberty, suggesting a role for estradiol. Bulimia nervosa usually emerges somewhat later. In contrast to the traditional view that anorexia nervosa and bulimia nervosa are caused by psychosocial factors, twin studies have shown that there is a 50–80% genetic component. Hypersensitivity could play a role in the development of anorexia nervosa, although clinical data about manipulation of estradiol levels are infrequent and inconclusive. Some polymorphisms have been found in the estradiol receptor gene in anorexia nervosa and bulimia nervosa patients. Estradiol affects expression of many other genes, so it could easily indirectly affect feeding behavior.

Hormones and Cognition

In humans there are activational influences of hormones on cognitive function and circumstantial evidence for effects of hormones during sexual differentiation of the brain. In general, there are sex differences in spatial abilities (three-dimensional manipulation of objects in space or mental rotation tasks), perceptual speed and accuracy, and verbal fluency, with males having an advantage on tests of spatial abilities and females an advantage on tests of perceptual speed and accuracy as well as verbal fluency. While performance on these tests can be enhanced with learning, evidence from imaging studies using fMRI suggests that males and females use different parts of the brain to do tests that require 3D manipulation through space. It is thought that the female advantage in language comes at least in part from greater bilateral representation of language in women than in men due to sexual differentiation of the brain.

Evidence that hormones can influence these sex differences during development come from women exposed in utero to androgens due to congenital adrenal hyperplasia. These women tend to have better spatial abilities than their unaffected sisters, but perform slower on tests of perceptual speed and accuracy. Evidence from analysis of the amniotic fluid during gestation for testosterone concentrations has also led to evidence that suggests a correlation between the

concentration of testosterone and the degree of language lateralization. Girls and boys with lower testosterone in utero had more bilateral language representation than those with higher testosterone prenatally. As more studies use this approach to assess the relations between prenatal hormones in humans and subsequent behaviors, it may be possible to determine if there are causal effects of this hormone exposure in utero, and even where in the brain the hormones are acting during development.

There are also effects of hormones on these sexually dimorphic cognitive tasks in adults. In women, performance on a mental rotation tasks when the ovarian hormone estradiol is low and verbal abilities are enhanced when estradiol is high. This effect of estradiol on verbal ability can also be seen in postmenopausal women when their performance is assessed when on estradiol treatment compared with periods of hormone withdrawal. In men, spatial ability is correlated with testosterone, but the relationship is not linear. It seems that there is an optimal amount of testosterone and too much or too little testosterone is correlated with reduced spatial ability on mental rotation tasks.

The Stress Hormones and the Stress Response

Exposure to stimuli that threaten homeostasis (i.e., stressors) activates autonomic, behavioral, and neuroendocrine systems that permit the organism to respond to the threat. The hypothalamic–pituitary–adrenal (HPA) axis is exquisitely responsive to stress exposure and its activation is critical for the response to the current threat. The first phase of the stress response is due to the rapid activation of the sympathetic nervous system and release of hormones, like epinephrine (adrenaline) from the adrenal medulla. These hormones result in the ‘flight or fight’ response. Stressors induce a secondary response as well, referred to as the general adaptation syndrome: the activation of neural systems result in release of corticotropin releasing hormone (CRH) from the brain and adrenocorticotrophic hormone (ACTH) from the pituitary to induce the release of CORT as well as other hormones from the adrenal cortex. Together the two phases of the stress response allow an animal to mount both a rapid and a sustained response to a stressor. In the brain, CORT and CRH influence anxiety-related behaviors, memory and other cognitive functions, as well as the effect of drugs of abuse on subsequent drug-taking behavior. In general, the magnitude of the stress response is proportional to the magnitude of the stressor, and an individual’s energy needs are met by the metabolic effect of the stress response which mobilizes glucose to be used for energy while curtailing processes that utilize or store glucose. The HPA axis activity is regulated by a negative feedback mechanism at the level of the anterior pituitary and the paraventricular nucleus of the hypothalamus, thus preventing excessive levels of CORT. Dysregulation of this feedback mechanism has been found in addiction and stress-related disorders, like major depression and anxiety disorders.

Sex Differences in the Stress Response

In rodents and humans, there are sex differences in activation of the HPA axis that can play a role in behavior and physiology.

For example, in female rats, both basal and stress-induced CORT secretion are more pronounced than in males. Furthermore, HPA secretions vary across the estrous cycle in the rat. Females in proestrous or estrous show elevated basal and stress-induced CORT concentrations relative to diestrous animals. Similarly, women show greater ACTH and cortisol responses in the luteal phase (when estradiol and progesterone are elevated) compared to the follicular phase (when estradiol is slowly rising). Females are also less sensitive to suppression of the HPA axis by the synthetic glucocorticoid, dexamethasone, than are males.

Sex differences and ovarian hormones also affect the central neural circuits regulating neuroendocrine and behavioral stress responses. Proestrous and estrous females show attenuated cortical and hippocampal induction of c-fos relative to males or diestrous females, while during the luteal phase women demonstrate impaired glucocorticoid feedback relative to the follicular phase. In males, testosterone attenuates stress-induced CORT and ACTH secretion, and inhibits CRH gene expression in PVN neurons controlling the HPA axis response.

Stress and Drug Abuse

In humans and nonhumans it is widely accepted that the rewarding aspects of drugs of abuse are due to the ability of these drugs to activate the neural system known as the ‘reward’ system. The ascending dopamine system and its targets are part of a motivational system that regulates responses to natural reinforcers (e.g., food, drink, sex) and drugs of abuse. Importantly, activity in the ascending dopamine system is also modulated by the neural responses to stressors, and the effect of drugs of abuse and the neural stress response interact in a way that can influence drug-taking behavior.

First, drugs of abuse induce the activation of the HPA axis to induce an increase in CORT release. CORT in turn acts to enhance drug-taking behavior. With repeated exposure to the drug, there are long-term changes in both the neural system mediating the reinforcing effects of the drug and in the stress system. One way that drugs of abuse become addictive, in susceptible individuals, is by inducing activation of the stress axis. Drug-taking behavior also results in long-term changes in the stress response, which can induce increased drug-taking. In other words, exposure to drugs of abuse enhances the HPA response to stressful stimuli, and prior stress enhances drug-taking behavior.

Currently, adult men are 2–3 times more likely than women to have a drug abuse/dependence disorder, but this current gender difference is thought to reflect differences in opportunity during vulnerable periods, rather than sex differences in vulnerability to drug abuse. Historically, there have been periods of time when women outnumbered men in their use of drugs. During the ‘Gin Craze’ in England in the 1700s, for example, approximately 75% of users were thought to be women. Again in the 1800s, in the United States, 70–80% of the opiate addicts were women, addicted to laudanum and patent medicines that were sold legally. The perception of many was that this opium addiction among women was an upper-class affliction, but in fact when doctors were surveyed in a more systematic manner, there was no distinction by class, occupation, or regional location; all women were at risk.

The current male predominance in drug use may be waning, as data collected in the past 5 years in the United States indicate that among high school age males and females, there is no longer a sex difference in drug-taking behavior. Among individuals who use drugs, more females are using cocaine and other psychomotor stimulants than males. There are also sex differences in the rate of escalation of drug use, with women tending to increase their rate of consumption of alcohol, marijuana, opioids, and cocaine more rapidly than do men. The sex differences in the psychomotor stimulants are the best studied, and women begin using cocaine or amphetamine earlier in life and enter treatment at earlier ages than men. They also have more severe cocaine use and intake than men and more severe dependence upon cocaine. Furthermore, once addicted to a drug, women can find it more difficult to quit than men do. So, in the clinical populations patterns of drug use differ between men and women.

In animal models of drug use, sex differences have been reported during all phases of the addiction process: acquisition, escalation, maintenance, and relapse/reinstatement. Additionally, in females the ovarian hormone estradiol enhances acquisition of drug-taking, the motivation to take drugs, and relapse/reinstatement of drug-taking after abstinence. In animals that are reliably taking cocaine, for example, if female rats are given a choice between two doses of cocaine, females in estrous, following an elevation of estradiol in blood, prefer higher doses of cocaine compared with females in other phases of the estrous cycle or male rats. Furthermore, estradiol treatment increases the initial binge length and total amount of cocaine self-administered. These results show that estradiol enhances drug-taking as well as the motivation to take cocaine. Since the HPA axis is enhancing the response to drugs of abuse, establishment of drug-taking behavior, and subsequent neural changes resulting in addiction, sex differences in the HPA axis may play a role in the enhanced susceptibility of females for drug abuse.

Environmental Factors Influencing Hormones and Behavior

Humans, in general, are social creatures, and the presence of a social network has a positive influence on mental and physical health. More specifically, social support is known to attenuate the CORT response and the increased heart rate in response to stressors in both men and women, although women appear to be the more effective support providers. Social support also has beneficial effects on the outcome of stress-related disorders like major depression and can prevent relapse, possibly by reducing the impact of stressors. Interestingly, the amount of social support is associated with a reduced risk for a depressive episode in women but not men.

The neuropeptides oxytocin and vasopressin are two of the likely mediators of the positive effect of social support/contact. Although most data come from studies with rodents, human data have become available recently. Using nasal spray to deliver oxytocin or vasopressin to the brain, CORT responses to a psychological stress test were lowest in subjects given both social support and oxytocin, and highest in subjects without support who received a placebo. Trusting other people is an

important requirement for affiliative behavior, and intranasal oxytocin has been shown to increase trust in other people using a trust game. In addition, oxytocin nasal spray increases accuracy in recognizing the emotion of facial expression. Less is known about vasopressin and human social behavior. Interestingly, a sex-specific effect has been found for vasopressin, with men rating facial expressions as more unfriendly after intranasal vasopressin, whereas in women it had prosocial effects.

As is seen with the stress response, the way hormones and behavior interact is not a one-way street. Experience through all sensory modalities can influence hormone secretion, which can then impact behavior. For example, visual input regulates the release of melatonin from the pineal gland to control circadian rhythms and circannual rhythms in all species. Fear-inducing visual, auditory, and/or olfactory stimuli can induce the HPA stress response. Olfactory stimuli and chemical stimuli that activate the vomeronasal organ can induce a number of neuroendocrine responses including synchronization of woman's menstrual cycles. Tactile stimuli can induce oxytocin release that can influence subjective feelings in humans. A hormone that is quite sensitive to events and actions in humans is testosterone. In both men and women, winning a competition like playing tennis or soccer results in increased testosterone, and losing results in a decrease in testosterone. Successfully completing a mentally challenging test can also result in a boost in testosterone.

Summary

This brief overview of some of the ways that hormones and behavior interact is meant to give examples of the principles involved in these relations. The effects of hormones are wide reaching and powerful. From their influence during development to their effects on behavior of adults, hormones help an individual interact with the environment.

Introduction

The convergent scientific disciplines of human factors and ergonomics (HF/E) are primarily concerned with how human beings interact with technological systems in all their various forms. HF/E has focused particularly on ways of improving the quality and safety of human work. Contemporary HF/E encompasses the imagination, design, fabrication, operation, maintenance, and decommissioning of all technical systems. To accomplish these goals, HF/E draws heavily on the theoretical and empirical bases of experimental psychology and, more recently, the neurosciences. It combines these theoretical perspectives on human behavior with the practical tenets and principles of engineering. The aim of this fusion is to optimize the conjoint abilities of humans and technological systems. HF/E is also involved with the creative processes of design as well as the affective nature of user experience. In seeking to accomplish such aims, HF/E professionals draw information from a wide variety of allied areas, ranging from ethnology and sociology through engineering, modeling and simulation, to anatomy and physiology. While HF/E has been, since its inception, a pursuit directed to the practical improvement of human life, it is important that its future should be much more central in articulating and achieving the more fundamental purposes of humankind. This article begins with a brief perusal of the history of HF/E: for, to see clearly into the future, we have to look well into the past.

A Brief History of HF/E

One can argue that, in their essence, HF/E have been around since the very inception of human tool use. When humans first shaped tools, concern about finding ways to work more efficiently was born. However, the modern scientific foundations of these areas of study began much later. 'Ergonomics' was a term first coined by the Polish scientist Jastrebowski in his treatise of 1857 entitled *"An Outline of Ergonomics or the Science of Work Based Upon the Truths Drawn from the Science of Nature."* Later, the term ergonomics would be reinvented by the English scientist Murrell, as part of the gestation of the Ergonomics Society of Great Britain, one of the oldest such scientific societies in the world. Traditionally, ergonomics as a science and practice has been associated predominantly with human interaction with physical work. Growing out of the social concerns for industrial worker safety and productivity around the turn of the twentieth century, studies in time-and-motion research and in industrial fatigue represent the earliest expressions of ergonomic concern. Today, ergonomic practitioners collaborate directly with professionals in systems safety, industrial engineering, industrial hygiene, and occupational medicine to prevent damage and injury on the job. They mutually collaborate to eliminate or reduce the adverse effects of hazardous

occupational environments and poor physical work designs. Physical ergonomists work on issues such as manual handling of materials, slips and falls, and repetitive strain trauma which are the concern of agencies such as the National Institute for Occupational Safety and Health (NIOSH) in the United States, the Health and Safety Executive (HSE) in Britain, and the International Labour Organization (ILO) which is based in Switzerland. The historical antecedents of ergonomics lie largely within the countries that have emphasized the importance of safe working conditions. It is therefore no surprise that ergonomics has traditionally been considered to be of European origin. One of the classic texts *'Fitting the Task to the Man,'* for example, was produced by the Swiss scientist Etienne Grandjean. The name 'ergonomics' is retained in the title of many major scientific and professional organizations of Europe. Indeed, the name ergonomics is incorporated in many research societies worldwide, including the overall global organization, the International Ergonomics Association (IEA).

In contrast to ergonomics, the science of human factors can be considered the North American face of the same fundamental enterprise. Largely emanating from the technical difficulties that challenged the US military in the Second World War, especially the US Army Air Corps, human factors was motivated by a search for efficient and error-free operations. With its origins stemming from concerns about piloting aircraft, human factors was originally much more focused on elements of cognition than its European counterpart. Thus, a classic 1947 paper by Fitts and Jones on the origin, etiology and prevention of pilot error is emblematic of the earlier human factors' type studies in the United States. It should, however, be noted that the war had exerted the same pressures in England, and the 'Cambridge Cockpit' represents an expression of comparable concerns about cognitive performance in similarly complex military environments. This example illustrates how various aspects of the two disciplines have been inextricably interwoven over the years. A number of events and trends that followed the cessation of the hostilities of World War II conspired to initiate the emergence of human factors science. In particular, the promulgation and wide dissemination of Shannon's *'information theory'* provided a common language through which the more experimentally oriented behavioral psychologists could now interact with the more mathematically oriented engineering community. It was the presence of this *lingua franca*, as well as the tenets of emerging 'control theory,' that permitted some of the first fruitful forms of interaction at the base of human factors. Founded subsequently on the basis of advances in information theory and servomechanism theory, Norbert Wiener's invention of 'cybernetics' served to provide further valuable conceptual and quantitative basis for the generation of models of early human-machine interaction. However, the most important development along the path of convergence of HF/E was, arguably, the rise of the 'computer.' When the computational medium became the

setting of activity in most modern workplaces, it represented the collapse of the most important barrier between the cognitive and the physical nature of work that had previously separated HF/E. As the byte rather than the erg became the currency of work in most 'postindustrial' circumstances, many HF/E pursuits coalesced. However, there remain many circumstances in which physical labor is still very much the dominant element of human work. In such circumstances, traditional ergonomic concerns about manual handling of materials, repetitive strain trauma, and physical workplace injuries still predominate. This is especially true in parts of Europe and indeed a number of regions across the globe, including the emerging powers of China, India, and Brazil. Overall, the increasing unity of HF/E in the developed world is now reflected in the names of the respective scientific societies, which most often use both terms in their title. Nevertheless, even in the purportedly 'developed' nations, there remain segments of the economy, both in the manufacturing and service industries, in which the physical demands of work still predominate.

The Rise of Computer Influence in HF/E

In this article, it is not possible to deal with all of the various facets of HF/E, such as workplace safety and physical ergonomics. Such issues are fully explored in several of the handbooks cited for further reading. Here, I have chosen to emphasize one major facet of HF/E evolution that deals with human interaction with automated and semiautomated systems. Indeed, the central theme that has dominated computer-mediated work in recent decades has been the removal of the human operator from the inner loop of control. Perhaps the best example of this has occurred in aviation, which was perhaps the first setting for human factors research. Aircraft control of the early years, including the World War II era, featured hands-on piloting. Indeed, the competence of an individual pilot was judged by his or her so-called 'stick and rudder' skills. Even into the era of the Apollo space flights, most advanced systems still relied upon the manual flying skills of pilots as a critical backup capacity, as the first ever moon-landing so clearly illustrated.

In HF/E, this phase of development was reflected by a strong emphasis on the motor control aspects of system operators' responses. The landmark work of Kenneth Craik, who, sadly, died in a road traffic accident, very much reflected the notion of human-in-the-loop actions. A major series of conferences that focused on these issues was even nicknamed 'Annual Manual.' It featured energetic discussions of various engineering models of operator movement responses, typified by the 'transfer function model' and the 'optimal control model.' Such research led to helpful insights, which were incorporated into the later models of operator response capacity. These are still being used by various agencies and military organizations. Despite the progress made in understanding such manual response capacities, it was not too long before the advent of computer-mediated control enabled the human operator to reduce the need for hands-on response. In commercial aviation, this development took the form of the 'automatic pilot.' Similar forms of automation were developed for many other dynamic control situations, including, for

example, industrial process control. This evolution saw the human operator transition from an active, momentary controller of the system to a relatively passive supervisor, his or her requirement to interfere with the on-going processes becoming increasingly sporadic. Researchers such as Sheridan, Moray, and their colleagues revealed a hidden, but growing, problem in semiautomated control systems. That is, when systems rarely require people to respond, people will rarely respond when required. People are not good at passively monitoring systems that fail rarely. This shortcoming is reflected in the inherent problem of human vigilance or sustained attention.

Since the pioneering work of the English scientist Norman Mackworth in the late 1940s and early 1950s, we have known that human beings, in general, are rather poor at vigilance tasks. Asking individuals to monitor the repetitive actions of the more reliable automated systems is not an advisable strategy. Humans quickly get tired, bored, and fatigued in such circumstances. They end up failing to respond. This has been referred to as being 'awake at the switch,' but might be more realistically thought of as being 'asleep at the switch.' Despite this understanding, many systems are designed to take as much advantage of automation as possible. However, because all functions cannot always be automated, we see the human being employed as 'the subsystem of last resort.' Thus, vigilance tasks persist in many occupations and we see them everywhere, modern airport screening being a good example. Vigilance decrements are also very evident in the spectacular failures of many large scale semiautomated systems.

Sadly, it is a true observation that nothing has served to provide an impetus for the HF/E profession as much as the spectacular failures of large scale technical systems. Disasters that are commonly recalled today, such as the '*Chernobyl disaster*' and 'the *Bhopal gas tragedy*,' present evidence of HF/E related failures, and calls for improved HF/E applications quickly followed their occurrence. Perhaps the most famous of such events in the U.S. was the '*Three Mile Island*' accident. In March 1979, events at a nuclear power station in the Susquehanna River near Harrisburg, Pennsylvania, threatened to lead to the nightmare scenario of a nuclear explosion adjacent to a large urban area. Because of safety concerns associated with this incident, construction of nuclear power plants essentially ceased in the United States. However, with the current energy policies now favoring a return of investment in nuclear power generation, and the circulating fear of three decades ago now dissipated, HF/E has again emerged as a critical issue in the prospective safety of any new nuclear facilities. After the threat of immediate disaster had been averted at Three Mile Island, it became very clear that the critical situation had been created by a number of HF/E related failures. These included the poor design of the control room that prevented a clear representation of the state of the plant to the operators who were in charge of the plant and its complex control loops. In its essence, this was a human-machine interface problem made worse by the poorly designed rules of the operation. The impact of Three Mile Island on HF/E was crucial not only in terms of interest and the promotion of science, but also in terms of the many insightful conceptual advances that were made. One of the most profound of these was that of Perrow, whose text '*Normal Accidents*,' became an HF/E classic. The questions for HF/E were many: How should displays be created

to best represent system status to the operators? How should displays be grouped so that the closely related functions appear in appropriate proximity? How do we combat the vigilance decrement? How much cognitive load should each operator be asked to sustain and for how long? What balance is needed between hard rules and spontaneity in operating procedures? These questions provided a major impetus to areas of research such as sustained attention and mental workload evaluation. Also, it created fields of study, such as ecological interface design, that form the centers of discussion in the discipline even today, as do also studies of the social dynamics of teams and the design of operating procedures.

We are still developing our understanding of human interaction with increasingly automated technology. The selfsame questions of vigilance and interface design are still being asked in more modern contexts, such as the control of multiple unmanned aerial vehicles (UAVs). Here, we see the next stage of removal from the direct control loop. The nominal 'pilot' is now not even inside the vehicle itself. In the military context, remote piloting means that the 'operator,' 'controller,' 'supervisor,' and 'pilot' (the roles begin to blur with this progressive remoteness of control) can be, and is indeed on occasion, half a world away. As some UAVs are also armed now, this individual can potentially rain down death and destruction via remote control virtually anywhere on the planet. More than HF/E design questions, this 'remoteness' from the site of action raises moral questions about the technology that we are creating and the way in which it is being used. HF/E cannot divorce itself from such ethical issues.

The most recent trends in HF/E have seen expansions and elaborations into areas of interest beyond the central core discipline. Perhaps the first of such expansions of note concerns the area of sociotechnical systems or 'macroergonomics,' as it has sometimes been called. Traditional HF/E was mainly concerned with one operator acting in conjunction with one single system, just like a single person sitting at a Personal Computer (PC). This limited identification presents useful boundary conditions for scientific study. For example, one can focus on individual cognition, one single interface (i.e., keyboard, mouse, and screen) and one overall response loop. These immediate constraints mean that the problem is bounded and, therefore, somewhat amenable to immediate problem resolution. Unfortunately, people rarely work in isolation. PCs themselves are embedded in both a physical and social context. All too often, supposed 'solutions' that can be derived in the experimental laboratory prove to be unreliable, and even irrelevant, when used in the 'real' world. The importance of the operational context was emphasized in classic works such as Ed Hutchins's *Cognition in the Wild* and a series of HF/E related conferences on Organizational Design and Management (ODAM). It has become clear in the decades of the eighties and nineties that the context of work (e.g., its social and environmental setting), is at least as, if not more, important as the design of interfaces or the memory capacities of a particular operational system. It may well be that this emphasis was derived from earlier European concerns for the overall work environment. In Europe, the standards bodies have had particular influence on such working conditions since the earliest days of the Industrial Fatigue Board that operated in Britain in the early years of the twentieth century. In many

countries, legislation compels the use of ergonomic principles in workplace design.

In addition to the environmental context of work, there has been an increasing emphasis on the social conditions of work settings. Often, people work in teams, and the productivity of a team is contingent upon more than simply the action of each of its individual members. These emergent social properties add another layer of complexity to an already difficult study. Now it was insufficient to simply specify how, for example, the vigilance decrement might influence an operator. It became imperative to specify whether that individual was working alone or in a team setting, such as military special forces or typical industrial operators, where a team-mate might make up for any lapse. Examples such as these have led us to realize the importance of the much more complex evaluation of sociotechnical systems.

One approach to these increasing complexities was to build overall system models. Early models of this type focused on the performance of a single operator. They were often created as an assembly of modules related to the psychological dimensions of response capacity, for example, memory. The development of these models (e.g., SAINT, IMPRINT) were often funded by the military, which needs to predict the performance of servicemen and women. Such selection tools go all the way back to the very earliest efforts at intelligence testing. Other agencies such as NASA pursued their own version of these modeling efforts (e.g., MIDAS) because their particular context of performance had to be modeled in its own special detail. Although large scale sociotechnical models often have certain basic assumptions in common, in detail they tend to vary according to the particular needs of those who had the resources and the capacity to support their creation. Some HF/E modeling efforts have also derived impetus from painful system failures. Today, there are a number of such models, which are integrated with more 'micro' level models of cognition and they are used for the design, selection, and training of large numbers of individuals and systems. They continue to be refined as the empirical basis of understanding itself evolves. The degree to which they accurately portray reality continues to be strongly debated, and their application in real-world situations remains somewhat limited. However, their very formalization gives a solid basis to such disputes, a basis that is sometimes missing in other dimensions of HF/E.

In addition to reaching out to the social sciences, such as organizational design, ethnology, and sociology, one recent effort in HF/E has tried to combine the significant advances in the neurosciences with the control of technology. In HF/E, this effort has been termed neuroergonomics, which is a name first proposed by Parasuraman, a leading researcher in both realms. He defined neuroergonomics as "*the study of brain and behaviour at work.*" Largely as a result of the tremendous innovations in noninvasive brain imaging techniques, we are now able to get a much more detailed and dynamic representation of the brain in action. This view provides diagnostic information that can be used as control inputs for technical systems. Perhaps the most obvious example of this type of brain-machine interface derives from the clinical efforts to provide opportunities for the handicapped, especially those who suffer from what is termed as 'locked-in' syndrome. Such individuals may have unimpaired cognitive capacities but are unable to

express such acts of cognition through their own muscular system. Through the use of technologies such as EEG and imaging approaches, the electrical activity of the brain can be collected, analyzed, subjected to a degree of interpretation and then used as technology control inputs. These enable the individuals with very little or even no voluntary muscle control capacity to activate and operate mostly computer-mediated systems. It is true that at present these systems are often slow and unwieldy. However, these are communication bandwidth and interface issues. Such barriers to efficient interaction should be diminished in the near future. Similar augmented feedback designs can work equally well for unimpaired individuals. This promises an exciting avenue through which to conceive developing HF/E applications.

In these conceptions of mind-machine interfaces, the human operator is the source of intention and generates the command for action. This is then communicated to the computer, which acts as the intermediary and carries out the intended human desire by communicating that command to some other remote entity. However, this feedback loop can be run in a somewhat different fashion. If instead of a simple sequence of momentary events, that is, command, communication, interpretation, and response, we consider this channel as a more general flow of behavior and the operator as commanding the computer, those selfsame neurophysiologic signals can be used by the computer to monitor the state of the operators themselves. Let us hark back to an earlier concern about vigilance failures for an example of how this could work. Suppose that some of the brain signals being monitored by the computer could diagnose an incipient vigilance failure? The computer could then warn the individual of the failing state. Indeed, in extreme emergencies, the computer could take over the function of the operator to ensure that the overall system performed safely. It is this conception that lies at the heart of a program supported by the Defense Advanced Research Project Agency (DARPA) named AUGCOG (for Augmented Cognition). AUGCOG, a very successful program, was initially based on the principle of adaptive systems. To speculate on the future of such adaptive systems, we must delve briefly into their antecedents as human-machine symbiosis is one of the identified directions for future HF/E efforts.

The notion of mutual adaptation between human and machine runs as a general theme through the whole history of HF/E. In the earliest days, of course, the adaptation was slow and episodic. A craftsman may have made a tool to fit his own hand, but it may have been very poorly adapted to any other individual who tried to use it. In the age of mass production, standard sized tools were produced to try to accommodate as much of the population as possible. With later developments, greater ranges of users were catered to, which included the progressive inclusion of women as they entered the workforce and became an increasingly important segment of consumers. Thus, tools in general were fabricated to fit a sufficient number of individuals but for the most part, during the last century and a half, it was the human that did the adapting. This continued into modern times when early PCs were relatively slow, and both hardware and software difficult to use. The idea of static adaptation came with the notion of individualized design, and we can see bespoke products as early indicators of this form of customization. However, computational systems are much

more agile and dynamic in their capacities, and so, moment to moment task adaptation was proposed by Rouse. The extension of this idea by using dynamic physiological indicators, such as heart rate and EEG to perform adaptive, on-line changes in task demand and task structure was introduced by Hancock and Chignell in the early 1980s; from these origins, the notion of dynamic, adaptive systems has developed. It was in these notions and earlier observations of augmentation in the robotic realm of the early 1960s that the idea of going beyond adaptation to human augmentation was also born. Today's opportunities found in web-based applications and hand-held portable technologies, which can access such sources of augmented support, are examples leading toward an eventual state of human-machine symbiosis. However, before I turn to a brief examination of possible future trends for HF/E, I wish to look briefly at some current issues and also at what qualifications it takes to become an HF/E professional.

Contemporary Issues in HF/E

Given that HF/E professionals are looking to improving all forms of interaction with technical systems, it is unsurprising that they are often involved with the most pressing issues of the day. One of the more recent of such concerns has centered around the problems of medical error. Unlike errors in commercial sectors such as aviation, medical error has remained largely hidden. Traditionally, the medical profession has not been associated with extensive public scrutiny of medical failures. Such failures often resulted in the injury or death of only a single individual and as road safety professionals are very aware, such events are not as newsworthy as large scale failures, such as the crash of a commercial aircraft. This relative insulation has also served to inhibit the identification of systemic failures. Each particular incident tended to be seen as the failure of an individual and not the failure of some other element, such as inadequate equipment design or procedural shortcomings. Fortunately, the recent social emphasis on understanding medical error has begun to expose these various forms of failure and now the medical profession has begun to embrace disciplines, such as HF/E, that have now served to significantly improve the record of safety. This is a solid success story, not simply for HF/E, but for the medical profession in general. Although there remains much to be accomplished, the groundswell of effort has set medicine firmly on the track of systematic improvement here.

Another issue that has experienced strong and persistent social interest is sustainability. Care for the environment, in terms of pollution reduction and recycling have begun to have impact. Whether this expression of collective social conscience can be effective within the limited time available, is an inevitable source of concern. However, here the HF/E professional can make a profound contribution. Many incidents of major pollution, for example, *Exxon Valdez*, derive from operator (human) errors expressed in error-intolerant systems. HF/E contributions to improve system safety and reliability can help address these man-made ecologic disasters. As one HF/E luminary, Nickerson, has pointed out, there are in fact very few major social issues where HF/E cannot make a significant impact. From the simple improvements of design for filtering

potable water to the most complex industrial and manufacturing systems, HF/E can contribute not only to improved safety but also to enhanced productivity. One epithet used by many HF/E professionals is that "*good ergonomics is good economics*." Whether good economics is itself good, is a larger ethical issue that HF/E professionals have now begun to wrestle with. From the way in which we elect our representatives to the way we conduct war or provide aid and relief to those in need, HF/E can have a pivotal role in improving the quality of all aspects of life. It is an important and burgeoning profession.

On Being an HF/E Professional

One question that might then come to mind is where those in HF/E come from and how one might join such a profession. The answer to this question is that HF/E professionals come from a wide variety of backgrounds. This fact is evident as one looks through the membership roles of many of the professional societies. The majority of professionals in HF/E possess a background in either experimental/applied psychology or in industrial engineering. Formal programs of study are usually found in such departments in the major universities that teach HF/E in the United States. In Europe, Australia, and Japan also, this is often the case, but around the world, the parent Departments in which HF/E can be found tend to be more diverse. Although any professional can graduate in HF/E or some formally related discipline, there are always a significant proportion of people in HF/E, who have followed programs of study beyond these traditional core disciplines. For example, many from the medical sciences are involved, especially in ergonomics. The formal study of kinesiology also frequently provides a strong base from which to begin a professional career in HF/E. Thus, students of biomechanics can easily apply their knowledge and skills in the field of occupational ergonomics, and graduates in motor control have much of the foundational knowledge of skill development and operator performance assessment. More recently, those studying computer science with a particular focus on interface design and development have entered the field, through concern for usability and specific interest in related fields, such as serious games design. Also, many modeling and simulation graduates specialize in aspects of applied HF/E. Consequently, although there are a number of accepted paths, many diverse avenues of interest can eventually lead to a career in HF/E. Finally, HF/E has a strong and persisting link with Industrial Design. The diversity in the backgrounds of HF/E professionals has led to many debates about the core competencies and professional accreditation of those in HF/E. Indeed, there are a number of such accrediting bodies in existence. However, contentions over the inclusion of diversity while retaining the basic professional standards are issues that have still to be fully resolved in HF/E.

Future Concerns of HF/E

Kenneth Oakley's wonderful text of the mid-twentieth century '*Man the Tool-Maker*' emphasized the crucial relationship between early humans and their tools. Today, we might extend

this vision to suggest that, perhaps, it was not humans who created tools, but rather the tools themselves that served as one of the crucial factors that helped differentiate the human species from all others. However, the idea of tools cannot be confined to their physical representation alone. Indeed, non-physical tools such as language and mathematics have been just as influential in human progress, if not more so. Alongside the progressive evolution of all forms of tools, there has been a comparable evolution in interfaces. Interfaces provide the link between human and tool. Interfaces have also evolved across the ages. Interface evolution represents the growth in the level of intimacy between humans and technology.

For many millennia, we have lived in an active and progressively more symbiotic relationship with our tools. Now, in our own times, the tools are starting to invade our physical being. As we go about our daily activities, we carry many of our essential technologies in our pockets. One can scare people by threatening to take their 'Blackberry' from them. (For those who are reading this in the future, a Blackberry was a form of portable wireless device, which no doubt will soon seem dated, but descriptions of it, will be able to be accessed by existing computer database search engines.) Our current support tools are portable because of the development of microelectronics and the now almost ubiquitous wireless access across the globe. Much of the present size of portable technologies is actually dictated by the need for an interface to have a visible and usable screen, as well as an input device such as a mouse or a keyboard. These interface elements are still at the 'slow and clunky' stage compared to the actual information processing capacities of the devices themselves. But we are starting to do more than simply transport our technologies in our pockets. For example, with devices such as cochlear implants and heart pacemakers, technology is slowly becoming indwelling, within the body itself.

Internal devices, such as pacemakers, act as medical support technologies to help those suffering from disease and injury, or to compensate for inherent problems. Recently, there has been a significant increase in the number of implanted devices for damage mitigation and the amelioration of disease effects. While these are used as forms of function restoration, there is no barrier to their being employed as forms of functional enhancement. My automobile contains a device to provide an automated alarm, if there is an attempt to steal it. My dog has an implanted device to identify his owner, in case he is lost. It will not be long before we have technologies introduced into normal human beings to provide similar capacity enhancement. Devices will literally become a part of us. The future promises a much more radical increase in this form of physical and indeed cognitive intimacy. As the symbiosis between humans and tools is perfected, therefore, interfaces will become not merely transparent but, eventually, like the smile of the Cheshire Cat, they will disappear altogether. We shall have reached true symbiosis when our interfaces with our technology have become completely invisible. These are the optimistic upsides of technological innovation. However, there is a potential downside. For example, greater technological sophistication can mean greater vulnerability. Thus, if we lose the capability to manufacture such devices or the ability to produce energy dense power supplies, either through large scale natural disasters or even man-made global disasters,

our highly interdependent technical world could collapse easily, so much so that we would then envy even the ancient artisan and his 'primitive' survival capacities.

Such developments concerning our ineradicable intimacy with technology will be the subject of much social discussion about issues of privacy, personhood, etc. However, the current state of technology certainly permits such innovation, and there are very few examples of situations in which a technology once invented is intentionally not implemented somewhere in the world. These types of development will begin to force us to ask questions about what it is to be human. For example, where does an individual end? For instance, in education, we test individuals on their memory of learned material, but when memory can be extended by many orders of magnitude by access to distal storage facilities, why are we testing the individual's unaided capacities? Presently, we do not let students use web-access laptops into standardized test examinations. However, will we be able to prevent such access when the individual has an indwelling chip? Indeed, would we want to? This is just one simple example of the possibility of physical extensions of individual human capacities with the bodily insertion of technological support. But the next stage of evolution promises to go well beyond this.

As the physical and cognitive barriers between humans and technologies begin to crumble, we begin to reach what Kurzweil has called the 'singularity' or in De Chardin's prior conceptualization – the 'omega point.' Here, the very nature of consciousness promises to evolve to a following stage of development. When and how those barriers are overcome will have a direct effect upon the nature of this emergent consciousness, and so a direct influence on who and what human beings will turn into. Thus, the purpose of the process will dictate the process of the purpose. The science at the heart of that transition is HF/E.

Acknowledgments

I am very grateful to a number of reviewers who have commented on and greatly improved the content of this article. They include Professor Edward Rinalducci and Dr. Richard Pew, to whom I am exceptionally thankful. I am especially indebted to Professor Neville Moray for his help with editing, and his detailed comments on a previous version of this work.

Human Intelligence

R J Sternberg, Oklahoma State University, Stillwater, OK, USA

© 2012 Elsevier Inc. All rights reserved.

Glossary

Culture The set of attitudes, values, beliefs, and behaviors shared by a group of people, which are communicated from one generation to the next, via language and various other means of communication.

General ability An ability that applies across a very wide range of kinds of cognitive tasks, and, arguably, all cognitive tasks.

Heritability The proportion of phenotypic variation in a trait that is due to genetic influences.

Human intelligence A mental quality that consists of the abilities to learn from experience, adapt to new situations, understand and handle abstract concepts, and use knowledge to manipulate one's environment.

Modifiability The malleability of a trait – its susceptibility to change either in an upward or in a downward direction.

Human intelligence is a mental quality that consists of the abilities to learn from experience, adapt to new situations, understand and handle abstract concepts, and use knowledge to manipulate one's environment.

Several investigators have emphasized diverse aspects of intelligence in their definitions. For example, in a 1921 symposium, American psychologists Lewis M. Terman and Edward L. Thorndike differed over the definition of intelligence, Terman stressing the ability to think abstractly and Thorndike emphasizing learning and the ability to give good responses to questions. More recently, however, psychologists have generally agreed that adaptation to the environment is the key to understanding both what intelligence is and what it does. Such adaptation may occur in a variety of settings: a student in school learns the material he needs to know in order to do well in a course; a physician treating a patient with unfamiliar symptoms learns about the underlying disease; or an artist reworks a painting to convey a more coherent impression. For the most part, adaptation involves making a change in oneself in order to cope more effectively with the environment, but it can also mean changing the environment or finding an entirely new one.

Theories of Intelligence

Four of the most influential paradigms have been psychological measurement, also known as psychometrics; cognitive psychology, which concerns itself with the processes by which the mind functions; cognitivism and contextualism, a combined approach that studies the interaction between the environment and mental processes; and biological science, which considers the neural bases of intelligence. What follows is a discussion of developments within these four areas.

Psychometric Theories

Psychometric theories have generally sought to understand the structure of intelligence: What form does it take, and what are its parts, if any? Such theories have generally been based on and established by data obtained from tests of mental abilities, including analogies (e.g., *lawyer* is to *client* as *doctor* is to ___), classifications (e.g., Which word does not belong with the

others? *robin*, *sparrow*, *chicken*, *blue jay*), and series completions (e.g., What number comes next in the following series? 3, 6, 10, 15, 21, ___).

Psychometric theories are based on a model that portrays intelligence as a composite of abilities measured by mental tests. One of the earliest of the psychometric theories came from British psychologist Charles E. Spearman (1863–1945), who published his first major article on intelligence in 1904. Spearman concluded that just two kinds of factors underlie all individual differences in test scores. The first and more important factor, which he labeled the 'general factor,' or *g*, pervades performance on all tasks requiring intelligence. In other words, regardless of the task, if it requires intelligence, it requires *g*. The second factor is specifically related to each particular test. For example, if you give someone a test of arithmetical reasoning, performance on it would require a general factor that is common to all tests (*g*), and a specific factor of whatever mental operations are required only for mathematical reasoning as distinct from other mental tests. Thus, these specific (*s*) factors are not of great interest to theories of intelligence because they do not generalize. Spearman did not know exactly what the general factor was, but he proposed in 1927 that it might be something like 'mental energy.' He left the exact nature of mental energy largely undefined.

American psychologist L.L. Thurstone disagreed with Spearman's theory, arguing instead that there were seven factors, which he identified as the 'primary mental abilities.' These seven abilities, according to Thurstone, were verbal comprehension (e.g., knowledge of vocabulary and in reading), verbal fluency (e.g., writing and otherwise producing words), number (e.g., solving fairly simple numerical computation and arithmetical reasoning problems), spatial visualization (e.g., visualizing and manipulating objects, such as fitting a set of suitcases into an automobile trunk), inductive reasoning (e.g., completing a number series or in predicting the future on the basis of past experience), memory (e.g., recalling people's names or faces), and perceptual speed (e.g., proofreading to discover typographical errors in a text).

Although the debate between Spearman and Thurstone has remained unresolved, other psychologists – such as Canadian Philip E. Vernon and American Raymond B. Cattell – have suggested that both were right in some respects. Vernon and

Cattell viewed intellectual abilities as hierarchical, *g*, or general ability, being located at the top of the hierarchy. But below *g* are levels of gradually narrowing abilities, ending with the specific abilities identified by Spearman. Cattell, for example, suggested in 1971 in *Abilities: Their Structure, Growth, and Action* that general ability can be subdivided into two further kinds, 'fluid' and 'crystallized.' Fluid abilities are the reasoning and problem-solving abilities measured by tests such as analogies, classifications, and series completions. Crystallized abilities, which are thought to derive from fluid abilities, include vocabulary, general information, and knowledge about specific fields. American psychologist John L. Horn suggested that crystallized abilities more or less increase over a person's life span, whereas fluid abilities increase in earlier years and decrease in later ones.

American psychologist John B. Carroll, in *Human Cognitive Abilities* (1993), proposed a 'three-stratum' psychometric model of intelligence that expanded upon existing theories of intelligence. Many psychologists regard Carroll's model as definitive, because it is based on reanalyses of hundreds of datasets. In the first stratum, Carroll identified narrow abilities (roughly 50 in number) that included the seven primary abilities identified by Thurstone. According to Carroll, the middle stratum encompassed broad abilities (~10) such as learning, retrieval ability, speediness, visual perception, fluid intelligence, and the production of ideas. The third stratum consisted solely of the general factor, *g*, as identified by Spearman.

It might seem self-evident that the factor at the top would be the general factor, but it is not, in the sense that there is no guarantee that there is any general factor at all. Carroll, as well as many other psychometric theorists, posited that there is such a general factor.

Cognitive Theories

During the era dominated by psychometric theories, the study of intelligence was influenced mostly by those investigating individual differences in people's test scores. In an address to the American Psychological Association in 1957, American researcher Lee Cronbach, a leader in the testing field, decried the lack of common ground between psychologists who studied individual differences and those who studied commonalities in human behavior. Cronbach's plea to unite the 'two disciplines of scientific psychology' led, in part, to the development of cognitive theories of intelligence and of the underlying processes posited by these theories.

Underlying most cognitive approaches to understanding intelligence is the assumption that intelligence comprises mental representations (such as propositions or images) of information and processes that can operate on such representations. A more-intelligent person is assumed to represent information more clearly and to operate faster on these representations. Researchers have sought to measure the speed of various types of thinking. Through mathematical modeling, they divide the overall time required to perform a task into the constituent times needed to execute each mental process. Usually, they assume that these processes are executed serially (one after another) and, hence, that the processing times are additive. But some investigators assume parallel processing, in which more than one process is executed at the same time. Regardless of the type of model used, the fundamental unit of

analysis is the same – that of a mental process acting upon a mental representation. There is fairly good evidence at this point that speed in thinking is one of the sources of individual differences in intelligence. However, this finding needs to be viewed in the context of task needs. In some tasks, it is more intelligent to process information more slowly and more deeply, as when one studies for a test that will measure one's depth of knowledge.

A number of cognitive theories of intelligence have been developed. Among them is that of American psychologists Earl B. Hunt, Nancy Frost, and Clifford E. Lunneborg, who in 1973 showed one way in which psychometrics and cognitive modeling could be combined. Instead of starting with conventional psychometric tests, they began with tasks that experimental psychologists were using in their laboratories to study the basic phenomena of cognition, such as perception, learning, and memory. They showed that individual differences in these tasks, which had never been taken seriously before, were in fact related (although rather weakly) to patterns of individual differences in psychometric intelligence test scores. Their results suggested that the basic cognitive processes are the building blocks of intelligence.

The psychologists hypothesized that a critical ability underlying intelligence is the rapid retrieval of lexical information, such as letter names (e.g., the name of the written letter 'h') from memory. Hence, they were interested in the time needed to react to the question about letter names. By subtracting the reaction time to the question about physical match from the reaction time to the question about name match, they were able to isolate and set aside the time required for sheer speed of reading letters and pushing buttons on a computer. They found that the score differences seemed to predict psychometric test scores, especially those on tests of verbal ability such as reading comprehension. Hunt, Frost, and Lunneborg concluded that verbally facile people are those who are able to absorb and then retrieve from memory large amounts of verbal information in short amounts of time. The time factor was the significant development in this research.

A few years later, Sternberg suggested an alternative approach that could resolve the weak relation between cognitive tasks and psychometric test scores. He argued that Hunt and his colleagues had tested for tasks that were limited to low-level cognitive processes. Although such processes may be involved in intelligence, Sternberg claimed that they were peripheral rather than central. He recommended that psychologists study the tasks found on intelligence tests and then identify the mental processes and strategies people use to perform those tasks.

A different approach was taken in the work of British psychologist Ian Deary, following up on the work of Ted Nettlebeck among others. He argued that inspection time is a particularly useful means of measuring intelligence. It is thought that individual differences in intelligence may derive in part from differences in the rate of intake and processing of simple stimulus information. In the inspection-time task, a person looks at two vertical lines of unequal length and is asked to identify which of the two is longer. Inspection time is the length of time of stimulus presentation each individual needs in order to discriminate which of the two lines is the longest. Some research suggests that more-intelligent individuals

are able to discriminate the lengths of the lines in shorter inspection times.

Other cognitive psychologists have studied human intelligence by constructing computer models of human cognition. Two leaders in this field were American computer scientists Allen Newell and Herbert A. Simon. In the late 1950s and early 1960s, they worked with computer expert Clifford Shaw to construct a computer model of human problem solving. Called the General Problem Solver, it could find solutions to a wide range of fairly structured problems, such as logical proofs and mathematical word problems. This research, based on a heuristic procedure called 'means-ends analysis,' led Newell and Simon to propose a general theory of problem solving in 1972. More recently, Marcel Just, Patricia Carpenter, and others have devised computer-simulation models of problem solving of the kinds required for complex problem solving.

All of the cognitive theories described so far rely on what psychologists call the 'serial processing of information,' meaning that in these examples, cognitive processes are executed in series, one after another. Yet the assumption that people process chunks of information at a time may be incorrect. Many psychologists have suggested instead that cognitive processing is primarily parallel. It has proved difficult, however, to distinguish between serial and parallel models of information processing. Advanced techniques of mathematical and computer modeling were later applied to this problem. Possible solutions have included 'parallel distributed processing' models of the mind, as proposed by the psychologists David E. Rumelhart and Jay L. McClelland. These models postulated that many types of information processing occur within the brain at once, rather than just one at a time.

Recent cognitive work on intelligence has emphasized the importance of working memory, usually viewed as that portion of long-term memory that is activated at a given moment in time. Working-memory tasks usually involve some element of active information processing. For example, one test of working memory is to recall a string of digits in backward order – that is, the order opposite to that in which the digits were presented. Research by Alan Baddeley, Patrick Kyllonen, Meredyth Daneman, Randall Engle, and others has suggested that working-memory ability is highly correlated with and may be a precursor to the 'general ability' described in the section on psychometric models.

Cognitive–Contextual Theories

Cognitive–contextual theories deal with the way in which cognitive processes operate in various settings. For example, being smart in a hunting–gathering society might involve somewhat different skills from those involved in being smart in an industrialized society. There might be some, but not complete, overlap. Two of the major cognitive–contextual theories are that of American psychologists Howard Gardner and Robert Sternberg.

In 1983 and then at various times into the 2000s, Gardner first challenged the assumption of a single intelligence by proposing a theory of 'multiple intelligences.' Earlier, theorists had gone so far as to contend that intelligence comprises multiple abilities. But Gardner went one step further, arguing that intelligences are multiple and include, at a minimum, linguistic, logical-mathematical, spatial, musical, bodily kinesthetic, naturalist, interpersonal, and intrapersonal intelligence.

Some of the intelligences proposed by Gardner resembled the abilities proposed by psychometric theorists, but others did not. For example, the idea of a musical intelligence was relatively new, as was the idea of a bodily kinesthetic intelligence, which encompassed the particular abilities of athletes and dancers. Gardner derived his set of intelligences chiefly from studies of cognitive processing, brain damage, exceptional individuals, and cognition across cultures. He has also speculated on the possibility of an existential intelligence (a concern with 'ultimate' issues, such as the meaning of life), although he was unable to isolate an area of the brain that was dedicated to the consideration of such questions. Gardner's research on multiple intelligences led him to claim that most concepts of intelligence had been ethnocentric and culturally biased but that his was universal, because it was based on biological and cross-cultural data as well as upon data derived from the cognitive performance of a wide array of people.

An alternative approach that took similar account of cognition and cultural context was Sternberg's 'triarchic' theory, which he proposed in *Beyond IQ: A Triarchic Theory of Human Intelligence* (1985). Both Gardner and Sternberg believed that conventional notions of intelligence were too narrow; Sternberg, however, questioned how far psychologists should go beyond traditional concepts, suggesting that musical and bodily kinesthetic abilities are talents rather than intelligences because they are fairly specific and are not prerequisites for adaptation in most cultures.

Sternberg posited three ('triarchic') integrated and interdependent aspects of intelligence, which are concerned, respectively, with a person's internal world, the external world, and experience. The first aspect comprises the cognitive processes and representations that form the core of all thought. The second aspect consists of the application of these processes and representations to the external world. The triarchic theory holds that more-intelligent persons are not just those who can execute many cognitive processes quickly or well; rather, their greater intelligence is reflected in knowing their strengths and weaknesses and capitalizing upon their strengths while compensating for their weaknesses. More-intelligent persons, then, find a niche in which they can operate most efficiently. The third aspect of intelligence consists of the integration of the internal and external worlds through experience. This includes the ability to apply previously learned information to new or wholly unrelated situations.

Sternberg and his colleagues have found that this broader model of intelligence can be used as a basis for both instruction and assessment. They found that students instructed in ways that emphasize creative and practical information processing as well as memory and analytical processing show improved performance in school. Tests based on the theory can improve prediction of performance in the first year of university and can also reduce ethnic-group differences relative to more conventional psychometric tests.

Other intelligences were proposed in the late twentieth century. In 1990, psychologists John Mayer and Peter Salovey defined the term *emotional intelligence* as the ability to perceive emotions, to access and generate emotions so as to assist thought, to understand emotions and emotional knowledge, and to reflectively regulate emotions so as to promote emotional and intellectual growth.

The four aspects identified by Mayer and Salovey involve (1) recognizing one's own emotions as well as the emotions

of others, (2) applying emotion appropriately to facilitate reasoning, (3) understanding complex emotions and their influence on succeeding emotional states, and (4) having the ability to manage one's emotions as well as those of others. The concept of emotional intelligence was popularized by psychologist and journalist Daniel Goleman in books published from the 1990s through the first decade of the 2000s. Several tests developed to measure emotional intelligence have shown modest correlations between emotional intelligence and conventional intelligence.

Another kind of intelligence first proposed by Edward Thorndike early in the twentieth century, and then studied later by John Kihlstrom and Nancy Cantor and popularized by Daniel Goleman, is social intelligence, or one's ability to interact effectively with others. The basic notion underlying this work is that, without the ability to get along with others, people high in cognitive intelligence may find that they cannot adapt effectively to the social demands of everyday life.

Biological Theories

These theories seek to understand intelligence in terms of hypothetical mental constructs, whether they are factors, cognitive processes, or cognitive processes in interaction with context. Biological theories represent a radically different approach that dispenses with mental constructs altogether. Advocates of such theories, usually called reductionists, believe that a true understanding of intelligence is possible only by identifying its biological basis. Some would argue that there is no alternative to reductionism if, in fact, the goal is to explain rather than merely to describe behavior. Although relatively little is known about the biological bases of intelligence, progress has been made on three different fronts, all involving studies of brain operation.

Hemispheric studies

One biological approach has centered upon types of intellectual performance as they relate to the regions of the brain from which they originate. In her research on the functions of the brain's two hemispheres, psychologist Jerre Levy and others found that the left hemisphere is superior in analytical tasks, such as are involved in the use of language, while the right hemisphere is superior in many forms of visual and spatial tasks. Overall, the right hemisphere tends to be more synthetic and holistic in its functioning than the left. Nevertheless, patterns of hemispheric specialization are complex and cannot easily be generalized.

The specialization of the two hemispheres of the brain is exemplified in an early study by Levy and American neurobiologist Roger W. Sperry, who worked with split-brain patients – that is, individuals whose corpus callosum had been severed. Sperry, a Nobel-Prize winner, was a pioneer in this field. Because the corpus callosum links the two hemispheres in a normal brain, in these patients, the hemispheres function independently of each other. Michael Gazzaniga has also been active in this field and has suggested that, to some extent, the left hemisphere of the brain serves a monitoring function, including monitoring the activities of the right hemisphere.

More recently, lesion studies have suggested areas of the brain particularly associated with intelligence. They include

but are not limited to the superior colliculus, posterior cingulate, dorsal hippocampus, posterolateral hypothalamus, parietal cortex, and occipitotemporal cortex. Further studies have implicated the ventrolateral thalamus, pontine reticular formation, dorsal caudatoputamen, globus pallidus, substantia nigra, ventral tegmental areas, and median raphe as well.

Brain-wave studies

A second front of biological research has involved the use of brain-wave recordings. German-born British psychologist Hans Eysenck, for example, studied brain patterns and speed of response in people taking intelligence tests. Earlier, brain-wave research had studied the relation between these waves and performance on ability tests or in various cognitive tasks. Researchers in some of these studies found a relationship between certain aspects of electroencephalogram (EEG) waves, event-related-potential (ERP) waves, and scores on a standard psychometric test of intelligence. The results of this approach have been inconsistent and not always promising. However, use of averaged evoked potentials by Aljoscha Neubauer and his colleagues have suggested that speed of processing is associated with individual differences in intelligence.

Blood-flow studies

A third and more recent front of research involves the measurement of blood flow in the brain, which is a fairly direct indicator of functional activity in brain tissue. In such studies, the amount and location of blood flow in the brain is monitored while subjects perform cognitive tasks. Psychologist John Horn, a prominent researcher in this area, found that older adults show decreased blood flow to the brain; that such decreases are greater in some areas of the brain than in others; and that the decreases are particularly notable in those areas responsible for close concentration, spontaneous alertness, and the encoding of new information. Using positron emission tomography (PET), the psychologist Richard Haier found that people who perform better on conventional intelligence tests often show less activation in relevant portions of the brain than do those who perform less well. In addition, neurologists Antonio Damasio and Hannah Damasio and their colleagues used PET scans and magnetic resonance imaging (MRI) to study brain function in subjects performing problem-solving tasks. These findings affirmed the importance of understanding intelligence as a faculty that develops over time.

Development of Intelligence

There have been a number of approaches to the study of the development of intelligence. Psychometric theorists, for instance, have sought to understand how intelligence develops in terms of changes in intelligence factors and in various abilities in childhood. For example, the concept of mental age was popular during the first half of the twentieth century. A given mental age was held to represent an average child's level of mental functioning for a given chronological age. Thus, an average 12-year-old would have a mental age of 12, but an above-average 10-year-old or a below-average 14-year-old might also have a mental age of 12 years. The concept of mental age fell into disfavor, however, for two apparent reasons. First, the concept does not seem to work after about the age of 16. The mental

test performance of, say, a 25-year-old is generally no better than that of a 24- or 23-year-old, and in later adulthood some test scores seem to start declining. Second, many psychologists believe that intellectual development does not exhibit the kind of smooth continuity that the concept of mental age appears to imply. Rather, development seems to come in intermittent bursts, whose timing can differ from one child to another. Third, it assumes that all abilities mature at roughly the same times and at the same rates.

The Work of Jean Piaget

The landmark work in intellectual development in the twentieth century derived not from psychometrics but from the tradition established by Swiss psychologist Jean Piaget. His theory was concerned with the mechanisms by which intellectual development takes place and periods through which children develop. Piaget believed that children explore the world and observe regularities and make generalizations – much as a scientist does. Intellectual development, he argued, derives from two cognitive processes that work in somewhat reciprocal fashion. The first, which he called assimilation, incorporates new information into an already existing cognitive structure. The second, which he called accommodation, forms a new cognitive structure into which new information can be incorporated. Cognitive development, according to Piaget, represents a dynamic equilibrium between the two processes of assimilation and accommodation.

As a second part of his theory, Piaget postulated four major periods in individual intellectual development. The first, the sensorimotor period, extends from birth through roughly age 2. During this period, a child learns how to modify reflexes to make them more adaptive, to coordinate actions, to retrieve hidden objects, and, eventually, to begin representing information mentally. The second period, known as preoperational, runs approximately from age 2 to age 7. In this period, a child develops language and mental imagery and learns to focus on single perceptual dimensions, such as color and size. The third, the concrete-operational period, ranges from about age 7 to 12. During this time, a child develops so-called conservation skills. Conservation skills enable a person to recognize that things that may appear to be different are actually the same, that is, that their fundamental properties are ‘conserved.’ For example, suppose that water is poured from a wide short beaker into a tall narrow one. A preoperational child, when asked which beaker has more water, will say that the second beaker does (the tall thin one); a concrete-operational child, however, will recognize that the amount of water in the beakers must be the same. Finally, children emerge into the fourth, formal-operational period, which begins at about age 12 and continues throughout life. The formal-operational child develops thinking skills in all logical combinations and learns to think with abstract concepts. For example, a child in the concrete-operational period will have great difficulty determining all the possible orderings of four digits, such as 3-7-5-8. The child who has reached the formal-operational stage, however, will adopt a strategy of systematically varying alternations of digits, starting perhaps with the last digit and working toward the first. This systematic way of thinking is not normally possible for those in the concrete-operational period.

The Environmental Viewpoint

The views of intellectual development described earlier all emphasize the importance of the individual in intellectual development. But an alternative viewpoint emphasizes the importance of the individual’s environment, particularly his social environment. This view is related to the cognitive-contextual theories discussed earlier. Championed originally by Russian psychologist L.S. Vygotsky, this viewpoint suggests that intellectual development may be largely influenced by a child’s interactions with others: a child sees others thinking and acting in certain ways and then internalizes and models what is seen. An elaboration of this view is the suggestion by Israeli psychologist Reuven Feuerstein that the key to intellectual development is what he called ‘mediated learning experience.’ The parent mediates, or interprets, the environment for the child, and it is largely through this mediation that the child learns to understand and interpret the world.

The role of environment is particularly evident in studies across cultures. In her research on the cultural contexts of intelligence, Greenfield, studying indigenous Mayan people, found that the Mayan conception of intelligence is much more collective – group oriented – than the conception of intelligence in European or North American cultures. To the Maya, much of being intelligent involves being able to work effectively with others. In addition, psychologist Elena Grigorenko and her colleagues, in *The Organization of Luo Conceptions of Intelligence: A Study of Implicit Theories in a Kenyan Village* (2001), reported that rural Kenyans have a broad conception of intelligence that emphasizes moral behavior, particularly duty to others.

Children who grow up in environments that do not stress Western principles of education may not be able to demonstrate their abilities on conventional Western intelligence tests. Sternberg and others have found that rural Tanzanian children performed much better on skills tests when they were given extended instruction beyond the normal test instructions. Without this additional instruction, however, the children did not always understand what they were supposed to do, and, because of this, they underperformed on the tests. Similarly, a study in Kenya measured children’s knowledge of natural remedies used to combat parasites and other common illnesses. Tests for this type of knowledge were combined with conventional Western tests of intelligence and academic achievement. Results showed a negative correlation between practical intelligence (knowledge of medical remedies) and academic achievement. These findings suggested that in some cultures, academic skills may not be particularly valued; as a result, the brighter children invest more effort in acquiring practical skills.

Research also suggests that people around the world have somewhat different conceptions of just what it means to be intelligent. For example, North American and Northern European notions of intelligence have emphasized cognitive skills, whereas African notions have more emphasized social ones. Asian views have often deemphasized the importance of intelligence as an individual-differences variable and instead have focused upon the importance of group products and of effort. According to Richard Nisbett in *The Geography of Thought* (2004), Asians often perceive things quite differently. For example, in a picture of fish swimming against a background context, Americans more notice the fish and Asians more notice what to the Americans is the background context.

Measuring Intelligence

Almost all of these theories employ complex tasks for gauging intelligence in both children and adults. Over time, theorists chose particular tasks for analyzing human intelligence, some of which have been explicitly discussed here – for example, recognition of analogies, classification of similar terms, extrapolation of number series, and performance of transitive inferences. Although the kinds of complex tasks discussed so far belong to a single tradition for the measurement of intelligence, the field actually has two major traditions. The tradition that has been discussed most prominently and has been most influential is that of French psychologist Alfred Binet (1857–1911).

An earlier tradition, and one that still shows some influence upon the field, is that of English scientist Sir Francis Galton. Building on ideas put forth by his uncle Charles Darwin in *On the Origin of Species* (1859), Galton believed that human capabilities could be understood through scientific investigation. From 1884 to 1890 Galton maintained a laboratory in London where visitors could have themselves measured on a variety of psychophysical tasks, such as weight discrimination and sensitivity to musical pitch. Galton believed that psychophysical abilities were the basis of intelligence and, hence, that these tests were measures of intelligence. The earliest formal intelligence tests, therefore, required a person to perform such simple tasks as deciding which of two weights was heavier or showing how forcefully one could squeeze one's hand.

The Galtonian tradition was taken to the United States by American psychologist James McKeen Cattell. Later, one of Cattell's students, American anthropologist Clark Wissler, collected data showing that scores on Galtonian types of tasks were not good predictors of grades in college or even of scores on other tasks. Cattell nonetheless continued to develop his Galtonian approach in psychometric research and, with Edward Thorndike, helped to establish a center for mental testing and measurement.

The IQ Test

The more influential tradition of mental testing was developed by Binet and his collaborator, Theodore Simon, in France. In 1904, the minister of public instruction in Paris named a commission to study or create tests that would ensure that mentally retarded children received an adequate education. The minister was also concerned that children of normal intelligence were being placed in classes for mentally retarded children because of behavior problems. Even before Wissler's research, Binet, who was charged with developing the new test, had flatly rejected the Galtonian tradition, believing that Galton's tests measured trivial abilities. He proposed instead that tests of intelligence should measure skills such as judgment, comprehension, and reasoning – the same kinds of skills measured by most intelligence tests today. Binet's early test was taken to Stanford University by Lewis Terman, whose version came to be called the Stanford-Binet test. This test has been revised frequently and continues to be used in countries all over the world. The Stanford-Binet V (fifth edition) test, and others like it, has yielded at the very least an overall score referred to as an intelligence quotient (IQ). The fifth edition, published in 2009, also yields scores for fluid reasoning, knowledge, quantitative reasoning, abstract/visual

reasoning, visual-spatial processing, and working memory. Each is assessed in verbal and nonverbal domains. Some tests, such as the Wechsler Adult Intelligence Scale IV (fourth edition, published in 2008) and the Wechsler Intelligence Scale for Children IV (fourth edition, published in 2004), have verbal and performance tests. The scales yield an overall IQ as well as scores for verbal comprehension, perceptual reasoning, working memory, and processing speed. An example of a verbal subtest would be vocabulary, whereas an example of a performance subtest would be picture arrangement, the latter requiring an examinee to arrange a set of pictures into a sequence so that they tell a coherent story.

Later developments in intelligence testing expanded the range of abilities tested. For example, in 1997 and in 2004, psychologists J. P. Das and Jack A. Naglieri published the *Cognitive Assessment System*, a test based on a theory of intelligence first proposed by Russian psychologist Alexander Luria. The test measured planning abilities, attentional abilities, and simultaneous and successive processing abilities. Simultaneous processing abilities are used to solve tasks such as figural matrix problems, in which the test taker must fill in a matrix with a missing geometric form. Successive processing abilities are used in tests such as digit span, in which one must repeat back a string of memorized digits.

IQ on these and other tests was originally computed as the ratio of mental age to chronological (physical) age, multiplied by 100. Thus, if a child of age 10 had a mental age of 12 (i.e., performed on the test at the level of an average 12-year old), the child was assigned an IQ of $12/10 \times 100$, or 120. If the 10-year-old had a mental age of 8, the child's IQ would be $8/10 \times 100$, or 80. A score of 100, where the mental age equals the chronological age, is average.

The concept of mental age has fallen into disrepute. Many tests still yield an IQ, but they are most often computed on the basis of statistical distributions. The scores are assigned on the basis of what percentage of people of a given group would be expected to have a certain IQ.

The Distribution of IQ Scores

Intelligence test scores follow an approximately normal distribution, meaning that most people score near the middle of the distribution of scores and that scores drop off fairly rapidly in frequency as one moves in either direction from the center. For example, on the IQ scale, about 2 out of 3 scores fall between 85 and 115, and about 19 out of 20 scores fall between 70 and 130. Put another way, only 1 out of 20 scores differs from the average IQ (100) by more than 30 points.

The significance of a given test score can be different for different people. A certain IQ score may indicate a higher level of intelligence for a person who grew up in poverty and attended an inadequate school than it would for a person who grew up in an upper-middle-class environment and was schooled in a productive learning environment. An IQ score on a test given in English may also indicate a higher level of intelligence for a person whose first language is not English than it would for a native English speaker. Another factor that affects the significance of test scores is that some people are 'test-anxious' and may do poorly on almost any standardized test. Because of these and similar drawbacks, it has come to be

believed that scores should be interpreted carefully, on an individual basis.

Heritability and Malleability of Intelligence

Intelligence has historically been conceptualized as a more or less fixed trait. A minority of investigators believe either that it is highly heritable or that it is minimally heritable, while most take an intermediate position.

Among the most fruitful methods that have been used to assess the heritability of intelligence is the study of identical twins who were separated at an early age and reared apart. If the twins were raised in separate environments, and if it is assumed that when twins are separated they are randomly distributed across environments (often a dubious assumption), then the twins would have in common all of their genes but none of their environment, except for chance environmental overlap. As a result, the correlation between their performance on intelligence tests could identify any possible link between test scores and heredity. Another method compares the relationship between intelligence-test scores of identical twins and those of fraternal twins. Because these results are computed on the basis of intelligence-test scores, however, they represent only those aspects of intelligence that are measured by the tests.

Studies of twins do in fact provide strong evidence for the heritability of intelligence; the scores of identical twins reared apart are highly correlated. In addition, adopted children's scores are highly correlated with their birth parents and not with their adoptive parents. Also significant are findings that heritability can differ between ethnic and racial groups as well as across time within a single group. That is, the extent to which genes versus environment matter in IQs depends on many factors including socioeconomic class. In general, the heritability of intelligence is estimated to average around 0.50, meaning that 50% of phenotypic (observable) variation in IQ is a result of genetic causes. However, work by Eric Turkheimer and colleagues suggests that heritability is lower in people of lower social classes than in people of higher social classes, presumably because environment has more of an effect on the former than on the latter. Moreover, psychologist Robert Plomin and others have found that evidence of the heritability of intelligence increases with age; this suggests that, as a person grows older, genetic factors become a more important determinant of intelligence, while environmental factors become less important.

Whatever the heritability of IQ may be, it is a separate issue from whether intelligence can be increased. Evidence that it can was provided by American-born New Zealand political scientist James Flynn, who showed that intelligence test scores around the world rose steadily in the late twentieth century. The reasons for the increase are not fully understood, however, and the phenomenon thus requires careful further

investigation. Among many possible causes of the increase, for example, are environmental changes such as the addition of vitamin C to prenatal and postnatal diet and, more generally, the improved nutrition of mothers and infants compared with earlier in the century. The so-called 'Flynn effect' appears to have tapered off in the twenty-first century.

In their controversial book, *The Bell Curve* (1994), Richard Herrnstein and Charles Murray argued that IQ is important for success in life, and that differences between ethnic and other groups in life success can be attributed in part to differences in IQ. They speculated that these differences might be genetic. As mentioned earlier, at this time, this statement remains speculative.

Recent research, reviewed by Samuel Mandelman and Elena Grigorenko in 2009, attempts to identify the genetic loci of individual differences in intelligence. Research in this area has been challenging, as some of it has utilized small numbers of cases, or only extreme cases. Some possible loci of intelligence have been identified, but replications are needed. Moreover, intelligence almost certainly appears to be diffusely represented across genes rather than localized in any small number of genes.

Richard Nisbett in 2009 reviewed the literature on the malleability of intelligence and concluded that, although it is not possible to transform people with intellectual disabilities into geniuses, there is good evidence that intelligence can be improved through good schooling and through various kinds of mental exercises. Thus, there is reason to believe that, for those who wish to improve their intelligence, at least small gains are well within the realm of plausibility.

Glossary

Allomothering An arrangement between a collective of females to cooperate in rearing their offspring.

Estradiol A hormone that co-occurs with ovulation.

Fecundity cues These are cues that signal an individual is likely to bear numerous offspring.

Heuristic A decision shortcut that is best described as a 'rule of thumb.'

Life history theory A mid-level evolutionary theory accounting for species-level and individual-level tradeoffs

between the allocation of bioenergetic resources to survival and mating.

Proximity Located near one another.

Serotonin A neurotransmitter associated with feelings of bonding, empathy, and happiness.

Sex ratio More specifically, the operational sex ratio refers to the ratio of sexually reproducing members of each sex.

Socioecology A composite of biological, environmental, and social factors that compose the environment.

Introduction

What do women want? What do men want? Why do people cheat? Why does sexual harassment and rape occur? Modern answers to these questions come from two paradigms. The sociocultural paradigm argues that because of differing access to economic resources either today or over generations, men and women have different mating psychologies. Specifically, because women have historically had limited access to economic resources, it makes sense for them to acquire such resources through their mates. The other approach is based on evolutionary theory, and posits that men and women differ with respect to unique, recurrent adaptive challenges they faced over evolutionary time. Whereas the sociocultural paradigm tends to be based on cultural norms and proximate factors, an evolutionary approach emphasizes on more ultimate causations, drawing upon theories and findings from biology, anthropology, and ethology. Specifically, humans may have evolved certain psychologies in mating and other domains that enable them to reproduce more successfully. In this article, we focus on the evolutionary perspective, as much of the theoretical developments and empirical findings in human mating have emerged from this perspective in recent years.

Parental Investment Theory

Parental investment theory enables evolutionary psychologists to formulate hypotheses and make predictions regarding sex differences in mating strategy. According to this theory, the sex that is physiologically required to invest more in offspring evolves to be more choosy regarding mates, because a mating error (mating with a low-quality or noninvesting partner) is more costly to that sex. In other words, it is in the reproductive interest of the higher-investing sex (actually, their genes) to avoid mating with low-quality mates. In contrast, it is in the reproductive interest of the non- or lesser-investing sex to be intrasexually competitive in order to gain access to members of the more valuable sex. In the vast majority of mammals,

females are physiologically required to invest more heavily on their offspring; thus, they have evolved to be the choosier sex.

For humans, sexual activity can lead a woman to incur several months of pregnancy and (in ancestral times, when mating psychologies evolved) years of nursing. Although human males often invest in their children, a copulation is the extent of their physiological obligation to parenting. Thus, relative to one another, women, who have to invest much more, have evolved to prefer long-term, committed relationships with high quality and resourceful partners, whereas men have evolved to prefer short-term, casual sexual relationships with numerous fertile partners (those who, upon having sex, are likely to become pregnant).

Consistent with this theory, research has shown that women, more than men, try to slow the speed at which relationships escalate to sex, have a lessened willingness to engage in casual sex, and engage in short-term mating as a way to better access long-term relationships. In contrast, men, who have low costs associated with casual sexual encounters, tend to desire easy and quick access to willing partners, be patrons of adult entertainment (i.e., strippers, prostitutes, and pornography), fall in love quickly (in order to convince partners of their commitment and thus, to induce sexual activity), be aroused by fecundity cues, and be more willing to engage in casual sex.

Mating Systems

Because human offspring require several years of nurturance and benefit greatly from biparental care, human mating systems tend to be centered around long-term relationships and marriage. The exact form that such relationships take depends on both biological and socioecological constraints that occur both intersexually and intrasexually.

Marriage and Long-Term Relationships

The sex ratio for each marriage can involve one man and one woman (monogamy), one man and many women (polygyny),

or two or more men with one woman (polyandry). Which form predominates depends on the access that men have to resources. Polyandry tends to occur where resources are difficult to acquire. For instance, in mountain farming communities, resources are scarce – they are extracted from the earth in a labor-intensive manner whereby the collective effort of multiple males are necessary to produce enough resources to sustain a single family. In other words, on their own, men in these communities cannot individually afford a wife and family, so they team up. However, they team up not randomly, but with brothers, who are genetically related. These ecological constraints instigate a situation that, on average, is beneficial to the female, but less than ideal for the individual males.

In contrast, polygyny tends to occur where there is large variance in the amount of resources that men have. Whereas many men are very poor with little or no resources, some are able to accumulate and defend an immense amount. If famines occur, men with plentiful resources would still be able to feed their families, whereas poor men may have no means of keeping their families alive. In such circumstances, wealthy men are able to attract and secure many wives. Indeed, various kings and emperors have each had hundreds of wives and evidence suggests that polygyny has been pervasive throughout human history. In today's societies, mating arrangements seem to follow a form of mild polygamy. That is, most people mate with more than one person throughout their lifetime, but do not commit to more than one person at the same time for a life-long partnership.

Long-term relationships encompass not only marriages but also (at least in modern societies) monogamous dating relationships. In long-term mating contexts, both sexes would be investing heavily in a single partner and any subsequent offspring. As such, it makes sense that each sex would have high standards in mate quality and value traits that denote good long-term potential. Indeed, social and evolutionary psychologists have found that this is the case: for committed, long-term relationship partners, both sexes are very selective. Both large-scale international studies and smaller-scale studies have shown that men and women both want long-term mates who are kind, have a sense of humor, and are intelligent. However, in line with sex differences in what constitutes reproductive value, men value physical attractiveness and youth (because women who are young and physically attractive are likely to be fertile and have many fertile years remaining) in their long-term mates more whereas women place higher value on a potential partner's social status and resources (and thus, ability to invest in potential offspring).

Short-Term Relationships

Although most people in most societies get married, not all human mating relationships are for the long term. Some individuals mate by engaging in casual sex. Short term, casual sexual relationships have recently been investigated by various researchers. Typically, researchers have focused on the one-night stand. In such relationships, individuals meet and go relatively quickly from zero-acquaintance to the act of sex and then back to zero-acquaintance. There is little promise of future relationship potential. Although relatively rare in actual occurrence, the one-night stand is theoretically

important because, when compared to the committed, long-term relationship, it illustrates key sex differences.

Although men are by no means exclusively interested in this type of relationship, they are much more willing to engage in such behavior than women are. In a noted study that has been replicated numerous times, confederates asked strangers in a campus mall one of three questions: Will you go on a date with me? Will you go back to my apartment with me? Will you go to bed with me? Although half of women and half of men said yes to a date, very few women agreed to going back to a stranger's apartment and not a single woman agreed to the overtly sexual invitation. In contrast, men's likelihood of agreeing increased as the prospect of sexual activity increased (about 75% of men said yes to sex; many of the other 25% apologized or attempted to reschedule).

Women do engage in casual sex behavior, albeit more sparingly and perhaps more strategically. Although women reproductively benefit the most from having a long-term partner who is both genetically fit and who invests plentiful resources, such men tend to be in short supply and to not be monogamous. Thus, women may enact a mixed mating strategy: securing the investment of one man as a long-term partner, but obtaining higher quality genes from another (more physically attractive) man, via sexual affairs. Indeed, an extensive line of research on women's menstrual cycles has found that when they are ovulating (and thus, most likely to conceive), women are most likely to engage in extrapair sex and their psychology seems to be aligned toward attracting extrapair partners. Women who are ovulating tend to be more scantily dressed, more likely to go out without their long-term mate, likely to have more sexual fantasies – but about men other than their primary partner, and may even release a pheromone that increases sexual arousal in men. Moreover, when women are ovulating, their male partners tend to guard them more (e.g., keeping tabs on their whereabouts). Around ovulation, women have a pronounced preference for men with masculine and symmetrical features, who presumably are more genetically fit.

In addition to those playing a mixed mating strategy, women may seek sexual encounters when they are single. Such women tend to be those who have more testosterone and score high on measures of sociosexuality (i.e., willing to have sex without signs of love and commitment), but may also be attempting to secure a long-term relationship partner by casting a wider (sexual) net or to extract immediate resources from a man who lavishly spends money.

Hybrid Relationships

Whereas long-term, committed relationships (e.g., marriage) and short-term, casual sexual relationships (e.g., one-night stands) represent opposite types of relationships, there are various relationships that are somewhere in between, with elements of each. Such relationships include the booty-call, friends-with-benefits, and swingers. The former two are situations in which individuals with some level of acquaintance engage in sex, but are not committed to each other. Between one-third and one-half of college students report engaging in these types of mateships.

Such relationships can potentially be viewed as market-driven compromises between men's and women's ideal

relationship types. That is, men would prefer to have casual sex with whomever they want, but women are unlikely to provide this. In contrast, women tend to want commitment, but men are not always offering that. Hybrid relationships tend to provide women with access to mates they would be unable to attain as monogamous, fully committed partners. For men, these couplings may provide sexual access for a relatively low level of investment. Thus, in the process of implicit negotiations taking place between individuals in the mating market, each sex gives some ground in order to facilitate a mateship that takes the form of a hybrid relationship.

Another form of compromise between the sexes might be consensual nonmonogamy (CNM). Between 25% and 75% of Americans have reported engaging in extramarital sex, but it is unknown how much of this is cheating and how much is actually consensual. CNM consists of three main types of relationships: swinging, polyamory, and open relationships. Swinging consists of couples who are involved in a serious, romantic relationship (usually marriage), but also engage in some degree of partner-swapping. Polyamory is based on the idea that one can be in love with, and committed to, multiple partners. Open relationships are quite variable and can consist of anything from casual to committed dating with more than one individual. All of these relationships typically involve explicit negotiation. First, both partners discuss whether or not they want to be nonmonogamous and what the terms of their relationship will be. Second, each sex may be motivated to pursue this relationship option to satisfy some of their needs that are not being met in their current relationship. For instance, CNM may provide increased sexual variety (more appealing to men) and the chance to obtain further intimacy (more appealing to women). Scientific understanding of such relationships is still, however, rather limited. Thus, future research is needed to more carefully explore the motives behind these relationships.

Homosexuality

A common criticism of evolutionary psychology is that it only explains heterosexual behavior. From noteworthy reports by Janus and Kinsey, we know that up to 10% of men and 5% of women report being homosexual; these rates have remained reasonably stable over the last 60 years. Furthermore, twin studies have indicated that homosexuality is up to 50% heritable. Superficially, being homosexual should decrease one's inclusive (reproductive) fitness because the person does not mate. Thus, it does not seem to make sense how homosexuality persists. Evolutionary psychologists suggest three adaptive mechanisms under which homosexuality can be maintained in a population. First, it is possible the relatively low rates of homosexuality in either sex are detecting random variation in sexuality – mutations occurring at constant rates over time. Second, homosexuals, although not reproducing themselves, might increase their fitness indirectly by helping their nieces and nephews; a prediction not well-supported, however. Third, it could be that homosexuality, especially in females, is a conditional mating strategy. Research on conditional mating strategies describes how individuals adjust their mating strategies as result of being unable to satisfy their fitness interests.

If there is limited access to quality men in a population a woman may benefit from allomothering. Sex, in this case, would confer upon two females the important function of bonding as it plays in Bonobos. There is evidence in sea-birds that two females will pair-up to rear an offspring together when there are limited males. In this case, male homosexuality could either be a by-product of the flexibility or erotic plasticity present in females, or have alternative nonreproductive functions (e.g., establishing dominance, releasing sexual aggression).

Whatever the mechanisms maintaining homosexuality in the population, sexual orientation may be separate from other elements of a person's psychology. For instance, even though many homosexual men have hundreds more sexual partners than typical heterosexual men do, this is not because of having a greater sex drive *per se*. Rather, homosexual men have similar preferences for casual sex with young and attractive mates; however, because they serve as each other's mates, they do not encounter the more selective constraints imposed by women. Relative to men, women have a higher need for emotional intimacy and lower needs for sexual variety, and these aspects tend to be characteristic of homosexual female couples. Implicitly, heterosexual couples must reach an agreement in order to have a relationship. Such negotiation may be less applicable or contentious among homosexual relationships wherein both sexes share preferences and psychological dispositions regarding sexual interactions.

Clash of the Sexes

Once individuals have implicitly negotiated their way into relationships, the sexes may also come into conflict once such relationships are under way. In this section, we review research on infidelity, how men and women conflict on inferring sexual intent, and aggression in relationship contexts (i.e., sexual harassment and rape). All three of these may be manifestations of a breakdown of the implicit negotiation between sexes.

Infidelity

Perhaps the most well-known manifestation of intersexual conflict is the case of infidelity. While marriage occurs in all known cultures, rates of extramarital affairs hover between 25% and 75% in reports by Hite and Kinsey. In cross-cultural research, it appears in as many as 160 cultures and is the primary reason for divorce. Why might people cheat? Popular media portrays cheating as the acting out of juvenile fantasies or the result of some psychological impairment such as low self-esteem or a dysfunctional parent-offspring relationship. Although these are possible explanations, there are also more systematic factors to consider.

Proximate factors abound mostly in personality traits. The most popular taxonomy of personality is the Big Five personality traits – extraversion, emotional stability, conscientiousness, and openness. The Big Five provide a cross-culturally replicated, methodologically robust, and highly predictive means of understanding individuals. Low agreeableness and conscientiousness have been implicated in infidelity in small and large-scale international studies. As would be expected,

individuals' sociosexuality – the degree to which individuals find casual sex acceptable and their casual sexual behaviors – is also associated with rates of infidelity.

Unfortunately, most of this work tends to be descriptive. Some new work that has a strong theoretical backing is based on a mid-level theory called Life History Theory. This theory suggests those who have antisocial personality traits like the Dark Triad – narcissism, psychopathy, and Machiavellianism – may enact an opportunistic life strategies. The Dark Triad appear to be associated with (1) a short-term mating disposition, (2) a rejection of long-term mating, (3) a high number of sex partners in one's lifetime, (4) increased rates of mate defection, and (5) generally, a *fast* life strategy. Effectively, these personality traits predispose individuals to have a 'take the money and run' life strategy and a 'hit and run' mating strategy. Although these traits are higher in men than in women because men suffer fewer costs by inhabiting a *fast* life strategy than women do, women who are high on these traits may also benefit from short-term matings enacted through infidelity.

Numerous reasons have been proposed for why people may engage in some form of short-term mating. All of them suggest a more strategic approach to short-term mating in women than in men. That is, men engage in short-term mating as a function of their generalized disposition toward low investment sex. Women, who may pay a higher penalty for infidelity, may engage in infidelity for more specific reasons. For example, a woman might be unfaithful (1) to test her value on the market, (2) to motivate her partner, (3) to get good genes from the partner with whom she cheats, (4) to access greater resources, (5) for more protection for her and her offspring, and perhaps more. Whatever the reason may be, personality traits may predispose individuals to pursue certain fitness-relevant goals on different time-scales.

However, the primary limitation of most work on infidelity we have discussed thus far is based on self-report data; the problems of which have been clear in psychology since at least 1978. Modern research has begun to integrate non-self-report measures in the form of physiological and hormonal assays; data that tends to pack more of a punch. This is because it is rather hard to argue that a biological/physiological factor could be the result of some social role or learned behavior. As far as we know, individuals have no control of or access to their hormones. Therefore, findings links between hormones and infidelity provides strong evidence consistent with an evolutionary approach. In men, greater levels of testosterone and lower level of serotonin are associated with greater numbers of sex partners and a greater likelihood of committing infidelity. In particular, men who have high testosterone and low levels of serotonin are selected by women as short-term partners and, therefore, are able to pursue their preferred mating strategy.

When women are ovulating they experience high levels of estradiol and they report a large series of attitudes and commit behaviors that facilitate committing infidelity. Ovulation is linked to (1) conception rates, (2) preferences for the odor of men who are high in testosterone, more masculine faces, more masculine bodies, lower voice pitch, and men who display social presence and direct intrasexual competitiveness, (3) more flamboyant dancing, (4) a tendency to wear more revealing clothing, (5) self-reports of increased willingness to flirt, kiss, date, have a one-stand, and a serious affair with

another man, and (6) tendency to go out with their friends instead of their partner. Estradiol also seems to make women more attractive in terms of a lower waist-to-hip ratio and lower levels of fluctuating asymmetry (the degree to which a person deviates from a bilaterally symmetrical appearance). Women have a generally slower mating disposition, but during ovulation women may benefit enough from short-term sexual interactions to risk infidelity.

Adaptive functions of infidelity and reactions to infidelity

From an evolutionary perspective, infidelity signals the diversion of important reproductive resources. For a woman, an unfaithful partner may be investing resources in another woman. This is a particular concern for women given the high degree of investment they are saddled with for their offspring. As we noted above, women are attuned to not only detect a man's willingness to commit but to also slow down his rate of access to sex until he shows clear signs of investment potential and commitment. Consistent with these inclinations, women tend to be more bothered by emotional infidelity than sexual infidelity.

In contrast, sexual infidelity poses a more serious reproductive problem for men than women. Sexual infidelity from a female partner greatly increases the level of paternity uncertainty. Because men cannot be certain that any children are theirs, they may have evolved to be attuned to cues of an unfaithful partner. Ancestral men who were indifferent to sexual infidelity risked investing in other men's children and tended not to leave descendants. Indeed, men are more bothered by sexual infidelity than emotional infidelity. Stronger female reactions to potential emotional infidelity and stronger male reactions to potential sexual infidelity are generally consistent across populations, techniques, and researchers.

However, it is noteworthy that there is at least some work suggesting that men and women should not differ in the degree to which these types of infidelity bother them because (1) both sexes feel that one type of infidelity will lead to the other type and (2) individuals in the Environment of Evolutionary Adaptedness (the time during human history when heritable psychologies, such as ones for jealousy, would have arisen) would not necessarily be aware of the direct connection between sexual relations with a particular man and the birth of a child given the 9 month gestational delay between sex and childbirth. Some cultures still believe in partible paternity – that is, the idea that more than one father can contribute biological materials to a child, and share in paternal responsibility. This idea of paternity might be beneficial to females, and could mean that human mating is more complex than previously assumed.

Moreover, there is a battery of behavioral albeit indirect evidence to show that men are especially attuned to sexual infidelity. For instance, step-children and children who do not resemble the male parent are at much greater risk of being neglected and abused. Children living with one genetic and one step-parent are 40 times more likely to be physically abused. Preschool aged stepchildren are 40–100 times more likely to be killed. Not only are men more likely to endanger the life of stepchildren and those who do not physically resemble them, they may commit partner-directed violence. Men who do not perceive physical resemblance to their children are more likely to severely beat their wives. Evidence also suggests that

when dating a particularly attractive woman, men may actually aggress toward the woman and the woman's extra-pair partner in response to infidelity. However, these problems do not just trigger one's response. Indeed, when a man is mated with a highly attractive, youthful, and potentially fertile mate he may be more willing to tolerate cuckoldry. Generally, men who tend to be of lower value on the mating market than their partners are more likely to engage in mate guarding and mate retention. As an enticement for their partners to stay in the relationship, these men may dole out gifts and affection to compensate for shortcomings, including low physical attractiveness. Whether it takes the form of mate retention, mate guarding, or aggression, males seem to have evolved mechanisms in response to the problems of female infidelity.

Although jealousy is the most well studied emotional response to ongoing or potential infidelity, depression, anger, and self-reproach are other large categories of emotional reactions to infidelity. These systems seem to be finely tuned to the nature of the infidelity. Individuals, upon learning of infidelity, attempt to gauge the nature of it by probing for more information in order to decide what to do about the apparent violation. Emotions give people heuristic-based information about how to proceed. In cases where individuals had an ongoing relationship with their infidelity partner, this is likely to cause more distress compared to a single episode. Indeed, women are more likely than men to forgive a single sexual transgression.

Sex Differences in Inferring Sexual Intent

How does one know if someone else wants to have sex? Do men and women have a predisposition to make judgments that may serve their fitness interests? In a word, yes. Studies by social and evolutionary psychologists indicate women underestimate the degree to which a man will commit to them and men overestimate the degree to which a female wants to have sex with them. Many decisions effectively pit a Type I error (i.e., falsely assuming a particular state exists) against a Type II error (i.e., falsely denying the existence of that state), whereby one error is costlier than the other. For situations of reproductive consequence that recurrently presented themselves in ancestral environments, humans should have evolved a systematic bias to make decisions that favor the less costly error. For males, a Type II error – inferring a lack of sexual interest when it is actually present – would be more costly because female sex partners are in short supply. For a woman, a Type II error, falsely interpreting that a man's commitment is insufficient, and thus requiring more evidence of commitment before engaging in sexual relations is not a costly error: it encourages displays of quality, greater investment, and more commitment from would-be partners.

Research demonstrates men are not simply projecting their own views onto their perceptions of sexual intent in opposite-sex others – a man's perceptions of women's sexual intent is not the same for a potential mate as it is for his sister. This suggests men are not simply ascribing greater sexual intent to all women; rather, only to those who constitute potential partners. Indeed, self-reports suggest women who are friendly have experienced men's tendency to think that those women are sexually interested. In short, this causes conflict between the sexes because of evolved cognitive biases in how they interpret the actions

of those with whom they could mate. These biases are the result of recurrent asymmetries in the costs associated with decisions in the mating contexts. Here we discuss a number of ways in which this misunderstanding manifests itself.

Sexual Harassment

In the modern workplace, men and women spend much time coming into contact with each other and getting acquainted. As a result of this propinquity, the workplace is an environment that may be especially conducive to the development of potential romantic relationships. However, this also means it is a setting in which conflicts in mating strategies may readily occur. Up to 90% of women report having been sexually harassed at work, with about 10 000 cases filed in the United States in the last 20 years costing \$48 million in victim-compensation. By today's standards, sexual harassment in the United States includes staring in a sexually suggestive manner; making offensive remarks about looks, clothing, or body parts; touching (e.g., patting, pinching, or intentional brushing against another's body); telling sexual jokes or displaying sexually suggestive posters; making sexual gestures; and sending, forwarding, or soliciting sexually suggestive letters, notes, emails, or images. Consistent with the divergence in reproductive strategies, the large majority of complainants are female, although the percentage of male complainants is slowly increasing.

From an evolutionary perspective, sexual harassment occurs when people in the workplace experience a conflict between the mating strategy they desire to utilize and what is allowed by other persons or contextual factors. Because men are (1) more eager to engage in sex with others and (2) likely to overestimate sexual interest in target females, they may pursue women who do not want them or in work contexts where it is deemed by societal standards to be inappropriate. Those who are sexually harassed most commonly are women who have the most reproductive value vis-à-vis being youthful and attractive. In addition, individuals perceive it is these women who pose the greatest threat for filing sexual harassment claims. Laws governing sexual harassment discourage and punish the perpetrator, typically men, from pursuing an eager sexual strategy and acting upon potential overperceptions of sexual interest.

Importantly, the definition of sexual harassment suggests sexual attention may not be considered harassment if it is welcome. In other words, if no strategic interference has taken place and both parties are explicitly or implicitly amenable to potential sexual relations, then no one will be motivated to seek legal redress, and they may not be awarded any compensation if they do. Such a distinction appears to be reflected in perceptions of sexual harassment. In short, the interpretation of sexual harassment is a function of the degree to which the target of the advance is attracted to the advancer. Advances from men who are viewed as having high value in the mating market vis-à-vis being successful and physically attractive are less likely to be seen as harassment.

Rape

Sexual harassment, although expensive and even psychologically troubling, is relatively benign compared to perhaps the

most drastic result of the failed negotiation of the sexes in mating: rape. A note of caution to the reader: evolutionary accounts of rape by no means justify the behavior. Explaining phenomena by no means excuses it. There are numerous reasons to be appalled by this behavior, but one must not allow moral judgments to interfere with one's ability to examine a phenomenon dispassionately as scientists strive to do. Nevertheless, because this is such a contentious topic we delineate the research about this topic in detail.

Rape in humans is a subject of intense study, with the number of studies on the topic steadily increasing since the 1960s and rates that are fairly consistent around the world. Between about 15% and 50% of females in countries like the United States and New Zealand report some experience with sexual coercion/rape. However, these events seem to most commonly be perpetrated by nonstrangers such as acquaintances, boyfriends, or husbands (80%) and much more rarely by strangers (20%). Thus, studies indicate the majority of sexual coercion occurs not between strangers, but between acquainted individuals who are within a mating context. Therefore, as with sexual harassment, the role of differing mating strategies should be viewed when considering and understanding rape. It is between those who know each other that negotiations can break down, and sexual conflict can occur.

Within an evolutionary psychological framework, some theorists have proposed that rape might be an adaptive, conditional mating strategy. As a result of being unable to get the mates one wants, some men may use rape as a last-ditch solution to solve the adaptive problem of mating. However, this is a rather risky solution given that women, her family, and her friends may have antirape adaptations (e.g., women may have male friends to act as body-guards) and any subsequent offspring may not have two parents or that child may be abused or neglected, thereby decreasing the chances that any resultant offspring will survive. Therefore, while rape might provide some reproductive benefits, the rapist must take into consideration the costs of pursuing this mating strategy. Nevertheless, there may actually be some psychological systems that have evolved to allow men to detect which potential victims would incur fewer of these costs. Some of these psychological adaptations include being able to assess the vulnerability of potential rape targets, a rape mindset that activates when sexual access to consenting partners is not attainable, preferences for young and fertile females, and sexual arousal in response to female resistance to men's sexual advances.

The most direct evidence of rape's potential reproductive benefits comes from pregnancy rates of rape victims. When researchers adjust for contraceptive use, rape-pregnancy rates are near 8%, significantly greater than consensual pregnancy rates of about 3%. The majority of rape pregnancies were also concentrated in the 15–24-year-olds; of the 26 rape pregnancies reported, 21 (81%) occurred in this age range. However, rapists' targeting of reproductively aged women may be a by-product of men's preferences for women within this age range – they are at peak fertility – or some unknown mechanisms to detect ovulation in men. It might be argued that this finding is a by-product of women in this age group being more likely to associate with young men, who are themselves the age group most likely to engage in criminal activities in general. However, when age distributions of rape and murder victims were compared,

murder victims tend to be older than rape victims, and are not concentrated among individuals in their 20s.

The mate deprivation hypothesis has not received much support with respect to its prediction that men who are unable to obtain mates because of low value in the market (e.g., socioeconomic status) are any more likely to commit rape. In fact, men who reported being physically and nonphysically sexually coercive also reported having higher mating success and more sexual experience. Such an account suggests that rape may not be an evolved, condition-dependent mating strategy, but instead, could be a by-product of men's increased sexual desire. However, this may be because men's rape adaptations may be more varied than previously thought. Recent work suggests as many as five domain-specific types of rapists that respond to certain contextual cues to motivate the act of rape: disadvantaged men, specialized rapists, opportunistic rapists, high-mating-effort men, and partner rapists. More research in this area is certainly needed to better understand this phenomenon.

Summary and Conclusions

Because of fundamental differences in minimum required parental investment, men and women have evolved to ideally prefer different types of relationships. On the one hand, women tend to prefer having long-term relationships with high quality men who commit and invest plentiful resources. On the other hand, men tend to favor having easy sexual access to many fertile women. Because human infants benefit greatly from a long period of biparental care, human mating tends to be centered around long-term, committed relationships. Indeed, some form of marriage, whether monogamy, polygyny, or polyandry – is found in most societies.

Nevertheless, noncommitted sexual relationships are also quite prevalent. For instance, individuals may seek sexual affair partners outside of an ongoing long-term relationship. In particular, around the time of ovulation, women are more open to having sexual affairs with physically attractive men, who may be more genetically fit than their current partner. In addition to mixed mating strategies that involve having long- and short-term relationships at the same time, individuals may engage in hybrid relationships (e.g., booty-calls, friends-with-benefits, and swinging), which tend to be largely sexual but contain at least a minimal level of investment or continuity. Such relationships may effectively represent compromises in the mating market between men's and women's ideally preferred relationships. Sometimes, however, the sexes' opposing interests result in conflict, wherein the pursuit of one's own mating strategies comes at the expense of one's partner's. Specifically, conflicts can take the form of sexual harassment, intimate partner violence, or rape.

In presenting this article on human mating, we have relied on an evolutionary approach to mating psychology. Although not the only perspective on mating, an evolutionary approach has fueled much of the interesting research that has emerged in recent years on mating. It is also the only perspective that is connected to theories of all living things, including biology, anthropology, and ethology. At all levels of human mating, evolutionary theory is informative about the pursuit of sex as well as the battle of the sexes.

Hypnosis

S J Lynn, Binghamton University, Binghamton, NY, USA

© 2012 Elsevier Inc. All rights reserved.

Glossary

Hypnotherapy Addition of hypnotic procedures to accepted psychological or medical treatment.

Hypnotizability or hypnotic suggestibility Observed or reported responsivity to suggestions following a hypnotic induction, as indexed by behavioral and subjective measures.

Indirect suggestion Compared to traditional authoritative suggestions, they generally contain more subtle, indirect, or implicit cues, are more permissive, ambiguous, and less obviously related to the response sought by the hypnotist.

Induction Verbal or nonverbal communications or procedures intended to induce a 'hypnotic state' or increase subsequent responsivity to hypnotic suggestions.

Simulator Low suggestible subject instructed to fake the behavior and/or subjective reports of an excellent hypnotic subject. This is typically done in accordance with Orne's simulation paradigm in which the simulator is informed that the experiment will stop if the hypnotist sees through the deception.

Introduction

The term 'hypnosis' refers to a social influence situation in which a person designated as a hypnotist attempts to influence the experiences and behaviors of a subject or patient. The suggestions administered in the hypnotic situation typically call for changes in sensation, perception, affect, memory, cognition, and control over behavior or psychophysiological processes. It is useful to think of these suggestions as divided into two phases, induction and application, although in practice these may not be entirely distinct. Historically, a wide variety of induction procedures have been used. These include waving hands over patients and having them ingest substances. Many of these methods are rarely if ever used now. Procedures that are currently in vogue involve asking subjects to close their eyes and telling them to sleep, instructing them to relax, having them fix their gaze on an object or their attention on an idea, suggesting various images or automatic movements, telling them stories, and so on. Most inductions include suggestions for relaxation. However, inductions involving physical tension and alertness are as effective as relaxation inductions in enhancing suggestibility. The suggestions included in many hypnotizability scales typically involve motor behaviors (e.g., hand levitation), challenges to the subject (e.g., 'try to lift that heavy hand, just try'), and the so-called cognitive-perceptual suggestions that encompass positive and negative hallucinations, dreams within hypnosis, and posthypnotic amnesia.

People vary substantially with respect to their ability to experience hypnotic phenomena, and range on a continuum of hypnotizability, according to the number of suggestions they pass. For example, subjects who pass 3 or fewer suggestions on a 12-point standardized scale of suggestibility are, conventionally, regarded as low hypnotizable (about 15–20% of the population), subjects who pass 4–8 suggestions are regarded as medium hypnotizable (about 60–70% of the population), and subjects who pass 9–12 suggestions (about 15–20% of the population) are regarded as high hypnotizable. Many people are more responsive to suggestion after an

induction than they were before, but the average increase in suggestibility is on the order of 10–20%. Moreover, the nature of the induction appears to have little bearing on hypnotizability.

Hypnotic suggestibility is relatively stable, with test–retest reliability as high as 71 at 25-year follow-up. This stability has been variously described as a reflection of the trait-like aspects of hypnotizability versus a reflection of subjects' attitudes and beliefs about hypnosis, and interpretations of hypnotic suggestions that remain stable over time, unless subject to modification procedures described below.

A hypnotic induction is not, in itself, a treatment for psychological disorders. After the induction, a wide variety of applications have been used in hypnotherapy, which often involves a blending of ideas and techniques from different theoretical perspectives. The appropriate use of hypnosis is an adjunctive treatment, rather than a treatment in itself for any disorder. Hypnotherapy can be defined as the addition of hypnosis to accepted psychological or medical treatment. As such, it should only be practiced by professionals, who have the appropriate training and credentials to provide the treatment that is being augmented by hypnosis.

Often, perhaps in the majority of the cases in which hypnosis is used clinically, hypnotic procedures are framed in terms of self-hypnosis. Many clinicians inform clients that they are ultimately responsible for generating suggestion-relevant imagery, experiences, and behaviors. Self-hypnosis is most frequently taught by first introducing the client to traditionally administered hypnotic techniques and then encouraging the client to assume increasingly greater responsibility for devising suggestions appropriate to achieving treatment goals. In self-administering therapeutic suggestions, the client replaces the therapist as the active agent in the therapeutic proceedings. Therapists often make customized tapes for clients to listen to at home or at work. This is done in order to minimize dependency on the therapist, generalize treatment gains, and encourage mastery of self-suggestions that can be implemented, in the absence of the tape and the hypnotist, in a variety of situations.

History of Hypnosis

Since the beginning of recorded history, procedures that are today labeled 'suggestive' have been used to treat a wide range of physical disorders and psychological disturbances. For example, religious healing rituals such as 'dream healing' in Ancient Greece, and exorcism in Medieval Europe, attest to the importance of psychological factors in easing discomfort and, at times, producing beneficial physiological changes.

In the seventeenth and eighteenth centuries in Western Europe, religious explanations and treatments for physical and psychological disturbance practiced were gradually replaced by naturalistic explanations and treatments. Mesmer, a Viennese physician, developed one of the best-known naturalistic explanations in the eighteenth century. Mesmer believed that an invisible fluid that he labeled animal magnetism permeated the universe. Supposedly, sickness resulted from a disruption in the harmonious flow of this fluid through the body, and a healer (magnetizer) could produce a cure by passing his hands close to the patient's body and thereby transmit the magnetic fluid. During this process, patients frequently experienced a range of unusual sensations and behavioral changes that ended in convulsions and in a diminution of symptoms.

Mesmer moved his practice to Paris where he quickly became a sensation among the cultural elite and gained ardent supporters, as well as powerful enemies among the medical establishment. Eventually, two Royal commissions, with luminaries including Benjamin Franklin and Lavoisier, investigated Mesmer's claims. With a series of clever experiments, the commissioners demonstrated that the behavioral changes seen in magnetized patients did not result from the flow of an invisible fluid, but instead reflected the patients' expectations, beliefs, and imaginings. On the basis of the negative reports by the commissions, French physicians were banned from practicing magnetism. Despite the ban, magnetism flourished. It soon became associated with the occult as well as with healing and, in various forms, was transported to countries throughout Europe and also to America.

In England, as in France, magnetism underwent oscillating periods of acceptance and rejection by the medical establishment. In the middle of the nineteenth century, Braid, a Scottish physician, witnessed a stage demonstration in which a subject got magnetized by staring at a shiny object. Braid rejected the fluid theory of magnetism and hypothesized, instead, that the behaviors of magnetized subjects resulted from neural inhibition that flowed backwards from the eyes (strained by staring) to the brain and produced a condition akin to sleep. Braid labeled this phenomenon as neurohypnosis, and the shortened name, 'hypnosis,' gradually replaced the name magnetism.

As Braid gained more experience, he realized that the behavior of hypnotic subjects was greatly influenced by ideas and expectations transmitted to them by the hypnotist. He modified his earlier theory of neural inhibition and developed the theory of monoideism. Monoideism was based on ideomotor action in which vivid ideas or images that remain uncontradicted in the mind of a subject lead automatically to the corresponding action. Thus, if a person vividly imagines that his or her arm is light and rising in the air, and if this vivid imagining is not

contradicted by other thoughts, then the vivid imagery will lead the arm to rise automatically.

Braid's early ideas about neurohypnosis strongly influenced the famous French neurologist Charcot. Unfortunately, Charcot was not influenced by Braid's later notion of monoideism or by his emphasis on how the hypnotist's expectations influence the subject's responses. Charcot studied patients who were diagnosed as hysterics and came to believe that hypnosis, like hysteria, reflected a neurological weakness, and that only hysterics could be hypnotized. According to Charcot, there were three stages to hypnosis, and each stage was associated with invariable behavioral symptoms. Charcot's notion of an association between hypnosis and hysteria influenced his pupil Pierre Janet, who came to believe that both hysteria and hypnosis involved dissociations between sets or subsystems of ideas.

Braid's work also influenced Bernheim, a well-known French physician from Nancy. According to Bernheim, hypnotic behavior resulted from suggestion. People differed in terms of suggestibility, and suggestions produced their effects by leading subjects to develop corresponding ideas that led via ideomotor action to hypnotic behavior. Bernheim rejected Charcot's notions that hypnosis was related to hysteria and that degrees of hypnosis were associated with invariant behavioral symptoms. Instead, Bernheim argued that Charcot inadvertently suggested to his hysterical patients those very behaviors that he came to erroneously believe resulted automatically from hypnosis. Charcot's ideas nevertheless remain significant today in so far as they underline the fact that by understanding hypnosis and suggestibility, it may be possible to better understand a wide range of experiences associated with psychopathology and unusual experiences (e.g., functional disorders of psychogenic origin, phantom limb pain, psychotic hallucinations).

Freud studied briefly with both Charcot and Bernheim. Nevertheless, he rejected the therapeutic use of hypnotic procedures. Freud's psychoanalysis became highly influential in both Europe and America and his rejection of hypnosis served to relegate it to the fringes of medicine and psychology for much of the first half of the twentieth century, with notable exceptions including the work of Hull and Young, whose systematic experimental studies and the development of suggestibility scales constituted important contributions.

Toward the beginning of World War II, White reviewed the available data concerning hypnosis and concluded that, because of their overly mechanistic nature, neither the theory of dissociation nor the theory of ideomotor action could adequately explain hypnotic responding. White argued that hypnotic behavior was goal-directed social action and that hypnotic subjects responded in terms of their ideas about what the hypnotist wished them to do. At the same time, however, White continued to believe that hypnotic behavior occurred during an altered state of consciousness that was characterized by subtle cognitive changes.

White's ideas greatly influenced the subsequent generations of hypnosis researchers and theorists, who variously described hypnosis in terms of an altered state of consciousness versus the product of suggestion and social and cognitive variables. White particularly influenced M.T. Orne, who apart from emphasizing the role of social factors in hypnosis attempted

to delineate cognitive changes unique to hypnotic response. Orne devised a simulator control methodology that compared the performance of low suggestible individuals who role-played the behavior of an excellent hypnotic subject with highly suggestible individuals who genuinely tried to experience hypnotic suggestions. Orne believed that this paradigm would enable the separation of those subtle cognitive characteristics that constituted the 'essence' of hypnosis from what he considered to be behavioral artifacts produced in response to social demands. Research using Orne's simulation design was important in demonstrating that a wide range of hypnotic responding that had been assumed to reflect a hypnotic state could be explained more parsimoniously in terms of the expectations transmitted to subjects by the social demands of the experimental situation.

The development of well-constructed, reliable standardized hypnotizability scales has done much to advance the scientific study of hypnosis. Early scales developed in the 1930s were important precursors to the more psychometrically sophisticated tests devised by Hilgard and Weitzenhoffer, who created the widely used 'Stanford scales' of hypnotic susceptibility in the 1960s, and Orne and Shor who developed the Harvard Group Scale of Hypnotic Susceptibility.

Since these pioneering efforts, many hypnotizability scales have been developed for different purposes and populations. These include brief tests for hypnotizability and tests for assessing waking suggestibility, hypnotizability in a group context, and hypnotizability with child populations. Scales of hypnotic depth have also been developed along with well-validated scales that tap the subjective aspect of hypnotic responsiveness. In general, hypnotizability tests are highly and positively correlated with one another, although some scales are better able to capture the subjective aspects of hypnotic experiences than other scales.

Neurophysiological research is one of the most intriguing and active areas of hypnosis-related inquiry. Researchers have established that hypnotic suggestions can produce impressive changes in brain activation that correspond, more or less, to those produced by actual perceptual experiences. Neurophysiological studies of hypnosis have implicated the anterior cingulate area of the brain involved in some alterations of consciousness experienced during hypnosis. To some researchers, findings like these provide evidence that hypnosis is a discrete state of consciousness. However, critics of this position reply that that merely documenting the physiological changes is insufficient to demonstrate causality between the altered subjective experiences than other scales.

Since the 1950s, interest in clinical hypnosis has bloomed in tandem with advances in the scientific understanding of hypnosis. Erickson's writings and his creative use of permissive, nonauthoritative, and indirect hypnotic suggestions, including the use of metaphors and storytelling, sparked interest in a wide range of clinical applications of hypnosis.

Over the past 40 years or so, hypnosis has increasingly moved into the orbit of mainstream psychology. Today, hypnosis research is routinely incorporated into empirically supported psychotherapies; myths and misconceptions regarding hypnosis have been dispelled by careful research; and hypnosis studies are published in well-respected psychology journals and have informed cognitive science (and vice versa) in meaningful ways.

Misconceptions About Hypnosis

Public education about hypnosis is important in so far as misconceptions (e.g., the Svengali-like power of the hypnotist) persist in the general population, partly as a result of the media's sensationalized depiction of hypnosis. Indeed, since the nineteenth century, mesmerism and later hypnosis have been associated with the idea of unusual and even supernatural capabilities. For instance, some of the nineteenth-century investigators argued that magnetized (and later hypnotized) subjects could see without the use of their eyes, travel mentally to distant planets and report back accurately about the inhabitants, spot disease by seeing the internal organs through the skin of sick individuals, and communicate with the dead.

Although scientific investigators no longer take these outlandish ideas seriously, unusual claims for hypnosis continue to be made. For example, some investigators argue that the use of hypnotic procedures enables people to recall their earlier abduction by space aliens, and others argue that hypnotic regression to past lives supports the theory of reincarnation. There is no more scientific evidence to support notions like space alien abduction and reincarnated past lives than there is to support nineteenth-century notions of mental space travel or seeing without using the eyes by magnetized somnambulists.

Many misconceptions and stereotypes about hypnosis derive from what is popularly known as stage hypnosis. The outlandish actions of people in shows have nothing to do with a trance state. In stage shows, the hypnotist carefully selects potential performers by observing how they respond to waking suggestions. Moreover, volunteers often feel compelled to do bizarre things because they are under intense pressure to entertain the audience. Many stage hypnotists also use the stage whisper technique, in which they whisper instructions ("When I snap my fingers, bark like a dog") into the volunteer's ears.

The study of hypnosis has done a great deal to eradicate many misconceptions about hypnosis. These include the belief that hypnosis produces a sleep-like state; that hypnosis is a dangerous procedure that robs people of their willpower; that hypnosis involves a radically altered state of mind and that one cannot 'come out' of this state; that hypnotized people cannot remember what occurred during hypnosis; and that only weak-willed people can be hypnotized.

We now know that hypnosis (1) is not related to sleep; people are just as responsive to hypnotic suggestions administered while exercising on a stationary bicycle as they are following hypnotic suggestions for sleep and relaxation; (2) is something done by the subject rather than by the hypnotist; and (3) does not produce spontaneous amnesia for the events that transpire during hypnosis. Scientists have also established that subjects neither lose touch with their surroundings nor relinquish control of their behavior – in fact, they can resist and even oppose suggestions. Moreover, many people do not experience hypnosis as much different from waking consciousness and instead report that they experience hypnosis as a state of focused attention. Finally, contrary to popular belief, subjects can experience many hypnotic phenomena, such as hallucinations and pain insensitivity when they receive suggestions alone, even without hypnosis.

Contemporary Theories and Research

Virtually, all hypnosis theorists agree that most people who receive a hypnotic induction, and are motivated to think and imagine along with suggestions can experience a wide variety of alterations in consciousness. Indeed, Amir Raz and his colleagues demonstrated that some highly suggestible individuals can completely eliminate Stroop interference following a posthypnotic suggestion to see the words in a foreign language. There is also agreement that most individuals, who undergo hypnosis, do not merely fake their subjective experiences or comply to please the hypnotist. However, beyond these points of consensus, there are sharp differences among theorists in their explanations of hypnotic phenomena. Indeed, theorists have proposed different and often conflicting accounts about the feeling of involuntariness that often accompanies responses to hypnotic suggestions and individual differences in suggestibility.

Psychoanalytic Theory

Freud was so impressed by the apparent submissiveness of certain hypnotized subjects, that he likened hypnosis to being in love. There is no evidence to support the idea that hypnosis fosters an erotic or sexual 'transference' relationship between the therapist and patient. Contemporary psychoanalytic theorists, including Baker, Fromm, and Nash, have instead relied more on concepts allied to ego psychology (e.g., relaxation of the general reality orientation, regression in service of the ego) in which hypnosis increases subjects' primary process thinking (e.g., fantasy, imaginative activity) and their ability to temporarily relinquish critical judgment and deliberate control of behavior.

Based on a review of more than 100 studies, Nash concluded that hypnosis does not permit subjects to literally 'age regress' and reexperience the events of childhood or function in a truly childlike fashion. Rather, Nash maintains that hypnosis engenders a type of regression with specific properties that include an increase in the primary process material, more spontaneous and intense emotion, unusual body sensations, the experience of nonvolition, and the tendency to transfer or displace core attributes of important others onto the hypnotist.

Support for psychoanalytic concepts has come from a number of quarters. Several studies are consistent with the proposition that hypnosis increases primary process thinking. Nevertheless, it is unclear whether increased primary process during hypnosis is attributable to suggestions for eye closure, relaxation, and attention to imagery, rather than to unique characteristics of hypnosis.

Many subjects report unusual perceptual and bodily experiences during and after hypnosis. However, studies indicate that the reports of the experiences of hypnotized subjects are indistinguishable from that of nonhypnotized subjects in a variety of different test conditions such as (1) sitting still with eyes closed, (2) relaxing, (d) imagining suggested events, and (e) focusing on parts of the body that are parallel to the parts that are the targets of hypnotic suggestions. Thus, although altered experiences are readily produced by hypnotic suggestions, they are by no means unique or specific to hypnotic conditions.

Studies support the hypothesis that certain hypnotic subjects evidence an especially motivated involvement with the hypnotist or cognitive commitment to respond to hypnotic tasks. Indeed, researchers have shown that improving hypnotic rapport may increase the responsivity of low hypnotizable subjects, while degrading hypnotic rapport has no appreciable effect on the responding of high hypnotizable subjects, who seem to be prepared to respond to the hypnotist, regardless of the nature of the hypnotic relationship.

Evidence of shifts in affect is mixed. However, the finding that hypnosis is associated with brain activation linked with emotional regulation provides support for the role of affect in hypnosis. Although psychoanalytic constructs provide a plausible account for reports of suggestion-related involuntariness, a variety of other theories do so as well.

Neodissociation Theory

After a long hiatus of interest in dissociation, in 1977, E.R. Hilgard published an influential book that revitalized the concept. Hilgard proposed a neodissociation theory on the basis of a contemporary cognitive model of divisions of consciousness, in which multiple cognitive systems or cognitive structures in hierarchical arrangement exist under some measure of control by an 'executive ego.' The executive ego or 'central control' structure is responsible for planning and monitoring functions of the personality. The induction of hypnosis serves to temporarily dissociate relevant subsystems of control from conscious executive control. Under these circumstances, hypnotic suggestions can directly activate dissociated subsystems (e.g., sensory and motor activity in the arm and hand, visual perceptions). This lack of conscious controls largely depends on an amnesic barrier or process that walls off ideas, emotions, and fantasies from consciousness. This diminished executive control and failure to monitor the ongoing action is responsible for the subjective impression of nonvolition that typically accompanies hypnotic responses.

The empirical roots of neodissociation theory can be traced to Hilgard's introduction of the metaphor of the 'hidden observer' to describe the phenomenon by which a person registers and stores information in memory, without being aware that the information had been processed. Hilgard and his associates' initial research on the hidden observer phenomenon involved experimental studies of pain and hearing. In a typical pain study, high hypnotizable subjects were able to recover concealed experiences or memories of pain during hypnotic suggestions for analgesia, when they were informed that they possess a hidden part that can experience high levels of pain during analgesia, and that this part can be contacted by the hypnotist with a prearranged cue. Research in Hilgard's laboratory has demonstrated that hidden observer reports can penetrate hypnotic blindness, hypnotic deafness, and positive hallucinations.

Hidden observer studies and their interpretation have been controversial. For instance, Spanos and his associates have shown that hidden observer reports vary as a function of the nature and explicitness of the instructions that subjects receive about the nature of the hidden observer. According to this perspective, the hypnotist implicitly or explicitly suggests experiences that produce the 'hidden observer.' The hidden observer, therefore, can be thought of as no different from

any other suggested hypnotic phenomenon that is guided by the subjects' expectancies and situational demand characteristics. Whether the hidden observer reflects a true or preexisting division of consciousness that is directly accessed by hypnotic suggestions, or whether it is a product of suggestion, continues to stimulate research and theoretical controversy.

Bowers and Woody presented a modified version of Hilgard's neodissociation model of hypnosis called dissociative experience theory, which rejects amnesia as fundamental to dissociation. Instead, Bowers and Woody proposed that dissociation is largely a function of the direct and automatic activation of subsystems of control by the hypnotist's suggestions. Kihlstrom has also extended neodissociation theory in interesting directions that incorporate concepts of modern cognitive psychology, including memory models and the distinctions between procedural and declarative knowledge. Kihlstrom's theoretical work emphasizes changes in the executive monitoring of thought and action, more so than control, and he has argued that such alterations in monitoring can account for a wide variety of hypnotic phenomena, including posthypnotic suggestion, hypnotic blindness, and hypnotic analgesia.

The Sociocognitive Perspective

Another influential view of hypnosis – the sociocognitive perspective – rejects dissociation as an explanatory mechanism. The term 'sociocognitive' captures this perspective's dual emphasis on the social and cognitive dimensions of hypnosis. Sociocognitive hypnosis theorists contend that hypnotic behavior is fundamentally mundane, role- or expectancy-governed social behavior.

The sociocognitive perspective can be traced to attacks on the concept of hypnosis as an altered state of consciousness. In 1950, Sarbin challenged the traditional concept of hypnosis as a state (e.g., hypnotic trance, hypnotic state). Sarbin contended that hypnosis could be conceptualized as 'believed in imaginings' and developed a theory that relied heavily on the metaphor of role to capture parallels between the hypnotic interaction and a theatrical performance in which both the hypnotist and the subject enact reciprocal roles. Sarbin and Coe elaborated the theory and conducted research that highlighted the contribution of the following variables to subjects' hypnotic responsiveness: knowledge of what is required in the hypnotic situation, self- and role-related perceptions, expectations, imaginative skills, and situational demand characteristics.

T.X. Barber was influenced by Sarbin's theories and criticized the state concept because of its logical circularity (i.e., hypnotic responsiveness can both indicate the existence of a hypnotic state and be explained by it). In an extensive series of studies in the 1960s and early 1970s, Barber and his associates Spanos, Chaves, and Calverley demonstrated the important roles played by subjects' attitudes, expectations, and motivations in hypnotic responding.

Barber and his colleagues repeatedly demonstrated that nonhypnotized subjects showed increments in responsiveness to suggestions that were as large as the increments produced by hypnotic procedures. This research supported the idea that despite external appearances, hypnotic responses were not particularly unusual, and therefore did not require the positing of unusual states of consciousness.

Later in his career, Barber advanced the hypothesis that the great majority of people respond in keeping with 'sociocognitive variables' (e.g., expectancies, beliefs, attitudes), whereas much smaller numbers of participants respond because of an extensive history of fantasy involvements, and a still smaller number of participants experience profound dissociative reactions (e.g., spontaneous amnesia) following an induction. Barber's theory, while largely untested, represents a tentative integration of sociocognitive and dissociation accounts of hypnotic responding.

Spanos has conducted an extensive research program that has drawn particular attention to the importance of social psychological processes (e.g., subjects' attributions and interpretations of their own behaviors and hypnotic communications, response biases) and the importance of subjects' goal-directed activities and strategic responding (e.g., imagery, fantasy, allocation of attention) in the hypnotic context. This emphasis can also be seen in the writings of Wagstaff and Lynn and his colleagues, who view hypnotizable subjects as creative problem-solving agents, who seek to integrate information from an array of situation, personal, and interpersonal sources to respond to hypnotic suggestions.

Spanos and his associates have developed a social learning, cognitive skills-based hypnotizability modification program that provides low hypnotizable subjects with information designed to modify their attitudes about hypnosis, increase their involvement in imaginings, and interpret hypnotic communications in a manner consistent with passing hypnotic suggestions. This program has successfully modified the hypnotizability of about half of the low hypnotizable subjects tested, so that after training they tested as high hypnotizable subjects. This research has thus challenged the idea that hypnotic responsiveness is trait-like and cannot be substantially modified.

Sociocognitive theories have drawn critical fire from researchers who have questioned whether treatment gains that follow hypnotizability training represent genuine changes in hypnotic ability, or whether they can be accounted for in terms of compliance and conformity with demands for improved performance inherent in the training program. Spanos has addressed this critique by showing that treatment gains generalize to a variety of novel items and subjective measures; that trained subjects respond comparably to nontrained 'natural' high hypnotizable subjects; and that skill trained subjects continue to respond to hypnotic suggestions while they are surreptitiously observed, whereas untrained simulating subjects cease responding when they believe that they are not being observed. However, it is true that hypnotizability training is typically effective with no more than half of the participants, implying that variables other than those emphasized by sociocognitive theorists are associated with hypnotic suggestibility.

Irving Kirsch's response expectancy theory, which is an extension of Rotter's social learning theory, is based on the idea that expectancies can generate nonvolitional responses. Kirsch's research has shown that a wide variety of hypnotic responses (e.g., amnesia, experienced nonvolition, response to motoric suggestions) covary with people's beliefs and expectancies about their occurrence. According to Kirsch, expectancies, motivation, and responsiveness to waking imaginative suggestions can account for the lion's share of variance in

responding to hypnotic suggestions. In fact, Kirsch and Braffman have argued that hypnotic suggestibility should be measured as the increase in suggestibility produced by hypnotic induction, above and beyond responsivity to waking imaginative suggestions.

Kirsch and Lynn's response set theory proposes that all actions, mundane or novel, planned or unplanned, hypnotic or otherwise, are at the moment of activation initiated automatically, rather than by conscious intentions. Actions are prepared for automatic activation by response sets (i.e., intentions, expectations), and hypnotic suggestions can trigger response sets that influence thoughts, feelings, and actions. Similarly, Dienes and Perner's cold control theory of hypnosis argues that unconscious intentions influenced by beliefs and expectations can account for the feelings of involuntariness that often accompany hypnotic suggestions. These theories represent a bridge between sociocognitive and dissociation theories.

Bowers has been the most forceful critic of sociocognitive theory in marshaling evidence that: (1) compliance and social influence may account for the behavior of low hypnotizable subjects, but different (dissociative) mechanisms apply to high hypnotizable subjects; and (2) response to hypnotic analgesia suggestions can occur in the absence of goal-directed fantasies (e.g., suggestion-related fantasy activity, such as imagining that a hand and arm are made of rubber following an analgesia suggestion), indicating that such patterns of imaginative activity are more limited in their ability to account for the experience of nonvolition and response to suggestion than sociocognitive theorists acknowledge.

Phenomenological/Interactive Models

Theories that place particular emphasis on understanding the subjects' experience and the interaction of multiple variables during hypnosis have been termed 'phenomenological/interactive' theories. Sheehan's contextual model highlights the interactive reciprocal relations between an active organism and an active context, the 'fine-grained variation' in response to suggestion that exists among very hypnotizable subjects. Sheehan's research has also established the relevance of hypnotic rapport to a range of hypnotic phenomena (e.g., hypnotic dreams, hypnotically created memories). Sheehan contends that hypnosis can be distinguished from waking behavior by hypnotized subjects' 'motivated cognitive commitment' or problem-solving attempts to respond appropriately to suggestions.

According to McConkey, in order to understand the essential variability that characterizes subjects' hypnotic responses, it is necessary to examine the meaning that subjects place on the hypnotist's communications, the idiosyncratic ways in which they cognitively process suggestions, and intraindividual differences that can occur in responding across suggestions. McConkey's research, as well as studies by his former students Barnier and Bryant on posthypnotic suggestion, hypnotic blindness, and suggested sex change, have supported the hypothesis that high hypnotizability reflects the ability to process information that is both consistent and inconsistent with a suggested event in such a way that facilitates the belief in the reality of the event. Sheehan and McConkey's models are related to other interactional hypnosis models (e.g., Nadon,

Laurence, and Perry) in so far as they call attention to the need to examine multiple, potentially interactive determinants of hypnotic responding.

Clinical and Forensic Aspects of Hypnosis

The available clinical evidence indicates that hypnotic treatments are often effective in helping to treat a wide variety of clinical problems. Reviews and meta-analytic studies consistently document the effectiveness or promise of adding hypnosis in treating a wide variety of psychological and medical conditions including depression, anxiety, obesity, posttraumatic conditions, smoking cessation, irritable bowel syndrome, asthma, and conversion disorders. Hypnosis has applications in dentistry, interventional radiology, and pre- and postsurgical situations. Indeed, hypnosis may provide varying degrees of pain relief for as many as 75% of the population. Furthermore, meta-analyses have shown that hypnosis enhances the effectiveness of both psychodynamic and cognitive behavioral psychotherapies. However, it has not been conclusively demonstrated that hypnotic treatments are more effective than nonhypnotic treatments for a variety of problems.

Fortunately, for most therapeutic tasks involving hypnosis, high suggestibility is not a prerequisite. Although there is no universally close relation between hypnotic suggestibility and treatment gains, suggestibility is not completely irrelevant to outcome. In no study reported to date, is high hypnotic suggestibility associated with a negative treatment outcome. Moreover, in the following disorders or conditions, the findings regarding suggestibility and treatment outcome are at least somewhat promising: smoking cessation, obesity, warts, anxiety, somatization, conversion disorders, and asthma.

Hypnosis has received a great deal of attention in the forensic arena. One common misconception holds that hypnotic procedures can greatly enhance the ability of people to accurately recall forgotten events. On the basis of this misconception, police departments in a number of countries have often arranged to have eyewitness to crimes hypnotized in the hope that the recall of the witnesses would thereby be enhanced.

Most of the laboratory evidence available now indicates that the hypnotic procedures do not dramatically enhance accurate recall and do not enhance the accuracy with which witnesses identify perpetrators, whom they have observed commit mock crimes. Although sometimes subjects do recall new information following an hypnotic interview, they may also recall as much new information when motivated by nonhypnotic instructions. When hypnotic (and sometimes nonhypnotic) procedures are used to obtain new information from witnesses, the new information obtained often is inaccurate (i.e., a pseudomemory). Moreover, in most real-life situations, there is nothing that enables either the witnesses or the interviewer to discriminate between the accurate and inaccurate aspects of the recall.

Some investigators have argued that hypnotic subjects are likely to be influenced by leading questions such as, "What color was the suspect's mustache?" The proposition that misleading questions influence and degrade the accuracy of recall is not in dispute. This effect of leading questions has long been

known and has been elegantly demonstrated in the laboratory in a large number of studies conducted by Elizabeth Loftus as well as others. Indeed, several studies indicate that the effects of the leading questions can exceed that of hypnosis in producing false memories, although in one study, leading questions and hypnosis combined to enhance the likelihood of inaccurate recall.

A serious concern in forensic contexts is that hypnosis enhances witness confidence in inaccurate as well as accurate memories. In the majority of studies that examined witness confidence, witnesses who received hypnotic interviews were more confident about the inaccurate aspects of their recall or about their misidentifications than nonhypnotic witnesses. Questions surrounding the accuracy and unwarranted confidence of hypnotically elicited memories have led to courts in 27 states to ban the admission of testimony of people who have undergone hypnosis to augment recall. However, because several studies indicated that hypnotic testimony was no more resistant to cross-examination than nonhypnotic testimony, a ban on hypnotically assisted testimony remains subject to debate. Less controversial than the issue of admitting hypnotic testimony in the courtroom is the fact that extreme caution needs to be exercised in administering hypnotic procedures to victims and witnesses.

The field of hypnosis will advance apace with careful experimental and clinical research and by way of theoretical tensions and rapprochements between competing paradigms. In this process, the study of hypnosis will continue to enrich the broader field of psychology by contributing insights into the affective, cognitive, behavioral, and relational dimensions of human experience.

Hypochondriasis or Health Anxiety

I Wilhelmsen, Haraldsplass Deaconal Hospital, Institute of Medicine, University of Bergen, Bergen, Norway

Glossary

DSM-IV-TR Diagnostic and Statistical Manual of Mental Disorders, the official diagnostic manual of the American Psychiatric Association.

ICD-10 International Classification of Diseases, the official diagnostic manual of World Health Organization.

Introduction

Hypochondriasis, or hypochondria, is often called excessive health anxiety. Some health anxiety is considered normal and is the reason why people seek medical attention when appropriate. Health anxiety can gradually increase, and in hypochondriasis it has exceeded the normal range and is now an energy-consuming and disabling problem for the patient. Hypochondriasis covers both disease conviction and fear of having or getting a serious disease. The term is one of the oldest medical terms and used to describe disorders believed to be situated in the hypochondrium, which is the area under the 'khondros,' the cartilage, ribs, especially stomach, spleen, and liver. In ancient times, it was synonymous with melancholia, which was believed to be caused by mela chloe = black bile. Gradually, the meaning of hypochondriasis changed and from the seventeenth century, it came to describe health anxiety, while melancholy described a depressive state. Excessive health anxiety is described by the famous French playwright and actor Jean-Baptiste Poquelin (1622–1673), best known as Molière, in his play 'La Malade imaginaire,' 'The Imaginary Invalid' from 1673. Molière suffered from tuberculosis, and ironically he died hours after collapsing on stage due to coughing and hemorrhaging while playing the part of the hypochondriac Argan.

Many people associate hypochondriasis with malingering, and should the doctor introduce the diagnosis, patients might feel offended or not taken seriously. For the doctor, it may seem easier to continue searching for a somatic or organic cause than to sit down with the patient and reflect upon what his attitudes to various symptoms, to life and death, uncertainty, and risk are. For many patients, the term health anxiety is more acceptable than hypochondriasis. Hypochondriasis leads to time-consuming worrying, reduced social and occupational functioning, and overutilization of health care services. The disability and impairment in role functioning is comparable to major depression, anxiety disorders, and many chronic medical diseases. Hypochondriacs are found to be high utilizers of primary and secondary medical care services. Untreated, the prognosis is dubious and 50–70% of patients do not recover. Psychiatric comorbidity does not seem to influence the course of hypochondriasis. How a possible genetic vulnerability factor might interact with environmental factors is still unclear and a subject of ongoing research. The environmental effect is evident in findings of transient increased health anxiety in medical students while entering the clinical years followed by a

significant decrease later on. In older medical textbooks, hypochondriasis was considered an untreatable disorder, resistant to psychological treatment. This has now changed dramatically with the advent of effective psychotherapeutic treatments, especially cognitive-behavioral therapy (CBT).

Diagnostics and Prevalence

There is a continuum between normal health anxiety and persistent, disabling health anxiety. Hypochondriasis has always been part of our diagnostic systems. In both ICD-10 Hypochondriacal disorder F45.2 and DSM-IV-TR, Hypochondriasis 300.7 is found under the heading Somatoform disorders. According to ICD-10, "The essential feature is a persistent preoccupation with the possibility of having one or more serious and progressive physical disorders. Patients manifest persistent somatic complaints or a persistent preoccupation with their physical appearance. Normal or commonplace sensations and appearances are often interpreted by patients as abnormal and distressing, and attention is usually focused upon only one or two organs or systems of the body." These criteria are under discussion. The additional requirement of 'persistent refusal to accept medical reassurance' often is a bottleneck in the diagnosis of hypochondriasis in primary care, as many patients transiently accept the doctor's reassurance. Fear of death has been found to be an integral part of hypochondriasis, but is not included in the diagnostic criteria. Body dysmorphic disorder (BDD) is included in the F45.2 Hypochondriasis in ICD-10, and is characterized by an extreme focus on an imagined or slight physical defect, often in the face but can be in any part of the body. Most patients with BDD consider themselves extremely ugly, and many seek plastic surgeons to correct the defect. BDD differs from 'regular' hypochondriasis in many aspects, and in DSM-IV-TR it has its own identity alongside, but separate from, hypochondriasis. In DSM-IV-TR, hypochondriasis is described as "preoccupation with a fear or belief of having a serious disease based on the individual interpretation of physical signs or sensations as evidence of physical illness. Appropriate physical evaluation does not support the diagnosis of any physical disorder that can account for the physical signs or sensations or the individual's unrealistic interpretation of them." It is stated in DSM-IV that the symptoms must persist for 6 months or more. Both ICD-10 and DSM-IV-TR agree that the main feature of hypochondriasis is the tendency to misinterpret bodily symptoms and sensations as signs of a serious physical illness.

The patients will also often have a tendency to misinterpret and catastrophize medical information, either given by the doctor, media, or the Internet. Most hypochondriacs seek reassurance and have frequent visits to doctors, ask friends and family what they think, check their body for signs of disease, and review medical literature or the Internet, but some avoid all factors that might provoke their anxiety (like watching TV, physically working out, etc.). If the patients' fear is focal and they avoid any situation that may lead to contracting an illness, the diagnosis Specific Phobia might be used. In contrast to a hypochondriac, the patient with Specific Phobia does not believe that he has the disease and he recognizes that the phobic fear is excessive and unreasonable. The fear in Specific Phobia can be cancer or heart disease, and also for example fear of vomiting. Delusional syndromes of somatic type, where the patient's thoughts are usually bizarre, are not included in hypochondriasis as defined by ICD-10 or DSM-IV-TR. If hypochondriasis is secondary to another psychiatric disorder, like major depression, schizophrenia, panic disorder (PD), generalized anxiety disorder (GAD), obsessive-compulsive disorder (OCD), etc., this disorder is the one diagnosed, and not hypochondriasis.

Excessive health anxiety can be triggered by life changes, for example, getting a baby, which makes it very unsuitable to die, by being close to a person dying from a serious and painful disease, focus by media on specific dangers, or even from something the patient learned from his parents. It has been documented that hypochondriasis is connected with reduced quality of life and represents a high cost to the medical society because of many unwarranted CT-scans, MR, doctor visits, etc. Untreated hypochondriasis has a tendency to persist.

Diagnostic Interviews and Questionnaires

The diagnosis of hypochondriasis is usually based on interview, where the patient's fear and tendency to catastrophize becomes evident, in combination with a normal physical checkup. A clinician-administered semistructured interview to assess hypochondriacal thoughts and behaviors, known as "The Hypochondriasis Yale-Brown Obsessive-Compulsive Scale" (H-YBOCS), was published in 2009. H-YBOCS is a modification of a commonly used interview in OCD. It covers 16 items, among which the three factors, hypochondriacal obsession, compulsion, and avoidance are identified. Interrater reliability is good, internal consistency satisfactory, and construct validity low. The low discriminant validity will have to be examined further, and could be due to comorbid anxiety or depression. H-YBOCS is promising but its contribution to the assessment of hypochondriasis is not yet established. So far, structured or semistructured interviews giving ICD-10 or DSM-IV-TR diagnoses are used in research.

Several self-administered questionnaires have been developed to evaluate and diagnose excessive health anxiety. The older ones include Whiteley Index (WI) developed by Pilowsky in 1967, Illness Behaviour Questionnaire (IBQ) developed by Pilowsky and Spencer in 1975, and The Illness Attitude Scale (IAS) published by Kellner in 1986. WI has traditionally been the most commonly used questionnaire. In the original version, it was dichotomous (true/false), but has later been used mostly in a Likert scale version. Factor analysis of

WI has identified three factors, 'bodily preoccupation,' 'disease phobia,' and 'conviction of the presence of disease with non-response to reassurance.' WI has adequate test-retest reliability, internal consistency, and convergent and concurrent validity. As a screening instrument, it is unspecific, and a person with a diagnosed serious disease will also have high scores on some of the questions, such as: 'Do you think there is something seriously wrong with your body?' WI is a good measure of health anxiety and the score is a good indicator of the effect of treatment. IBQ is not only a measure of hypochondriasis but has a wider approach as it focuses on inappropriate ways of responding to the state of one's health. IAS is a commonly used self-report measure and also has a wider focus than specific hypochondriasis. It has 29 items and nine subscales: 'worry about illness,' 'concerns about pain,' 'health habits,' 'hypochondriacal beliefs,' 'thanatophobia,' 'disease phobia,' 'bodily preoccupation,' 'treatment experiences,' and 'effects of symptoms.' It has been found to have good reliabilities and the subscale 'bodily preoccupation' (three questions) has been found to be a useful screening instrument for hypochondriasis. The Minnesota Multiphasic Personality Inventory (MMPI) has a hypochondriacal scale but is more a measure of somatization than hypochondriasis.

More recently developed questionnaires include Health Anxiety Questionnaire (HAQ) from 1996 and the Reassurance Questionnaire published in 2000. HAQ has 21 questions. This questionnaire also has good internal consistency. The scale has four factors: worry and health preoccupation, fear of illness and death, reassurance-seeking behavior, and the extent to which symptoms interfere with a person's life. The latest addition to the self-administered questionnaires is The Health Anxiety Inventory (HAI), in a short and long version. HAI is, like HAQ, based on the cognitive-behavioral theory of health anxiety and was published by Salkovskis in 2002. HAI has 64 questions, including additional questions about how much the person worries about specific conditions like heart attacks, strokes, cancer, multiple sclerosis, AIDS, or other and the following themes: own death, pain, death of a relative, death of a friend, being unable to look after yourself, and going mad. The last two forms to be filled in register avoidance of consulting the family doctor, talking about illness, watching TV programs about illness, etc. and finally how the person seeks reassurance. The initial study reported good internal consistency and test-retest reliability and the scale was sensitive to change in health anxiety due to treatment. The short form of 18 questions, which is easy to use in daily practice, was found to have comparable properties to the full length scale. Short form, SHAI, consists of two factors assessing their perceived likelihood of becoming seriously ill ('illness likelihood') and the perceived negative consequences of being seriously ill ('negative consequences'). However, the factor analysis, whether it is two or three factors, is still open for discussion. An advantage of HAI compared to WI is that patients with a serious disease do not tend to get a high score.

Is Hypochondriasis a Somatoform or Anxiety Disorder?

The main similarities between hypochondriasis and the other somatoform disorders are the presence of medically unexplained symptoms, a tendency to interpret physical complaints

and symptoms as signs of a physical disorder or disease, an urge for medical examinations in order to identify the cause, and a general preoccupation with health and illness. However, hypochondriacs are in many aspects different from other somatoform disorders. A patient with somatization disorder or persistent pain will usually readily accept treatments that can relieve their pain, be it painkillers or other interventions. They believe that their symptoms have an organic cause, but they usually accept that it is not dangerous, it will not kill them. A hypochondriac with headache, on the other hand, will not readily accept paracetamol or other analgesics to relieve the pain. He wants to get rid of the tumor, not the pain! In fact, many patients with hypochondriasis claim that if they could just know for sure that the pain is not caused by a serious disease, the symptom itself would not be the main problem. Another difference between hypochondriasis and other somatoform disorders is the lack of secondary gain. In somatization disorder or persistent pain, attention from significant others, economic compensation, or other benefits are common and will often complicate the therapeutic alliance in treatment. In hypochondriasis, the secondary gain is usually low. There is not much gain in being anxious, and an imagined cancer disease seldom evokes compassion and understanding from family or friends. Another difference between a person with somatization and a hypochondriac is what kind of physical causes they tend to come up with in search for an explanation to their problem or symptoms. Hypochondriacs usually stick to normal, mainstream diseases like cancer, coronary heart disease, tuberculosis, multiple sclerosis (MS), etc., while some patients with somatization syndrome tend to be open to more speculative explanations, which are hard to prove or discard completely, for example, be radiation, electricity, food intolerance, amalgam, postvaccination complications, etc.

There are many similarities between hypochondriasis and anxiety disorders, for example, the intolerance of uncertainty, which drives many patients to develop avoidance and safety behaviors. This is typical also in patients with hypochondriasis. Perhaps the best argument why hypochondriasis is best considered an anxiety disorder is the development of a cognitive-behavioral model of the disorder by Warwick and Salkovskis, which has led to effective treatment. According to this model of hypochondriasis, the basis is a tendency to misinterpret harmless bodily symptoms as threatening. This results in higher body vigilance, leading to higher awareness of normal physiological alterations and higher anxiety caused by catastrophic misinterpretations. Anxiety-symptoms due to autonomic activation like palpitations, chest pain, nausea, dizziness, etc. are in the patients' mind interpreted as a sure sign that there must be something seriously wrong with their body. This way, a vicious circle is established. This model was derived from observation of similarities between symptoms and symptom presentations in hypochondriasis and panic disorder (PD), generalized anxiety disorder (GAD), and obsessive-compulsive disorder (OCD). Patients with GAD worry about almost everything that can happen, including death and diseases. In some presentations of OCD, health concerns are evident, especially in fear of contamination. In some patients with a specific fear of already having or getting HIV/AIDS, the differential diagnosis between hypochondriasis and OCD can be difficult. One striking difference is that while the

hypochondriac makes little effort to resist his self-checking, self-examination, and reassurance-seeking, the obsessional often tries to hide his behavior from others. Both patients with PD and hypochondriasis are hypervigilant to bodily symptoms and readily misinterpret the common physiological reactions to elevated adrenalin levels as a sign of serious heart disease, stroke, going mad, or imminent death. The difference between a patient with PD and a hypochondriac is that the hypochondriac has this focus more or less all the time, while the panicking person only misinterprets symptoms during attacks. Under attack, patients with PD fear that they are dying, while a patient with hypochondriasis fears death all the time, and may worry just as much about progressive diseases like lung cancer as heart attack or stroke.

Prevalence

The prevalence of hypochondriasis in the general population is around 0.05–1.3% and in primary care settings between 3 and 9%. Hypochondriasis is most commonly found between the ages of 25 and 45 years and equally distributed between both sexes. The prevalence does not seem to vary remarkably from one culture to the other.

Treatment

Psychotherapy

The conceptual shift when hypochondriasis changed from being untreatable and chronic to a treatable disorder started when pilot studies in the 1980s indicated that CBT could be useful. This has later been confirmed in several studies, and reviews have concluded that psychotherapy reduces symptoms of hypochondriasis compared with waiting list, placebo, or treatment as usual. Few randomized controlled trials have compared different types of psychotherapy to each other, but overall CBT is the best-documented treatment available. CBT given individually or in groups has been compared with interpersonal therapy, psychoeducation, brief psychodynamic therapy, counseling, hypnotherapy, and relaxation training. The first controlled clinical study of CBT in hypochondriasis was published by Warwick et al. in 1996. Thirty-two patients were randomly assigned to waiting list or 16 sessions of CBT. At 3 months follow-up, the patients in active treatment were better than the waiting-list patients. In a later study published by Clark et al. in 1998, 48 patients were randomized to CBT or behavioral therapy focusing on stress management. At the 12 months follow-up, both treatment groups were better than the control group. Patients in CBT had lower health anxiety, but CBT as well as behavioral therapy were effective. This has later been confirmed on other randomized controlled studies, and in four of four trials involving 345 patients CBT has been found to be beneficial in terms of hypochondriacal cognitions and behaviors. The recovery rate is however still relatively low in most studies, ranging from 30% to 50%.

Increased health anxiety can be secondary or coinciding with somatic disease. For example, a patient with coronary heart disease can develop a heightened awareness of any sign of relapse or a new infarction and develop serious heart disease. CBT has been found to be beneficial even if the patient

has an underlying organic disease. Recently, a study was reported where greater improvement was seen in HIA in patients treated with brief (mean 4.3 sessions) CBT compared to the control group in a genitourinary medicine clinic. These patients had a score of HIA lower than what would be expected in patients with hypochondriasis. The patient number was low (23 allocated to CBT-group) and the selection of patients was not randomized, but this study suggests that CBT can be used in a wider medical setting and applied to patients with bothersome health anxiety, even though they might not fulfill the criteria for ICD-10 or DSM-IV-TR Hypochondriasis. Similar results have been published from pain clinics.

Lately, elements of mindfulness have been included in CBT of hypochondriasis. This approach not only takes into account the dysfunctional beliefs patients have about health and their tendency to misinterpret normal physiological complaints but also focuses on dysfunctional cognitive processing, for instance, attentional biases, and rumination. In a pilot study by Lovas and Barsky from 2010, ten patients with hypochondriasis received 8 weeks of mindfulness-based stress reduction (MBSR) and mindfulness-based cognitive therapy (MBCT) in groups. The participants were taught mindfulness meditation; they were provided with guided meditation CD and were asked to practice formal meditations for at least 30 min every day. The main outcome measure was WI. The results showed significant reductions in hypochondriacal health anxiety at post-treatment and 3 months follow-up. The patients also demonstrated improvement in somatic symptoms, a finding which is relatively rare in other studies. This pilot study has been supplemented by a randomized clinical trial including a mindfulness-based approach published by Sørensen et al. in 2011. In this study, CBT (a combination of individual CBT and mindfulness training in groups) was compared to short-term psychodynamic psychotherapy (STPP) and no intervention (waiting list). The treatment consisted of 16 sessions and lasted up to 6 months. The main outcome measures were Health Anxiety Inventory short version (SHAI) and Hamilton Anxiety Rating Scale for general anxiety. Twenty patients were allocated to CBT, 40 to waiting list, and 20 to the STPP group. The patients were followed up at 6 and 12 months after treatment. Patients in the CBT group did significantly better on all measures compared to the waiting-list control group and on HAI also compared to the STPP group. The STPP group did not differ from the waiting-list group on any primary or secondary outcome measure.

Studies of Long-Term Follow-Up After Psychotherapy Has So Far Not Been Published

Pharmacological Treatment

So far, relatively little research has been done on pharmacological treatment of hypochondriasis. Most studies have been open and uncontrolled, and due to similarities between hypochondriasis and OCD and other anxiety states, mainly serotonin reuptake inhibitors (SSRI) have been studied. In open studies, Fluvoxamine has been found to be beneficial, but a relatively high portion of the patients discontinued the treatment.

In a randomized controlled study by Greeven et al. published in 2007, both CBT and paroxetine, another SSRI, were

superior to placebo, but no statistical difference was found between the treatment groups. Responders were defined as at least one standard deviation below the mean pretest score on the WI. Percentages of responders were on the intent-to-treat and completer cohort 45% and 54% in the CBT-group, 30% and 38% in the paroxetine group, and 14% and 12% in the placebo group. The patients have later been followed up and 45% of the patients of the intent-to-treat sample of the CBT group and 30% of the paroxetine group were considered responders. No significant difference between CBT and paroxetine was found in the follow-up. However, significantly more patients in the paroxetine group (12 out of 22) received psychological or pharmacological treatment during the follow-up period compared with patients in the CBT group (7 out of 28). The relapse rate in both groups was small. Effect sizes for SSRI seem to be smaller than for CBT and dropout from treatment seems to be higher in pharmacological treatment than in psychotherapy. This is not surprising, considering the hypochondriac's hypervigilance to bodily symptoms and tendency to misinterpret bodily sensations.

Several treatment options are available, but most review articles agree that CBT is best documented and should be the treatment of choice. Psychotherapy is not always available and there is some scientific support that treatment with SSRI can be beneficial, but further studies are necessary.

The Cognitive-Behavioral Approach to Treatment

The treatment of hypochondriasis has changed after the introduction of a cognitive-behavioral model. At Haraldsplass Deaconal Hospital in Bergen, Norway, we have used this model since 1996 in an outpatient clinic specifically designed for patients with hypochondriasis. Around 100 patients are accepted every year and the number of sessions has gradually been reduced from initially 16 to presently around 5. The main aspects of the treatment will be outlined here. Usually, the diagnosis of hypochondriasis is established with a semi-structured interview and WI is filled in by the patient. This establishes a baseline from which change can be monitored. After a relatively short life history, focusing mainly on the important factors that might have established or triggered the health anxiety, the main themes in hypochondriasis are highlighted.

The point in CBT is to help the patient reflect upon his attitudes and behavior. With attitudes we mean basic assumptions, schemas, or worldview. There are many situations or problems in this world which are beyond our reach; we cannot do anything about them. But our attitudes and the way we evaluate a situation, a problem, or a symptom can always be changed.

Death

Since fear of death usually is an integral part of hypochondriasis, this is focused in the first session. We usually ask our patients if they are willing to be mortal. A typical answer is: 'In principle yes – but not now! It is too early.' In other words, they try to control death. The problem is that to control death, irrespective of how many good arguments you might have and

how important it is that you stay alive, is impossible. None of us know how or when we are going to die. It is normal to fear death, but it is questionable to try to control it. This can in some patients be the driving force behind their tendency to check the body and be hypervigilant to any physical complaint. If the patient tries to control death we ask him how he actually does it. A typical question could be: 'Do you choose a broad approach and try to control all causes of death, or do you specialize?' Most of our patients choose not to focus on all causes of death, but to specialize only on some. It can be causes of sudden death, like heart attacks, stroke, etc., or it can be more slowly developing causes like cancer, HIV, etc. If the patients are especially concerned about cancer, they try to detect the disease as soon as possible, at least before it spreads. This means that they cannot wait and see how a symptom or complaint evolves and often disappears, as it then might be too late! The problem with this approach is that most people, also completely healthy people, have a lot of subjective somatic complaints. Several studies have shown that normal people often have a transient headache. It is very seldom caused by a brain tumor. May be they have drunk too little, or may be too much. They might have had some distress leading to tension headache, or it might be migraine. Sometimes we just do not know why. It is also normal during a month to have some back pain, nausea, dizziness, etc. This is all part of life, and usually not deserving of attention. However, if you are not willing to be mortal now, you cannot admit yourself the luxury to wait and see. You must act now, which either means to check every day or seek the doctor immediately. It is common in CBT to give the patients homework assignments, and the first question we want them to reflect upon is this: 'Am I willing to be mortal?'

A theme that often comes up in therapy is the question of control. Most people want to be in control in their life. We usually tell our patients that it is perfectly normal and OK that they want to be in control in their life, but we suggest that they stick to factors that are controllable. Death is not one of them. To most normal people, death is very negative; it is an enemy, an unwanted guest. We do not suggest idealizing death or making the bitter pill sweeter than it is. The point is to accept that it is uncontrollable. The nice thing about being willing to be mortal is that we then can focus on living and spend our energy and time on that, instead of spending it on not dying.

Consequences of Disease

To some patients, fear of death is not the biggest problem, but they have the notion that they will not be able to cope with a specific disease or prolonged suffering and uncertainty. This is usually not a fact or something they have tested out, but a thought, something they believe. If it is a fact, they might have to focus on increasing their coping skills, but most people have not so far tried this theory in practice. Many people minimize their own coping capacity. In fact, most of us have no idea how we some day in the future will handle a nasty situation or cope when facing, for example, real cancer. To some people, the biggest challenge in life is not real problems but the imagined catastrophes. Some patients argue that if they are terribly scared just thinking about a problem, it must be

even worse if it actually manifested itself in reality. This is usually not the case. Most people handle imagined and real problems very differently. Imagined problems are hard to deal with, they are just thoughts, and they cannot be reached using normal coping skills. Real problems are different. They are limited by time and space, while imagined problems are only limited by the patient's phantasy. The question to reflect upon at home is: 'Are you really going to keep this negative view on your own coping abilities?' Patients who are trying to control death usually fear mostly life-threatening diseases like cancer, heart disease, stroke, etc., but those who distrust own coping abilities tend to focus on diseases like MS, amyotrophic lateral sclerosis (ALS), HIV/AIDS, etc.

Worrying

Since hypochondriasis in many aspects resembles anxiety disorders and the patients are very good at catastrophizing, it is important to reflect upon the question of worrying. How much worry are we going to have in our life, and what are we going to worry about? It is perfectly normal to spend some time worrying about real problems, diseases which are diagnosed, conflicts, bills, etc. That is why we have worry and anxiety, so that we can find good solutions. The question is how many of the things that might happen are we going to worry about. Patients with GAD have a wide approach when they worry and can worry about almost all that might happen. Patients with hypochondriasis have specialized on health issues, and worry about cancer, heart disease, ALS, etc. Usually, people have some kind of reasoning why they worry, but it has seldom been articulated and reflected upon. Some common arguments are: 'I want to be prepared for the worst!' 'If I don't worry, anything can happen!' 'If I am too happy and optimistic the chances that it might happen increase!' 'I am an unlucky person – it would be so typical that it happened to me!' etc.' Depending on what reason they come up with, we look into it and ask ourselves: 'Is this a good argument, something we would recommend to others?' The idea behind being prepared for the worst is that it will take some of the pain out of a bad diagnosis or accident. Is that true? Can we rehearse real catastrophes? If something bad actually happens to one of your children, and you have rehearsed this for many years, will you then say that it was a good thing that you were prepared, otherwise you would not have coped? The answer is no. Real challenges can be tough, and it does not help to rehearse. Another problem is that we can rehearse the wrong challenge. Actually, it is hard to find good reasons why we should worry today about things that might (or might not) happen tomorrow. If the patient believes that it is dangerous to be too happy, we ask them if they really believe that their emotional life really can influence what happens in this world. It is hard to explain the connection between their emotional status and the occurrence of real accidents, diseases, etc. Most people realize that this is magical thinking, and they then have a choice to keep or dismiss it.

If the patient decides to worry about only real problems and factors he can actually control, he has to figure out how this is done in real life. Some aspects of mindfulness can be very useful in applying this new attitude. Many patients complain that even though they have decided not to worry, they still get

their catastrophizing thoughts. They want to get rid of them completely; they distract themselves or try to suppress thoughts. This is impossible and unnecessary. Thoughts are just thoughts. It is important to differentiate between thoughts and facts. We cannot decide what kind of automatic thoughts we get, but we can choose how we react to them. In mindfulness, people are encouraged to accept their thoughts. Let them come, and go. Be passive, observant, and nonjudgmental. Just let thoughts come, they are just thoughts anyway. Do not give them power and energy by focusing on them and reacting strongly to them. When a worrier gets a catastrophizing thought, he tends to think: 'Oh, that was a terrible thought! Let me ruminate on it and follow it to the bitter end!' This kind of thinking is usually neither fun nor rewarding. It is like treating thoughts as if they were a thin, stray cat passing by. You feel compassion and give the cat some food, milk, and TLC. Eventually you say: 'You must not come back! You don't live here!' This is usually not very effective. A mindful approach is to accept the thoughts when they come. Do not judge it or involve yourself in it, just let it pass, like a cloud in the sky! Thoughts are just actions in my mind, not in reality. If the therapist is trained to do it, he can anchor the mindfulness training in breathing. The homework question after this reflection is: 'How many of the sorrows you cannot do anything about that might happen tomorrow are you going to worry about today?'

Symptom Interpretation

Hypochondriacs are preoccupied with their body and all kinds of complaints and symptoms. In psychotherapy, it is more important to focus on how symptoms are interpreted than the actual symptom itself. Many hypochondriacs view a bodily complaint as if it was a red light on the dashboard of a car. Only a stupid person would ignore that. However, this is not a good comparison. Bodily complaints are very common and usually not important. When you experience pain or subjective complaints, it is extremely important how you evaluate them. Our brain is very interested in our survival and well-being. If you tell it that there is something going on in a certain place in your body, keep an eye on it, it puts on the magnifier, scanner, and danger light and amplifies whatever it detects. If you on the other hand tell your brain that the danger is over, 'I have decided to believe that everything is OK, you can now focus on other tasks!', the brain will do so, and hence the symptom loses some of its power and strength.

Intolerance of Uncertainty

The question of risk and uncertainty nearly always comes up when dealing with a hypochondriac. If they fear heart disease, they have already been to GP and sometimes even cardiologist, who have assured them that there is nothing wrong with their heart, but they have chosen to doubt this. In our hypochondria-clinic, we seldom discuss with the patients whether they have a disease or not, but we encourage them to examine how they evaluate the thought that they might have, for example, a heart disease. A person cannot choose if he has a real heart disease or not, but he can choose whether he will believe that he has a heart disease or not. The question is if

he is willing to make this decision while still in doubt. If the patient insists that he must seek 100% assurance, there is not much the therapist can do. If, on the other hand, the patient accepts that he has to make his decision under some uncertainty, this will be his next homework assignment. Studies have found that to have an imagined heart disease can lead to a lower quality of life than a real one. People with real coronary heart disease often live good lives. If you ask them whether they work out, they will often say: 'Yes, I am in better shape than before my heart attack!' People with imagined heart disease, on the other hand, have not got any stents or medication and do not know what their heart can take. If you ask them if they work out, they usually answer no, they do not, it might kill them. It is an important choice whether you decide to trust your heart or distrust it, as it directly influences what you dare do or not do in your daily life.

When these basic attitudes are discussed and reflected upon and the patient hopefully has made new choices, these new attitudes can be applied in their lives. In CBT, it is not enough to change cognitions or attitudes; you must also behave as if you mean it. Otherwise, this is just theory, intellectual insight, but of no value in real life. There will come a time, sometimes surprisingly short but sometimes longer, when the patient must struggle with a new way of thinking and behaving. Avoidance must be challenged and safety behaviors be done away with (checking the body, frequent visits to the doctor, etc.). Many patients find it liberating to no longer bear the responsibility of staying alive, and they can now focus on living instead of on not dying.

Empathy is always important in therapy. The patient must be understood, and most people like it when the therapist briefly summarizes what he has heard and adds an emotional touch, like 'this must be scary! make you feel sad.' However, empathy has its limits, and there is also a time for confrontation. It can strengthen the therapeutic alliance if the therapist is frank, sincere, polite, honest, and direct in his communication. Questions like: 'Is what you are saying now really true, or is it an opinion?' 'Do you really mean this?' or 'Would you suggest that I adopt the same attitude as you now have displayed?' can help the patient to reflect upon his attitudes in life. Most patients haven't really thought through why they live like they do, and in particular they have not been aware that they have a choice of how to interpret and evaluate the different problems they face. When a person understands that he has spent a lot of time trying to control factors which are in principle uncontrollable, he might wonder if he is stupid, since he has not understood this before. The answer is no. The patient is not stupid, but scared of death. And that is a big difference.

Discussion

As it has been pointed out, health anxiety is a continuum with patients with ICD-10 or DSM-IV-TR hypochondriasis at the extreme end. Several studies have found that even slight increase in health anxiety has a strong negative effect on well-being. When Gureje et al. did their study of hypochondriasis in 15 different sites from a broad diversity of cultures and socioeconomic development, they found that when they

lowered the diagnostic threshold and introduced abridged hypochondriasis, many more people fulfilled the criteria. Interestingly, these new people now included in the category of hypochondriasis were no less disabled than the people who fulfilled the ICD-10 or DSM-IV-TR diagnostic criteria and they found that subjects with abridged hypochondriasis were significantly more psychologically impaired than non-hypochondriacal subjects. This is in accordance with findings from our own research group. In a study published by Mykletun et al. in 2009, we found that health anxiety was a strong predictor of disability pension award, exceeding the effect of general anxiety, and comparable to the effect of depression. The effect was not limited to high symptom level but followed a dose-response association. However, it was not recognized as medical diagnosis in any awards of disability pension in the study population. Our conclusion was that health anxiety is a strong, independent, and underrecognized risk factor for health disability pension award. Today, we have focused, time-limited, and effective therapy, and hence health anxiety deserves increased attention also in primary care settings.

Conclusion

Hypochondriasis seems to defend its position as a distinct mental disorder and deserves a place in our diagnostic manuals. Whether it is best conceptualized as a Somatoform or an Anxiety disorder remains to be decided, but with the development of a cognitive-behavioral model of the disorder, the similarity to the anxiety disorders has been emphasized. The addition of mindfulness techniques to CBT is promising, but more research on the possible added effect is needed. Health anxiety, also when it has not developed into full-blown hypochondriasis, has been found to be a strong, independent, and underrecognized risk factor for health disability pension award in a Western society.

Glossary

Eros One of the two classes of instincts that motivate behavior. It is described as 'life' instinct, the 'preserver of all things,' incorporating the elements of sexuality and self-preservation. This is in contrast to the opposing tendency to reduce life to an inanimate state, or the 'death instinct,' which is revealed by aggression and sadism.

Erotogenic zones The zones of the body (oral, anal, phallic) that are sequentially invested with sexualized energy (libido), and are hence the source of autoerotic pleasure. The sexual instinct is thus a composite instinct, only to become organized in the service of reproductive, genital sexuality upon maturity.

Libido The name reserved for the sexual instincts.

Oedipus complex The libidinal cathexis of phallic erotogenic zone leads to a desire for union and contact with the opposite-sex parent, and a concomitant desire to displace the same-sex rival parent. The competition for the opposite-sex parent engenders anxiety, insofar as the

retaliation of the rival is feared ('castration complex'). This is resolved by repressing incestuous desires, and identifying with the same-sex parent, which is the foundation of superego formation. Freud once suggested that the course of Oedipal development between boys and girls was exactly analogous, but later formulations postponed the resolution of the Oedipal conflict for girls until marriage and childbirth.

Pleasure principle The motivating principle of behavior is the pursuit of tension reduction, which is experienced as pleasure.

Primary process The workings of unconscious (id) processes. Instinctual energy is freely mobile, and capable of displacement and condensation. In contrast, secondary process, attributed to ego functioning, attempts to postpone, revise, or otherwise deflect instinctual motivations.

Transference In the therapeutic situation, the (unconscious) incorporation of the analyst in the internal conflicts of the patient.

Freud in Context

Psychoanalysis is one of those rare intellectual achievements that had the effect of radically transforming human self-understanding. Indeed, Freudian notions have so thoroughly permeated human culture that the jargon (if not the substance) of psychoanalysis is accessible to even the most untutored observers of human behavior, so much so that the poet W.H. Auden could write that for us, Freud is not so much a person but rather *a whole climate of opinion under whom we conduct our different lives*. By Freud's own estimation, psychoanalysis effectively completed the intellectual revolution begun by Copernicus, and advanced by Darwin, a revolution that undermined human conceit regarding its putatively special and privileged position in the cosmos and in nature. While Copernicus displaced mankind's planet from the center of the universe and Darwin showed that no comfort can be taken in the idea that mankind is nonetheless above the forces of nature, Freud completed the assault on human pretense by showing that even human reason is not what it has been supposed, that human psychology is, in fact, besieged and driven by irrational, unconscious motivations.

Freud's discovery of a hidden psychic reality that is beyond the pale of sensible consciousness was thought (by Freud) to be an application of the same Newtonian dualism that accepted the distinction between human sensory abilities (percepts) and a hidden physical reality that could only be apprehended by mathematics and the armamentarium of physical science. The Newtonian scheme was invoked by psychoanalysis to advance an understanding of psychic life, an application that hinges on the distinction between conscious and unconscious mental life.

Just as physics develops scientific techniques to apprehend a physical universe that is beyond human sensibility, so also psychoanalysis attempts to pierce hidden unconscious realities with its special clinical techniques. Psychoanalysis, then, according to Freud, is to be counted among the natural sciences; it is a specialized branch of medicine (with the caveat that medical training gives no necessary expertise in psychical affairs), with mental life being the object of inquiry.

Although psychoanalysis shocked conventional sensibilities, particularly with its claims regarding unconscious mental dynamics and infantile sexuality, it was grounded nonetheless in themes common to nineteenth century science. The Freudian theory of instincts seemed at home in a culture that was getting used to the ideas of Darwinian biology. Freud's use of spatial models to locate psychic structures was in keeping with the efforts in neurology to localize brain functions. And the mechanistic Freudian image of the psychological architecture as an apparatus for channeling instinctual drive energies was not out of step with the energy mechanics of nineteenth century physics. Yet, for all the trappings of scientific positivism that Freud wanted to claim for psychoanalysis, the Freudian project was met with considerable resistance, and the history of the psychoanalytic movement is a history of struggle for academic, clinical, and popular respectability, a respectability that is still not completely won.

Freud himself was at pains to recount this struggle in a number of histories, outlines, and encyclopedia articles. Although one aim was to popularize the new science of mental life, Freud was also keen to demarcate psychoanalysis from rival depth psychology (e.g., Jung, Adler) and to show that the controversial psychoanalytic claims were the result of careful

scientific investigation of the positivist, natural science kind. He would claim, for example, that the hypothetical entities and forces of psychoanalysis were not different in kind from the hypothetical entities and forces claimed in the ostensibly harder, more respectable sciences. It will be of interest for our purposes to recount the early development of psychoanalysis to set the proper context for considering Freud's account of the tripartite personality. The structural notions of id, ego, and superego were rather late theoretical developments that can be understood properly only in the context of prior theoretical revisions – revisions that Freud would claim were forced upon psychoanalysis by evidentiary warrant.

The Cornerstone of Psychoanalysis

Freud was initially drawn to the dynamics of depth psychology by the inability of the neurological community to come to grips with the problem of hysteria. Hysterics appeared to suffer a host of somatic and physical maladies (e.g., motor paralysis, glove anesthesia) that had no apparent neurological basis. One promising treatment was the use of hypnosis. Josef Breuer, a medical colleague of Freud, claimed to have relieved the hysterical symptoms of a female patient ('Anna O.') by such means. In *Studies on Hysteria* (1895), Breuer and Freud presented a series of case studies and theoretical articles on the etiology of hysteria and the role of hypnosis in treating it. The authors claimed that hysterical symptoms have a symbolic meaning of which the patient had no conscious knowledge. Symptoms are substitutes for mental acts that are diverted from taking their normal course because the affect associated with the mental processes becomes 'strangled' (as a result of trauma) and channeled into physical symptoms ('conversion'). That is, a strong affect is prevented from being consciously worked out in consciousness, and is diverted instead into 'the wrong path,' taking the form of somatic symptoms. Under hypnosis, this strangled affect can be set free or purged ('abreacted'), allowed normal discharge into consciousness, thereby leading to a removal of symptoms. This treatment was called *the cathartic method*. Moreover, patients under hypnosis tended to recall 'psychic traumas' from a remote past, extending to early childhood, so that Breuer and Freud could claim that hysterics 'suffer from reminiscences.' When these traumas are allowed expression in the hypnotic state, strangled affect is released and directed into normal consciousness.

One sees in these studies and in the papers that followed the preliminary delineation of some of the foundational notions of psychoanalysis. To observe that traumatic 'reminiscences' could be recalled only under hypnosis suggests that their conscious expression is met with certain resistance (defensive repression). These reminiscences, though resisted, continue to exert pathogenic effects (as symptoms), which are suggestive of unconscious mental processes.

Freud was soon to abandon the hypnotic technique for the good reason that not all of his patients were amenable to hypnotic induction. In addition, Freud observed that the amelioration of symptoms seemed to depend more on the nature of the patient-analyst relationship. If this relationship was disturbed, symptoms reappeared. This clinical insight was later reformatized as transference love. Transference describes

a phenomenon that emerges during the course of psychoanalytic treatment, whereby the patient comes to involve the analyst as a substitute for a past interpersonal relationship, a finding that some consider being one of Freud's great discoveries. The hypnotic technique was replaced by the method of free association, a method that requires the patient to read off the content of conscious experiences and memories without judgment or embarrassment.

Free association depends on the assumption of strict determinism, which holds that associated ideas and memories are not randomly yoked, but are instead determined by a dominant (and often pathogenically repressed) trend of thought, which is unconscious (but is causally active nonetheless). Given the assumption that symptoms have sense and meaning, and are substitutes for actions that are omitted or repressed, the task of the analyst was to interpret the free associations in a way that successfully deciphered their meaning, a meaning that was otherwise obscured by censorship. To distinguish this technique from the cathartic method, Freud called this treatment 'psychoanalysis.' Freud claimed that the transition from catharsis to psychoanalysis yielded two important novelties: the extension of psychoanalytic insights to phenomena associated with normality, and the discovery of the significance of infantile sexuality for understanding the etiology of neuroses.

In *The Interpretation of Dreams* (1900) and in *The Psychology of Everyday Life* (1901), Freud extended this notion of mental determinism to include not just the symbolic character of neurotic free associations, which of necessity require analytic interpretation, but also the various parapraxes of normal life ('Freudian slips,' accidental self-injury, and other putatively 'haphazard' acts) and dreams. These too are like neurotic symptoms in that they express a meaning that can be deciphered by analytic interpretation. The difference between normality and neurosis was not as great as had been supposed. Indeed, the interpretation of dreams was to provide important clues to the nature of the unconscious and the process of symptom formation.

Freud distinguished between the manifest and the latent content of dreams. The manifest content was simply the recollected dream, often bizarre and strange. The latent content is provided by analytic interpretation. Latent dream thoughts are distorted and condensed 'residues' of the previous day. They are arranged so as to allow pictorial representation and, through 'secondary revision,' are given a sense of coherence. The motivation for dream formation is a repressed unconscious wish that seeks satisfaction ('wish fulfillment') in the form of the latent material of the dream. Dreams represent, then, a disguised attempt at the fulfillment of an unconscious wish that was denied satisfaction. The attempt is disguised, that is, the manifest content is strange and bizarre, because of the efforts of a restrictive, disapproving agency in the mind (e.g., the ego). Dream censorship, according to Freud, points to the same mental process that kept the wish repressed during the day. So, on the one hand, there is an unfulfilled, repressed wish that is striving for expression. On the other, there is a disapproving, censoring ego that is striving to repress it. The result is a compromise formation that takes the form of dreams, in normality, and of symptoms, in the case of neurosis. Dream formation and symptom formation, then, are the expressions of identical mental dynamics. Both are compromise formations

that reflect the conflict between unconscious impulses (wishes) and the censoring ego.

The second novelty revealed by the psychoanalytic method was that the search for pathogenically significant traumatic experiences typically took one back to early childhood. And these experiences were invariably a reflection of a disturbance of infantile sexual life. This remains one of the most controversial aspects of Freud's theory. 'Infantile sexuality' refers to the sensations of pleasure that accompany holding, maternal caressing, and oral and anal satisfactions. Freud's use of the term 'sexuality' is thus much broader and more general than the common use of the term. Freud claimed that the development of human sexuality was diphasic. There is, first of all, an infantile period when the sexual instincts are sequentially invested in different zones of the body ('erotogenic zones'), and then a more adult period when the component sexual instincts (oral, anal, phallic) are organized in the service of genital, reproductive sexuality. Intervening between the infantile period and adult period is the latency period of childhood, when the sexual motivations are diverted to other purposes (e.g., skill building, school work).

The sexual instinct is thus an organization of component instincts that takes the adult form only at puberty, and it is decisive for understanding the etiology of neuroses. This is particularly true when libido becomes invested in the phallic region, which gives rise to the 'Oedipus complex' (ages 2–5). The Oedipus complex is foundational for the emergence of the superego and more will be discussed about it in the following pages. Suffice it to say here that this emotionally charged complex of family relationships is the source of the neuroses. As Freud noted, normal individuals survive and master their Oedipal feelings; neurotics continue to be mastered by them.

To this point, we have reviewed what Freud called the 'cornerstones' of psychoanalytic theory: the discovery of unconscious mental processes, the theory of repression and of transference, and the importance of infantile sexuality and the Oedipus complex for understanding neuroses. No one could be called a psychoanalyst unless one accepted these tenets. Yet, we are still far from articulating the structural features of the personality (id, ego, and, superego). This is best done by further recounting the evolution of his thinking on these important constructs.

Evolution of Theory and the Emergence of the Tripartite Personality

The division of mental life into conscious and unconscious suggests a topographical hypothesis, viz., that mental life can be demarcated into psychic portions or regions. Unconsciousness is at once a quality that can be attributed to a repressed idea or impulse and also a region or 'province' (the 'system *Ucs*') to where the idea is banished. Consciousness and its precursor ('preconsciousness') too were formulated as psychic provinces ('system *Cs*, *Pcs*'), and attributed to the workings of the ego. Psychic conflict, then, was a matter of unconscious ideas, emanating from the system *Ucs*, struggling against the repressive forces of the conscious ego. Furthermore, unconscious and conscious processes follow different laws. The *Ucs* consists of 'instinctual representatives' or impulses that seek

discharge. These impulses are illogical (not subject to contradiction) and timeless (not ordered temporally) and not oriented to reality. They are driven by the pleasure principle and are characterized by *primary process*. This means that the wishful, instinctual impulses are undirected and freely mobile, and therefore could be displaced or connected to various objects. This is in contrast to the *Cs* (*Pcs*), where secondary process is dominant. Secondary process is a later developmental achievement associated with ego. As a reality oriented process it revises, censors or binds the discharge of instinctual impulses.

Although Freud never abandoned the notion of primary and secondary process, he did come to revise the provisional *topographical model* of the psychic architecture as one involving 'systems' and also the *dynamic hypothesis* that the unconscious was in conflict with the conscious ego. These notions were revised in light of Freud's clinical observation that his patients were often unaware of the fact that they were employing certain resistances. If the ego is responsible for repression, it is also the seat of consciousness, then it is inexplicable how one could not be conscious of one's own resistances and one's own act of repression. Freud concluded that much of the ego, too, must be unconscious. In other words, the unconscious does not consist entirely of that which is repressed (although all that is repressed is unconscious), a fact that makes the division of the psychic architecture into systems *Ucs* and *Cs* (*Pcs*) less compelling.

The concept of ego was further clarified as a result of revisions to the instinct theory. Instincts arise from internal sources and exert a constant force or pressure demanding satisfaction. The relentless pressure of instinctual drive energies makes it possible for the nervous system to remain in an unstimulated condition ('principle of constancy'), and hence motivates psychic adaptations so as to effect the satisfaction of internal needs. The *pressure* of an instinct is a 'motor' factor, that is, a demand for psychic work. The *aim* of an instinct is gratification through tension reduction. The *object* of an instinct is anything through which satisfaction can be achieved. The *source* of an instinct is a somatic process experienced as a kind of 'hunger' or 'need.' Indeed, Freud often described instincts as the 'psychic representatives' of somatic processes.

In *The Three Essays on Sexuality* (1905), Freud identified sexual instincts as 'libido.' Libido is both a quantitative and qualitative variable – quantitative in the sense that it serves as a measure of the forces of sexual excitation, qualitative in the sense that it can be distinguished from other kinds of psychic energy. Psychoneurotic conflict could then be described as a clash between sexuality and the various functions of the ego (e.g., reality testing, resistance, and repression). However, in addition to libidinal (sexual) instincts, Freud later identified a second group of primal instincts, called *ego instincts*. Ego instincts subsumed the functions of self-preservation, repression, and all other impulses that could be distinguished from sexual (libidinal) instincts. By identifying a second group of primal instincts, Freud could now characterize psychoneurotic conflict as a clash between libidinal (sexual) and the self-preservative (ego) instincts.

Matters are further complicated, however, by the pivotal paper *On Narcissism* (1914). Here, Freud argues that the sexual instincts are attached originally to self-preservation, which is an ego instinct. The sexual instincts detach from

self-preservation only later, when libido seeks external objects (e.g., mother). Libido that cathects with external objects was called object libido. Yet, Freud observed that libidinal attachment toward objects (such as mother) could be derailed. Instead of seeking an external object, it was possible to libidinally cathect oneself. That is, rather than choosing one's mother as an object of love, one chooses oneself. Libido could be apportioned, then, depending on the kind of object choice one made. Libido apportioned to oneself was called 'narcissistic' (or ego) libido, to distinguish it from the libidinal cathexis of external objects (object libido). In Freud's view, the narcissistic libidinal cathexis of the ego is the original state of things, and therefore the initial phase of libidinal development was one of *primary narcissism*. It is from the stance of primary narcissism that one seeks out interpersonal relations.

By 1920, however, in *Beyond the Pleasure Principle*, Freud rejected the dualism between libidinal instincts and ego instincts. In his view, this distinction is no longer tenable because narcissistic self-preservative instincts were also libidinal. It would thus seem that all of instinctual mental life could be reduced to sexual instincts after all, a conclusion that would either justify Jung's monistic use of 'libido' as a term denoting a generalized psychic drive or vindicate those critics who accused Freud of pan-sexualism.

One solution to this theoretical problem was to group the libidinal instincts as *Eros*, or the life instincts, the 'preserver of all things,' and to contrapose to the life instincts (*Eros*), a contrary instinctual impulse that seeks to restore organic life to an inanimate state, which Freud called the *death instincts*. Freud was led to postulate the existence of death instincts by his observation that those who suffer from traumatic neuroses tend to repeat traumatic dreams. The dreams of war neurotics, for example, seemed contrary to the general case that dreams represent symbolic wish fulfillment. The compulsion to repeat traumatic experiences appeared, then, to operate 'beyond the pleasure principle,' and to point toward an instinctual tendency at odds with libidinal self-preservation.

The struggle between *Eros* and death instincts can be observed at every level of biology, in every particle of a substance, even in molecular organisms. *Eros* attempts to preserve life through combinations, and this is to neutralize the instinctual striving toward death. The two instincts can also fuse together which results, at the psychic level, in sexual sadism. Defusion can result in the discharge of death instincts toward objects, which then takes the form of aggression, destructiveness, or sadism. Masochistic tendencies result if the ego is the object of discharge. Indeed, if it is possible for erotic libido to cathect the ego and to result in a phase of primary narcissism, it must correspondingly be possible for the death instinct to cathect the ego and result in a phase of *primary masochism*, a possibility that Freud did not reject outright.

Freud's account of the two classes of instincts, *Eros* (sexuality and self-preservation) and death (aggression), allowed him to preserve a dualistic classification of the instincts. The question that now loomed is how these twin instincts interacted with topographical features of the mind, now that the notions of 'consciousness' and 'unconsciousness' no longer had any straightforward implications for a structural depiction of mental life. This issue would be taken up in Freud's seminal work, *The Ego and the Id* (1923). In this work, Freud amends the

structural theory to include three psychic provinces, id, ego, and superego. He also describes how instinctual drive energies can be economically transmuted among these structures, and how certain neurotic conditions can be explained as a result of this hydraulic model of the mind.

Id, Ego, and Superego

The mature structural theory largely replaces the ill-defined notions of unconsciousness and the system *Ucs* with the 'id.' The id becomes a psychical province that incorporates instinctual drive energies and everything else that is part of our phylogenetic inheritance. The id operates unconsciously, accords with primary process, and impels the organism to engage in need-satisfying, tension-reducing activities, which are experienced as 'pleasure.'

Within the id are undifferentiated elements that would later emerge as the 'ego.' Freud's conceptualization of the ego and its functions shows clear lines of theoretical development. In early formulations, it was identified with the system *Cs* (*Pcs*), and known largely in terms of its repressive and self-preservative functions and for its putative opposition to things unconscious. As noted above, a clear change is evident in the paper *On Narcissism*, where Freud argued not only that ego instincts were libidinal, but also that ego functions were largely unconscious. Two further developments are evident in this paper. First, the ego begins to be described not as an impersonal 'apparatus' whose function is to detension the biological strivings of the organism, or as a 'device' for mastering excitations, but rather as a personal self. A second development is Freud's tentative hypothesis that ego development entails the renunciation of narcissism in favor of the idealization or aggrandizement of cultural and ethical ideals, which is represented to the child by the influence of parents. This 'ego ideal' becomes a substitute for lost infantile narcissism, at which time the child has his or her own ideal. Freud goes on to suggest that perhaps a special psychical agency emerges to observe the ego and to measure it by its ideal. This self-observing agency, and the ego ideal, will later take the form of a third psychical province, the superego.

What is the nature, then, of ego and superego formation, as outlined in *The Ego and the Id*? At the outset, the psychic system is described as an undifferentiated id-ego matrix. Topographically, a portion of the id lies in proximity to the boundaries of preconsciousness and external perceptual systems (system *Pcpt*), which brings the influence of the external world upon it. The resulting modification results in the formation of the ego. Hence, the ego is that part of the id, which is modified as a result of the perceptual system and by its proximity and access to consciousness, although the ego itself, like the id, is unconscious.

The ego takes on a number of functions. It commands the voluntary movement. It has the task of self-preservation and must therefore master both internal (id) and external stimuli. The ego masters external stimuli by becoming 'aware,' by storing up memories, by avoidance through flight, and by active adaptation. Regarding internal drive stimuli, it attempts to control the demands of the instincts by judiciously deciding the mode of satisfaction, or if satisfaction is to be had at all.

Indeed, the ego attempts to harness instinctual libidinal drives, so that they submit to the reality principle. If the id is a cauldron of passions, the ego is the agent of reason, common-sense, and defense. Yet the ego is never sharply differentiated from the id. Freud argues that the 'lower portion' of the ego extends throughout the id, and it is by means of the id that repressed material communicates with (presses 'up' against the resistances of) the ego.

The nature of the function of the ego is further clarified, and complicated, by superego formation. One clue to understand superego formation was provided by Freud's analysis of melancholia. He suggested that when a personal (or 'object') relationship is 'lost,' the lost object can be regained nonetheless by 'identification,' that is, the lost object is 'set up again inside the ego.' When the sexual object is given up, the ego is altered, insofar as the abandoned libidinal object is now set up inside the ego. The ego incorporates the object within itself (as introjection), 'identifies' with it, and thereby builds up its structure or 'character.' In this way, an object cathexis is substituted by an introjection. Freud suggests that perhaps the id can give up its objects only by identifications of this sort and that the ego can consequently be considered a precipitate of abandoned object cathexes.

It was from this analysis of how the ego can be built up and altered by identification that Freud found the theoretical foundation of superego formation. He argued that the initial identifications in early childhood would be those that would have lasting and momentous significance in the sense that here would be found the origins of the 'ego ideal.' Moreover, the necessity for making these identifications would be found in the triangular character of the Oedipus complex.

For illustrative purposes, consider the simple Oedipal situation for boys. A boy develops a libidinal attachment to his mother while identifying himself with his father. Eventually, the erotic investment in the mother intensifies and the father then comes to be seen as an obstacle or as a jealous rival. The boy desires not only to possess his mother but also to displace his rival, who is now viewed with some ambivalence. Yet this engenders considerable anxiety insofar as the powerful rival is capable of significant retaliation through the threat of castration. Hence, the Oedipal situation is untenable for the boy given the surge of castration anxiety. The libidinal cathexis must be given up. Although many complications are possible, some with pathological consequences, the standard maneuver is for the boy to repress his Oedipal desires for his mother.

Yet the infantile ego is still too feeble to carry this out effectively. Since the expression of oedipal desires is met with an obstacle in the person of the boy's father, one way of repressing these desires suggests itself: to set-up the obstacle within himself by intensifying his identification with his father. In this way, the boy musters the wherewithal to carry out the required act of repression, insofar as this identification is a way of borrowing the strength of the powerful father. But, as we have seen, identification typically results in an alteration of the ego. Indeed, the identification with the father as a solution to Oedipus complex is so momentous that a new psychical agency emerges from within the ego, the superego, which will thereafter retain the character of the father. Furthermore, every act of identification results in a sublimation of libido. Libido is 'desexualized.' But this sublimation also

means that the aggressive (death) instincts are no longer bound to erotic libido – it is now 'defused,' set free, and no longer neutralized. Freud suggested that herein lies the source of the cruel harshness of the dictatorial injunctions ('Thou shalt') of the superego – it lies in the pool of aggressive energies set free by the act of identification and libidinal diffusion.

The superego is thus a precipitate of family life. It is an agency that seeks to enforce the striving for perfection, as it holds out to the ideal standards of ego and moralistic goals. As a consequence, the superego is the 'conscience' of the personality, and it can retaliate against the imperfections of the ego by inducing guilt. Insofar as the superego is derived from the id's first object cathexis (in the Oedipal situation), the superego remains close to the id 'and can act as its representative' (in contrast to the ego, which represents reality). And because the origin of conscience is tied to the Oedipus complex, which is unconscious, the corresponding sense of guilt, too, must be unconscious. Indeed, Freud asserts that the superego reaches down into the id, and is consequently 'farther from consciousness than the ego is.' This leads to an interesting paradox that was noted by Freud. Because one is unconscious of having irrational libidinal and aggressive desires, one is far more 'immoral' than one believes. But because the superego (and the guilt that it imposes as punishment) is also unconscious, one is also more moral than one knows.

Superego formation, and the ideals that it represents, allows one to master Oedipus complex. And because it emerged at a time when the ego was still vulnerable, it retains a dominant position with respect to the ego. Freud was keen to point out that the superego is that part of his theory that expresses the 'higher nature' of man. He argued that as children we knew the higher nature in the person of our parents, 'we admired and feared them; and later we took them into ourselves' as introjections. And if religion, morality, and sociality are held to be what is higher in mankind, these too find their psychological origin in the workings of the superego. The religious longing for a protective and nurturing God finds its origin in the fact that the superego is a precipitate of our infantile longing for father. Our religious humility in the face of a judgmental God is a projection of the self-criticism of an ego that has fallen short of the ideals held out by the superego. With development, the injunctions of the father (which are introjected as the superego) are supplemented by other moral authorities, which then fortify the workings of conscience and thereby intensifies the feelings of moral guilt. And social feelings of all kinds are rooted in the kind of object identification of which superego formation is the model.

In addition to representing that which is higher in human nature, the superego is also implicated in a variety of pathological conditions. It is implicated in a 'resistance to therapeutic recovery,' since the prolongation of neurotic suffering is a kind of punishment for failing to meet the exacting demands of the superego. Melancholia results when the superego appropriates the violence of aggressive instincts and directs them against the ego. Certain kinds of obsessional neuroses ('tormenting' the object, as opposed to the self), too, can be linked to the harsh reproaches of the superego.

It should be clear that the ego is besieged from two directions. It must cope with the libidinal and aggressive drives of the id, from 'below,' and also the harsh moralistic and

perfectionistic demands of the superego, from 'above.' The ego must further reconcile these contrary tendencies with the demands of external reality. 'Whenever possible,' Freud writes, "it [the ego] clothes the id's *Ucs.* commands with *Pcs.* rationalizations; it pretends that the id is showing obedience to the admonitions of reality, even when in fact it is remaining obstinate and unyielding; it disguises the id's conflicts with reality and, if possible, its conflicts with the superego, too." Freud also likened the ego to a man, who struggles to check the superior power of a horse, to a constitutional monarch, who is ultimately powerless to frustrate the will of parliament, and to a politician, who too often "yields to the temptation to become sycophantic, opportunist and lying." One has to take recourse to psychoanalysis when such a struggle batters the personality into neurosis.

Summary

One way to summarize Freud's account of the tripartite personality is to make explicit the meta-psychological assumptions that have until now remained only implicit. Freud's *topographical* perspective is that the critical determinants of human behavior are unconscious, emanating from a biological province which he calls the 'id.' The *dynamic* point of view is that these critical determinants are instinctual drives, of which two classes can be identified: Eros (sex, self-preservation) and the death instinct (aggression, sadism). The *economic* point of view is that the 'hydraulic' dispositions of these drive energies among the psychic regions is a regulator of behavior.

Selected Post-Freudian Developments

Although there are still many adherents to Freud's classical theory, a palpable development since Freud has been the proliferation of competing psychoanalytic theories, all of which claim some support or other from the many searching insight to be found in the vast Freudian corpus. The most important post-Freudian development is a collection of related theories that is referred to as the 'object relational' school. Although these theories can be clearly distinguished on both obvious and subtle theoretical points, it is fair to say that they share in common a distaste for Freud's emphasis on energy dynamics as the foundation of human personality and for his division of personality into tripartite, evolutionary layers. They deny, for example, that the human organism is at first asocial, convulsed by bestial instinctual passions, embedded in primary narcissism, and only later to become social and socialized. To picture a human being as one driven by libidinal and aggressive energies is to liken the human being to a 'centaur' – the mythological creature with a human head affixed to the body of a beast.

One objection to the 'Centaur model' is that it is yoked to an implausible notion of 'instincts.' Freud suggested that human motivation can be explained with reference to two instincts, sex and aggression. But sex is not an instinctual impulse that exerts constant pressure, but is rather like an 'appetite' that shows a measure of periodicity. Aggression is not even an appetite, but is rather a reaction of the ego to a threat to the personality. And both sex and aggression are aspects of personhood that are ineradicable from interpersonal relationships. Furthermore,

Freud's notion that human psychology is driven by the energies afforded by the struggle between life and death instincts has been dismissed by some critics as mere 'biological mysticism.'

A related criticism concerns Freud's account of the ego. In Freud's theory, the rational ego emerges from a portion of the irrational id, but only as an impersonal apparatus or device for channeling drive energies and for securing the detensioning of the organism. What Freud describes is a control system and not a personal self that is involved in motivated relationships from the very beginning. When Freud describes the tripartite personality as consisting of 'provinces' that are 'extended in space,' he is describing a material reality that is based on a biological model of localization, and not the psychodynamic reality that whole human selves are formed in meaningful relationships that begin at birth. Hence, object relations theory rejects the Centaur model, rejects the instinct theory, rejects primary narcissism (and masochism), and rejects the impersonal ego.

Yet the object relations approach is often thought of as a movement that develops Freud's own best object relational insights. The notion of transference, for example, and the Oedipus complex of family relations, and the account of the ego as an 'agency' (as opposed to a 'province') would be ready examples of object relational insights that counter Freud's own preoccupation with impersonal, biological energy mechanics. It is ironic that the Oedipal theory, which is generally considered to be that which is most unpalatable about Freud's theory, is actually the foundation of the keen object relational insight – that personality is grounded in the nexus of family relationships. Of all the psychic structures, the superego is the only one to emerge as a consequence of interpersonal relationships. It comes to represent the influence of family and societal institutions on the formation of personality. Transference enshrines the view that the history of our experience of interpersonal relationships provides us with a template by which we attempt to manage our current relationships. Hence, the object relations approach tends to focus on the agentic whole self (the 'person ego') whose personality develops within the dynamics of complicated, meaningful relationships – and the warrant for this conceptualization, too, is often to be found in Freud's own writings.

Freud's theory is rarely studied in modern psychology departments, other than for historical purposes, although it still has a certain appeal in theology, literature, and other interpretive, hermeneutic disciplines. Freud did not view psychoanalysis as a form of literature, but as a set of scientific propositions about personality development, psychopathology, and treatment. Yet, it is on this score that psychoanalysis is found wanting. If the propositions of psychoanalysis are treated as scientific claims, then their probative value should be attested by the canons of scientific scrutiny. But many Freudian claims are simply unfalsifiable, fantastic, or the product of flawed analysis and reasoning (Grunbaum, 1984, 1993).

We noted at the outset that psychoanalysis has revolutionized human self-understanding in this century. Yet, for all that, the theory is still very much a product of nineteenth century conceptions of science. While one has cause to question Freud's reliance on outdated biological and physical science metaphors, his mechanistic conception of energy dynamics and his preoccupation with brain physiology and with localization, what will survive are the psychodynamic features of his

theory and the clinical insights about human personality that have given everyone new vocabulary. Defense mechanisms, ego, insight therapy, unconscious processes, the symbolic nature of symptoms, dreams, parapraxes, and transference – these are notions that are not far from even lay discourse. Indeed, some core Freudian notions such as unconsciousness, and the localization of ‘psychic provinces’ in the brain, are being rehabilitated by recent developments in cognitive and social neuroscience. Contemporary attachment theory has strong object relational elements that bear resemblance to Freud’s theory.

Although it is not easy to divorce the clinical facts attributed to Freud from the theories developed to explain them, especially when the probative and epistemic status of the theory is at stake, it is fair to say that the contemporary study of psychopathology and personality, the conduct of clinical practice, and the way ordinary people confront themselves and others would be very different were it not for Freud’s monumental, pioneering work. When one adds to this the whole domain of ‘applied psychoanalysis’ – the extension of psychoanalytic insights for understanding the artistic process, group psychology, esthetics, religious experience, and other cultural products – then the truth of W.H. Auden’s elegy is apparent. Freud lurks wherever one considers the human condition: a ‘whole climate of opinion under whom we conduct our different lives.’

Implicit Memory

H E Schendan, Plymouth University, Plymouth, UK

© 2012 Elsevier Inc. All rights reserved.

Glossary

Adaptation Phenomenon in which an exposure to a sensory input, such as seeing the color red, continues so long that the neural response decreases when the sensory input repeats a brief time later (usually immediately or within about 1 s). Many mechanisms have been proposed and vary with the particular circumstances of adaptation.

Amnesia Syndrome where memory is impaired selectively relative to other cognitive abilities, such as language, attention, and perception. For example, in medial temporal lobe amnesia, patients have problems encoding and consolidating explicit memory following the brain damage. Implicit memory is relatively spared in amnesia.

Conscious Experience of being aware of oneself and the environment. This encompasses any perceptions, thoughts, and feelings that one is aware of at the moment.

Dissociation In neuropsychology, this can be single or double or more. A single dissociation is demonstrated if patient(s) with a particular kind of brain dysfunction (e.g., in temporal cortex) are impaired on one task (e.g., an implicit memory test) but normal relative to a matched control group on another task (e.g., an explicit memory test). Better evidence comes from a double or higher dissociation. A double dissociation is demonstrated if the patient(s) with one kind of brain dysfunction (e.g., in temporal cortex) are impaired on task A (e.g., an implicit memory test) but not another task B (e.g., an explicit memory test), whereas other patient(s) with another kind of brain dysfunction (e.g., in frontal cortex) are impaired on task B but not task A, both relative to their matched healthy control groups.

Lesion In the brain, this refers to damage to neuronal cells due to a variety of causes, such as stroke, tumor, or gunshot wounds.

Mental simulation A pattern completion process that can occur when retrieving memory. This process re-enacts the modal processing that had occurred originally during learning. Mental simulation includes conscious mechanisms implicated in mental imagery but can also occur nonconsciously and automatically, as when reading a word for meaning. Mental simulation is thought to involve activity across chains of hierarchically-organized zones of convergence and divergence in association cortex. These zones have reciprocal connections with lower-level modal processing areas. Activating a zone triggers feedback input to

lower-level modal processing areas from which the memory was initially constructed. Consequently, seeing an object or reading its name re-enacts associated features (e.g. shape, color, motion, actions) that were stored during prior learning experiences, thereby constructing cognition.

Neocortex Newly evolved cerebral cortex of the central nervous system. It has six layers and four lobes (occipital, temporal, parietal, and frontal). Implicit memory is stored in the neocortex, particularly in areas beyond the primary sensorimotor areas.

Neuropsychology A clinical specialization or field of science focused on characterizing cognitive problems in patients with brain dysfunction.

Occipital cortex Located in the occipital lobe, this is the most posterior region of neocortex and is responsible for visual perception. It includes the primary visual area (V1) in striate cortex at the occipital pole and adjacent extrastriate (prestriate) visual cortex. This lobe is retinotopically organized such that adjacent neurons receive input from adjacent parts of the visual field (and corresponding retinal locations). Neurons adjacent but displaced laterally from each other across the cortex represent adjacent but likewise displaced visual field (and retinal) locations. Consequently, this cortex effectively represents an orderly image of light hitting the retina, though distorted to magnify central over peripheral retina. Extrastriate visual areas contribute to perceptual implicit memory.

Temporal lobe Neocortex located ventrally that includes association areas for visual processing, primary and association areas for auditory processing, and multimodal association areas. Lateral parts of the temporal lobe support advanced visual and auditory perceptual processing, perceptual and conceptual knowledge and implicit memory. By contrast, medial temporal cortex (parahippocampal region) is implicated in explicit memory.

Transcranial magnetic stimulation Noninvasive, reversible neuroscience technique that uses an electromagnetic coil to produce weak electrical activity in superficial regions of the cortex. This alters neural activity temporarily in these regions, typically disrupting processing so as to impair function. This enables the causal role of these regions in cognition to be inferred. Logic of using the technique is the same as neuropsychology. Dissociations are produced transiently in healthy participants.

Memory can influence behavior based on people's prior experience in the world, even without them being aware that this has happened. For example, people ride bicycles years after initially learning how, read a book faster and with greater comprehension the second time around, and make decisions about objects around them faster and more accurately as they

gain more experience with them. In such cases, memory can influence performance implicitly, without awareness. By contrast, people are consciously aware of explicit memory when they categorize objects or read words or when they recognize people, places, and objects as familiar or recollect details from prior experience with them.

Early History

The notion of memory without awareness has been traced to thinkers as early as Descartes. This philosopher referred essentially to fear conditioning in which frightening childhood experiences can have a lifelong influence, even though one cannot remember the origin of the fear-inducing event. Leibniz also referred to insensible or unconscious perceptions that influence behavior without conscious memory of the source of such influences. However, among early thinkers, Maine de Biran offered the most detailed and the deepest analysis of memory for unconscious habits and their influence on cognition and behavior. This philosopher has been credited with explaining that a habit can, with sufficient experience, eventually influence performance automatically and without being accompanied by awareness of using memory. He also distinguished between habits of motor actions and habits of emotional expression, and distinguished these two types of habits from conscious recollection (i.e., explicit memory). This essentially characterizes an initial version of the now predominant, multiple systems theory of memory that distinguishes between systems for implicit memory and explicit memory. Herbart further proposed that ideas can lie below a threshold for awareness but still influence conscious cognition. Around this time, many philosophers started to develop further ideas about unconscious processing. For example, Hering criticized the large body of earlier scholarship for focusing exclusively on explicit memory and introduced the idea of organic or unconscious memory. Also around this time, psychologists, biologists, and medical scientists further articulated ideas about organic (implicit) memory and how it relates, or does not, to explicit memory. For example, by the 1890s, Freud described how his hysterical amnesia patients could not recall the traumatic events leading to the hysteria but still revealed memory for those events in other indirect ways, and Freud is well known for emphasizing the importance and power of unconscious memory on behavior. Notably, Ebbinghaus conducted the first true experiments on memory, but he focused exclusively on explaining explicit memory. Nonetheless, his primary testing method assessed savings on relearning previously studied lists. To assess this savings on relearning did not require recollecting the preceding study episode or lists but rather just relearning the list now presented again better this time. This improved performance for repeated than newer information, regardless of conscious memory, fits the definition of an implicit memory phenomenon. Indeed, Ebbinghaus acknowledged that his method of measuring savings on relearning assessed unconscious memory, as has been confirmed empirically more recently. Finally, it is notable that McDougall was the first psychologist to use the terms implicit and explicit memory.

Indirect Memory Tests Reveal Implicit Memory

Implicit memory can be reactivated without a conscious strategy to retrieve memory or without intent to use memory. Moreover, a cardinal feature is that it can occur without conscious awareness that the memory has been reactivated. Consequently, changes in behavioral performance due to experience demonstrate implicit memory. Such tests of memory are

indirect. People are not instructed to use memory to do the task as they are on direct memory tests, such as categorization, recognition, or recall. Instead, on an indirect memory test, they just do the task. They perform differently depending upon their prior experience with elements of the task and do so without awareness of this, demonstrating implicit memory.

Indirect memory tests are the standard approach to assess implicit memory. On the other hand, direct tests are the standard approach to assess explicit memory. However, a thorny issue in memory research is that both direct and indirect memory tests can potentially reactivate both explicit memory with awareness and implicit memory without awareness to some extent. This remains a problem despite decades of research aimed at dissociating implicit and explicit memory. Nonetheless, several aspects of implicit memory have become clear.

Implicit Memory Supports Priming

To reveal implicit memory on an indirect test, by definition, people are not asked to report memory. A conscious report about memory cannot be used to measure implicit memory, at least not directly; note, implicit memory can occur during a direct test of conscious memory but special methods must be used to reveal it. Instead, using an indirect test, while people perform a task, a measure taken in response to an item that is old (i.e., repeated, studied) is compared to that to a new item (i.e., nonrepeated or nonstudied item). New items are basically the control condition for the experimental memory condition. Priming is the difference in behavioral performance between an old item relative to a new item (**Figure 1a**). For example, people press one of two keys to report whether an object is larger or smaller than a shoebox. Faster and/or more accurate key presses to old than new objects demonstrate priming. The priming difference is taken to reveal the magnitude of implicit memory.

Numerous studies have revealed some factors that consistently affect or do not affect priming. One factor is prior knowledge. Priming is greater for known or meaningful than unknown or meaningless items (e.g., real words *vs.* nonsense letter strings). Priming can be specific to the sensory modality, becoming smaller when the modality changes from study to test. Priming can be perceptually specific, becoming smaller when perceptual features of the stimulus change from study to test. While depth of processing (i.e., shallow perceptual *vs.* deep semantic) affects explicit memory (e.g., recognition), it has less or minimal effects on priming. Based on these findings, implicit memory thus varies with prior knowledge and is modality-specific, perceptually specific, and relatively insensitive to the depth of processing.

Varieties

Short- and Long-Term

Implicit memory can last briefly (short-term implicit memory) or indefinitely (long-term implicit memory). Priming effects have been shown to last to some degree for 48 weeks or more, especially with meaningful pictures. In general, priming reflects long-term implicit memory when it is shown to last

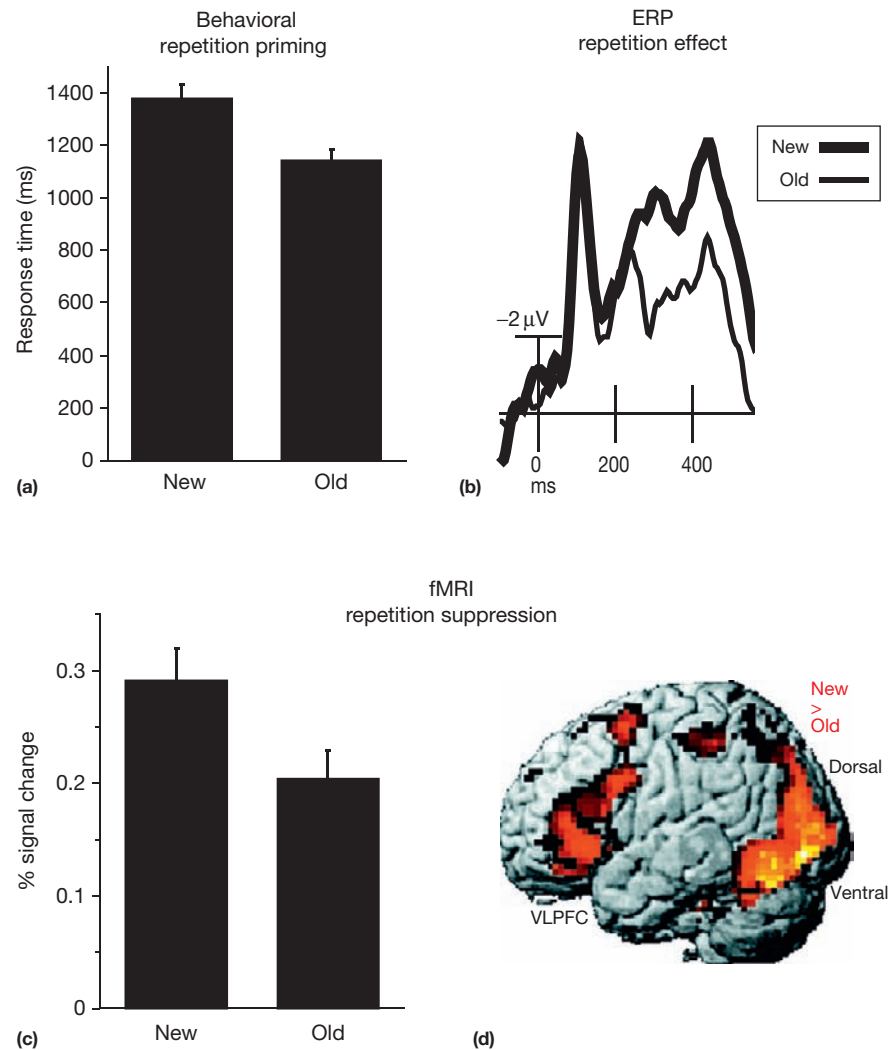

Figure 1 Behavioral and neural repetition effects related to implicit memory on an indirect test. Shown are results during visual categorization of a new object and an old object studied earlier in a separate learning session; note, data obtained by the author from a combined fMRI and ERP extension of Schendan and Kutas' (2003) experiment. (a) Response times (RTs) are faster for old relative to new items, demonstrating behavioral priming. (b) Event-related brain potentials (ERPs) show that long-term repetition effects are observed only after about 200 ms. Shown is the repetition effect on the N3 complex to objects at a right frontal scalp site referenced to the mean mastoids. The N3 is smaller (i.e., less negative) for old than new visual objects. (c) Relative to new items, repeated items show a reduced blood oxygenation level dependent (BOLD) response, known as repetition suppression. Percent signal change extracted from lateral occipital sulcus in a ventral object processing area (see brightest yellow region in (d)). (d) fMRI activation (new greater than old objects) is shown on an individual canonical brain (Montreal Neurological Institute). Neural repetition suppression related to implicit memory is found in ventrolateral prefrontal cortex (VLPFC) and ventral and dorsal visual object processing areas of association cortex.

for 2 min or more or 4–9 or more other items are shown between the first and second presentation of the repeated item. Short-term implicit memory includes cases of immediate repetition in which an item is repeated with no other items in between first and second presentations, and items repeat with a very brief time interval of usually <2 s and as little as no time between them. While long-term priming depends upon associative and long-term implicit memory processes, immediate repetition priming depends upon other memory mechanisms. Immediate repetition priming depends upon (1) working memory, (2) automatically sustained activation in knowledge networks, and/or, (3) for extremely brief presentations of items (e.g., <1 s) and extremely short delays (i.e., 200 ms or less), on

nonassociative habituation (including sensory adaptation). Most research on implicit memory has focused on long-term priming. Short-term varieties have been the focus of studies of working memory, perception, and semantic memory. Thus most of the rest of this review focuses on long-term priming.

Processing

Implicit memory varies not only in how long it lasts (i.e., short- or long-term) but they also vary in the processes that drive the effects. To appreciate the different varieties of implicit memory revealed by priming phenomena, a few words about the relation between processing and memory are needed.

Transfer appropriate processing and encoding-specificity theories of memory emphasize the relation between information processing at study and the processing during the memory test. For example, transfer appropriate processing theory says that memory depends upon the degree to which the processes recruited during the study (or learning) phase transfer appropriately to the memory test. Transfer will depend upon the degree to which the memory test recruits the same processes that take place during learning. The more similar the processes at study and test, the better memory will be.

In a similar vein, some memory accounts distinguish between data-driven and concept-driven tasks. Data-driven tasks during the memory test depend heavily on nonsemantic (i.e., perceptual, surface, or motor) processing. Consequently, the memory revealed on such tasks will be greatest if the study task also engaged the same nonsemantic information processing. On the other hand, concept-driven tasks during the memory test depend heavily on conceptual processing (i.e., meaning, semantic, categories). Consequently, the memory revealed on such tasks will be greatest if the study task also engaged the same conceptual information processing.

Content

Repetition priming is thought to facilitate processing due to recent experience with the same or similar information. Repeating the exact same stimulus produces the most priming. Why? Repeating the exact same stimulus repeatedly activates the same processes and representations (i.e., memory contents). This content could be perceptual, conceptual, or semantic, or all of these.

Perceptual

Perceptual implicit memory has been revealed by changing perceptual processing. On a data- versus concept-driven account, perceptual repetition priming will be revealed best when data-driven tasks are used for the memory test. For example, on perceptual identification tasks, a word or object is presented very briefly (e.g., 50 ms). People try to read the word or name the object. Performance on such tasks is typically less accurate than when people have unlimited time (e.g., <70% correct). Repeating the same word or object can increase this accuracy. The implicit memory driving the priming is perceptual to some extent. This is because the priming effect is larger when the perceptual form of the item remains the same between the study and test phases than when the perceptual form changes. For example, when reading a word again, priming is greater if the font has stayed the same than if the font now differs from the original experience. Likewise, when categorizing an object, priming is greater if one's viewpoint is the same as before than if one is now viewing the object from a different angle. Nonetheless, repetition priming typically does not drop to zero even when the perceptual form changes substantially as long as the core concept of the item remains the same between repetitions. For example, the word 'dog' printed in lowercase and uppercase ('DOG') still means the same, and a dog seen from above or the side is still the same object. The priming effect remaining after a change in perceptual form from study to test is thought to reflect conceptual implicit memory. Thus, when

exactly the same item is repeated, it is likely that both perceptual and conceptual implicit memory drive the repetition priming effect.

Conceptual

By the data- versus concept-driven account, conceptual implicit memory will be revealed best when concept-driven tasks are used for the memory test. For example, when the perceptual form of the item changes between the study and test phases, any priming effect must depend upon aspects of the item that remain the same despite these perceptual changes, such as the meaning of the item. Conceptual implicit memory has been demonstrated when the modal (i.e., sensorimotor) form of the item changes from study to test. For example, repetition priming has been found when a picture of an object is studied and then its name is presented at test, and *vice versa*, though picture to word priming is often larger and more robust than the reverse.

Semantic

Semantic priming can be considered a special case of conceptual priming in the sense that conceptual information or meaning drives the effect. However, both perceptual and conceptual implicit memory are revealed using repetition priming paradigms, and both can be long-lasting. By contrast, semantic priming paradigms all involve immediate repetition. No other items and only a brief time of typically 1 s or less intervene between the prime (i.e., study phase item) and the target (i.e., test phase version of the repeated item). Indeed, semantic priming effects do not typically last for more than a second or at most a few seconds.

On semantic priming tasks, the critical prime and target stimuli share no perceptual features, only some aspect of meaning. For example, the priming word 'nurse' may be presented 500 ms before the target word 'doctor.' Subjects may read the priming word and then perform a lexical decision task on the target letter string. They decide whether the letter string is a real English word or not (e.g., a nonword like 'XPFQNV' or pseudo-word like 'BRILLIG'). Semantic priming is demonstrated when response times to target words are faster when they are related than unrelated to the prime words. Semantic priming effects depend upon the associative links among aspects of knowledge in a cortical neural network.

Brain Basis of Implicit Memory

Theories

Convergent evidence for dissociations between implicit and explicit memory and other varieties of memory led to the multiple systems theory of memory. By this account, different types of memory depend upon different brain systems. The implicit system supports implicit memory, and the explicit system supports explicit memory. The most important evidence for the multiple systems theory has come from dissociations between measures of implicit and explicit memory in patients with brain damage. However, convergent evidence from other methods (i.e., behavioral, neuroimaging, and brain potentials) is required to establish a memory system based on at least three criteria. (1) Double dissociations must establish that different brain systems are necessary for two different memory systems. For example, for implicit and explicit memory, damage to the

implicit system impairs implicit but not explicit memory, whereas damage to the explicit system impairs explicit but not implicit memory. (2) Class-inclusion operations must be established, showing that the memory system operates on diverse information (e.g., words, objects, faces, places, visual, auditory) during a particular class of tasks (e.g., categorization *vs.* recall). (3) A list of properties of the system must be specified that also describes how the system relates to other systems. All such evidence has been found to establish an implicit memory system in the neocortex outside of medial temporal lobe regions. Nonetheless, it is important to realize that single process accounts, including computational models, have been proposed that use a single memory system. Such single process accounts can explain findings of differences between different memory phenomena, such as priming and episodic recognition. This can be taken as evidence against the multiple systems theory. However, to date, support for these single system alternatives primarily constitutes evidence that they can, in principle, explain dissociations between memory phenomena and other results; positive evidence for single process accounts has not yet been compellingly provided.

A possible exception could be single process accounts emerging from grounded (embodied) cognition theory. By this account, memory depends upon modality-specific systems for sensory processing (i.e., vision, hearing, touch, taste, smell) and motor action processing, as well as introspective states (e.g., emotion). In this view, memory, including implicit memory, also involves the cortical processes of mental simulation that recapitulate prior processing. During a mental simulation, prior information processing of the study item is activated again when a repeated item is processed later. This simulation takes place in the divergence–convergence zones of the cortex beyond the primary sensorimotor areas. The critical difference between the theories lies in the organization of the semantic memory system, which is part of the explicit memory system. Specifically, the multiple systems theory proposes an amodal system that lies apart from any sensorimotor areas and supports conceptual knowledge and semantic memory for word, object, person, and place meanings. This amodal semantic system underlies semantic and conceptual varieties of implicit memory. In contrast, the grounded cognition framework says that modal information (sensorimotor, emotional, and mental state) processing areas underlie semantic memory, either wholly or partially in partnership to an amodal system. Thus the distinction between perceptual and conceptual implicit memory in the multiple systems account disappears in a grounded cognition account, which would instead have a single implicit memory system embodied in the modal processing (e.g., sensorimotor) systems. While some grounded cognition theories posit a single memory system for all types of memory (e.g., both implicit and explicit varieties), other versions of grounded cognition also make no perceptual–conceptual distinction but are otherwise compatible with (or identical to) the multiple systems theories of memory.

Neuropsychological Evidence

Implicit memory in medial temporal lobe amnesia

The first clues about the brain basis of implicit memory came from cases of neurological patients with memory problems due to amnesia. These amnesic patients have medial temporal

lobe damage and are impaired severely on direct memory tests of recall and recognition. Korsakoff, the eponymous neurologist, recorded the earliest anecdotal evidence of implicit memory in his Korsakoff syndrome patients. One such amnesia patient was given an electric shock but failed to recollect this experience. Nonetheless, upon seeing the same device, he thought that the doctor might shock him. Likewise, Claparade pricked an amnesic with a pin. This patient later refused to shake the doctor's hand, despite having no recollection of the earlier unpleasant event.

Studies of patients with amnesia syndrome have provided perhaps the most important information about implicit memory. This is because these patients can be considered examples of people who have a selective impairment in explicit memory but spared implicit memory. As mentioned, an indirect memory test used to reveal implicit memory, in principle, also can be contaminated incidentally with explicit memory. For example, when categorizing an object repeated from a prior study episode, a healthy subject will do the task faster and more accurately with old than new objects, demonstrating repetition priming. However, they may also incidentally consciously recognize that they saw the object earlier in the experiment, demonstrating conscious episodic explicit memory for the prior study experience. In contrast, a patient with medial temporal lobe amnesia will be severely impaired on the latter conscious recognition process. Consequently, in contrast to healthy people, in amnesia, any implicit memory measure is minimally or not contaminated with episodic explicit memory. Amnesic patients can thus provide potentially the purest behavioral measures of implicit memory. However, this advantage of amnesia research was not realized until studies of the famous patient Henry Molaison (HM) who had exceptionally severe memory problems following bilateral medial temporal lobe removal in 1953. Research with HM since the 1960s demonstrates remarkably intact abilities to improve performance on some tasks with repeated experience, despite failing to recollect having experienced the materials before or recognize them as familiar. This was taken to demonstrate spared nonconscious memory, that is, implicit memory, in amnesia. Since then a large body of research has aimed at defining the memory preserved in amnesia, which is working memory, implicit learning, and implicit memory.

The large body of research with HM and other amnesics has demonstrated long-term memory without conscious awareness for a wide variety of perceptual and conceptual repetition priming tasks and for semantic priming. Most of these studies used materials that were already known to the subjects, mostly real words and real objects. In contrast, evidence for spared implicit memory in amnesia is more mixed when novel materials are used that are not meaningful or include information with no preexisting representation, such as nonwords, novel visual patterns, or unrelated word pairs. Some studies show priming in amnesia, while others do not. The evidence suggests that implicit memory for novel information depends on the task and perhaps also the severity of the amnesia.

While damage to the medial temporal lobe can produce amnesia for episodic explicit memory, it is important to note that the rest of the brain is intact, including the rest of the neocortex and subcortical structures. Consequently, spared implicit memory in amnesia indicates that implicit memory

depends upon these spared structures. In particular, the implicit memory that supports priming depends upon the neocortex, particularly secondary and associative areas beyond primary sensorimotor regions.

To avoid the circularity of defining any memory preserved in amnesia as implicit memory, it is important to obtain convergent evidence from other methods, of which evidence is substantial, though not without controversy. The vast literature on priming from studying normal subjects in cognitive psychology experiments using behavioral measures provides one set of evidence. Other evidence comes from other areas of neuroscience beyond neuropsychological work on amnesia.

Impaired implicit memory with cortical lesions

The gold standard in neuropsychology is to obtain a double dissociation. Impaired explicit memory with spared implicit memory in amnesia constitutes a single dissociation. To demonstrate a double dissociation, patients also need to be identified who show spared explicit memory with impaired implicit memory, preferably in the same experiment. Indeed, this has been found. Patients with lateral occipital cortex damage or disconnection between right and left occipital cortex show spared episodic explicit recognition and spared conceptual implicit memory but impaired perceptual repetition priming. Patients with lateral anterior temporal lobe lesions show spared explicit memory and perceptual implicit memory and spared episodic explicit memory. Alzheimer's disease damages the medial temporal lobe plus higher association areas, especially in the temporal lobe, including lateral parts. These patients have impaired episodic explicit recognition and recall, as well as impaired conceptual implicit memory, but relatively spared perceptual implicit memory. Altogether, such dissociations implicate occipital cortex in perceptual implicit memory, anterior temporal cortex in conceptual implicit memory (and semantic implicit memory), and the medial temporal lobe in episodic explicit memory. Transcranial magnetic stimulation (TMS) disrupts neural processing transiently and has been used to show that disruption of processing in left ventrolateral prefrontal cortex (VLPFC) reduces both the cortical and behavioral effects of repetition priming during a categorization task. Consequently, VLPFC may be necessary to express implicit memory behaviorally in a priming paradigm.

Neurophysiological Evidence

Neuronal repetition effects in non-human animals

The best candidate for defining the neurophysiological basis of implicit memory is neural repetition suppression. For example, neurons in inferior temporal cortex along the ventral visual pathway are selective for object shape, and activity of these neurons decreases with repetition. This neuronal repetition suppression occurs whether the repeated stimulus is the target stimulus for the behavioural task or is instead a non-target for the task or is merely passively viewed (i.e., no overt task on any stimulus). This suggests that repetition suppression is automatic, as would be expected for the neuronal mechanism of implicit memory. However, most of this research in animals has involved short-term or immediate stimulus repetition. Further, many studies used pictures of objects, scenes, or faces that would be unknown to these nonhuman subjects. In contrast,

most human implicit memory studies use meaningful word stimuli or other known and meaningful stimuli. The extent to which nonhuman animal findings can explain the neuronal mechanisms of human implicit memory, especially long-term varieties, thus remains unclear. So far, evidence suggests that short-term repetition suppression involves an input-fatigue mechanism in which the synaptic inputs to a neuron reduce their efficacy with repetition. However, several other mechanisms have been proposed to explain neuronal repetition suppression and implicit memory and may apply to other types of implicit memory (e.g., long term). After all, like the human behavioural phenomenon of priming, neuronal repetition suppression varies with delay between first and repeated presentations and duration of the stimuli. Both also vary with the similarity between the test and study items, consistent with transfer appropriate processing and encoding-specificity accounts of memory.

Repetition suppression in human functional neuroimaging reveal the brain location

Functional brain imaging suggests similar neurophysiological effects in humans (i.e., neural repetition suppression effects) by measuring changes in regional blood oxygenation or flow related to neural activity. Relative to the activation level in response to new items, repeated items show a reduced response, known as the neural repetition suppression effect (**Figure 1(c)**). This effect is sometimes referred to as functional magnetic resonance adaptation (fMR-A) when the paradigm involves immediate repetition or very short delays or interstimulus intervals between first and second presentations. Notably fMR-A uses suppression to infer the representational characteristics of perceptual processing areas (e.g., representation of view, position, size). This is analogous to the visual cognition approach of using priming to infer how objects are represented (e.g., parts or multiple views of an object). However, human and animal evidence indicates that the neural mechanism differs between different varieties of priming (e.g., immediate, short- and long-term). Mechanisms proposed for long-term implicit memory may not apply to short-term varieties, and conversely. This important consideration has, however, not yet been addressed systematically, leaving the neural mechanism unknown for the many neuroimaging studies involving repetition suppression.

Nonetheless, some recent work has started to address this, and some general principles about repetition suppression have emerged. Neural suppression occurs in secondary and associative cortex as opposed to primary sensorimotor cortex. For example, in the visual modality, early studies of priming-related suppression implicated only the ventral visual stream beyond primary visual cortex. This was consistent with multiple systems accounts of memory, which implicated only the ventral visual stream in perceptual implicit memory. Recent work, however, shows that short- and long-term suppression occurs along both the ventral and dorsal visual streams (**Figure 1(d)**). Evidence also indicates that suppression effects increase as processing proceeds from posterior to anterior visual processing areas. This is consistent with the larger priming effects found behaviorally for conceptual priming (e.g., involving more anterior temporal areas) than for perceptual priming (e.g., involving more posterior occipitotemporal

areas). Like behavioral priming measures of implicit memory, neural suppression can show perceptual specificity, especially in posterior perceptual processing areas. For example, suppression in object processing areas along the ventral stream becomes smaller when objects repeat from different viewpoints or under different lighting conditions.

At a network level, the brain regions that show suppression effects are parts of the active task network implicated in selective attention and working memory. This network also includes secondary perceptual processing areas, lateral prefrontal cortex, and intraparietal sulcus. Activity in this network is anticorrelated with activity in a default mode network implicated in episodic explicit memory, mind wandering, and internally directed attention. The default mode network includes medial prefrontal cortex, cingulate cortex, retrosplenial cortex, lateral posterior parietal cortex, and superior temporal gyrus. Consistent with anticorrelation between these networks, the default mode network shows the opposite repetition effect. They show repetition enhancement, that is, greater activation for old than for new items. This is typically observed on episodic memory tests (e.g., recognition of an item as old and familiar).

As can be the case with behavioral priming, neural suppression can show task specificity. For example, when the task changes between the study phase and the memory test phase, suppression is reduced, especially in prefrontal regions and fusiform gyrus in the left hemisphere. This finding can be considered an example of violation of the transfer appropriate processing principle of memory, which predicts that processing differences between study and test will reduce memory. The task changes that reduce suppression can include inversions of the decision (e.g., Larger than a shoebox? *vs.* Smaller than a shoebox?). Even inversions of the response key mapping may reduce behavioral priming (e.g., yes and no mapped to 1 and 2 keys *vs.* 2 and 1 keys, respectively). However, whether decision or motor-related aspects of the response are the locus of the stimulus–response mapping effect remains to be established. Nonetheless, the effect of switching response clearly increases with repetition, as the reduction is substantial with multiple repetitions and less or none with a single repetition. Notably, most research on implicit memory and behavioral priming has involved a single repetition and so cannot depend substantially on stimulus–response learning. Consistent with this, studies with amnesia patients indicate that stimulus–response learning effects depend upon the medial temporal lobe system for episodic explicit memory. Intriguingly, this suggests that stimulus–response mapping influences on repetition priming are more properly considered an episodic memory phenomenon in which episodic memory incidentally influences priming, instead of a characteristic of the implicit memory system. After all, indirect memory tests can recruit not only implicit but also explicit memory. This also suggests that stimulus–response learning cannot explain the remarkably spared priming effects established in amnesia patients. Nonetheless, studies of stimulus–response mapping and neural suppression have indicated that top-down processing from prefrontal cortex to other brain regions has a role in the task switching effect on behavioral priming. Transiently disrupting processing in the VLPFC reduces stimulus–response learning effects, demonstrating a causal role.

Neuronal mechanisms

Altogether, human neuroscience findings implicate multiple different mechanisms for repetition suppression in priming paradigms. The first mechanism, referred to here as the tuning account, is the classic explanation. This account suggests that neural repetition suppression depends upon sharpening or tuning of neuronal receptive fields due to learning. The neural representation of the stimulus becomes more precisely tuned to its preferred stimulus (e.g., the shape of a particular dog from a specific view) with experience with that stimulus. Such effects show perceptual specificity such that memory decreases with changes in the perceptual form between the learned version of the stimulus (e.g., a different view of the dog or a different type of dog, say, poodle instead of collie) and the memory test version of it. Suppression due to neuronal tuning probably occurs in posterior perceptual processing areas implicated in perceptual representation or knowledge systems. Tuning-related suppression can also occur, to some extent, in more advanced stages of stimulus processing, such as in anterior temporal cortex for visual stimuli, implicated in conceptual knowledge about stimuli (e.g., meaning of a word or object). However grounded (embodied) theories of cognition would implicate both posterior and anterior stimulus processing areas because sensorimotor processing areas support not only perception and action but also meaning and memory. However, tuning-related suppression seems to have a limited relationship with priming of behavioral performance on tasks that require processing stimulus meaning, such as categorization.

Consequently, a second mechanism has been proposed more recently following new evidence that VLPFC has a causal role in behavioral priming that is response-specific. This account was motivated by the stimulus–response mapping findings that switching the task decision mapping from study to test reduces priming and repetition suppression. By this account, top-down inputs from prefrontal cortex onto other brain regions influence behavioral priming. Prefrontal cortex is implicated in cognitive control, attention, and working memory. These control processes can become more automatic with increasing experience with an item. Consequently, the association between the stimulus and these control processes becomes stronger. This learning results in memory and behavioral priming that is response-specific. However, as mentioned, this mechanism clearly applies to priming after multiple repetitions, but evidence so far suggests its involvement after a single repetition is minimal or none.

Another explanation uses a perceptual memory-based caching system to explain short-term priming with meaningless perceptual patterns, which does not show stimulus–response learning. By this computational account, perceptual processing results in perceptual representations. While meaningful stimuli engage processes related to categorizing and verbally labeling the stimulus, meaningless perceptual patterns do not; instead, they engage other perceptual processes based on the task requirements, such as the size of the object. A short-term perceptual memory process (i.e., the ‘cache’) briefly stores the binding of the percept and other task-specific perceptual information. In posterior cortex, this caching mechanism could presumably operate along with the tuning mechanism to explain implicit memory and priming, regardless of a task switch from study to test.

At the neuronal level, several mechanisms may underlie repetition suppression. Three examples discussed so far are the input-fatigue mechanism (for adaptation with immediate repetition) and the tuning and caching system mechanisms (for long-term perceptual repetition suppression). However, other mechanisms are possible and could also explain response-invariant suppression. Like the input-fatigue version, a firing rate-dependent fatigue mechanism (for adaptation) suggests that neuronal responses decrease with use (i.e., the neuron becomes fatigued). However, in this case, repetition suppression is proportional to the firing rate elicited in response to the first presentation. Evidence so far has not favored this account. By contrast, a facilitation model suggests that the time course of the neuronal response (i.e., onset latency and/or duration) decreases with repetition. While neuroimaging has provided some support, this can be assessed better using neurophysiological measures with temporal precision within the range of neuronal activity (milliseconds). In humans, electromagnetic brain potentials have supported facilitation models of long-term repetition, as category knowledge is activated about 50 ms earlier for repeated than for new objects.

Repetition effects on human electromagnetic potentials reveal the timing

Event-related electrical potentials have defined the time course of memory processes. This evidence indicates that, for everyday cognition, long-term implicit memory starts relatively late in information processing, after the initial bottom-up activation through perceptual processing areas. Brain potentials show that long-term repetition effects are observed only after about 200 ms (**Figure 1(b)**). The repetition effects are relatively long-lasting, until around 400 or 500 ms or so after the stimulus appears, indicating that implicit memory effects on information processing typically last for about 300 ms or longer. In particular, repetition typically affects mid-latency negativities between 200 and 500 ms that reflect activation of knowledge about words, objects, and faces. Negativity is typically reduced for repeated relative to new items. With meaningless stimuli, these effects are minimal or none. This is consistent with the idea that implicit memory substantially affects perceptual and conceptual knowledge representation systems. While priming can occur for nonsense stimuli, such effects are short-term and response-invariant, and explained using the caching mechanism. By contrast, long-term implicit memory of meaningful stimuli involves facilitation, tuning, and perhaps stimulus-response mapping mechanisms of neuronal suppression. The time course evidence indicates that all these mechanisms, under most circumstances, involve top-down inputs from prefrontal to posterior perceptual and conceptual processing areas and/or feedback inputs among the processing areas themselves. For example, by 200 ms, electrical potentials have been recorded intracranially from human prefrontal cortex. Brain potential evidence thus indicates that long-term implicit memory that supports behavioral priming is associated with neural repetition suppression. This neural mechanism for this implicit memory involves top-down from prefrontal cortex to other posterior information processing regions.

Nonetheless, a handful of studies have shown repetition effects on earlier brain potentials not only for short-term but also long-term repetition. These effects are found on transient

potentials related to the initial feedforward pass through perceptual processing areas, as well as automatic recurrent and feedback within these areas. The input-fatigue mechanism has been implicated in short-term and adaptation (immediate repetition) effects. The long-term effects are related to perceptual priming, regardless of meaning, and have been found with meaningful and meaningless stimuli. At last one such early repetition effect has been clearly linked to perceptual grouping processes. However, to observe effects of long-term implicit memory early in processing, the task may need to focus attention on perceptual details. For example, one study required subjects to determine whether a nonsense visual pattern had a loop or not. Another study made stimulus categorization highly challenging visually by presenting fragmented line drawings very briefly (for 20 milliseconds).

Notably, convergent evidence from cognitive psychology, neuropsychology, and neuroimaging suggests that implicit memory can influence explicit memory performance on recognition tests in which people decide whether an item is old and familiar from a prior study experience or is a new item. For example, electrical potentials during explicit episodic memory (recognition) tests have revealed repetition effects between 200 and 400 ms. This is found when people can recognize items with some accuracy but report being unaware of retrieving memory and just guessing. This has been taken as an implicit memory process that influences recognition performance but without awareness.

Other Priming Phenomena and Their Mechanisms

Masked Priming and Short-term Implicit Memory

In immediate repetition priming paradigms (e.g., semantic priming), when the study item is presented very briefly (e.g., for 50 ms) and masked, this prime stimulus is typically not reported by people. The prime is thus taken to have been processed only unconsciously. While it is as problematic to establish that the prime is unconscious as it is hard to establish that implicit memory is unconscious, clearly the prime is minimally available to conscious report under these masking conditions. In the standard paradigm, masking involves presenting a perceptually similar stimulus immediately before the prime (e.g., for 500 ms). This is the forward mask. The target item, which constitutes the memory test, is presented immediately after the prime (e.g., for 500 ms) and also serves as a backward mask, though some studies use an additional backward masking stimulus similar to the forward mask. In studies of perception, such masking seems to minimize or eliminate influences of top-down feedback from the frontal lobe on posterior processing. Elimination of this feedback is thought to be the reason why the prime is processed largely or wholly outside of conscious awareness. Using the masked priming technique, early perceptually specific repetition effects have been found on electrical potentials as early as 100 ms after the appearance of the item. Overall, priming effects from these studies reveal contributions from bottom-up processing in posterior secondary and association cortex to sensory feature, orthographic, lexical, and conceptual levels of word processing and perceptual and conceptual levels of object processing. This variety of implicit memory, however, depends upon recent activation of the knowledge network by the prime

that is ongoing when the target item appears shortly thereafter, as opposed to tuning or facilitation mechanisms. The fatigue mechanisms may also apply. Repetition suppression has been associated with masked priming in neuroimaging studies.

Antipriming

Priming studies use new items as the baseline condition to assess memory. Responses to new items are compared to those for repeated (old) items. However, recent evidence suggests that a new item that has been intermixed with old items is not an entirely neutral baseline control. Instead, these new items reflect not merely processing of the novel item but also small antipriming effects on these new items as a by-product of the previous experience with the repeated items. Antipriming happens because objects are represented in perceptual systems in a distributed, overlapping fashion organized according to feature similarity. Further, individual neurons are tuned broadly to sets of features of objects, and a population code of sparse sets of neurons represents each object. Consequently, when an object is experienced, its representation becomes strengthened, consistent with tuning and facilitation mechanisms. However, the process of strengthening this representation also weakens the representations of other objects with which it shares features. For example, a dog has a head, body, and four legs. Experience with a dog strengthens its representation while also weakening the representation of other objects sharing one or more of its features (e.g., other animals with similar head, body, and/or leg features). Crucially, when an item with these overlapping features is later presented as a new item (mixed with repeated items) on a priming test, its neural activity is actually greater (than for repeated items) as part of a late process of connecting its relatively weaker representation back up. Electrical potentials indicate that this effect occurs after 1100 ms, which is over 200 ms after the behavioral response, and well after earlier perceptual and conceptual implicit memory and even after any incidental episodic recognition of the item. Instead, antipriming effects reflect a very late relearning effect, essentially encoding of new information into memory. However, in neuroimaging studies, due to the long time course of the blood response on which they depend (i.e., several seconds), neural repetition suppression effects likely reflect some combination of perceptual and conceptual implicit memory plus a small contribution of antipriming effects, at least in the left inferotemporal and left and right lateral occipital areas where antipriming effects appear.

Implicit Memory Can Result from Implicit Learning

Memory results from learning. Consequently, implicit learning (i.e., skill learning, procedural learning, motor learning, perceptual learning) can lead to implicit memory. This is not typically included as implicit memory proper, which instead focuses on priming phenomena. While memory following implicit learning could be explicit and revealed on recognition or recall tasks, it could also be implicit. Indeed, the typical method for demonstrating that learning has occurred in an implicit learning experiment is to test memory indirectly. Moreover, to demonstrate that learning is implicit, the memory that results from this learning must be demonstrated to be implicit. To do so, both indirect tests and direct tests (i.e., recognition, recall) of memory are used.

The indirect tests measure changes in performance for old relative to new information. The difference measured is not referred to as priming but, nonetheless, does fit the definition. The main exception is that implicit learning effects can be observed only after more than one experience with the repeated information. In fact, typically, many experiences are required to observe implicit learning effects. By contrast, repetition priming occurs routinely following a single presentation of the item at study (i.e., during learning). In fact, typically many experiences are required to observe implicit learning effects.

For example, one of the most widely studied implicit learning tasks is the serial response time (SRT) task. In the spatial version, people see different locations on a computer screen light up one at a time (e.g., one of four boxes will light up). People press a key corresponding to the location on the screen that is lit. Locations light up either in a repeating sequence or a new order (e.g., random locations). Faster responses to repeated than new locations demonstrate implicit learning. This can be taken as a kind of location priming that demonstrates implicit memory for the repeating sequence of locations. If direct memory tests also indicate no conscious awareness of memory for the repeating sequence, then the implicit memory demonstrated on the task is taken to indicate that learning has occurred implicitly. Consistent with this, the large body of research with HM and other amnesics has also demonstrated memory without conscious awareness for perceptual, cognitive, and motor skills (e.g., mirror-reversed reading), rule learning, and SRT task learning. However, amnesic patients are impaired on implicit SRT task learning, if higher-order associations among multiple locations must be learned. Further, neuroimaging of normal subjects has demonstrated learning-related activation in the medial temporal lobe during implicit learning, despite no conscious awareness of having learned anything. This is observed during the early phase of implicit learning of higher-order associations when the most new information needs to be encoded. Evidence for medial temporal lobe involvement without awareness of memory has also been found for probabilistic classification learning and context learning. Thus the role of the medial temporal lobe is not in conscious (explicit) memory per se (but rather can have a role in some types of implicit learning and memory). Instead, the computational demands of the learning task determine whether the medial temporal lobe is recruited (e.g., for higher-order associations, sequence disambiguation, or contextual associations). In contrast, the basal ganglia, which connect in closed circuits with the cortex, have an established role in implicit learning. Neuroimaging demonstrates basal ganglia activation during implicit learning on a wide variety of tasks. Further, patients with Parkinson's disease have basal ganglia dysfunction and impaired implicit learning with spared episodic memory, whereas amnesic patients have impaired episodic memory and relatively spared implicit learning (and consequent implicit memory). This demonstrates a double dissociation between implicit learning and memory versus explicit memory.

Conclusion

Perceptual, conceptual, and semantic varieties of implicit memory prime behavior. This nonconscious, effortless, automatic memory affects performance at immediate, short, and

long delays and can last for years. Implicit memory can result from implicit or explicit learning. However, implicit memory is specific for the sensory modality and perceptual features of the stimuli and the task response. Implicit memory is related to neural repetition suppression and depends upon in neocortical information processing areas that lie outside the medial temporal lobe and primary sensorimotor areas. While short-term varieties may involve neural fatigue during bottom-up processing, some long-term types involve top-down inputs to posterior cortex occurring after about 200 ms of processing. The brain basis of implicit memory varies with the cortical areas involved and the delay between study and test.

Glossary

Brain lesion studies Studies in which the function of an area of the brain is inferred from behavior that people can no longer perform after their brain is damaged in that region.

Event-related potentials (ERPs) Electrical potentials that are generated in the brain as a consequence of the synchronized activation of neuronal networks by external stimuli. They can be noninvasively recorded by placing electrodes on the scalp.

Functional magnetic resonance imaging (fMRI) A noninvasive imaging technique that measures oxygen levels in the brain's blood vessels. Based on the assumption that brain regions recruit more oxygen the more active they are, recording differences in oxygen levels can be used to localize brain activity.

Impression formation The process by which one integrates various sources of information about a target person into an overall judgment.

Ingroup/outgroup A terminology that originates from social identity theory. Ingroups are social groups toward which an individual feels loyalty and respect, usually due to membership in the group. In contrast, outgroups are groups that an individual does not belong to.

Mentalizing A term referring to the process by which humans make inferences about the unobservable mental states of other social agents.

Point-light animation studies In work of this kind, movement is portrayed via a small number of point-light markers that are positioned on the head and the joints of a person's body. From the assembly of moving lights, naïve observers can readily recognize a human shape and its actions.

Introduction

In 1946, the American social psychologist Asch examined, in an impressive series of studies, how people combine various pieces of information about another person into a holistic impression. His work set the stage for over 60 years of active impression formation research. The enduring interest may not be surprising given the topic's immense relevance for everyday life: When we choose a flatmate or a partner, register with a doctor, trust a sales person, or ask a stranger for help, our decisions and actions are likely to be determined by our impression of the individual in question. Importantly, these impressions tend to be not only descriptive (e.g., Mark can play the violin) but also evaluative (e.g., I really like Mark). As such, they can become powerful forces that fundamentally shape the course of social interactions. But how exactly do humans form impressions about each other?

The famous reminder not to judge a book by its cover is indicative of two sources of information that humans can use when forming impressions: On the one hand, the outer appearance of books and people alike seems to invite spontaneous evaluative processing. Daily experience attests that within the briefest of glances, we can easily extract information about another person's facial features and expression, hairstyle, gaze direction, head and body orientation, posture, and choice of apparel. From these visual cues alone, one can quickly draw inferences about a person's sex, age, race, emotional status, attractiveness, personality, and social attention. On the other hand, however, neither the content of a book nor the character of a person may be reflected in what easily meets the eyes.

Beyond the person information that can be gleaned from merely looking at someone, a wide array of additional information about others can be gathered by interacting with them.

For example, within a very short encounter the timbre of a target's voice as well as his or her accent, way of expression, and mannerism can be encoded. In addition, prolonged and repeated interactions allow for experiencing someone's behavior over time and across different types of situations. Not surprisingly, these additional person cues can greatly enrich the impression formation process.

Importantly though, forming impressions about others is not only influenced by the appearance and the attributes of the target person or the duration of an acquaintance, but also by characteristics of the perceiver. Expectations, variations in mood or attentional state, as well as aspects of similarity between perceiver and target can profoundly influence the type of person inferences drawn during an encounter. Therefore, the purpose of the present article is to provide an overview on target- and perceiver-related factors that shape the course and products of the impression formation process.

Impression Formation at First Glance

Consider for a moment the last time you strolled through a supermarket. Besides thinking about what to buy and which aisle to visit, observing other people in the store can be a constant source of distraction. For example, depending on the time of day, one is likely to see happy couples grabbing a pizza for a quiet night in, stressed businessmen hunting for microwavable food, or a desperate homeless person stocking up on cigarettes and cheap wine. But how is it that one comes to know these things about other people? What does it take to discern that someone is happy or stressed, desperate or in love, homeless or a businessman in the absence of any interaction with them? Research exploring the visual cues that humans

rely on when forming impressions of others suggests that a person's physiognomy (i.e., facial features), outer appearance (i.e., clothing), or demeanor (i.e., posture, style of walking) are of particular importance. But exactly what sort of impressions are we capable of creating on the basis of such visual information alone?

Inferring Personality Traits

It comes as no surprise that people readily draw personality inferences when perceiving others. Such spontaneous trait judgments can have far-reaching consequences in many domains of everyday life. Evaluations of competence based on a target's facial appearance, for instance, have been found to be predictive of people's political voting decisions. In addition, increased body height – a feature that tempts observers to ascribe social dominance to others – has been demonstrated to be positively related to increased occupational success. Moreover, wearing revealing clothes, a signal of immodesty and apparent promiscuity, has been shown to cause lay people, judges, police officers, and prosecutors alike to hold victims of rape to be responsible for their assault. These brief examples illustrate how fundamentally the appearance of others can determine our impressions of them.

Interestingly, people often agree on the traits and qualities they infer from visual person cues, a phenomenon that has been termed consensus at zero acquaintance. Notwithstanding this observation, certain traits seem to be more inferable than others and elicit higher consensus across perceivers. For example, while judging a person's extraversion and conservatism from appearance cues elicits high consensus across perceivers, judgments of neuroticism or openness reveal little or no agreement. Research also indicates that people are particularly inclined to judge others according to their agreeableness (i.e., how warm and friendly they are). Nevertheless, perceivers seem to be particularly bad at making this verdict. Put differently, what people typically judge during first encounters is often something that they are not able to judge with much success.

Given people's tendency to infer traits from visual cues alone, an obvious question arises: Exactly which features do people use to guide their judgments? At present, this issue is poorly understood, although it is apparent that the selection of features is clearly trait-dependent. For example, people are deemed to be highly extraverted when they have a round face and stylish hair, wear extravagant clothing, show a friendly expression, display frequent and rapid body movements, and walk in a relaxed manner. In order to further elucidate the process of trait ascription following person perception, recent studies have explored the persistence of these inferences and the extent to which they can be drawn under impoverished viewing conditions. This work has demonstrated that a mere 100 ms exposure to an unfamiliar face is sufficient for participants to draw likeability, trustworthiness, competence and aggressiveness inferences about the target that are similar to those generated under longer viewing times. Beyond facial features, initial work using point light displays has revealed that inferences regarding a person's extraversion, warmth, and trustworthiness can also be drawn from patterns of body movement alone.

Inferring Emotional States

Besides determining personality traits at one glance, forming impressions about others has also been tightly associated with inferring their emotional states. According to the famous expression 'laugh and the world laughs with you, weep and you weep alone,' people tend to prefer others who radiate positivity. Also, by observing someone's emotional responses to events in his or her environment (e.g., Does Mark feel sad for a friend who lost his job? Does seeing a sunset make him happy?), perceivers can draw inferences about the person's character. Many studies suggest that a whole range of static and dynamic person cues is routinely used to understand the emotional states of others. For instance, humans are able to recognize at least seven basic expressions of emotion (i.e., happiness, fear, surprise, anger, sadness, disgust, and contempt) with high accuracy and consistency from facial expressions alone (more details on this topic is dealt elsewhere within the encyclopedia). In addition, successful emotion recognition is also enhanced by processing a person's bodily posture such that facial expressions of emotions are recognized most rapidly when they are paired with emotionally congruent body postures. Furthermore, although perceivers can read emotions from static images of people, motion cues significantly enhance emotion recognition. Even the motion of isolated body parts, such as the manner in which an arm is moved while drinking, waving or lifting, can be sufficient to infer the emotional states of others. For example, movements that accompany anger or elation tend to be faster, more energetic, and spatially expansive than those that signal passive emotions such as contempt, sadness, and boredom.

Inferring Social Attention and Intention

A person's direction of gaze can also play a prominent role in processes of impression formation. For instance, perceivers seem to profit from using gaze information when trying to decipher the emotional states of others. Expressions of anger are perceived more accurately, categorized more quickly, and rated as more intense when eye gaze is directed 'toward' than 'away from' the perceiver. Interestingly, the opposite is true for expressions of fear. Findings such as these suggest that the perception of facial emotions is influenced by the potential behavioral intent of the cue provider to approach or avoid the perceiver. According to this line of reasoning, while direct gaze is thought to enhance the detection of approach-oriented emotions such as anger and joy, averted gaze is assumed to enhance the recognition of avoidance-oriented emotions such as fear and sadness.

Moreover, gaze cues can also readily signal whether an object of significance has appeared in someone's immediate environment or if one is the target of another person's attention (e.g., Is Mark looking at me or at the attractive person over there?). It has been demonstrated that under conditions of direct gaze, the processes supporting person perception are optimized. One of the consequences of mutual gaze is that faces with direct compared to averted gaze are more likely to be attended to and to be remembered. Also, faces with a neutral expression and direct gaze are rated as more likeable than faces with an averted gaze. Given the role that eye gaze can play during processes of emotion recognition and social attention,

it does not come as a surprise that perceivers are highly accurate at decoding the gaze direction of others. The structure of the human eye facilitates just such a task. Comprising a small dark area (i.e., the pupil and iris) surrounded by a region of white (i.e., the sclera), human eyes are well adapted to signaling where they are looking.

Inferring Group-Based Characteristics

In order to form impressions about others rapidly and without investing too much time in getting to know them, perceivers also regularly rely on categorical knowledge structures to simplify the impression formation process. As a result, evaluations of others are influenced not only by a person's specific appearance, but also by stereotypic expectations. As consensual beliefs about individuals based on knowledge of the groups to which they belong, stereotypes are engrained in the very fabric of society. Dominant stereotypes in Western society, for example, target a person's sex, race, and age and typically comprise beliefs regarding the traits and behaviors associated with membership in these groups. Compared to men, women are believed to be less intelligent, competent, and ambitious. However, if they are communal and conform to traditional female roles, women are deemed to be wonderful. Similarly, African Americans are stereotypically assumed to be lazy, criminal, and uneducated but also musical and athletic, whereas Asian Americans are considered to be intelligent, industrious, conservative, and shy. In addition, stereotypes about age groups suggest that lovable, dependent, and weak infants will turn into belligerent, moody, and irresponsible adolescents, before they suffer physical and mental decline including tiredness, forgetfulness, and self-pity by the time they reach old age (more details on this topic is dealt elsewhere within the encyclopedia).

Importantly, the likelihood of stereotype activation and application during impression formation is sensitive to the extent to which individuals possess features that are deemed to be typical of the groups to which they belong. In this respect, faces with more Afrocentric features have been shown to elicit stronger activation and application of the African-American stereotype than faces with less prototypical features. This form of feature-based stereotyping has also been observed in criminal-sentencing decisions, such that targets with very obvious Afrocentric features, for instance, are punished most severely. Of course, perceivers also can determine a person's typicality for a respective social category based on cues other than a target's facial appearance. Information about age typicality, for example, can be gleaned from people's movements, for instance, individuals are believed to be stronger and happier when they display a youthful gait rather than when their gait resembles that of an elderly person. In addition, clothing has been shown to signal a target's typicality. Depending on whether a Black individual is encountered in prison dressed as a criminal or a lawyer, the typical pattern of racial stereotyping can even be reversed. Importantly, research has also shown that category-based first impressions are highly susceptible to situational influences. Viewing an Asian woman performing a typical female activity (e.g., applying cosmetics) or a typical Asian activity (e.g., eating with chopsticks), for example, was found to be sufficient to prompt either the sex or the race of the target, respectively, to dominate the associated impression

formation process. In a similar vein, forming an impression about a Black target based on African American stereotypes was found to be more likely when the target was encountered in expected rather than unexpected settings (e.g., street corner vs. outside a church).

Impression Formation over Time

The impression formation process is not usually aborted as soon as we have had a brief glance at another individual. Especially, if we encounter someone repeatedly, our observations of his or her behavior over time and across situations will continually shape our thoughts and feelings toward the individual. Thus, as time elapses additional aspects of the impression formation process can begin to unfold.

Multiple Categorization

Several influential social psychological models suggest that the starting point of the impression formation process is often a target's social category memberships that are easily gleaned from visual facial and bodily markers such as sex, race, and age. Indeed, recent evidence indicates that such category-based construal of others is easily and frequently done – primarily when people are encountered for the first time. However, people do not usually belong to only one social category, and many social categories they belong to are not always easily gleaned from their appearance (e.g., religion, nationality, political views). Through prolonged observation and/or repeated interaction, however, perceivers are likely to learn about the multiple group memberships of others. Imagine Fred, for example, who is an adolescent vegetarian from Italy aspiring to become a lawyer. Or Susi, a middle-aged Black school teacher and animal rights activist from Sweden. When forming impressions, perceivers seem to find some conjunctions of categories easier to integrate than others. Depending on the specific combination of categories, completely new impressions may be formed about a person. A Harvard educated carpenter, for example, may be judged to be nonmaterialistic, even though this trait would not be spontaneously used to describe a Harvard graduate or a carpenter. Thus, especially surprising category combinations seem to cause the ascription of completely novel traits to others.

Person Individuation

Apart from trying to integrate multiple group memberships into a holistic impression of a person, repeated encounters can also lead to a fundamental shift from mainly category-based judgments about others toward more individualized assessments. Thus, over time perceivers often begin to consider a target not only as a random instance of various generic social categories but rather as a unique entity. Increasingly individuated impression formation is likely when perceivers pay particular attention toward another individual either because he or she is of heightened relevance or importance to them or because the target consistently fails to conform to category-based expectations. Once individuating information is taken into consideration, perceivers are likely to develop complex

theories about the person in question. The resulting lay theories about significant others are then used to explain and predict their behavior. For example, under the assumption that my friend Lucy is very insecure and shy, I will not be surprised to find her not talking easily to others at a party.

Attribution Theories

How exactly the transition from a group-based to a more individuated impression takes place and how categorical and person-specific information become integrated is still a matter of debate. It appears to be the case, however, that a single category-inconsistent behavior is not sufficient to modify a category-based impression. In this respect, one rational decision by Anne will not easily tempt us to assume she is a rational person, given that we know that women are quite emotional per se. In contrast though, temporally consistent behavior seems to have the potential for permanently overriding category-based judgments. According to attribution theories, observing and interacting with others elicits the constant attempt to understand whether their behavior reflects their character or is merely the product of normative or situational forces. In order to decide whether a certain behavior is really reflecting a person's personality, perceivers seem to use consensus, consistency, and distinctiveness information. Put differently, the more unusual a behavior is, the more often it is displayed, and the more a person shows this behavior across a wide range of different situations, the more likely it is assumed to be related to a person's character (more details on this topic is dealt elsewhere within the encyclopedia). By using such attribution strategies, initial impressions of others can be validated or falsified over time.

Biases in Impression Formation

Despite most people's intuition that their impressions of others are unbiased and reliable, accumulating evidence has shown that their judgment of others often suffers from systematic short-comings. Below the most prominent biases are described in alphabetical order.

The Accessibility Bias

The enhanced accessibility of certain constructs due to frequent or recent use has been found to fundamentally shape the impression formation process. For instance, exposing people to positive or negative trait items (e.g., adventurous vs. reckless) causes them to interpret ambiguous behavior of others soon afterward as correspondingly positive or negative, depending on the meaning that has been primed. In a similar vein, it has been shown that activation of the construct sex can influence how perceivers construe others. In a study set up to investigate this effect, male participants were asked to view a series of advertisements. Half of the participants were shown adverts that had women displayed in sexual postures, while the other half was presented with sexually neutral spots. Afterward, all individuals were asked to conduct an interview with a female student for a job as a research assistant. It turned out that those participants who had seen the arousing spots chose

to sit closer to the woman, asked her more personal questions, and judged her more likeable but less competent after the interview than those that had seen the neutral spots. More generally speaking, such research demonstrates that the temporal accessibility of certain constructs can majorly influence the in which manner in which information about others is sought out and used for forming impressions about them.

The Babyface-Overgeneralization Bias

Adult faces that are round and comprise large eyes, high eyebrows, small nose bridges, thick lips and a high forehead as well as a short chin tend to be perceived as babylike. Research has demonstrated that adults with a babylike facial appearance are often considered to have childlike traits such as being naïve, submissive, weak (physically, socially, and intellectually), warm and honest as well. The consequences of such a babyface-related trait judgments have been found to be far reaching. Babyfaced individuals, for instance, are favored for jobs that require agreeableness, but they are very likely to be passed over for mentally challenging tasks and leadership positions.

The Beauty-Is-Good Bias

Attractive people are generally seen to possess more desirable characteristics than their less attractive counterparts. The force of being considered more outgoing, socially competent, powerful, and healthy can be clearly quantified across the life span. Attractive kids elicit more attention and affection, and are punished less severely than unattractive children. In adulthood, heightened attractiveness is related to increased mating opportunities, better employment prospects, advantageous work evaluations, increased earning potential, and longevity. But what exactly does heightened attractiveness mean? Although recent work provides evidence that personal taste significantly impacts judgments of beauty, it appears that specific facial attributes have consistently been linked to enhanced attractiveness. Besides bilateral facial symmetry, facial averageness (a facial configuration close to the population mean), sexual dimorphism (i.e., high femininity in female faces and high masculinity in male faces), a healthy skin and dental appearance, a pleasant expression, youthfulness, and good grooming, bodily information also contributes to assessments of attractiveness. This becomes most apparent when considering evaluations of the overweight. Men and women who deviate from societal standards of bodily attractiveness by being overweight are seen as flawed not only in their appearance, but also in terms of their personality. Participants ascribe more negative traits (e.g., lazy, incompetent, boring, undisciplined) to overweight than average-weight individuals, an outcome that precipitates serious discrimination in health, work, and educational settings.

The Categorization Bias

The mere categorization of humans into groups tempts perceivers to judge identical behavior of others differently, depending on the social groups to which they belong. For instance, a classical study revealed that when white students watched a

heated discussion between two men that ended in one man shoving the other, the observed action was considered more aggressive when the shove was delivered by a Black relative to a White man. In addition, studies have shown that perceivers tend to attribute positive behaviors of ingroup members to advantageous dispositions and negative behaviors to situational factors, while positive and negative acts of outgroup members are explained in the opposite way. Also, members of the same group are considered to be more similar (i.e., within-group assimilation) and members of different groups to be more different from each other (i.e., between-group contrast) than when they are seen as mere individuals.

The Correspondence Bias

Humans are inclined to attribute the behavior of others to their inner dispositions rather than the consequence of social roles or situational constraints – a phenomenon termed the correspondence bias. For instance, when women are encountered in roles that call for nurturing and supportive behaviors (i.e., as nurses) and men in roles that require independence and assertiveness (i.e., as managers), perceivers are likely to infer that persons enacting those roles have corresponding dispositions rather than that they display efforts of role fulfillment. In consequence, the influence of normative or situational factors on the observable behavior of others is often underrated, resulting in biased personality attributions.

The Familiarity Bias

Sometimes targets are encountered on numerous occasions, yet no specific target-related knowledge is acquired (i.e., the woman one sees on the bus every morning). Perceivers seem to regard perceptually familiar people as more likeable, intelligent, and warm-hearted compared to unfamiliar targets, an effect that is likely driven by the misattribution of positive affect elicited by increased perceptual fluency. Recent work also suggests that perceptually familiar individuals are construed in a stronger stereotype-based manner than unfamiliar others, perhaps reflecting perceivers' need to make sense of frequently encountered targets.

The Negativity Bias

Negative information about others has been found to be unusually influential in guiding our impressions of them. This bias has been explained by the enhanced distinctiveness and diagnosticity of such information. For example, if one is trying to determine whether another person is honest, learning that he or she is faithful to his or her partner is less informative (because such a behavior is normative) than learning negative information such as that the person is cheating (which is often considered unusual). Thus, negative information has a powerful impact on impression formation because it is more useful for distinguishing between alternative interpretations of a person's behavior. In addition, evidence suggests that impressions that are initially negative tend to be more stable than positive impressions because negative experiences decrease the probability of future interactions that would allow the sampling of additional information about a person.

The Physical Resemblance Bias

People we encounter for the first time occasionally resemble friends, family, celebrities, or acquaintances in their appearance or mannerisms. A consequence of this similarity can be that these strangers are ascribed the same traits, attributes, and characteristics as the targets they resemble. For example, when the face of a stranger reminds one of a good friend, traits descriptive of the friend are readily attributed to the unknown other. In a similar vein, a study has shown that people express a preference for a stranger whose face resembled that of someone who treated them kindly rather than irritably.

Self-Fulfilling Prophecies

The term self-fulfilling prophecies refers to the observation that sometimes our beliefs about others can lead us to treat them in such a way that they subsequently become what we expect them to be. Originally, the effect was demonstrated in the classroom and called the 'pygmalion effect.' In a seminal study, teachers were told at the beginning of a school year that certain of their students were potential late bloomers, who would be expected to excel during the school year under proper guidance. Even though there was nothing in actual fact that set those students apart from their colleagues, several months later their schoolwork had improved considerably. Since this initial observation, numerous similar investigations have testified to the robustness of the effect with regard to both, positive and negative expectations. Follow-up studies also demonstrated that perceivers sometimes unintentionally transmit their expectations through nonverbal signals. In a mock interview situation, for instance, it has been shown that when an interviewer's negative expectation about another person was reflected in his or her nonverbal behavior (i.e., keeping more physical distance), the interviewee actually performed more poorly (more details on this topic is dealt elsewhere within the encyclopedia).

Serial Position Effects

Accumulating evidence also suggests that the order in which individuals learn information about others can fundamentally shape the impression formation process. In his original study Asch, for instance, asked his participants to read a list of adjectives about another person and found that the same words could yield very different overall judgments, depending on their order of presentation. When adjectives with more positive meaning were presented first, followed by attributes with less positive meaning, the participants tended to rate the person more positively than when the order of words was reversed. Subsequent research found further evidence that information acquired while beginning to form an impression is particularly potent in influencing one's overall judgment – a phenomenon referred to as the primacy effect. Additional work has also revealed that the last information acquired can have a particularly strong impact on one's overall impression – an observation termed the recency effect.

The Similar-to-Me Bias

This bias describes the human tendency to judge people whom we consider similar to ourselves more positively than those we

consider less similar. For example, strangers who resemble one's own appearance often receive elevated ratings of trustworthiness. Furthermore, employees tend to trust their superordinates more and act more honestly around them, if they consider them to be similar rather than dissimilar to themselves. At this point, it remains uncertain which dimensions are of particular importance when determining someone's similarity (e.g., whether it refers to shared attitudes, habits, or demographics). Initial evidence suggests, however, that even similarity on a completely irrelevant dimension, such as being born on the same date, can elicit enhanced positive evaluations.

Perceiver-Driven Biases

Researchers constantly add to the list of factors that can modulate and even bias aspects of the impression formation process. In this respect, evidence is accumulating that shows that the eye of the beholder fundamentally shapes the way information used to infer the personality of others is encoded. For example, emotion recognition has been found to be influenced by the sex and age of perceivers. Men appear to be less accurate at recognizing emotions than women and as adults get older, they display decrements in their ability to identify emotions from visual cues. Intriguingly, a perceiver's own emotional state also influences recognition performance such that congruent emotions are identified most readily in others. Moreover, judging the attractiveness of others has been found to be dependent on the characteristics and status of the perceiver. For example, a person's preference for specific personality traits can elevate the attractiveness of faces that appear to display the desirable characteristics in question. In addition, hormonal changes in men and women can modulate ratings of the attractiveness of potential partners. Also, the link between person perception and stereotype-based impression formation has been found to be moderated by preexisting prejudiced beliefs. Compared to prejudiced persons, egalitarian individuals seem to rely less on stereotypes when forming impressions of others. Taken together, this body of work confirms that the manner in which people construe others is shaped not only by the available information about them, but also by a host of perceiver-related characteristics that moderate the course and products of the impression formation process.

Automatic and Controlled Aspects of Impression Formation

What is perhaps most striking about the impression formation process is that judgments about others are often made without perceivers' intention or conscious awareness. For example, recent work suggests that personality traits such as trustworthiness are gleaned from faces regardless of the goals or intentions of the perceiver. Similarly, it has been shown that even under conditions in which no explicit evaluation of an individual is required, heightened attractiveness elicits feelings of positivity. In addition, research has demonstrated that impression-related consequences of physical resemblance can take place outside of awareness. In this respect, when exposed to photographs of a few short-faced professors who were known to be fair

and a few long-faced professors who were considered to be unfair, college students were found to subsequently judge an unknown short-faced professor to be more reasonable than an unknown colleague, even though they were unaware of the relationship between facial length and fairness. Observations such as these suggest that impressions can be elicited rapidly and unintentionally.

Despite the fact that many aspects of the impression formation process are shaped by relatively automatic and unintentional perceptual, evaluative, and interpretative processes, researchers have begun to show that the extent or impact of typical biases on the impression formation process can be limited as well. For instance, according to numerous studies, impressions about others are likely to become more accurate once perceivers invest time in getting to know them rather than relying on their immediate responses. Furthermore, judgments tend to be less flawed when humans predict specific behaviors (e.g., Mark does not like greeting people) rather than global personality traits (e.g., Mark is unfriendly). Additionally, the motivation to be open-minded and accurate can dramatically change the way impressions of others are formed. In this respect, being aware of one's own expectations as well as stereotypes and actively searching for disconfirming rather than confirming information is likely to result in a more accurate judgment of others. Nevertheless, further investigations are necessary to elucidate which aspects of the impression formation process can be reliably influenced by deliberate mentalizing.

Neural Correlates of Impression Formation

Social psychologists have recently begun to complement classic impression formation research by using data from neuroimaging, event-related brain potentials, and lesion studies. Through the adoption of neuroscientific methods, the researchers are trying to further elucidate how faculties and processes in the human brain differ depending on whether humans form impressions about conspecifics rather than inanimate objects or nonhuman creatures. Converging evidence indicates that when looking at others, a dynamic representation of an individual's facial and bodily appearance can be achieved through the combined effort of five localizable cortical regions. Two face-specific areas, the occipital face area (OFA) in the posterior inferior temporal sulcus as well as the fusiform face area (FFA) in the posterior fusiform gyrus, show increased activity when humans look at faces of their conspecifics compared to other common objects and nonsense stimuli. Similarly, two body-specific areas, the extrastriate body area (EBA) in close proximity but slightly superior to the OFA and the fusiform body area (FBA) situated adjacent to and overlapping with the FFA, display selectively enhanced activity to human bodies. While these four brain regions encode static facial and bodily features and their structural configuration (i.e., person snapshots), an additional brain region – the posterior superior temporal sulcus (pSTS) – integrates dynamic person-related information. Robust pSTS activity occurs when people watch facial as well as whole-body or body-part motion relative to motion of nonhuman stimuli. Together, these data indicate that human faces and bodies are reliably discriminated from other object categories early in the visual processing cascade (more details on this topic is dealt elsewhere within the encyclopedia).

Most importantly in the context of impression formation, however, further work indicates that the generation of inferences based on these person percepts depends on the recruitment of additional brain regions in concert with the core person perception regions. One of the neural substrates found to be most diversely involved in such person inferences is the amygdala. Although still poorly understood with regard to its functional contribution, the amygdala has been found to be activated by processes of social categorization, trustworthiness perception, emotion recognition, and the identification of familiar others. For instance, neuroimaging studies have revealed that, compared to neutral faces, emotional faces elicit not only an increased response in core regions of the face processing system, but also a concomitant increase in activity in the amygdala. Furthermore, faces that are considered to be particularly untrustworthy seem to elicit an elevated amygdala response, and patients with damage to this structure have a tendency to consider trustworthy faces (as rated by healthy individuals) to look quite untrustworthy. Amygdala activity has also been found to track with a target's racial status (i.e., it exhibits increased responses to faces that do not match the perceiver's own race) when participants are asked to judge a person's sex or age. Finally, a weaker amygdala response has been noted to accompany the perception of familiar rather than unfamiliar faces – a difference in activation that has been argued to reflect lower levels of vigilance toward familiar others than strangers.

In contrast to the amygdala, the orbitofrontal cortex (OFC) seems to have a highly specific role during person-based inferences. As a brain region dedicated toward tracking attractiveness, it potentially contributes toward the widely spread beauty-is-good-bias. Interestingly, while attractive male faces elicit stronger OFC activation in heterosexual women and homosexual men than attractive female faces, in heterosexual men and homosexual women, attractive female faces evoke stronger OFC activation than attractive male faces. These findings suggest that the OFC responds not only to the attractiveness of a person per se, but also to the attractiveness of others who are sexually relevant for a particular perceiver.

In addition to the amygdala and the OFC, perceiving the others in action (i.e., during the exhibition of intentional motor behavior) and trying to understand the intentions behind these actions has been tightly linked to activation in the premotor and parietal cortices. Studies that have elicited the temporal deactivation of this frontoparietal network have shown that such a disturbance significantly impairs people's ability to discriminate and understand what others are doing. Thus, the functional significance of the frontoparietal network seems to lie in making sense of the behavior of others. It has been argued that one strategy that people can adopt to interpret the actions of others involves the use of their own 'motor knowledge' as a guiding framework. That is, incoming bodily-related visual information from others is mapped onto one's own motor system (i.e., motor simulation). As it turns out, the premotor and parietal cortex are involved in both the perception and execution of action. There is also evidence that activity in the critical frontoparietal network is elevated when perceivers observe actions that can be easily mapped onto their own motor representations. Specifically, individuals show stronger activity in premotor and parietal cortices during the perception of actions they regularly perform themselves compared to actions they rarely enact.

In this respect, evidence that action perception can be subserved by motor simulation has begun to accumulate.

Finally, one of the most important regions in the extended person processing system is the anterior temporal lobe (aTL). Neuroimaging investigations have repeatedly demonstrated that the perception of familiar others, either because they are personal acquaintances or famous celebrities, is associated with elevated activity in the aTL. Most tellingly, following damage to this structure the ability to identify familiar faces deteriorates dramatically. Although this converging evidence suggests that the aTL plays a pivotal role in the detection of identity, it remains uncertain how it does so exactly. It has been speculated that the crucial contribution of the aTL toward person perception is based on its representations of specific semantic and biographical knowledge about others that is accessed once a familiar person is encountered.

Interestingly, even though first insights have been gained in how the human brain accomplishes a few specific person inferences such as encoding the attractiveness, personality, emotional status, group membership, or familiarity of other social agents, how these subimpressions are combined into an overall judgment remains uncertain at this point. Initial evidence suggests, however, that various types of person-based inferences result in enhanced activity in the dorsomedial prefrontal cortex (DMPFC). In particular, increased DMPFC activation is observed when people are explicitly asked to form impressions about others, and also when they are required to judge whether specific attributes (e.g., *assertive* vs. *seedless*) can be descriptive of them, or when they need to infer the mental states or intentions of other social agents. Such findings indicate that the DMPFC may act as a binding site that enables us to integrate various sources of person knowledge into a holistic judgment.

Summary

Based on the pioneering work of Asch, a field of study dedicated toward elucidating how people form impressions of each other has begun to flourish over the last few decades. The outcome of many studies to date indicates that the impression formation process commences as soon as we lay eyes on others. By encoding facial and bodily person cues, perceivers are inclined to spontaneously judge a target's race, age, sex, emotional status, social attention, and personality. In addition, person-specific characteristics are inferred from people's behaviors using consensus, consistency, and distinctiveness information. But it is not target attributes alone that modulate the impression formation process. Characteristics of the perceiver also shape the course and outcome of person judgments. In this respect, forming impressions of others is an inherently subjective process that is likely to be biased by numerous factors. Given that these biases can result in serious discrimination, uncovering and understanding biasing influences enables people to limit their impact and thus avoid unwarranted person judgments.

Glossary

Behavioral inhibition A distinct temperamental category, originally identified by Kagan, involving excessive fear and wariness in response to social and nonsocial forms of novelty.

Brain electrical activity Fluctuating patterns of voltage generated by the biophysical mechanics of thousands of synchronously activated neurons. Measured as continuous electroencephalogram (EEG) activity or discrete event-related potentials (ERPs; phasic brain responses to presentation of stimuli).

Endophenotype An intermediate phenotype; an inherited characteristic (e.g., insulin resistance) that is normally associated with some condition but is not a direct symptom of that condition (e.g., diabetes).

Gene–environment interaction The developmental effect of a particular genetic variant that differs depending on environmental conditions, or of a particular environmental effect that differs depending on genetic factors.

Genotype The complete genetic make-up of an organism that determines or regulates a specific characteristic or trait.

Neurotransmitter A chemical substance (e.g., norepinephrine, dopamine) that is released

across the gap between neurons, thereby mediating communication between neurons.

Phenotype The manifestation/expression of a specific trait (behavioral, anatomical, or physiological characteristic of an organism), resulting from a genotype, environmental influences, gene–environment interactions, and stochastic influences.

Polymorphism A naturally occurring genetic variation that gives rise to distinct forms or phenotypes within the same population (e.g., human blood types) and appears in >1% of the population.

Probabilistic epigenesis A principle in developmental psychobiology holding that genes are not autonomous agents of development but rather, there are bidirectional influences among multiple levels of analysis: genetic, neural, behavioral, and environmental. In contrast, predetermined epigenesis postulates unidirectional information flow from genes to structure to function.

Temperament A persisting pattern of behavioral and emotional traits that appear early in life and have strong links to physiological and biological processes.

Introduction

Understanding the basis for individual differences in temperament has been a focus of human inquiry from ancient to modern times. This interest stems from the curious observation that individuals have unique ways of responding to any given experience, and maintain a certain consistency in their responses across situations and time. Most contemporary investigators agree that temperament refers to inherited variation in the expression of emotion and patterns of behavior that is consistent over time (see Table 1). Individual differences in these domains provide the platform on which personality begins to develop and crystallize. The purpose of this article is to address five questions: (1) What is temperament? (2) How is temperament measured? (3) What determines temperament? (4) How does temperament predict developmental outcomes? (5) What does the future hold for the field of temperament research?

What Is Temperament? Psychological and Physiological Perspectives

The oldest Western classification of temperament we know was outlined in Greek civilization more than 2000 years ago. The early philosopher–physicians Hippocrates and Galen described

temperament in the context of the dominant biomedical model of their time that was based on four fundamental bodily fluids. Temperament was believed to reflect the relative balance among the fluids, resulting in sanguine, choleric, phlegmatic, or melancholic types of people. These types were consulted up until the nineteenth century, and endured in recognizable form into the twentieth. After a long and rich history, the physiological basis of temperament remains part of its working definition to the present day.

Modern temperament researchers vary in their predilection for theory driven approaches to the study of temperament or data-driven views. For example, Rothbart has focused on psychological sources of data to understand individual differences in reactivity and self-regulation, and the moderating influence of experience on temperament. Complex, person-centered concepts such as social behavior, effortful control, and conscience have been derived largely from the application of sophisticated, statistical tools (e.g., factor analysis) to subjective ratings gathered from parental, teacher, peer, and self-report questionnaires.

By contrast, physiological concepts such as arousal level and neurotransmitter availability operate at the level of biological processes assumed to be causal in the maintenance of observed temperamental variations. This distinction does not imply that those temperament researchers who rely primarily on psychological concepts wish to deny that temperament has

Table 1 Criteria for core temperament characteristics as viewed by contemporary investigators

Individual differences in domains related to emotional reactivity and behavioral responding are as follows:
Apparent in the first few years of life
Rooted in and proximal to a biological level of analysis (i.e., genetics, neurophysiology, and neuroanatomy)
Relatively stable and enduring across life
Apparent across different cultures
Observed in other nonhuman animals, such as primates and some social mammals

a strong biological foundation. Indeed, there is near universal acceptance among contemporary researchers that temperament incorporates processes that are much more proximal to a biological level of analysis than are other important features of human psychology (e.g., intelligence, personal motivations). However, these two approaches to the study of temperament begin from different starting positions and each leads to a conceptualization of temperament that differs from the other in important respects. A current challenge is to reconcile these approaches in a way that demonstrates a nuanced and sophisticated appreciation of their complex and complementary contributions.

Psychological Approaches

Over seven decades ago, Allport described temperament as the “characteristic phenomena of an individual’s emotional nature . . . susceptibility to emotional stimulation . . . strength and speed of response, the quality of his prevailing mood and . . . fluctuation and intensity in mood.” Then there followed a two-decade-long gap during which learning models prevailed in developmental psychology and much of mainstream psychology. Individual characteristics such as temperament were largely ignored until Thomas and Chess initiated the New York Longitudinal Study (NYLS) in 1956. From factor analysis of parental reports of infant behavior, nine dimensions of temperament were derived. These included activity level, attention span/persistence, distractibility, bodily rhythmicity, adaptability, intensity of reaction, approach/withdrawal tendencies, sensory threshold, and mood. Scores for each dimension were computed from responses to individual items in questionnaires. Further analysis of these responses grouped infant temperament into three types labeled ‘easy,’ ‘difficult,’ or ‘slow to warm up.’ The difficult temperament was at the greatest risk for subsequent psychological problems and therefore, the object of much study. However, because what is termed ‘difficult’ may vary depending on parental values and child-rearing practices, Thomas and Chess emphasized the interaction between infant temperament and its environment, that is, the ‘goodness of fit’ between the infant’s characteristics and the reactions of its caregivers. Optimal development was likely when parenting needs and the child’s temperament matched.

Subsequently, Bates questioned whether the ‘difficult’ construct reflected qualities pertaining only to the child. As assessment of temperament was derived from parental reports, he argued that the description of a child as ‘difficult’ was partly based on the parents’ perceptions. Nonetheless, parental

attributions might be very important to the child’s development and social functioning in the long run through their influence on parent–infant interactions. In this respect, Bates located risk and resilience in the context of the family, an idea that shared considerable conceptual ground with goodness of fit.

Contemporaneous researchers Buss and Plomin viewed temperament as a constellation of four independent attributes – emotionality, activity level, sociability, and impulsivity (EASI). To be considered an aspect of temperament, a trait must occur in infancy, be reflected in nonhuman primates, and demonstrate continuity across time. Traits that were observable in the first year or two of postnatal life were assumed to have a genetic basis. Genetic influences were believed to determine emotionality (particularly with respect to negative emotions such as fear and anger), activity level, and sociability, i.e., the infant’s responsiveness to others and interest in shared activities. Impulsivity was later removed because it did not appear as a reliable individual difference until school age and only some of its components were replicable in factor analyses.

Representing another school of thought, Rothbart and colleagues conceptualized temperament as individual variation in two broad characteristics: a child’s constitutionally based tendency to (a) emotional reactivity, and (b) self-regulation. In this formulation, temperament was assessed in terms of reactive behaviors (fear, amount of smiling and laughter, and activity level), and regulatory behaviors (frustration with limitations, soothability, and duration of orienting). Reactive behaviors such as fearful inhibition and unrestrained approach were thought to generate increased arousal in somatic, affective, autonomic, and endocrine systems. Over the course of development, however, these behaviors were increasingly modulated through effortful control. High levels of effortful control related positively to social competence, elicited the approval of others, and simultaneously served to reduce children’s risk for externalizing and some internalizing disorders. The development of effortful control depended crucially on the efficiency of neurobiological networks in frontal regions of the brain supporting attention, inhibition, approach/withdrawal, and self-soothing, processes that together lead to optimal alertness, arousal, and interpretation of information.

A psychological view of temperament representing all of these theoretical positions has been summarized by McCall as ‘the relatively consistent, basic dispositions inherent in the person that underlie and modulate the expression of activity, reactivity, emotionality, and sociability. Major elements of temperament are present in very young children, and those elements are likely to be strongly influenced by biological factors. As development proceeds, the expression of temperament increasingly becomes more influenced by experience and context.’

Physiological Approaches

The modern era of temperament research and its physiological basis began with Pavlov. Pavlov’s early contribution to temperament resulted from his discovery of individual differences in the classical conditioning of dogs, namely, the marked variation in the speed and strength with which dogs associated neutral stimuli with food rewards. To explain these differences,

Pavlov theorized that individual variation in nervous system functioning was important to understanding the degree of adaptation to various classes of stimuli.

Pavlovian concepts exerted a considerable influence on subsequent generations of Soviet and eastern European scientists studying temperament. Beginning in the late 1950s and continuing into the 1980s, Soviet scientists explored the biological bases of temperament with respect to neuronal excitatory–inhibitory dynamics. These investigators studied ‘involuntary reactions’ of the nervous system (e.g., differential susceptibility to fatigue or conditioning), which were believed to be relatively uncontaminated by higher order sociocognitive influences. The emphasis on a physiological approach was rooted in both the intellectual tradition of Pavlov and political currents in the Soviet state. In Soviet intellectual culture, ‘mentalistic’ (i.e., psychological) constructs in the description of human behavior were explicitly eschewed and biological concepts strongly favored. Investigators such as Teplov, Nebylitsyn, and Strelau made important contributions to this approach by applying Pavlovian ideas of nervous system function to humans.

Certain concepts investigated by this group were revisited and elaborated by Eysenck and Gray. Balance between neural excitation and inhibition is central to Eysenck’s hypotheses that extraversion reflects the degree of biological arousal in the brainstem reticulocortical activating loop, and that neuroticism is related to the threshold for excitability in the limbic lobes of the brain. These ideas are alive and well today. Similarly, Gray’s approach–withdrawal theory extended basic notions of neural energetic interactions to systems that mediate behavioral activation (BAS) or behavioral inhibition (BIS). Several decades later, Cloninger and Zuckerman updated the ‘biochemical bases of individuality’ proposed by Nebylitsyn, relating the activity of diffuse neurotransmitter systems to individual differences in novelty seeking (dopamine) and harm avoidance (serotonin).

It is important to note that the works of investigators like Eysenck, and Gray address issues of adult personality. While a distinction between temperament and personality is warranted (with the latter consisting of various social influences in addition to constitutional bases), the line between these concepts is admittedly fuzzy. Eysenck, in fact, did not differentiate between temperament and personality. Indeed, the list of criteria outlined by Eysenck for basic personality traits – appearance early in life, strong biogenetic basis, similarity with traits observed in nonhuman animals, and stability – is remarkably similar to the criteria outlined by Buss and Plomin for temperamental traits.

An additional principle in developmental psychology concerns the timing of any developmental process. Kagan addressed this by adopting longitudinal research strategies in studies of behavioral inhibition. Behavioral inhibition/fearfulness is probably the most well established temperament in both humans and nonhuman animals. In their seminal book *Birth to Maturity*, Kagan and Moss identified a group of 3-year-olds who exhibited fearful and withdrawn behaviors in response to novelty, many of whom became timid and cautious young adults. Kagan’s insight was to connect these behavioral observations with an emerging neuroscience literature. The amygdala was identified as a key brain structure in the manifestation of fear. In rats, the capacity to associate innocuous stimuli

(auditory tones) with threat-related information (electric shock) was shown to depend on the function of amygdalar circuits. Hypothesizing that a behaviorally inhibited temperament in humans reflected a lowered threshold for amygdala responsivity, Kagan tracked autonomic, hormonal, and brain patterns in a group of infants who exhibited highly negative reactions to novelty. By following longitudinal cohorts, Kagan and others showed that patterns of physiological activity remained relatively stable across development and, moreover, predicted later behavioral adjustment problems, especially at the extremes of behavioral inhibition.

Kagan’s combined psychological and physiological approach helped to focus attention on constitutional factors residing within the child, using objective indices of behavior and biology obtained in controlled laboratory settings. This approach shifted the field from accounts of temperament that were mainly descriptive toward an appreciation of their causal underpinnings.

How Is Temperament Measured? Subjective, Behavioral, and Physiological Measures

The types of data most often used to assess temperament come from subjective reports (e.g., parental ratings in questionnaires), behavioral observations, and physiological measures. Each of these approaches possesses particular strengths and limitations.

Subjective Report

Of the three approaches to assessing temperament, parental report has been the most commonly used. Ease of administration is certainly a factor in the proliferation of studies using temperament questionnaires, but the real advantage of this method lies in the richness of its data source. Parents and caregivers are in a unique position to assess how their child behaves in a wide variety of circumstances, and across multiple occasions. Temperament questionnaires average parental responses about the frequency or quality of their children’s behavior in common situations during a recent, specified period of time. The situations vary with the target age of the child being assessed. For example, the Infant Behavior Questionnaire (IBQ) asks a parent to rate how often in the last week their 3–12-month-old cooed and vocalized for 5 min or longer. The Toddler Behavior Assessment Questionnaire (TBAQ) on the other hand, asks how often their 12–24-month-old ran through the home or climbed over the furniture during the last month.

Statistical analysis of the responses reveals relations among some traits and not others, grouping them into a small number of independent, superordinate dimensions (factors). The number of factors must be relatively small because large numbers of factors are unlikely to be conceptually independent. Only two of the nine dimensions originally identified by the NYLS – attention span/persistence and soothability – were validated in an early factor analysis.

Most temperament questionnaires have undergone revisions since their original introduction and new editions appropriate for older ages have been added that are consistent with

the theoretical viewpoint of the investigators. The Colorado Child Temperament Questionnaire has combined NYLS dimensions with the EASI dimensions of Buss and Plomin. Rothbart's original IBQ assessed children on six dimensions, but its revision (IBQ-R) added to these vocal reactivity, sadness, perceptual sensitivity, pleasure, cuddliness, soothability, and rate of recovery from distress. The revised TBAQ now measures inhibitory control, attention, object fear, sadness, soothability, and sensory defensiveness, in addition to social fearfulness, the tendency to express pleasure, anger proneness, and interest/persistence. From the scale names, it is clear that there are commonalities in the constructs assessed, despite the plethora of available instruments. A selection from the most widely used questionnaire assessments is presented in [Table 2](#).

One major difficulty with the use of subjective reports is that parents are vulnerable to certain biases concerning their children, such as contrast effects. Behavioral characteristics of a child may be amplified or diminished in the parent's mind as compared to another child in the family. Other problems affecting informant accuracy include memory biases, inadequate attention to instructions, social desirability considerations, and any parental interpretations of a child's behavior that may be unwarranted. For these reasons, agreement between parental ratings and ratings based on laboratory observations is typically low. The question of whether questionnaire responses reflect the child's behavior or characteristics of the parent also remains an important issue to be addressed by temperament researchers. This situation can be improved by aggregating responses from multiple raters (e.g., from teachers or other caregivers as well as parents), on grounds that individual biases tend to cancel each other out. In addition, validation studies between parent reports and home

observations have found substantial enough agreement to assure correspondence between questionnaire results and objective measures of a child's behaviors.

A second difficulty in subjective reports concerns item characteristics. Questionnaires tend to avoid asking invasive questions and necessarily select vocabulary that can be understood by a majority of respondents. The reasons for these limitations are obvious, but they have the unintended effect of restricting what can be measured by the questionnaires. This issue is important because investigators' conclusions are typically based on factor analyses of item responses. A critical constraint of this statistical approach is that the variance explained by any factor depends on the number of items in the questionnaire reflecting it. Excluding some issues from the initial input will necessarily influence the number and type of factors generated.

Finally, there is unease over the fact that temperament questionnaires have not been normed on diverse ethnic and cultural groups. This concern is reasonable, as particular temperament traits may be more highly valued in one culture than in another. For example, a shy and timid demeanor is often discouraged in Western societies but receives approval in Eastern ones. There is evidence that this concern is now being addressed. As a case in point, the Rothbart questionnaires (e.g., IBQ-R and Early Childhood Behavior Questionnaire) have been translated into multiple European and Asian languages, and validation is ongoing.

Taken together, the evidence for and against the use of questionnaires in measuring temperament suggests that they are convenient and helpful, provided that their limitations are taken into consideration. The problem of conceptual interdependence among factors can only be addressed by continuing research and the appropriate refinement of questionnaires. However, problems associated with reporter bias and item characteristics may be reduced if subjective reports are used in conjunction with temperament measures from the other two approaches, described next.

Table 2 Selected index of questionnaires used to measure temperament

Bates:
ICQ: Infant Characteristics Questionnaire
Buss and Plomin:
EASI: Emotionality, Activity, Sociability, Impulsivity Temperament Survey
EAS: Emotionality, Activity, Sociability Temperament Survey
CCTI: Colorado Childhood Temperament Inventory
Carey and McDevitt:
EITQ: Early Infancy Temperament Questionnaire
ITQ: Infant Temperament Questionnaire
RITQ: Revised Infant Temperament Questionnaire
TTS: Toddler Temperament Scale; 1–3 years
BSQ: Behavioral Style Questionnaire; 3–7 years
MCTQ: Middle Childhood Temperament Questionnaire; 8–12 years
Rothbart et al.:
IBQ: Infant Behavior Questionnaire
IBQ-R: Infant Behavior Questionnaire, Revised
TBAQ: Toddler Behavior Assessment Questionnaire
ECBQ: Early Childhood Behavior Questionnaire
CBQ: Children's Behavior Questionnaire
TMCQ: Temperament in Middle Childhood Questionnaire
EATQ: Early Adolescence Temperament Questionnaire
EATQ-R: Early Adolescence Temperament Questionnaire, Revised
ATQ: Adult Temperament Questionnaire
Thomas and Chess:
PTQ: Parent Temperament Questionnaire
TTQ: Teacher Temperament Questionnaire

Behavioral Observation

Laboratory assessments allow for precise control of the experimental parameters that elicit participant responses. Assessment of a child in a laboratory situation provides a unique source of objective information that cannot be obtained by other means. The researchers who administer them typically have no relationship with the child, thereby providing data that are unbiased by parental aspirations or the child's relationship with the parent. Observations are often quantified in terms of rate or frequency of response, duration of response, and intensity of response. Because laboratory assessments are expensive and time-consuming, however, they are usually limited to one or two occasions. Thus, they can provide only a brief sample of a child's behavior in an unusually controlled environment. In addition, response parameters need to reflect the development of more complex and organized behaviors that appear in the repertoire of older children.

Better correlations may be obtained with researcher observation of the child in a naturalistic setting that is familiar, such as the home. A familiar environment has the advantage of ensuring high ecological validity, while maintaining observer objectivity. Limitations remain though, as the setting and

sequence of events are not standardized, and there may be confounds between the features of child behavior and features of the home. Aggregating home observations across multiple sessions will improve the concordance between laboratory observations and parental report.

Physiological Measures

As the observational approach supplements the use of questionnaires, the measurement of physiological processes involved in temperament is meant to work in conjunction with behavioral assessment. Physiological measures provide additional evidence about the state of the child that allows inferences about the biological bases of overt behavior. Relatively noninvasive measures have been used with pediatric populations to assess central, autonomic, and neuroendocrine functioning.

Measures of central brain activity

Electroencephalographic (EEG) activity is a relatively noninvasive measure of central nervous system physiology that can be related to individual differences in temperament. By recording at the scalp, researchers can measure patterns of neuroelectric voltage generated by thousands of synchronously firing brain cells. The electrical oscillations they produce may be measured as tonic levels of firing in resting conditions or phasic changes in firing during information processing. The magnitude of spectral power (computed as the amount of electrical energy in specific frequency bandwidths of the signal) reflects underlying brain activation in a given condition.

Davidson and Fox developed a theoretical model of brain function that reflects individual differences in approach and withdrawal. This model, based on evidence from numerous sources, suggests that frontal brain regions are specialized for distinct types of emotional responding. The left frontal cortex is specialized for appetitive, approach responses and the right frontal cortex is specialized for withdrawal-related emotional responses. Greater relative activity of left frontal regions is correlated with an exuberant emotional style, whereas greater relative activity of right frontal regions reflects an inhibited emotional style.

Infants who exhibit stable patterns of greater resting right frontal brain activity across the first 2 years of postnatal life are more behaviorally inhibited than infants who show stable patterns of greater left frontal brain activity. Furthermore, asymmetrical brain activity predicts continuity of behavioral inhibition up to 4 years of age. Similarly, infants who were highly reactive to novelty and inhibited as toddlers exhibit more resting right frontal activity into late childhood. Shy and withdrawn individuals exhibit resting right frontal EEG asymmetry even in young adulthood. Temperamentally shy children also exhibit greater increases in right versus left frontal brain activity during affective challenges.

In order to effectively track real time brain processing, investigators cannot rely solely on classical EEG measures, but must employ event-related techniques instead. Event-related potentials (ERPs) are short epochs of EEG activity that are time-locked to discrete stimuli or responses. The use of ERPs in temperament studies is relatively recent. With this approach, researchers have found that individual differences in the way the brain processes information also reflect

temperamental variation. For example, infants selected for inhibited temperament at 4 months of age exhibit enhanced evoked brainstem responses to auditory stimuli at 10–12 years of age. Interestingly, the brainstem regions that are highly reactive in these children receive reentrant nerve projections from the amygdala, consistent with Kagan's hypothesis of amygdala sensitivity in temperamentally inhibited children. Further evidence of atypical sensory processing in socially withdrawn children comes from examining differences in the brain's responses to sensory change. Most recently, ERP researchers have shown that electrocortical measures reveal differences in preferences for novelty that in turn reflect temperamental approach or withdrawal tendencies. Infants who tended to react positively to stimulation showed greater ERP responses to complex forms of novelty, whereas infants who react negatively to stimulation oriented to milder forms of novelty, and showed little electrocortical response to more complex forms of novelty.

Measures of brain electrical activity are not without limitations, some of which relate to the difficulties involved in recording sensitive electrical signals from children, and the fact that children's ERP components may not be fully mature. Investigators also need to be aware of the inferential context within which EEG and ERP measures are used to derive conclusions about psychological significance. Many brain and behavior relations remain tenuous, especially in developmental populations. For this reason, investigators should be cautious about drawing inferences from brain measures that are not supported by behavioral observations or, if possible, self-report data. However, if these caveats are addressed, electrophysiological measures can provide invaluable information about brain processing and will continue to provide original insights in temperament research.

Autonomic measures

Variation in autonomic reactivity is of interest to developmental researchers because of associations between heart rate control and the behavioral style associated with inhibited temperaments. To assess cardiac autonomic regulatory capacity, continuous cardiac electrical signals are collected over a period of minutes while the child is relaxed or attending to a mild stimulus. Heart rate and measures of heart rate variability such as respiratory sinus arrhythmia (RSA) are usually calculated offline. RSA is the naturally occurring variability in the length of time between heart beats that is coordinated with the respiratory cycle. It is often used as an index of parasympathetic control. During rest, cardiac output is dominated by activity in the parasympathetic division of the autonomic system through the vagus nerve. Typically, when environmental demands increase, parasympathetic outflow is withdrawn, reducing RSA and allowing heart rate to increase. The ability to successfully disengage and reengage the 'vagal brake' at an early age in response to changing environmental contingencies is associated with greater capacity for emotional regulation. Measurement of autonomic reactivity also includes assessment of sympathetically mediated measures such as skin conductance reactivity, prejection period, and pupil-size, in addition to blood pressure and baroreflex sensitivity.

For infants, high levels of resting RSA and greater RSA reactivity have been linked to positive developmental outcomes, good preschool adjustment, fewer behavior problems

in toddlerhood, and social engagement. Infants with high resting RSA and those who competently reduce RSA during common physical or mental challenges also soothe more easily and are able to maintain attention longer. Kagan and colleagues have shown that behaviorally inhibited children have faster and less variable heart rates than do uninhibited children, suggesting that autonomic control may be less flexible in these children, with possible consequences for emotional and social development. The mechanism underlying positive associations between RSA and developmental outcomes may lie in the contribution RSA makes to cardiorespiratory efficiency. Alternatively, RSA may reflect the functional capacity of a set of brain structures, including prefrontal cortex, that support physiological and emotional regulation.

While positive or negative psychological or developmental states may be associated with a given level of RSA, RSA cannot be construed as a biological 'marker' for these states without additional information. Strong inferences about psychological states such as behavioral inhibition cannot be made from RSA alone. Converging evidence from additional sources is needed to create a stable physiological profile that may be related to a given psychological state. It is also important to note that RSA represents only a portion of heart rate variability; that is, it represents the variability mediated by activity of the parasympathetic system. Other sources of variability include postural changes, physical activity, respiration and activity of the sympathetic system. Measurement of RSA must be made in light of these restrictions, with participants maintaining the same posture across conditions and minimizing movement during recording.

Neuroendocrine measures

Variation in cortisol production is of interest to developmental researchers because high levels of cortisol have traditionally been associated with temperamentally inhibited behavior styles. Produced by the hypothalamic-pituitary-adrenocortical (HPA) system, cortisol is considered a 'stress hormone.' Released in response to environmental challenges, cortisol mobilizes the body for behavioral response by temporarily boosting energy metabolism and suppressing immune activity. As such, cortisol production may be seen as a regulatory response that helps with the management of severely challenging situations, rather than as a panic reaction to stress. Indeed, in some circumstances, cortisol protects the nervous system and facilitates cognitive processing. Cortisol is generally assayed from samples of saliva, plasma, or urine and measured as the difference between some basal level and the level obtained in conjunction with a stressor condition. Basal levels of cortisol are highest in the morning and lowest some hours after sleep onset.

Behaviorally inhibited children are known to have higher baseline levels of cortisol activity as well as higher resting heart rates than uninhibited children. However, in recent research, Schmidt and colleagues found that baseline salivary cortisol levels varied significantly among inhibited children, indicating that a shy temperament is a necessary but not sufficient condition for elevated cortisol production. Over time, environmental factors also influence cortisol levels. Under conditions of chronic stress, the HPA system may downregulate its activity. Early chronic stress may lead to hypocortisolism, in which morning cortisol production is markedly suppressed and cortisol reactivity is dampened as a result.

Researchers have noted that it is often difficult to activate the HPA system within the context of controlled laboratory settings. Subtle psychological stimuli in the laboratory are often not potent enough to elicit significant cortisol production. Additional concerns involve apparent inconsistencies in the relations between temperament and cortisol levels or HPA reactivity. For example, shyness in children may be correlated with higher basal levels of cortisol, yet HPA reactivity to anxiety-provoking events in the laboratory may be no greater in shy children than in nonshy children.

What Determines Temperament? Behavioral and Molecular Genetic Investigations

The concept of temperament presumes a level of continuity in behavioral style across the lifespan. Although behavioral repertoires change with development, the underlying motivation or mechanism for the expression of particular behaviors remains largely consistent. An 'inhibited' infant who displays fear when confronted with a novel stimulus is likely to be shy in childhood, and may suffer from heightened levels of anxiety in adulthood. In genetic studies, such a behavioral phenomenon is referred to as a behavioral phenotype. Most recently, in the attempt to understand how behavioral phenotypes arise, temperament researchers now investigate genotypes and their interactions with the environment in studies of behavioral and molecular genetics.

Behavioral Genetic Studies

The contribution of genetic versus environmental factors to behavioral phenotypes has been investigated in twin and family studies. Studies of twins strongly suggest that both behavioral inhibition and biological regulation of development are heritable. Indeed, the direct contribution of environment to the development of temperamental traits appears to be relatively small. However, these conclusions rest on the assumption that it is possible to isolate the contributions of biology and experience to complex traits. Recent advances, reviewed next, suggest that this separation is no longer tenable.

Molecular Genetic Studies

Studies in molecular genetics have begun to link neural and psychological outcomes to genes that code for variation in brain chemistry. A decade ago, researchers found an association between increased neuroticism, anxiety, and inhibition in adults and a short polymorphism of the transporter gene (5-HTT) for one of the brain's neurotransmitters, serotonin. Around the same time, orienting in infants, attention in typically developing children and those with clinical disorders (ADHD), and novelty-seeking in adults were associated with long variants of the gene that controls the expression of dopamine receptors (DRD4), and therefore the efficiency of dopamine processing in the brain. However, very small effect sizes and frequent failures to replicate these links have raised questions about whether there are direct linear relations between single genes and behavioral expressions of temperament.

Despite such setbacks, molecular genetic studies have highlighted very important concepts. A major theme to emerge is that genes and environmental factors are inextricably linked in producing complex behaviors. Relations between genes and environmental factors take the form of gene by gene and gene by environment interactions. Where one gene may confer risk, this may be offset by resilience conferred by a different gene, or moderated by an environment that includes social support or self-coping mechanisms. A gene may even have a different role depending on the environmental influences to which the person is exposed. Children carrying a particular genetic variant may be at increased risk of negative outcomes if they are raised in maladaptive environments, but at the same time, more likely to experience positive outcomes if they are exposed to positive environments. For example, the long-repeat DRD4 polymorphism that promotes externalizing behaviors in the presence of insensitive parenting has been shown to produce the least externalizing behaviors in the context of sensitive parenting. Three-way interactions among genes and environmental factors have also been demonstrated.

The fact that multiway interactions, rather than specific genes, are better predictors of complex behavioral phenotypes implies that behavior is the product of probabilistic epigenesis, a concept specifying multiple and bidirectional influences in the relations among genes, structure, and function. Indeed, one can safely assume that main effects of single genes are extremely unlikely. This state of affairs has profound implications for predictions of behavior, with the potential to influence medical diagnostics, insurance practices, and stigmatization based on genetic endowment. Whereas constitutionally based difficulty or inhibition can predict (to a degree) developmental outcomes and lifelong consistencies in behavior, predictions from genotype to temperament or behavior are necessarily indirect, and belong to a different level of analysis that involves far greater levels of complexity.

This concept points away from genetic predictions of complex behavioral phenotypes or personal traits, and suggests instead that a given polymorphism may influence the regulation of biological systems that form the substrates for temperamental traits. By predicting its endophenotype, that is, the biological substrate it codes for, a polymorphism may affect the full spectrum of a particular ability rather than a specific disorder at the extreme end of a continuum.

In addition, researchers need to reconsider the meaning of environment in studying developmental processes. Traditionally, environmental factors have been conceptualized as purely exogenous (e.g., maltreatment, family dynamics). However, recent studies have shown that the internal milieu or endoenvironment (including, e.g., frontal electrocortical asymmetry) may also moderate the effects of genes on behavioral outcomes. Long recognized by plant physiologists and embryologists, endoenvironmental considerations have, until recently, been overlooked by developmental psychologists.

How Does Temperament Predict Developmental Outcome? Risk and Resilience

Thomas and Chess initially argued that variability in temperament conferred differential susceptibility to future psychopathology. Children with difficult or inhibited temperaments

were presumed to be at greater risk for developing psychological and behavioral problems, while a child with an easy temperament was considered to possess resilience in coping with life's stressors. However, Thomas and Chess qualified this stance by emphasizing that the fit between a child's temperament and his/her environment was critical to determining the child's developmental trajectory. Constitutional factors do not predict increased risk for psychopathology across the board. Only some children with a difficult temperament go on to develop externalizing disorders or major depression. Therefore, environmental factors would appear to moderate the effects of temperament on development.

Today, the notion of 'goodness of fit' can be expressed in light of new knowledge involving genes, environments, and complex outcomes. The interplay between constitutional factors (temperament) and environmental contingencies is now examined in genetic studies. If some polymorphisms confer risk, the implication is that alternate polymorphisms of the same gene confer protection. Even genetic risk may develop into psychopathology only for children in adverse circumstances, or for those with particular experiential histories, that is, for those who possess a vulnerable genotype and also grow up in a poor-fitting environment. Improving the environment can offset a high-risk constitutional predisposition. Adjusting parental behavior or adding social support, for example, reduces the risk of the 'difficult' child's developing aggressive or antisocial behavior. In addition, recent longitudinal studies by Eisenberg and Kochanska have shown that the development of effortful control – a temperamental dimension that encompasses capacities for focusing and shifting attention, as well as motor control – protects against deficits in a wide range of socioemotional domains. Clearly, prediction of developmental outcomes will require the simultaneous consideration of constitutional and environmental factors for risk and resilience.

What Does the Future Hold? Moving Forward

Temperament is a natural phenomenon that is not determined by factor analyses, but is imperfectly reflected by them. Questionnaires provide a rich and unique source of data, but they are primarily descriptive and should not be relied on as the sole arbiters of scientific truth. It has become apparent that the reliability of findings is strengthened when, in addition to questionnaire data, complementary evidence concerning temperament is gathered from direct observations of behavior and physiology. An ideal strategy would be to collect data from multiple sources, including subjective report, behavior, physiology, and genetics, to provide converging evidence on the nature and mechanisms of temperament. Multimethod studies, employing measures that span different levels of analysis will be important in advancing the field of temperament research beyond where it stands today.

Genetic studies are likely to continue testing the sorts of higher-level dynamics (e.g., gene by gene by endo- and exoenvironment interactions) that approximate the complexities involved in linking specific genes to temperamental outcomes. Researchers will need to focus on relating genetic polymorphisms to endophenotypic processes that are upstream from final behavioral expression. There appear to be diminishing returns

in the search for simple linear effects of genes on behavior. Of interest, nonhuman animal models may suggest important biological mechanisms that result in temperamental differences, although interpretations across species must necessarily remain cautious.

Finally, because development is time sensitive and different principles operate across the various stages of ontogeny, questions of development may not be fully answered by cross-sectional studies. Small studies do not provide conclusive answers to the gene-environment intricacies that underlie variation in temperament. Therefore, despite the expense of conducting large, longitudinal studies, they will continue to be a gold standard for research in the field of temperament.

Individualism

J Park and S Kitayama, University of Michigan, Ann Arbor, MI, USA

© 2012 Elsevier Inc. All rights reserved.

Glossary

Collectivism A constellation of daily practices, public artifacts, lay assumptions, and folk beliefs that is based on a model of the self as interdependent.

Independent self A prototypical model of the self that is conceptualized as separate from others and primarily defined by its internal attributes.

Individualism A constellation of daily practices, public artifacts, lay assumptions, and folk beliefs that is based on a model of the self as independent.

Interdependent self A prototypical model of the self that is conceptualized as interconnected with others and primarily defined by its social relations.

Individualism

Individualism, the love of enterprise, and the pride in personal freedom, have been deemed by Americans not only as their choicest, but their peculiar and exclusive possessions. (Bryce, 1888)

As the quote above illustrates, Americans are often described as individualists. They are said to have strong preferences for freedom, uniqueness, autonomy, and personal goal pursuit. Implicit in this assertion is that many other peoples in the world outside of the United States are not as individualistic. In fact, they are said to be more collectivistic. That is, they are in favor of social harmony, interpersonal similarities, duty, and group goal pursuit. This observation has its counterpart in the last two decades of research in cultural and cross-cultural psychology. Much of this literature is organized in terms of individualism and collectivism and the parallel constructs of independence and interdependence. The role of these constructs has been so dominating in the field of research that Steven Heine, a cultural psychologist, went as far as to claim that the individualism–collectivism dimension ‘may ultimately prove to be the most important dimension for capturing culture variation.’

In this article, we define individualism as a constellation of daily practices, public artifacts, and folk beliefs that is based on a model of the self as independent. Individualism is contrasted with collectivism, which may be defined as a constellation of daily practices, public artifacts, and folk beliefs that is based on a contrasting model of the self as interdependent. In what follows, we elaborate on these definitions first. We then discuss psychological consequences of engagement in the divergent cultural patterns of practices and beliefs. Much of the currently available evidence comes from systematic cross-cultural comparisons between people from Western cultures including European American cultures and those from Asian cultures. This discussion is followed by an examination of antecedent conditions for individualism and collectivism. We conclude by discussing some future directions of research.

Defining Individualism and Collectivism

Models of the Self as Independent and Interdependent

Every society offers some unique constellation of daily practices, public artifacts, folk beliefs, and corresponding psychological tendencies. It has been argued that these constituents of a society or culture are patterned in some systematic way and, furthermore, that this patterning follows certain socially shared models of the self. Markus and Kitayama have distinguished between two prototypical models of the self.

In many contemporary Western societies and cultures, including European American middle class cultures, there is a strong belief in the self as independent. The self is conceptualized as bounded and separate from others. As such, it is defined by its internal attributes such as traits, abilities, intentions, and desires. The self is affirmed when these internal attributes are recognized and valued as positive. According to this model of the self, other individuals are also defined in terms of their own internal attributes. Social relations are therefore derived from each person’s preferences and choices. This model of the self is illustrated in [Figure 1\(a\)](#). This model influences a variety of values, practices, and activities. A content analysis of 27 existing scales of individualism or independence found that these scales tap on seven distinct, although related, aspects including (1) valuing personal independence, (2) personal achievement, (3) self-knowledge, (4) uniqueness, (5) privacy, (6) clear communication, and (7) competition.

In contrast, in many non-Western societies and cultures, especially East Asian cultures, a far greater emphasis is given to social relations. The self is regarded as interdependent and fully embedded in relationships with others. According to this model of the self, social relations, especially those with in-group members are indispensable elements in defining the self rather than options one can choose to have or not to have. Thus, acting in line with social roles, norms, and expectations of others is centrally self-defining. The self is affirmed when the encompassing relations are affirmed as positive, as when one’s company, boss, or manager receives a public recognition. This model of the self is illustrated in [Figure 1\(b\)](#). According to the content analysis of the existing scales for collectivism or interdependence noted above, at least eight facets are included in the

Figure 1 Conceptual representations of the self. (a) Independent construal and (b) interdependent construal. Reproduced from Markus HR and Kitayama S (1991) Culture and the self: Implications for cognition, emotion, and motivation. *Psychological Review* 98: 226.

interdependent model of the self: (1) sense of duty to group, (2) relatedness to others, (3) seeking others' advice, (4) harmony, (5) working in groups, (6) sense of belonging to a group, (7) contextual self, and (8) valuing hierarchy.

Social Environments Reflecting Independence and Interdependence

The cultural models of the self as either independent or interdependent are not only internalized but are also out in the world. They are reflected in, fostered, and maintained by various elements that constitute the cultural environment such as daily practices and institutions, public artifacts, and folk beliefs.

For example, parental practices vary widely across cultures. Parents in Western countries are likely to encourage their children to be independent, assertive, self-reliant, and autonomous. These values, however, are not emphasized in Asian families at least to the same degree. Rather, child-rearing practices in Asia tend to promote interdependence, social harmony, sympathy, as well as filial piety – one central virtue in Confucian ethic that stresses social hierarchy. A similar observation has been made in respect to educational practices. It has been observed that whereas education is considered as a way of improving one's personal benefit and self-respect in Western cultures, it is seen as a tool to join higher social status groups in Asian cultures. In Western classrooms, adversarial discussion and debate is rather commonplace and, to a large extent, positively sanctioned, but social harmony tends to receive a greater emphasis in Asian classrooms. Researchers have pointed out that effective leadership in the workplace also varies across cultures. Leadership trainings in US companies focus on the needs of individuals who seek to maximize their interests, goals, and plans. Obligations toward group goals and group interests are less emphasized. In Asian companies, however, group interests tend to be emphasized relatively more than individual interests, and loyalty and duty to the in-group are strongly sanctioned.

Public artifacts that are displayed in a variety of media such as TV programs and magazines also vary across cultures. In a recent content analysis of advertisements in American and Korean magazines, it has been observed that American ads feature themes of uniqueness such as choice and freedom, but Korean ads emphasize themes of conformity such as group harmony and respect. In another study, researchers

analyzed the coverage of the 2000 and 2002 Olympics Games by Japanese and American media and found that American media highlights athletes' personal attributes such as their strengths and personalities whereas Japanese media attends to a broader set of factors including athletes' backgrounds and experiences such as difficulties, stress, hardships they had in preparing for the games (e.g., his mother passed away before the Olympics), or other people's influences (e.g., it was my dad's dream that I win gold). A similar cultural difference extends to the content of textbooks. One recent study finds that values of independence (e.g., autonomy, power, and self-reliance) are emphasized more in American elementary school textbooks than in Japanese textbooks, but a reversed pattern is evident for values of interdependence (e.g., social harmony, group norm).

Cultural Variation in Mentality

Various psychological tendencies may be shaped by each individual's active engagement in his or her culture. Consistent with this general proposition, the last two decades of research in cultural psychology has documented numerous cross-cultural differences in basic psychological processes such as cognition, emotion, and motivation. Evidence is growing that the psychological effects of culture can be understood in terms of the culturally shared models of the self as independent (dominant in Western cultures) or as interdependent (dominant in Eastern cultures).

Cognition

Cultural variations in the model of the self (i.e., interdependence vs. independence) are likely to entail corresponding variations in cognitive style. Three characteristics of cognitive style are worthy of note: focused versus holistic attention, dispositional bias in person perception, and analytic versus holistic reasoning.

Focused versus holistic attention

Independent versus interdependent social orientations may foster divergent modes of attention. Because social relations are more important and self-defining for interdependent people, these individuals are likely to allocate attention more broadly to the social relations. Their attention may become

more holistic as a result. In contrast, social relations are also important for independent people, but they are seen as important as far as they are relevant to their personal goals and desires. These individuals are then likely to allocate attention primarily to objects and events that are relevant to their personal goals and desires. Their attention may become more focused as a result.

The last two decades of cross-cultural work has supported this analysis. Overall, people engaged in independent Western cultures tend to focus their attention on focal objects in lieu of situational context, but those engaged in interdependent Eastern cultures tend to be more holistic, extending their attention to situational context. In one study, when shown animated vignettes of underwater scenes and asked to describe the scene, European Americans tended to start their stories with focal objects (e.g., 'there was what looked like a trout swimming to the right') whereas Japanese tended to start theirs by referring to a context that defines the scene at issue (e.g., 'there was a lake or pond'). Further, a recognition memory task revealed that Americans represented focal objects separate from their contexts, whereas Japanese represented them in conjunction with the contexts. Additional evidence comes from an eye tracking study, which has found that European Americans direct their gaze more frequently to focal objects, but Asian Americans direct their gaze more frequently to stimuli in context. A similar attentional bias has been demonstrated with geometric stimuli. The cultural variation in attention, then, appears to be ingrained into basic perceptual processing.

Dispositional bias in person perception

A similar cultural variation has been documented in the domain of social perception. Extrapolating from the findings from the cultural variation in attention, we may anticipate that independently oriented individuals (e.g., European Americans) may attend more to a person as a figural object, with relatively scant attention paid to the context. In contrast, interdependently oriented individuals (e.g., Asians) may be more likely to extend attention to the whole scene that includes the focal person. Consistent with this reasoning, European Americans show a strong cognitive bias to explain another person's behavior in terms of the person's dispositions while discounting available situational factors. This bias has been called the correspondence bias or the fundamental attribution error. However, Asians and Asian Americans may attend more holistically to situational constraints on the focal behavior. Indeed, they are less likely to show the dispositional bias.

In one earlier study, when asked to explain either prosocial or antisocial behaviors of their acquaintances, Americans produced more dispositional reasons. In contrast, Indians produced more situational reasons than Americans did. This cultural difference became more pronounced among adults than among younger children, suggesting that the cultural bias in attribution becomes enhanced with enculturation. In a subsequent study, researchers analyzed attribution patterns of American and Chinese young adults and observed that Americans are more likely than Chinese to make strong dispositional (vs. situational) attributions. Similar cultural variations have been repeatedly observed so that we can now be confident that the dispositional bias in social explanation is robust and replicable in Western,

independent cultural contexts, but probably not in Eastern, interdependent cultural contexts.

There is a small, but growing body of cross-cultural literature on attitude inference. When observing another person making an attitudinal statement, people may assign an attitude that corresponds to the statement of the person. It has been repeatedly demonstrated among European Americans that this phenomenon occurs even in the presence of a blatantly clear situational constraint on the person. It appears that people tend to ignore the constraint even when it can be used to fully account for the behavior (i.e., attitudinal statement). As may be expected, however, the dispositional attribution bias or the correspondence bias in attitude inference is substantially weaker among Asians and Asian Americans. When the situational constraint is made highly salient and indisputably clear, Asians rarely show any tendency for correspondence bias, whereas European Americans show the bias even under this same condition. This finding is quite consistent with the evidence noted above that Asians are more holistically attentive to situational constraints. They may not draw any strong corresponding inferences upon observing another person's behavior.

Analytic versus holistic reasoning

If attention is focused primarily on a central object in lieu of its context, individuals may scrutinize the object, identify its distinctive features, and use them to categorize the object. They may then rely on the categorical knowledge to draw further inferences on the object. Reasoning, therefore, tends to be linear and rule-based. This mode of thought is called analytic. In contrast, if attention is applied to the whole scene in which the object is embedded, individuals may be attuned more to the relationships among various elements in the scene. Their reasoning, therefore, tends to be thematically based, dialectical in the sense that balance of various elements, rather than linear logical relationships, is highlighted. This mode of thought is called holistic.

Evidence for the hypothesis that independent people (e.g., Westerners) tend to be more analytic and interdependent people (e.g., Asians) tend to be more holistic in reasoning is quite substantial. In one task, participants are presented with a target flower and asked to judge to which of the two groups of flowers the target belongs (see [Figure 2](#)). The target has a much greater family resemblance with one of the two groups (Group A), but there is no single feature that is common to both – all the flowers of this group and the target. Flowers in the other group (Group B) do not bear any overall resemblance to the target flower, but there is one feature (e.g., straight stem) that is common to both – all the members of Group B and the target. If participants use overall resemblance as the classification criterion, they should judge the target as belonging to Group A, but if they use any simple rules, they should judge the target as belonging to Group B. It has been shown that Asians tend to use overall resemblance in classification judgment whereas European Americans tend to be rule-based.

Another related study examined whether people preferentially use category versus thematic relatedness as the basis of classification. Participants are presented with sets of three pictures and asked to choose which two of the three in each set will go together. The pictures could be grouped by either

Figure 2 An example of stimuli in Study 2 of Norenzayan et al. (2002). Reproduced from Norenzayan A, Edward SEB, Kim J, and Nisbett RE (2002) Cultural preferences for formal versus intuitive reasoning. *Cognitive Science* 26: 664.

thematic relatedness (e.g., monkey and banana) or category membership (e.g., monkey and panda). As predicted, European Americans tend to prefer category membership to thematic relatedness, while Asians tend to prefer thematic relatedness to category membership.

With the analytic mode of thought, people may assume that the world is governed by simple rules, and thus, various relations are linear. With the holistic mode of thought, people may assume that various elements of the world are connected with one another and thus they are dynamically related to maintain balance. In one study, researchers provided European American and Chinese participants with a description of a certain event (e.g., global economic growth), which either linearly increased or decreased over a certain period of time (say, past 10 years). The participants were then asked to estimate what would happen in the future. Whereas European Americans tended to predict that the same trend (i.e., increase or decrease) would continue, Chinese tended to predict that the current trend would taper off and even reverse itself.

Emotion

Cultural variations in the model of the self (i.e., interdependence vs. independence) are likely to give rise to culturally distinctive emotional experiences. Three replicable patterns of cultural variation in emotional experience have been reported: socially engaged versus disengaged emotions, predictors of happiness and life satisfaction, and ideal affect.

Socially engaged versus disengaged emotions

First, people in different cultures may experience different emotions because of their commitment to the cultural values or normative requirements of independence or interdependence. Attaining goals or failing to achieve them can result in a variety of different emotions. However, exactly what emotions are experienced appears to depend on the nature of the goals at hand. When independent goals are achieved, people can be assured of positive characteristics of the personal self or they may be content with the relative superiority of the self over others. In these cases, they are likely to experience socially disengaged positive emotions such as pride in the self or feelings of confidence in the self. When the individuals fail to

achieve independent goals, however, they are likely to be frustrated and, as a consequence, they may feel sulky and even angry. These emotions, which typically produce a motivational drive to restore the thwarted sense of independence, are called socially disengaged negative emotions. The parallel distinction can be drawn for interdependence. When interdependent goals are achieved, people can be assured of their belongingness to the relevant social relationship or they may be content with the harmoniousness of the relationship. In these cases, they are likely to experience socially engaged positive emotions such as communal feelings or feelings of closeness to others. When the individuals fail to achieve interdependent goals, however, they are likely to feel guilty, shameful, or feel indebted to others. These emotions, which entail a motivational push to restore the thwarted sense of interdependence, are called socially engaged negative emotions.

It is reasonable to anticipate that Westerners are chronically oriented more toward independent goals than toward interdependent goals, but Easterners are chronically oriented more toward interdependent goals than toward independent goals. It would follow that the corresponding cultural variation should be observed in the relative salience of socially engaged versus disengaged emotions. In one demonstration of this point, European American, German, British, and Japanese participants were presented with ten mundane social situations (e.g., waiting to be seated at a restaurant) and asked to remember the most recent experience that fitted the description. They then reported how strongly they experienced each of ten different emotions that vary in both valence (i.e., positive vs. negative) and social orientation (i.e., engaged vs. disengaged). As may be expected, North Americans reportedly experienced disengaged emotions more strongly than engaged emotions across the ten situations. However, the pattern was completely reversed for Japanese, with engaged emotions reportedly experienced more strongly than disengaged emotions. The two European groups fell between the two extremes.

Predictors of happiness and life satisfaction

Second, if people habitually seek to realize either independent or interdependent goals, they may feel happy, content, or satisfied when the corresponding goals are achieved. The four country comparison study discussed above confirmed this prediction: Americans' happiness was better predicted by the experience of disengaged positive emotions whereas Japanese's happiness was better predicted by the experience of engaged positive emotions. Further, the patterns for the two European countries fell in-between. Other studies provided parallel evidence by using personality measures of social engagement and disengagement. The correlation between measures of social disengagement (self-esteem and personal control) and life satisfaction is typically positive. Importantly, however, the correlation is higher in independent cultures (e.g., North America and Western Europe) than in interdependent cultures (e.g., Asia). Measures of harmonious or stress-free social relations such as relational harmony, perceived social support, and sympathy to others tend to predict life satisfaction and other measures of wellbeing better in interdependent cultures than in independent cultures.

Although the direct effect of social engagement on measures of wellbeing tends to be weaker in North America, this does

not mean that social relations are unimportant for European Americans. Indeed, across many cultures, availability of social capital (e.g., engagement in local communities, marriage, and coresidency with one's own children) has been identified as a major protective factor of health and wellbeing. It is possible, however, that in independent cultures social relations may be beneficial only to the extent that they are useful in affirming one's sense of independence and self-worth. Thus, once the effect of social disengagement (e.g., self-esteem or sense of control) has been controlled, there might remain little variance uniquely explained by social engagement.

Ideal affect

A third set of findings that deserve discussion concerns cultural variation in ideal affect. Research has documented that Western cultures normatively sanction high-arousal positive emotional states such as excitement, enthusiasm, and elation. In contrast, Eastern cultures normatively sanction low-arousal positive emotional states such as calmness, peacefulness, and serenity. Highly arousing, energizing states may be culturally valued more in independent cultures because these emotional states are congruous with the cultures' normative expectation that one must actively influence other people and events. In contrast, interdependent cultures emphasize attunement to social cues and attendant effort to adjust to social expectations. Calm states may then be culturally valued because of their congruity with the strong value the cultures place on social attunement and adjustment.

The foregoing analysis on cultural variation in ideal affect is consistent with an observation that European Americans tend to prefer rigorous leisure activities (e.g., surfing, running, and rollerblading) whereas Asian Americans prefer less active ones (e.g., sightseeing, picnicking). It has also been observed that relative to their American counterparts, Japanese adolescents tend to prefer relaxing and calm music. Further, culturally variable ideal affect might influence drug use: stimulants such as cocaine and amphetamine (which elicit excitement) are more widely abused in the United States, but the illicit drugs of choice in much of Asia are opiates (e.g., heroin) that induce relaxation.

Motivation

Cultural variations in the model of the self (i.e., interdependence vs. independence) are also likely to entail corresponding variations in motivational processes. Even when people engage in a seemingly identical behavior (e.g., making a choice or decision), this same action can bear different psychological meanings because the action is necessarily made meaningful within a larger framework informed by a cultural model of the self. There are three notable themes of research that pertain to motivational processes: propensity toward uniqueness, self-enhancement, and choice.

Propensity toward uniqueness

Independent selves are defined by personal features that are distinctive and unique to them (e.g., personal preferences), but interdependent selves are defined by socially shared features (e.g., group membership). It may then be anticipated that independent people value, prefer, and seek uniqueness of the

self to a greater extent than interdependent people do. In one recent study, researchers went to one of the major US international airports and asked both Asian and European American travelers to fill out a short questionnaire and then offered a pen as a token of appreciation for their cooperation. The travelers were presented with five pens and asked to choose one of them. One or two of the five pens had a color that was different from the rest. As predicted, European American travelers were more likely than Asian travelers to choose a pen with the unique color. The greater liking for uniqueness over conventionality among European Americans relative to Asians or Asian Americans has been replicated with a standardized questionnaire.

Self-enhancement

One pervasive psychological tendency or bias observed among European Americans is self-enhancement or self-serving bias. People are motivated to maintain positive views of the self in a variety of different ways. Although often regarded as universal, this tendency may be rooted in an independent model of the self. If individuals believe that they are independent and separate from others, they may be strongly motivated to establish the positivity of this personal self by cognitively elaborating and emphasizing positive features of the self while, at the same time, dissociating the self from any potentially negative features. If, however, individuals believe that they are interdependent and closely connected with others, they may be motivated to fit in to significant relations. As a consequence, they may have little or no strong need to establish the positivity of the personal self. Moreover, in order to fit in to any given relationship, it is often advantageous to take a self-critical and disciplined stance to the self. Self-criticism or effacement may be a basis for positive evaluations from others in the relationship. These evaluations may accord honor or face on the person. It is also important not to stand out too much so as to remain as a good member of the relationship. In short, Asians and Asian Americans might sometimes show a self-critical or self-effacing psychological bias.

In one study, American and Japanese participants were presented with a number of situations involving success or failure and asked to estimate whether and to what extent their self-esteem would increase or decrease in each situation. To test the idea that the expected psychological tendencies of self-enhancement among Americans and self-criticism among Japanese might be encouraged by ways in which mundane social situations are defined and made meaningful, the situations had been preselected so that half of them were common in the United States and the other half were common in Japan.

Figure 3 shows the relative estimated self-esteem change – that is, the extent to which self-esteem is estimated to increase in success situations relative to the extent to which it is estimated to decrease in failure situations. The means are positive for Americans, indicating that they reported that their self-esteem would increase more in success situations than it would decrease in failure situations (i.e., self-enhancement). In contrast, the means for Japanese tend to be negative, suggesting that they estimated that their self-esteem would decrease more in failure situations than it would increase in success situations (i.e., self-criticism). The culturally dominant biases of self-enhancement and self-criticism were

Figure 3 The relative magnitude of estimated self-esteem increase versus decrease as a function of participant culture and situation culture. Positive (negative) scores show that self-esteem is estimated to increase (decrease) more in success (failure) situations than it decreases (increases) in failure (success) situations. The percentage within each bar represents the proportion of participants who show an effect that is congruous with the central tendency observed in the condition. For example, when responding to Japanese situations, Japanese in Japan as a group estimated that their self-esteem would decrease more in failure situations than it would increase in success situations. This effect was observed, in varying extents, among 86% of the participants in this group. Reproduced from Kitayama S, Markus HR, Matsumoto H, and Norasakkunkit V (1997) Individual and collective processes in the construction of the self: Self-enhancement in the United States and self-depreciation in Japan. *Journal of Personality and Social Psychology* 72: 1245–1267.

much more pronounced when the participants were responding to the situations that were common in their own cultures. Thus, nearly 90% of the Americans tested showed self-enhancement when responding to American situations, and conversely, nearly 90% of Japanese showed self-criticism when responding to Japanese situations. One clear implication is that the culturally dominant psychological biases are afforded, that is, being supported and reinforced, by certain ways in which mundane social situations are constructed and made meaningful. This study is noteworthy in yet another way. It tested Japanese sojourners in the United States. As shown in **Figure 3**, the results for these sojourners fell right between the European Americans and the Japanese in Japan. This pattern could be due to acculturation (i.e., influence of resocialization in the American culture), self-selection (i.e., greater likelihood of independent Japanese coming to the United States), or both.

Choice

The cultural models of the self may also moderate motivational effects of choice. Given an independent model of the self, a choice will be experienced as expressive of the self when it is unconstrained by any social concerns. If, for example, one helps someone out of a concern for social reciprocity, the help may not be experienced as genuine and internally motivated. The social imposition of this kind on choice can be very subtle. One recent study finds that when asked to make a choice while being watched by others, European Americans report that their choice is more constrained and less self-expressive. However, the foregoing effect of choice on motivational processes may take a different form among those with

Asian cultural backgrounds. Given an interdependent model of the self, choices that are made in the absence of any social context will not be experienced as self-relevant because such choices have little bearing on the interdependence of self. For example, Asians would perceive a help they offer to their neighbors as genuine and internally motivated when the help is prompted out of a concern for social reciprocity (and thus their social reputation). Likewise, for choices to be meaningful for the self, they should be situated in certain social contexts. It may then be anticipated that Asians and Asian Americans will be motivated by their choice, but only if the choice is made in the presence of witnessing others.

One early study observed that European American children were more strongly motivated to perform an anagram task if they had chosen the task by themselves rather than if the task had been assigned to them by the experimenter. However, the effect was significantly weaker for Asian American children. Of importance, this study included a condition in which a choice was made, not by the participants themselves, but by their in-group member (i.e., their mother or classmate). Because of their psychological identification with the in-group member, Asian American children might perceive the in-group member's choice as no different from what they would make. Further, the choice in this case is obviously public. As may be predicted, Asian American children in this condition were more strongly motivated by the task chosen by the in-group member even in comparison to the task they themselves had chosen.

Also consistent is a vast body of literature on cognitive dissonance. When making a choice between two equally attractive objects, the choice often leads to conflicting cognitions

(e.g., desirable attributes of a rejected item or undesirable attributes of a chosen item), which in turn produce negative arousal (dissonance). To reduce this dissonance, people try to justify their choice by increasing their liking for the chosen object and reducing their liking for the rejected object. Evidence is quite clear that for the justification effect to occur, the choice must be perceived as personal and internally motivated for European Americans. However, among Asians the dissonance effect can rarely be observed in the absence of witnessing others, but this effect is quite robust in the presence of such others.

Antecedents of Individualism and Collectivism

So far, we have examined psychological consequences of individualism (or independence) and collectivism (or interdependence). However, what factors can explain such cultural values and the attendant cultural models of the self? Why is it, for example, that Asian cultures are more collectivistic or more oriented toward interdependence or, conversely, why is it that European American cultures are so individualistic or independently oriented? In this section, we address these questions by reviewing available evidence for some antecedent conditions for individualism and collectivism.

Ecology and Subsistence Systems

Independence and interdependence are likely to be constrained by certain ecological conditions insofar as such conditions make certain forms of living far more feasible and realistic than certain others. Traditionally at least, herding is common in relatively dry highlands that are sparsely populated. Herding, in turn, is likely to encourage various values of independence such as self-reliance, assertiveness, and self-promotion. In contrast, traditionally farming is quite common in fertile plains with substantial precipitations and high temperature. Furthermore, agriculture supported emergence of large sedentary societies. Because farming requires a high degree of social coordination, it may foster values of interdependence such as social harmony, group duty, and social cooperation. In one classic study, farmers in East African culture were found to be more interdependent than herders in the same region. In support of the general hypothesis that social interdependence gives rise to holistic (vs. analytic) mode of reasoning, farmers have been shown to be more holistic in cognitive style than herders.

Pathogen Prevalence

One recent proposal in evolutionary psychology is that humans have evolved behaviors that can protect them against pathogen infections. In regions or communities that suffer from higher pathogen risks, individuals may develop behavioral tendencies that enable them to minimize potential contact with pathogens. For example, they may make a sharper distinction between in-group members and out-group members and avoid the latter, insofar as there may be some non-trivial risk to be exposed to unknown pathogens through contact with outgroup members. Likewise, there may be tighter

normative regulations of hygiene control. In short, the community as a whole may become less individualistic and more collectivistic under the conditions of pathogen risks. One recent study finds that indicators of both historical and contemporary pathogen prevalence correlate positively with measures of collectivism and negatively with measures of individualism. More research is required, however, because there are obvious exceptions in history. For example, England had very high rates of plague and tuberculosis in the late-medieval period and yet is one of the most individualistic cultures today. It remains to be seen if an exception like this could be accounted for once certain local historical factors are duly taken into account.

Social Resources: Economic Development and Social Class

A cultural psychologist, Harry Triandis, suggested that affluence leads to social independence, since it enables people to do 'one's own thing.' Social forces that emphasize economic independence, in turn, lead people to seek a sense of autonomy and to value personal choice and self-expression. These individualistic orientations have become increasingly widespread in advanced industrial societies. In support of this analysis, across numerous countries of the world today, individualism is highly correlated with the gross national product (GNP) ($r = 0.82$). In another related study, self-expression values – a component of individualism – is closely linked to economic prosperity.

If wealth and other related tangible and symbolic resources are linked to independent orientations across countries, the same relationship might also hold within each country. In fact, social class, as defined by income, occupational prestige, and educational attainment, has been shown to predict the level of independence (vs. interdependence). Large-scale survey studies have shown that middle class (vs. working class) standing is associated with higher levels of self-directness, self-efficacy, and personal mastery. Further, social class has been shown to influence more behavioral aspects of independence versus interdependence. In one recent study, college-educated (middle class) Americans tend to express their uniqueness more than high school-educated (working class) Americans. Likewise, middle class Americans seek to distinguish themselves from others when making a choice; but working class Americans seek to accentuate their similarities with others when making a choice.

Occupational and Residential Mobility

By definition, independent individuals are not tied up to any particular social roles or geographic locales in the way interdependent individuals might be. In a recent series of studies, researchers have found substantial evidence for the predicted association between independence (as typically defined in terms of self-definitions based on personal vs. social attributes) and residential mobility. Similar evidence exists for occupational mobility as well. It is reasonable that both residential mobility and occupational mobility foster an independent sense of the self. Equally likely, however, is the reverse causation wherein independent people are more likely to be on the move.

Voluntary Frontier Settlement

Worldwide, settlement in sparsely populated and uncultivated lands (the frontier) has occurred from time to time. The frontier appears to combine several factors that induce independence, including low population density, relatively low pathogen risk (due to low population density and, in many cases, relatively dry and cold climate), and social mobility, among others. It would seem quite reasonable to anticipate that voluntary frontier settlement is a major factor for independence and individualism.

A recent review shows that European Americans are more independent even as compared with their European counterparts. Within the United States, individualistic values tend to

be endorsed more in regions with longer frontier periods (e.g., Mountain West) than in those with relatively short such periods (e.g., New England). This pattern has been replicated with the likelihood of giving unconventional names to new babies as an index of individualism. Scatter plots presented in Figure 4 illustrate the point. When the year in which statehood was achieved was plotted on the x-axis and the percentage of babies receiving one of ten most conventional names was plotted on the y-axis, it is evident that the state-wise percentage of both baby boys (a) and girls (b) with conventional names tends to decrease as a function of the year of admission into the United States. It is also observed that, with this index, countries settled

Figure 4 State-wise proportion of baby boys (a) and girls (b) with conventional names as a function of the year of admission of the state into the United States. Reproduced from Varnum MEW and Kitayama S (2011) What's in a name? Popular names are less common in frontiers. *Psychological Science* 22: 179.

by Europeans (e.g., New Zealand and Canada) are higher in independence than the corresponding European countries. A similar finding exists outside of the West. A northern island of Japan called Hokkaido has undergone a relatively recent 100-year old history of settlement by ethnic Japanese. As may be expected, there is evidence for enhanced independence among Hokkaido residents relative to their mainland counterparts. The frontier is characterized at least in part by high-risk, and high-return payoff structures. Similar payoffs may be often associated with large city cosmopolitan centers such as New York and San Francisco in the United States, Berlin and Paris in Europe, and Tokyo, Seoul, and Shanghai in Asia. A recent study has shown that these city centers tend to attract independently minded individuals much more than regional, provincial cities do.

Conclusions

The last two decades of research in cultural psychology has provided substantial evidence for the proposition that cultures vary considerably in terms of individualism (vs. collectivism) and the corresponding model of the self as independent (vs. interdependent). Initially suggested by large-scale cross-cultural surveys, this hypothesis has been used to account for cultural variations in many distinct psychological tendencies. As compared to people in interdependent cultures (i.e., collectivists), those in independent cultures (i.e., individualists) tend to be more focused (vs. holistic) in attention, more dispositional in person perception and social explanation, more analytic in reasoning, socially disengaged (vs. engaged) in emotional experience, self-enhancing, and motivated more by private (vs. public) choices. Antecedent conditions for individualism (vs. collectivism) include herding economy, reduced pathogen risks, wealth and prestige, residential mobility, and frontier settlement.

Future work may focus on effects of engagement in multiple cultures, given that conditions will become increasingly common and widespread in many parts of the world. It has been suggested already that frame switching across different cultural assumptions and models is not only possible, but also, in fact, quite common. Moreover, switching back and forth across different cultural frames might in fact induce creativity and higher executive functions. Further research is justified to investigate implications of multiculturalism on socioemotional development and identity formation.

It is important to recognize that the currently available evidence for the effect of culture on psychological or neural processes comes, in large part, from a systematic comparison between Western and Eastern societies and cultures. This comparison has provided a model case for cultural psychologists just like rodents have defined a model animal of choice for a number of animal psychologists. As such, it has provided a number of invaluable insights into the nature of cultural influences. Yet, the field should now be pushed forward in various different directions by examining different subgroups or regions, or looking at different occupational groups or age groups.

Another important avenue of research would be to investigate brain processes underlying the behavioral effects of culture reviewed in this article. It seems plausible that environmental influences that are associated with culture are not only

reflected in our behaviors but also in our neural activities. Recent work on neural plasticity, for example, has suggested that nongenetic, environmental factors, such as repeated practice for acquiring a certain skill (e.g., abacus use), can lead to dramatic changes in neural connectivity of the brain. This emerging literature underscores the significance of cultural experience in neural development. Cultural neuroscience research will make great contributions to broaden our understanding of intricate interactions between culture, mind, and brain.

Last, but not least, with recent developments in population genetics, it has become reasonable to hypothesize that at least some of the cultural differences discussed here might be traced back to genetic differences across cultural groups. It has been established that gene expressions are contingent on environments, which could include cultural environments. Further, genes themselves (particularly, frequencies of very simple mutations called single nucleotide polymorphisms) are likely to be influenced by cultural conditions. These considerations will open up an exciting theoretical possibility that there are dynamic mutual influences among behavior (and the brain), culture, and genes. This general topic will constitute one important frontier of human behavioral sciences.

In sum, the notion of individualism (vs. collectivism) has been highly instrumental in the last two decades of research in cultural psychology. As the present review testifies, a substantive body of empirical knowledge has been accumulated. We anticipate that during the next decade this work will continue to grow by identifying different cultural patterns that cannot be reduced to individualism or collectivism, exploring multiculturalism, examining neural processes underlying known cultural differences in cognition, emotion, and motivation, and establishing, in greater detail, antecedent conditions for the cultural patterns that are identified.

Inner Speech

A Morin, Mount Royal University, Calgary, AB, Canada

© 2012 Elsevier Inc. All rights reserved.

Glossary

Ecological validity The degree to which the thoughts recorded in a study reflect the thoughts that actually occur in natural settings.

Inner speech The activity of talking to oneself in silence.

Left inferior frontal gyrus Also known as Broca's area, the brain region that gets reliably activated during inner speech production.

Predicativeness The syntactically compressed, condensed, abbreviated quality of inner speech. In inner speech, the speaker tends to only articulate the predicate, not the subject, for example, 'hungry' as opposed to 'I am hungry.'

Private speech Self-directed speech emitted out loud by children for self-regulatory purposes.

Rebound effect Rebound effect occurs when attempts at suppressing unwanted thoughts actually lead to experiencing them more often.

Scaffolding Scaffolding is adult assistance only on those tasks that are beyond children's skills.

Self-regulation Consists in altering one's behavior, resisting temptation, changing one's mood, selecting a response from various options, and filtering irrelevant information; also includes setting immediate and distant goals, problem-solving, planning, and decision-making.

Working memory System that keeps a small quantity of information in an active state for a short period of time.

Zone of proximal development The difference between what children can and can not do by themselves.

Overview

Definition

Inner speech is the activity of talking to oneself in silence. It is often equated with the phonological loop portion of short-term memory, which gets recruited when one needs to hold auditory information in an active state for a short period of time. However, inner speech does much more, as it plays a central role in self-regulation (e.g., planning, problem-solving, self-motivating), normal language functions such as reading and writing, task-switching performance, remembering the goals of action, rehearsing person-to-person communicative encounters, and self-awareness, which includes mental time travel into the past and the future. People report that around one-fourth of their conscious waking life consists of inner speech, indicating that it most certainly constitutes a significant human mental activity.

Related Terms and Manifestations

Typical expressions used to designate inner speech are self-talk, self-directed speech, subvocal, covert, or acommunicative speech, auditory imagery, speech-for-self, propositional thought, self-verbalizations, internal dialog or monolog, subvocalizations, self-statements, and silent verbal thinking. Jean Piaget used the term egocentric speech when discussing self-talk produced aloud by children in social situations. He proposed that egocentric speech served no function at all and was the manifestation of children's cognitive immaturity. Lev Vygotsky insisted rather that egocentric (private) speech served an important self-regulatory function. In Vygotsky's view, speech-for-self emitted out loud by children reflected intellectual development, not egocentrism.

Young children engage in echolalia when they repeat others' words in an automatic manner for language learning purposes or for the simple pleasure of using words. They emit

crib speech when producing soliloquies before falling asleep. The idiom-embedded private speech refers to adults' use of private speech during public talks in order to restructure the lecture or to self-regulate (e.g., OK, let's now move on to the next point). Inner speech writings represent hastily recorded memos for self in notebooks, personal journals, on shopping lists, etc. These messages may consist in single words or phrases, or full paragraphs written in a very condensed and often obscure style meaningful only to the self.

Theoretical Themes

Thought and Language

There exist two main views on the connection between thought and language (which includes inner speech): language basically *is* thought and thought can exist without language. Plato, an advocate of the first position, wrote that "When the mind is thinking, it is simply talking to itself, asking questions and answering them." Following John Watson's lead, behaviorists also held that thought is identical to inner speech. Charles Darwin seemed to agree with this theory when he proposed that "A long and complex train of thought cannot be carried on without the aid of words, whether spoken or silent, than a long calculation without the use of figures or algebra." Vygotsky concurred and suggested that thought is not expressed in words – it comes into existence through them. An alternative formulation of this first position is the Sapir-Whorf hypothesis, which suggests that the use of vocabulary that is unique to one's native language shapes one's view of the world. To illustrate, color terms within a language influence color perception. Present work shows that using interrogative language (e.g., Will I?) as opposed to declarative speech (I will) increases motivation and goal-directed behavior.

The Wurzburg's school of thought founded by Oswald Kulpe in the late 1800s was a major proponent of the second

theory: pure thought can exist without language (or inner speech); thought can be wordless. Experiments tentatively supporting this position were conducted by Karl Buhler at the beginning of the twentieth century. Participants listened to a proverb and then were asked to press on a button once they understood it. Most volunteers claimed that the button pressing was not accompanied by verbal thoughts or images, suggesting that understanding (i.e., thought) precedes language.

None of these two extreme views are embraced by modern cognitive scientists and linguists. Instead of asking if language creates thought or if thought causes language, the question being currently examined is: how does language affect thought processes?

Vygotsky's Position

Numerous theories of inner speech have been formulated. Vygotsky's theory, which emphasizes culture, language, and internalization, arguably represents the most complete, original, and coherent view available. In Vygotsky's system, children's cognitive development is affected by culture in two ways. First, children acquire most of their knowledge (the contents of thought) through culture. In addition, not only does culture teach children what to think but also how to think. Intellectual growth emerges out of a dialectical process in which problem-solving experiences are shared with parents, teachers, siblings, peers, etc. Children can solve some problems by themselves, yet other more challenging problems require help from social agents. Vygotsky named the difference between what children can and cannot do by themselves as the zone of proximal development. He insisted that not respecting this zone, either by helping children on tasks they can complete on their own, or by not helping enough on difficult tasks, impedes cognitive development. Ideally, people interacting with children initially should guide most of the problem-solving process and eventually transfer this responsibility to the child. Language represents the core type of interaction which allows social agents to convey information to children. Gradually, children's *own* language becomes their principal tool of intellectual growth, first as speech-for-self emitted aloud (private speech) to guide and control their own actions and eventually as silent self-talk (inner speech). Vygotsky called this internalization – the process of using an instrument of thought (*inner* speech) that was at first located outside children (*social* speech). Much of Vygotsky's theorizing has led to empirical predictions and most have received support.

Methodology of Research

Like other internal cognitive processes, inner speech cannot be directly observed but only indirectly inferred. Not surprisingly, early efforts aimed at assessing inner speech were based on introspection. Alfred Binet, for instance, would have his two daughters work on various tasks and would ask them what strategies they employed. He noted that the daughters often reported thoughts such as "I *told* myself this ..." or "I *said* to myself that ...". From these observations, Binet deduced that most thinking recruits inner speech.

Private Speech

Vygotsky held that studying the spontaneous production of private speech in children was the most reliable way to tap into inner speech. Although they both are not identical, private speech, nonetheless, retains some characteristics that inner speech is postulated to possess, and importantly, it is objectively measurable and quantifiable. Indeed, private speech has been extensively studied in natural settings (e.g., in the classroom) and in more controlled environments in numerous situations (e.g., with others vs. alone). Private speech is typically measured by calculating the total number of raw utterances, the number of verbalizations per minute, or the ratio of social to private speech. Private speech units are coded and classified into different categories. Typical categories are task-irrelevant private speech (e.g., word play, emotional release, conversations with imaginary others), task-relevant private speech (e.g., vocalizations about the task or the child's current or future task-related actions), and partly internalized private speech consisting of inaudible muttering, whispers, and silent lip movements. The frequency and content of private speech are then correlated with behavior or performance.

Only children's private speech has been used as a window into inner speech. Adults also engage in private speech, but only when alone and thus much less frequently than children. However, adults' private writing has been investigated. Private writing (also called introspective or inner speech writing) refers to scribbling that people write on a piece of paper (e.g., a grocery list) or on the margins of a book, as well as in a notebook (e.g., a writer's thoughts). Private writing is consistently condensed (like inner speech) and cryptic to others because it is uniquely addressed to the self.

Production Methods

Production (or self-revelation) methods usually entail the externalization of ongoing inner speech as a task is being performed; most are thus introspective, as opposed to retrospective. With the think-out-loud technique, recordings of adults' verbalizations are made as they are working on a given task; volunteers are clearly encouraged to vocalize their thoughts. It is assumed that the collected speech will mirror genuine inner speech, or at any rate will supply a representative sample of it. To reduce the likelihood of having participants produce a biased or unnatural sample, instructions explicitly specify not to edit thoughts or to worry about being understood. The videotape reconstruction method consists in showing participants video recordings of their behavior in precise situations (e.g., during task performance) and asking them to recall (reconstruct) inner speech content. A variation of this technique is the interview immediately following the execution of a given task, where volunteers are probed for inner speech use during task completion. With the thought listing technique, participants are asked to list their subvocal activity once a task has been completed. The thought-sampling method intends to collect a representative sample of people's inner speech in natural settings. Subjects wear a beeping apparatus that produces audio signals at random intervals throughout the day. Volunteers are asked to report the content of their inner speech upon hearing the beep. All measurement

techniques reviewed above include coding and classification of inner speech units into different categories that are then correlated with behavior or task performance.

Self-Reports

The most frequently used instrument to assess inner speech is questionnaires made up of self-statements along a variety of domains – for example, anxious versus nonanxious (This is so stressful; I will make it), positive versus negative (I feel fine; I just want to die), or social phobia (People don't find me interesting). Participants are invited to rate the frequency of their self-talk using a Likert-scale. The main advantage of questionnaires is that they can easily and quickly be administered to large groups of people. Conversely, because these scales consist of premade self-verbalizations, they significantly restrict the scope of natural inner speech that volunteers could otherwise describe. Q-methodology is also used to estimate the content and/or functions of inner speech. Participants are invited to sort out cards that depict inner speech units according to the extent of agreement. Another approach, called the cued recall technique, consists of eliciting self-reports of inner speech use by presenting cards containing cue words to participants.

More ecologically valid methods exist. Researchers may use an open-format question to gather spontaneously occurring inner speech in people's natural environments (e.g., When you talk to yourself, what do you typically say to yourself?). Compared to the random-sampling method, the open-ended format approach suffers from being retrospective (and thus potentially unreliable), but is not as limiting as the questionnaire. Slightly less retrospective is the use of diaries (or first-person narratives), which can also produce rich inner speech content.

Electromyographic Recordings

Alexander Sokolov wrote an entire book on the use of electromyographic recordings of movements of the lips and tongue to assess inner speech incidence during problem-solving tasks. Electromyography allows one to evaluate and record physiological characteristics of muscles. This is done with an electromyograph that measures the electrical potential created by muscle cells when these cells contract and are at rest. Movements of the lips and tongue observed during overt speech are also produced (with much less intensity) during covert speech. These movements represent an objective external expression of subvocal speech activity. Suction electrodes placed on the tongue, sublingual horseshoe electrodes located under the tongue, or surface electrodes attached to the lower lip are used to record the target articulatory movements. It is thus possible to infer inner speech activity (but not content) during completion of various cognitive tasks such as mental calculation, silent reading, listening to speech, recall of verbal material, and manipulation of graphic-visual information.

Articulatory Suppression

As seen above, articulatory movements accompany inner speech. Logically, interfering with those movements (articulatory suppression) will lead to inner speech interruption. In a typical experiment, participants are invited to complete a task while

concurrently reciting verses or mentally counting backward from 100. The forced articulation produced by the recitation or counting blocks any other articulation that would be otherwise required when spontaneously engaging in inner speech. Performance deterioration implies that the task normally benefits from inner speech use, although some argue that the deterioration could be due merely to the extra attentional demands. Articulatory suppression clearly does not assess inner speech per se but informs the researcher as to what types of cognitive work cannot be accomplished without inner speech.

Brain-Imaging

Recent advances in brain-imaging techniques such as positron emission tomography (PET) and functional magnetic resonance imaging (fMRI) make it possible to record brain activity of participants performing various cognitive tasks. Activation of the left inferior frontal gyrus (LIFG) can be taken as evidence of inner speech activity during task completion because the LIFG is reliably recruited during the silent generation of words or sentences (see [Neuroanatomy](#) section below). It will be possible in the near future to identify which mental activities rely on inner speech, as well as to dress a list of those which do not or partially do so. To illustrate, preliminary work examining self-referential activity suggests that focusing on one's personality traits or remembering personal past episodes engage inner speech, whereas recognizing one's face on a photograph does much less so. The latest brain-imaging tool that has been developed is repetitive transcranial magnetic stimulation (rTMS), which temporarily interrupts normal cortical activity. Current experiments are looking at the effects of applying rTMS on the LIFG. Brain-imaging techniques do not allow access into the content of inner speech – only its presence or absence is being objectified.

Summary

Each measurement technique described above presents specific advantages and disadvantages. Ultimately, it is the type of problem being studied that should determine what method to select. For instance, in a preliminary stage of an investigation, it would be reasonable to employ an open-format or thought-sampling approach to collect self-generated statements from depressed patients. In a second part of the study, a validated questionnaire could be created based on these vocalizations and administered to larger clinical and nonclinical samples. Several assessment techniques should be used to aim for convergent validity. For example, in three independent studies on inner speech in anxious people, one could use diaries (thus collecting self-generated content), the videotape reconstruction procedure following anxiety-producing social interactions, and a questionnaire administered to anxious and nonanxious participants. Results would then be integrated into one broader research report.

Development of Inner Speech

Social Origins

Vygotsky postulated that inner speech grows out of one's social environment. This hypothesis is supported by the fact that there exist high positive correlations between rates of social

interaction and private speech in children. Children immersed in cognitively and linguistically stimulating environments (situations more frequently observed in higher socioeconomic status families) start using and internalizing private speech faster than children from less fortunate backgrounds. Indeed, children raised in environments characterized by low verbal and social exchanges exhibit delays in private speech development.

Development of Private Speech

Cross-sectional and longitudinal studies support Vygotsky's original view that the frequency of children's private speech follows an inverted-U relation with age. Private speech use peaks at 3–4 years of age, decreases at 6–7 years of age, and gradually fades out to be mostly internalized by age 10. As private speech diminishes, one can observe more and more frequent whispering and inaudible muttering – typical manifestations of partially internalized inner speech. Intellectually gifted children tend to internalize private speech into inner speech earlier than their average counterpart, and girls usually show a faster private speech development than boys. Before the age of 4, children are largely unaware of engaging in private speech. The above trends seem to be universal and not sensitive to cultural differences. One study examined private speech in British and Saudi Arabian children and found no differences in frequency of private speech.

Vygotsky suggested that fully internalized inner speech does not reemerge as private speech. This assertion has recently been challenged. Healthy adults have been observed to engage in external speech when alone for self-regulatory purposes, as well as for spatial navigation and search, concentration, and emotional discharge and control. Ninety-six percent of all adults report sometimes talking to themselves aloud.

Verbal Self-control

Alexander Luria conducted a set of experiments on verbal mediation, aimed at determining the extent to which both social and self-generated speeches effectively control children's behavior. Participants were instructed to press a rubber bulb as they were told by the investigator to start, stop, or synchronize presses with a flashing light and with his own speech. At 1.5–2.5 years, the instigating function of speech by the adult (start) was successful but not the inhibiting function (stop). Self-initiating and inhibiting functions of speech at that age were lacking. At 3–4 years, both the initiating and inhibiting functions of the experimenter's speech and the initiating function of the child's own verbal activity were objectified but not the self-inhibiting function. The complete regulating function of the child's own speech was observed at 4.5 years.

The investigation of natural self-regulatory private speech in children shows that it first follows behavior, then it accompanies action, and finally it precedes it. Use of private speech for self-regulatory purposes significantly increases between 3 and 4 years of age. Social agents who actively include children in a collaborative effort to solve problems facilitate the development of self-regulatory private speech. Joint work on common problems helps children to internalize coping strategies and produce individualized vocalizations adapted to solving problems encountered when alone.

The Private Speech Transition

A significant shift in children's spontaneous use of private speech occurs between the ages of 3 and 4. Three-year-old children emit self-talk across a very large array of situations (e.g., goal-directed and unfocused activities), whereas 4-year-olds' private speech tends to be observed almost exclusively during self-selected but focused, sustained, goal-directed activity. This indicates that 4-year-old children start engaging in private speech in situations in which it is mostly required for self-regulatory purposes.

Characteristics of Inner Speech

Fully internalized private speech transforms into inner speech, and it takes a life of its own with distinctive characteristics that differ from those of social speech. The semantic aspect of speech becomes most prominent as its syntactic and phonological dimensions move to the background. Unlike social speech, inner speech is predicative: it is syntactically compressed, condensed, and abbreviated. The context of speech being always known to the self-talker, there is no need to explicitly identify the subject of a thought. In inner speech, sense prevails over meaning. The private significance of words becomes more salient than their conventional meanings. Agglutination refers to the creation of hybrid words that constitute complex and uniquely personal concepts. The predicative nature of inner speech explains why it is experienced as a series of fragmented units – not as a smooth sequence of fully developed verbal images. This actually accounts for the observation that the rate of inner speech is significantly faster than that of overt speech.

Inner speech often exhibits a dialogic quality because it grows out of social speech, itself being mostly a dialog between two persons. Inner speech is regularly described as including a speaking self (the inner voice) and a self talked to (the inner ear). Indeed, inner speech frequently adopts a format that approximates social verbal interactions, with a series of alternating lines, questions, and answers. Various acoustic qualities of overt speech perception (e.g., sex, loudness, accent, and language) are not reported during internal speech.

Neuroanatomy

Experiments employing PET and fMRI scans show that the LIFG is more active during inner speech production elicited by tasks such as silently articulating sentences or single words. The LIFG is also recruited when subjects undertake working memory tasks involving covert repetition of verbal material. The LIFG corresponds to Broca's area, which constitutes the neurological foundation of both overt and inner speech generation. The LIFG is also referred to as the left ventrolateral prefrontal cortex or left frontal operculum; it encompasses Brodmann's areas 44, 45, 46, and 47. Additional brain areas are activated during inner speech use, including Wernicke's area, supplementary motor area, insula, and superior parietal lobe on the left side, as well as right posterior cerebellar cortex.

Neuropsychological findings are consistent with brain-imaging studies: accidental damage to the LIFG disrupts inner

speech. rTMS applied to the LIFG interferes with internal speech. rTMS applied to the motor cortex of the left hemisphere, which is known to control mouth and tongue muscles, also inhibits inner speech – an observation in line with the view that covert speech necessitates articulation. The LIFG is not uniquely activated during inner speech production. Its activation can also be recorded during cognitive control (the orchestration of thoughts and actions in accordance with internal goals), working memory (temporary storage and manipulation of information), selection among competing alternatives to guide response, and interpretation of others' behavior. Note that naturally occurring inner speech, with its condensed and dialogic qualities, has never been imaged; what has been measured so far is inner speech defined as mental recitation.

Functions

Self-regulation

Overview

Fundamental human activities such as setting immediate and distant goals, problem-solving, planning, and decision-making are all part of a more global capacity called self-regulation. Private speech in children and inner speech in adults have been shown to be of critical importance for effective self-regulation. Not surprisingly, the expression verbal self-guidance is often used to designate self-regulation. Self-talk significantly increases performance on tasks that entail the creation of complex behavioral sequences and the concurrent judgment of multiple behavioral choices. Four main groups of effective self-verbalizations during problem-solving tasks have been documented: (1) a clear definition of the problem; (2) an efficient approach to the problem; (3) sustained concentration on the problem; and (4) regular assessment of progress that includes self-encouragement or strategic refocusing.

Private speech

Private speech use in children gradually increases as tasks become more challenging. It is most often observed when participants work on tasks that require executive control in the absence of regulation offered by adults. Representative tasks found in research reports are puzzles, memory tasks, picture classification and discrimination, and sequencing tasks. The following situations increase the likelihood of private speech use for self-regulatory purposes: (1) completion of goal-directed, academic, or problem-solving tasks as opposed to free play or other activities; (2) working on difficult yet achievable problem-solving tasks instead of easy tasks; (3) being either alone or with peers in contrast to being with a verbally regulating adult; and (4) working with an encouraging as opposed to highly controlling adult. This is referred to as scaffolding, which consists in adult assistance only on those tasks that are beyond children's skills.

That private speech use increases with task difficulty does not automatically imply that it actually improves performance. Two factors that need to be considered are task complexity and concurrent versus future performance. Private speech will most likely impede performance if the task is too difficult. It will enhance performance if the task is within the child's zone of proximal development – that is, if it is within the child's ability range. Also, private speech use is more beneficial on the long

term (future) than on the short term (concurrent). Increased performance following private speech use is delayed (diachronic) instead of instantaneous (synchronic). Better performance is typically observed during task sessions following the time at which private speech was produced.

Self-talk use in sports

Numerous studies have examined the self-regulatory use of self-talk in athletes while training and competing during sporting activities such as water-polo, skating, golf, gymnastics, wrestling, and basketball. Self-verbalizations have been shown to be superior to other mental strategies (e.g., mental imagery) in enhancing sport performance. Dimensions of self-talk that are usually measured or manipulated in studies are valence, overtiness, self-determination, self-instruction, self-motivation, and frequency. Valence refers to the emotional content of self-statements. While negative self-talk is associated with poorer performance, positive self-talk does not significantly increase it. Positive self-verbalizations are defined as those that help to concentrate on the present, not on past errors or a remote future. Negative self-statements constitute inappropriate, irrational, counterproductive, or anxiety-producing thoughts. Another quality of self-talk is overtiness, as opposed to covertness. It has been suggested that overt self-talk is more effective at improving performance because it allows the athlete to reproduce situations where his or her coach verbally guides performance aloud. Self-determined (i.e., self-selected) self-talk is postulated to possess more motivational power than preformulated self-talk assigned by a trainer. How-to-perform self-talk is called self-instructional talk and is especially effective in practice situations, whereas I-can-do-it talk represents motivational self-talk and is more appropriate in competitive settings. Frequency of self-talk often increases across various periods of a sporting season and is linked to superior performance, although extreme frequency (called paralysis by analysis) worsens it.

Language

Inner speech underlies basic language functions such as reading, writing, speaking, and calculating. Deterioration of inner speech caused by brain injury consistently produces language disorders such as aphasia, agraphia, alexia, acalculia, as well as reduced verbal short-term memory. Current studies indicate that speakers monitor their own subvocal speech to identify and correct phonological, lexical, or grammatical mistakes before they are spoken. Inner speech and crib speech are often recruited when one spontaneously practices pronunciation and thinks about grammatical correctness. Significant lip movements are observed during silent reading, and patients with frontotemporal dementia and Gilles de la Tourette's syndrome, who exhibit a loss of control over inner speech which manifests itself in coprolalia (emitting unwanted vocalizations in social situations), also cannot read in silence. These two lines of evidence strongly suggest that inner speech and silent reading are deeply associated.

Links between inner, oral, and written speech, reading, and composing

As seen earlier, because inner speech is solely addressed to the self, it is telegraphic, densely meaningful, fluid, dynamic,

idiomatic, agglutinative, elliptic, and predicative. Written speech, however, is produced for others and thus is fully expanded, maximally elaborated, and orthographically explicit. Composing refers to the process of putting ideas and words onto paper; inner speech allows the writer to engage in mental rehearsal, or planning, to determine what to write. Oral speech lies in between inner and written speech – it is more spontaneous and involuntary than written speech, it requires an interlocutor, like inner speech it is dialogic, and it is made up of actual sounds. Social speech develops first, followed by inner speech, then both written speech and reading. But relationships between inner and written speech are bidirectional. On the one hand, inner speech serves as an internal rough draft for oral and written speech. On the other hand, the very structure of written language forces an analytic (metalinguistic) stance on inner speech. The sophisticated, elaborated qualities of written speech encourage a less spontaneous and involuntary use of inner speech. Not only does inner speech constitute the basis of written speech but also underlies reading. In contrast with inner speech, writing and reading require much more voluntary attention to the phonological, syntactic, and semantic aspects of speech.

Language without inner speech?

One scientific article describes the case of a patient who retained normal language functions despite being incapable of inner speech. This evidence seems to contradict the claim that language functions require inner speech. However, careful neuropsychological assessment showed that the patient was using mental imagery to compensate for the absence of inner speech. That is, instead of verbalizing words to himself, the patient could create clear images of words when talking to himself – thus engaging in inner imaging as opposed to inner speech. Apparently, this visual communication with oneself effectively replaced inner speech and other language functions such as reading and calculating.

Do deaf people talk to themselves?

Individuals born deaf never experience hearing sounds and thus do not develop normal language skills, including inner speech. Simply put, since deaf people would never have heard spoken words, they cannot speak with or think in words. Can they nonetheless engage in a form of wordless self-talk? The answer is yes, with sign language. Use of sign language in deaf individuals activates the LIFG – the brain area known to sustain inner speech. As seen before, articulatory suppression interferes with performance on tasks that benefit from inner speech use in orally proficient individuals. A comparable deterioration in task performance is obtained in sign users by having signers hold objects firmly in their hands, which inhibits self-sign language use. Also, deaf individuals tend to wave hands when working on difficult tasks – the nonverbal equivalent of private speech.

Memory

Working memory

Inner speech plays an important role in memory functions, particularly in working memory. Working memory allows one to keep a small quantity of information in an active state for a short period of time. It is involved in numerous complex

cognitive abilities that include reasoning, decision-making, problem-solving, and language understanding. Verbal and spatial information are manipulated differently in autonomous neuroanatomical systems. Each system is made up of three functional parts with unique neural correlates. One component stores information, another one rehearses – reactivates, refreshes – it, and a third component (the executive one) controls the overall processing of information in working memory. Inner speech is synonymous with the rehearsal component, at work, for example, when one mentally repeats a phone number to assist later recall.

Autobiographical memory in bilinguals

Inner speech has also been shown to be involved in autobiography, the memory of one's own past. Phenomenological inspection makes it clear that images are often used when we store and recall personally relevant events. However, a recent study suggests that autobiographical information is also encoded and retrieved in words, or in narrative form. A related issue is: in what inner language do bilinguals recall their past? One cross-cultural study assessed inner speech of autobiographical memory in Polish people who emigrated to Denmark 30 years ago. Participants indicated retrieving personal memories in Polish for the decades prior to immigration and in Danish after immigration. This observation thus suggests that autobiographical material stored in one language is more easily retrieved in the same language. All immigrants spent 30 years in Denmark, but early immigrants (on average 24 years old at the time of immigration) indicated using more Danish inner speech, while late immigrants (about 34 years old at the time of immigration) reported more Polish inner speech use.

Self-awareness

It is becoming increasingly evident that fully developed human self-awareness depends on inner speech use. Self-awareness refers to the ability to analyze the self and to build a self-concept. It includes focus on private and public self-aspects and consists in self-definition, self-recognition, self-evaluation, self-esteem, mental time travel, and death awareness, to name a few self-referential processes. Inner speech allows one to identify and label various self-aspects – it makes it possible for a person to represent internal states and reflect on them. There is considerable empirical support for the notion of inner speech participation in self-awareness. Multiple validated questionnaires measuring frequency of self-focus and use of inner speech strongly correlate. Healthy participants claim to rely significantly on inner speech while thinking about their future. Brain-imaging studies of self-referential processing often report activation of the LIFG and thus, most probably, inner speech use. Brain injuries that produce a loss of inner speech are associated with self-awareness deficits. The development of theory-of-mind, which consists in thinking about others' mental states, is linked to private speech use in preschoolers.

Additional Functions

Inner speech does not uniquely play a role in self-regulation, language, memory, and self-awareness. It is also involved in

task-switching performance, the ability to switch back and forth between two cognitive operations such as multiplying and dividing numbers. Children learn to differentiate their own voice from those of others by repeatedly hearing their own voice through private speech use. People also talk to themselves when mentally preparing an upcoming social encounter. Inner speech is also activated when one focuses attention on a given target, forms concepts, remembers the goals of actions, or expresses emotions such as anger. Some have proposed that praying engages inner speech.

Dysfunctional Inner Speech

Overview

Ruminative inner speech that focuses on real or imagined negative self-aspects may amplify preexisting morbid conditions such as test anxiety, bulimia, anorexia, lack of assertiveness, insomnia, social anxiety, agoraphobia, sexual dysfunctions, low self-esteem, and depression. Inner speech may also accompany less severe and temporary negative states such as worry, guilt, and shame. The content-specificity hypothesis suggests that the aforementioned maladaptive conditions underlie negative self-talk associated with specific dysfunctional topics. To illustrate, anorexia triggers inner speech revolving around weight and physical appearances issues (e.g., I must lose weight), and low self-esteem is linked to self-worth cognition (e.g., I'm insignificant). Accordingly, compulsive gamblers have irrational thoughts about control of the game (e.g., I'm going to bet on those rows again, this is a good game).

Asymmetry Between Positive and Negative Self-verbalizations

There exists an important and counterintuitive asymmetry between positive and negative self-statements. Negative inner speech has a significantly more dysfunctional influence than positive self-talk on coping. Simply put, imagining the worst through pessimistic inner speech (e.g., failing an exam) has more negative impact than thinking positively (passing an exam). This fact clearly goes against the fashionable belief of positive thinking and suggests that eradicating negative verbalizations might be more efficient than formulating positive ones. Healthy functioning is associated with a 1.7:1 ratio of positive to negative self-verbalizations; maladaptive thinking is characterized by a 1:1 ratio. Studies that measure cognitive change following psychotherapy confirm that negative thoughts tend to decline while positive thoughts do not increase. Negative verbalizations (e.g., disfigurement) increase heart rate, but positive ones (e.g., harmony) have no significant effect.

The Rebound Effect

Also perplexing is the observation that trying to suppress undesirable thoughts in inner speech (e.g., I must stop thinking about this) makes the thoughts more accessible (they are experienced more often) and leads to increased anxiety, depressed mood, and lower self-esteem. This paradoxical phenomenon is called the rebound effect.

Hearing Voices in Schizophrenia

The most plausible explanation for auditory verbal hallucinations in schizophrenic patients is that they cannot properly monitor their own self-generated inner speech. There is little doubt that the voices are the result of patients' own subvocal activity. Indeed, the LIFG is active when schizophrenic patients are experiencing verbal auditory hallucinations, suggesting inner speech production. The precise underlying mechanism is unknown, but one view implicates a verbal self-monitoring deficit. Speech production in normal individuals generates a corollary discharge that sends a message to the left temporal lobe where verbal thoughts are identified. Basically, the message tells the brain that it just produced speech and thus the voice heard is one's own inner speech. This communication between the frontal and temporal lobes is postulated to be deficient in schizophrenic patients. Brain-imaging studies support this hypothesis: patients with auditory hallucinations show activity in the LIFG when engaging in inner speech but fail to exhibit activity in the left temporal cortex. That verbal hallucinations would be caused by an inner speech dysfunction per se is improbable. Performance on short-term memory tasks that require inner speech use is normal in patients experiencing severe auditory hallucinations.

Hyperactivity

Initial explanations of hyperactivity in children involved the notion of insufficient self-regulatory private (and inner) speech causing poor self-control. Cognitive-behavioral psychologists designed various techniques to increase the use of verbal self-guidance. A typical approach consisted of gradual stages producing the internalization of self-regulatory speech – for example, modeling, overt external guidance, overt self-guidance, faded overt self-guidance, and covert self-guidance. This method has recently been reevaluated, and most agree that it is actually ineffective. First, the aforementioned approach focuses on short-term results that apply to precise tasks; what would be needed is a technique leading to long-term gains that would generalize to broad academic and interpersonal behaviors. What used to be taught was self-control (i.e., copying adults' commands) instead of authentic self-regulation (i.e., self-generating flexible plans for action). Second, in point of fact, hyperactive kids produce adequate self-regulatory private speech. The nature of the deficit does not lie in lack of verbal self-guidance – it is most likely neurobiological.

Conclusion

Inner speech constitutes a fundamental cognitive activity not limited to working memory (the phonological loop) but including self-regulation (initiating, shaping, guiding, and controlling behavior), language functions, self-awareness (e.g., autobiographical memory, mental time travel), emotional release, task-switching, preparation for upcoming social encounters, and more. Various methods exist to measure inner speech, some easy to administer but limiting (e.g., questionnaires) and others more ecologically valid but time consuming (e.g., thought sampling). The general agreement is that inner

speech is social in origin, it is preceded by private speech, and once internalized, it becomes mostly abbreviated and predicative. Although various brain regions underlie inner speech production, the LIFG seems to represent the most important area. Inner speech resembles a double-edged sword – on the one hand, it is associated with positive consequences such as self-regulation, yet on the other hand, negative and ruminative self-talk may lead to or maintain psychological disorders such as anxiety and depression. Inner speech, nonetheless, remains neglected compared to other important psychological concepts. To illustrate, what people actually talk to themselves about is largely unknown and current work is precisely aiming at answering that and other exciting research questions.

© 2012 Elsevier Inc. All rights reserved.

Glossary

Adaptive behavior The set of behaviors necessary for individuals to function safely and appropriately in the range of activities and environments presented in daily life.

Autism spectrum disorders A spectrum of developmental disorders manifested by impaired social interaction and communication, as well as stereotypic behaviors.

Behavior skills training Training in a behavior or skill that involves teaching, modeling, rehearsal, and feedback.

Cognitive behavioral therapy Therapeutic treatments, based on cognitive and behavioral theories and research, used to address various mental health disorders.

Down syndrome A genetic disorder caused by the presence of an extra chromosome 21.

Dual diagnosis Comorbidity of intellectual disability and mental health disorder in an individual.

Etiology The cause or origin of a disability; in this text, the genetic cause of an intellectual disability.

Inclusive education Placement in the general education classroom with individualized supports and accommodations.

Intellectual disability Significantly subaverage intellectual functioning which leads to impairments in adaptive behavior, all of which are first manifested during childhood.

Prader-Willi syndrome A genetic disorder caused either by a deletion of a certain part of the chromosome 15 contributed by the father, or from having two chromosome 15s from the mother.

Psychopathology Behaviors symptomatic of mental illness or psychological impairment.

Task analysis The delineation of component steps required to complete a more complex task.

Williams syndrome A genetic disorder caused by a deletion on one of the chromosome 7s.

Issues Related to Intellectual Disabilities

Although long considered a less interesting or exciting area, the field of intellectual disabilities is beginning to hit its stride. Spurred by findings that are important to many disciplines, the past two decades have seen a growing interest in individuals with intellectual disabilities. Correspondingly, there has been a rapid expansion in our nation's disability-related service and training structures, the inauguration of several new journals, and the start of many research and clinical networks. In future years, we expect even greater numbers of sophisticated, interdisciplinary research projects and increased services to these individuals, all performed by professionals who have received academic, research, and clinical training focused on persons with intellectual disabilities and their families.

To appreciate these new developments, one needs only to juxtapose present advances with those in prior years. Until the early 1960s, the field of intellectual disabilities was in its infancy. Few studies existed, few professionals were trained in intellectual disabilities, and disability-related infrastructure was virtually nonexistent. But with the presidency of John F. Kennedy (himself the brother of a woman with intellectual disabilities), a formal field began to take shape. The Kennedy administration is generally credited with founding the National Institutes of Child Health and Human Development (NICHD), the United States' main supporter of biobehavioral research in typical and atypical development. Similarly, the Kennedy Administration started the movement to develop University Centers for Excellence in Developmental Disabilities to help in service delivery, as well as programs to provide training in intellectual disabilities to medical and nonmedical professionals.

More recently, the field has contributed to advances in genetics and biomedicine. Over 1000 different genetic conditions have now been associated with intellectual disabilities, but more importantly, certain genetic etiologies have been found to predispose individuals to specific maladaptive behaviors, profiles of cognitive-linguistic strengths and weaknesses, and medical or other conditions. Across many disciplines, researchers have begun to appreciate that individual genetic conditions may constitute model systems that may help in understanding specific cognitive processes, psychiatric diagnoses, or medical conditions.

Defining and Classifying Intellectual Disability

Formerly referred to as 'mental retardation,' intellectual disability has a long history of debate as to how it is best defined and classified. Here, we discuss the main system used to diagnose individuals with intellectual disabilities, as well as the several ways in which professionals have classified these individuals.

Three-Pronged Definition

While the field continues to debate the appropriate way to define an intellectual disability, at least in broad outline the definition of intellectual disabilities has remained relatively stable over time. According to the *Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition-Text Revision* (DSM-IV-TR), a three-pronged definition characterizes intellectual disability: (1) having significantly subaverage intellectual functioning that leads to (2) impairments in adaptive behavior, all of which are (3) first manifested during the childhood years.

First, in order for a diagnosis of intellectual disabilities to be warranted, the individual must have subaverage intellectual functioning. Subaverage intellectual functioning is operationalized as a score of 70 or below on an appropriately standardized, individually administered IQ test.

Second, individuals must show impairments in everyday adaptive behavior. Thus, individuals with intellectual disabilities often have difficulties in performing age-appropriate skills of daily living (i.e., caring for themselves and their environments); of communicating with others via expressive, receptive, or written communication; or of getting along with others and following rules. This second criterion highlights that intellectual disabilities are not solely related to intellectual deficits, but they are also associated with concurrent deficits in everyday functioning. To be diagnosed with intellectual disabilities, then, individuals must also display impaired adaptive behavior.

Third, individuals must also first exhibit deficits in both intellectual and adaptive behaviors prior to 18 years of age. Thus, an intellectual disability is not an appropriate diagnosis for individuals showing deficits related to accidents, illnesses, or aging that originate during the adult years.

While most would agree with these three diagnostic criteria, controversy abounds regarding how each is operationalized. In addition to the general criticisms leveled at IQ tests, all agree that few differences exist between individuals slightly below versus slightly above IQ 70 (the IQ cut-off line for intellectual disabilities). Similarly, professionals debate which specific skills should constitute adaptive behavior; even the field's main professional organization, the American Association on Intellectual and Developmental Disabilities, has changed the numbers and names of adaptive domains in subsequent definitional manuals. Concerns also exist regarding appropriate measures of adaptive behavior, the relation between adaptive and intellectual functioning, and the potentially limited opportunities that certain individuals have to develop adaptive skills. Still, while each issue has received varying attention over the years, most would agree that the combination of subaverage intellectual functioning, concomitant deficits in adaptive behavior, and onset during the childhood years, all characterize those with intellectual disabilities.

Classification: Level-of-Impairment Approach

Just as most would agree to the three-pronged definition of intellectual disabilities, so too do most agree that individuals with intellectual disabilities differ one from another. The problem, however, concerns how best to differentiate within this population.

A first perspective has been referred to as a level-of-impairment approach. That is, individuals with intellectual disabilities are differentiated by their level or degree of intellectual impairment. The most common level-of-impairment categorization is by IQ score: mild (IQ between 50 and 69), moderate (IQ between 35 and 49), and severe/profound (IQ between 0 and 34) levels of functioning. Another categorization – most often used by the school system – differentiates students into those who are Trainably Mentally Handicapped (TMH) or Educably Mentally Handicapped (EMH); this categorization would then direct the placement and instruction for the individual.

Another categorization is by the level of services that the individual needs. Technically, this system is not a level-of-impairment classification system, in that two individuals with the same IQ score might have different service needs. Still, particularly for those individuals at the moderate and severe-profound levels, a strong correlation exists between IQ and service needs (correlations are weaker for individuals with IQs in the mild range). The support needs noted by this system include: intermittent, limited, extensive, and pervasive. Intermittent support refers to occasional support, whereas limited support refers to a day program or sheltered workshop. Extensive support refers to daily, ongoing support, whereas pervasive support involves support for all activities of daily living (possibly including nursing care).

Classification: Etiological Approach

First begun by Edward Zigler in the late 1960s, the second approach to classification concerns the cause or etiology of the person's intellectual disabilities. In earlier years, researchers distinguished between those persons who had a clear cause of their intellectual disabilities from those who did not. Thus, Zigler and others wrote of persons who showed 'organic' intellectual disabilities, or disabilities that could be traced to any of hundreds of pre-, peri-, or postnatal causes. This 'organic' group was contrasted with a group of individuals whose intellectual disabilities could not be attributed to any clear causes. This latter group of individuals, called by a wide variety of names (familial, cultural-familial, sociocultural familial), have also been the subject of different theories with regard to the cause of their intellectual disabilities.

Over the past two decades, the group with 'organic' intellectual disabilities has been further divided into those with different genetic causes. At the last count, over 1000 different genetic causes of intellectual disabilities were identified, and many show etiology-related behaviors as well as medical and other characteristics. Such personal characteristics, in turn, have proven extremely interesting to professionals in a variety of disciplines.

Genetic Etiology

Before providing examples of three genetic etiologies, we first provide some background. First, a genetic disorder predisposes individuals to show a particular behavior, although not every individual with that disorder necessarily exhibits the behavior. Thus, not every person with Prader-Willi syndrome engages in hyperphagia (overeating), and not every person with Williams syndrome has relatively strong linguistic and weak visuospatial skills. Second, not every genetic condition is associated with its own unique outcome; indeed, several disorders may show a single behavioral characteristic or set of characteristics. Finally, there are many etiology-related outcomes. Some involve a specific pattern of cognitive, linguistic, or adaptive strengths and weaknesses; others pertain to certain times during development when rapid or slowed development occurs; still others predispose individuals to displaying one or more maladaptive behaviors. In addition to such behavioral outcomes, different genetic syndromes also predispose children and adults to specific physical characteristics and medical problems (e.g., heart disease, leukemia, Alzheimer's disease).

With this brief background, we now discuss three genetic syndromes: Down syndrome, Prader–Willi syndrome, and Williams syndrome. We have chosen to highlight these because each syndrome features a fair amount of behavioral research, and is associated with several interesting behavioral characteristics. Each in its own way helps to make intellectual disabilities interesting to researchers in various areas of psychology, psychiatry, and other behavioral sciences.

Down Syndrome

The most common genetic–chromosomal disorder causing intellectual disability, Down syndrome occurs in about 1 per 800 births. Caused in most cases by the presence of an extra twenty-first chromosome, Down syndrome is associated with distinct physical and behavioral characteristics. These individuals are often affected by poor muscle tone, congenital heart defects, thyroid problems, vision and hearing problems, leukemia, and other health issues. By age 40, all persons with Down syndrome are thought to have the plaques and tangles characteristic of Alzheimer’s disease, even though the dementia normally associated with Alzheimer’s disease appears only in some adults (usually by age 50). Although life spans have risen rapidly over the past few decades, the median age of death for individuals with Down syndrome is now about 60 years (some 15–20 years less than the life expectancies found in the general population).

Generally associated with intellectual disability in the mild to moderate range, individuals with Down syndrome also demonstrate a specific behavioral profile. Most persons with the syndrome show relative strengths in visual (as opposed to auditory) short-term memory, with relative weakness in several linguistic tasks. With only a few exceptions, most children and adults with Down syndrome struggle with expressive language and articulation, as well as with consistent use of grammatical morphemes (e.g., ‘-s’ for plural, ‘-ed’ for past) and other aspects of grammar.

In terms of personality, individuals with Down syndrome are often described as being cheerful, friendly, and eager to please. However, this commonly accepted description does not include other characteristics also frequently observed among individuals with Down syndrome. For example, some children and adults have been described as active, distractible, and stubborn. As with all behavioral profiles, variation exists and some individuals may exhibit these personality characteristics, while others may not.

Although maladaptive behaviors are found at lower rates than among others with intellectual disabilities, researchers nevertheless estimate that 13–15% of children with Down syndrome engage in maladaptive behaviors, such as stubbornness, defiance, and aggression. Also, children with Down syndrome have been found to exhibit repetitive, compulsive-like behaviors in more extreme forms and more frequently than typically developing children. However, like typical children, the frequency of these behaviors decreases as age increases. Also, individuals with Down syndrome may be affected by attention-deficit hyperactivity disorder (ADHD), oppositional and conduct disorders, and anxiety disorders. Such psychiatric conditions typically manifest during childhood and adolescence; researchers generally report higher prevalence rates among adolescent populations.

As individuals with Down syndrome reach adulthood, they may become more vulnerable to depressive disorders. Approximately 6–11% of adults with Down syndrome are thought to experience depression and affective disorders, including characteristic features such as being passive, apathetic, and withdrawn. Adult depression may originate in adolescence and early adulthood and may be confused with the early signs of Alzheimer’s disease, which often has a similar presentation.

Recent research has also described a change during adolescence among some individuals with Down syndrome, who became increasingly underactive and overweight. Likewise, as compared with their behavior during childhood, some adolescents may exhibit increasingly secretive tendencies and preferences to be alone. Even compared with other young adults with intellectual disabilities, young adults with Down syndrome may benefit from increased activity and engagement in community life. Negative physical and behavioral changes among adolescents with Down syndrome warrant attention, as they may anticipate depressive symptoms in adulthood.

Prader–Willi Syndrome

Occurring in about 1 per 15 000 births, Prader–Willi syndrome results from two distinct causes. Most cases (70%) result from a deletion on the long arm of the paternal chromosome 15. The remaining individuals diagnosed with Prader–Willi syndrome result from maternal uniparental disomy of chromosome 15, in which both chromosome 15s are contributed by the mother. Common to both causes is the absence of the paternal contribution to chromosome 15. Individuals diagnosed with Prader–Willi syndrome are often categorized in the mild range of intellectual disability (IQ scores averaging around 70), and show relative strengths in daily living skills.

The most notable behavioral characteristic of Prader–Willi syndrome is hyperphagia, or compulsive overeating. Hyperphagia, which begins in most children sometime between 2 and 6 years and continues throughout life, is thought to involve the hypothalamus and is characterized by incomplete satiation (hence the motto of the Prader–Willi Syndrome Association of the United States: “Always hungry, never full”). Behaviors associated with hyperphagia include food-seeking, foraging, and hoarding. If left unchecked, individuals with Prader–Willi syndrome become morbidly obese, and some adults can weigh 300 pounds or more. As might be predicted, obese individuals with Prader–Willi also experience heart disease, diabetes, and sleep apnea. Dietary interventions are critical to avoid these health risks and to decrease the prevalence of early death related to obesity.

Beyond hyperphagia, individuals with Prader–Willi syndrome also often display high rates of other maladaptive behaviors. Many engage in tantrums and aggressive behavior, and may be described as emotionally labile and stubborn. Individuals with Prader–Willi are also often described as underactive and lethargic, further contributing to health concerns.

These individuals also show high rates of obsessive and compulsive behaviors. Although such obsessions and compulsions often relate to food, individuals with Prader–Willi syndrome also engage in obsessive–compulsive behaviors unrelated to food, such as hoarding objects, performing rituals, and obsessive cleaning. Similar to their food-related obsessions,

other obsessive and compulsive behaviors typically emerge during the preschool years. The tendency toward these behaviors among individuals with Prader-Willi syndrome indicates the increased risk of obsessive-compulsive disorder (OCD) in this population.

While originating in childhood, obsessive-compulsive behaviors typically intensify in adolescence and adulthood. Awareness of this trend should inform the administration of assessments and development of interventions to address various compulsions and maladaptive behaviors. Additionally, the severity of behavior among individuals with Prader-Willi syndrome, particularly related to eating, often warrants highly restrictive interventions (e.g., dedicated 'Prader-Willi-specific' group homes with locked kitchens). Understanding both the trajectory of these maladaptive behaviors and their typical levels of severity can help professionals effectively intervene to benefit the physical and mental health of individuals with Prader-Willi syndrome.

Williams Syndrome

Williams syndrome results from a deletion on one of the chromosome 7s that includes the gene for elastin, a protein in connective tissue that supplies strength and elasticity to the organs. Occurring in about 1 in 10 000 births, those with Williams syndrome are often affected by health problems related to elastin insufficiency, such as cardiovascular disease. Individuals with Williams syndrome are also typically affected by hypercalcemia, as well as by musculoskeletal and renal abnormalities. Individuals with Williams syndrome also often experience hyperacusis, or an oversensitivity to certain sound frequencies.

Most notable to behavioral researchers has been the syndrome's characteristic cognitive-linguistic profile. Most individuals with Williams syndrome have limited visuospatial skills such that they have great difficulty in drawing and performing visual tasks on IQ tests. However, they are generally able to recognize faces, as well as understand and respond to facial emotions. In addition, most individuals with Williams syndrome show relatively strong abilities in expressive language, with well-developed vocabularies (often including atypical or low frequency words), use of relatively advanced syntax and semantics, and at times advanced prosody and story-telling skills.

Persons with Williams syndrome also often display an affinity for music. Although much has been made of musically talented individuals with Williams syndrome, such individuals are relatively rare. In contrast, most individuals with the syndrome are highly interested in music; these individuals seem to have exaggerated emotional responses to music that are currently being examined by researchers using functional MRI, ERP, and other real-time brain measurements.

In terms of personality, individuals with Williams syndrome are often described as unusually friendly, engaging, pleasant, and interpersonally sensitive. At the same time, however, many of these individuals are also described as impulsive, hyperactive, and inattentive, with a tendency to be socially disinhibited. Together, these behavioral characteristics often lead the individuals with Williams syndrome to be strikingly but indiscriminately social; as a result, many adolescents and adults with Williams syndrome have difficulties in developing

and maintaining friendships. Furthermore, their indiscriminately social behaviors may make these individuals more vulnerable to exploitation.

Recent research also highlights the tendency among individuals with Williams syndrome to become highly anxious, worried, fearful, and to have perseverative thoughts. Indeed, compared to those with other types of intellectual disability, persons with Williams syndrome are more prone to experience anxiety, and such fears and anxieties increase during adolescence. Many fears are about future events and health concerns. While many individuals with Williams syndrome experience some level of anxiety, it is unclear how this tendency relates to phobias and other psychiatric conditions.

In addition to appropriate medication, interventions to address anxiety among individuals with Williams syndrome might be developed based on the relative strengths of this group. Given the high verbal abilities of most individuals, interventions might prove particularly helpful when they involve talking to a therapist or participating in group therapy sessions. Finally, given most individuals' affinity for music, therapies involving music may be particularly helpful in addressing anxiety and other behavioral issues experienced by many persons with Williams syndrome.

Dual Diagnosis

Beyond the specific maladaptive behaviors and psychiatric conditions found in individuals with Down syndrome, Prader-Willi syndrome, and Williams syndrome, generally higher rates of maladaptive behavior-psychopathology occur within the overall population of those with intellectual disabilities. Until recently, this statement was in itself controversial, in that parents and advocates wanted to distinguish the interests and needs of those with intellectual disabilities from those with psychiatric diagnoses but who did not have intellectual disabilities. Recently, however, the field has realized that it needs to pay greater attention to the amounts, types, and treatments needed for those who are 'dually diagnosed,' who have both intellectual disabilities and emotional/behavioral problems.

The first issue relates to the sheer amount of mental health issues among those with intellectual disabilities. At present, estimates vary widely, with the prevalence of comorbid intellectual disabilities and mental health issues estimated to be as low as 10% and as high as 70% in all individuals with intellectual disabilities. Though imprecise, the median number, about 40%, indicates that many of these individuals have significant mental health concerns.

A second issue relates to the types of problems these individuals experience. It may, for example, be the case that persons with intellectual disabilities are at higher risk for certain kinds of psychopathology but not for others. Although this issue is difficult to resolve, so far most work has focused on several specific psychiatric diagnoses. For the sake of space, we discuss here the diagnoses of autism spectrum disorder, anxiety, and depression.

Individuals with intellectual disabilities who have autism spectrum disorders (ASD) may have higher rates of behavioral problems. ASD is a spectrum of developmental disorders manifested by impaired social interaction and communication,

as well as stereotypic behaviors. Prevalence rates for the dual diagnosis of intellectual disability and ASD range from 2% to 41%. Compared to those with an intellectual disability alone, individuals with both ASD and intellectual disability have higher levels of problem behavior, including stereotypy, aggression, and self-injurious behavior. Additionally, individuals with ASD and intellectual disability (vs. those with intellectual disability alone) have higher rates of pica (eating nonedible items) and sleep disorders.

As a second issue, individuals with intellectual disability are at a higher risk for anxiety. Prevalence of anxiety among individuals with intellectual disabilities has been estimated to be as low as 1.5% to as high as 24% of this population. As noted above, individuals with certain genetic conditions (vs. those with other genetic conditions or with unknown etiology) may be more likely to have heightened anxiety. For example, individuals with Williams syndrome are more likely to have anxiety, including generalized anxiety or worry about the future.

Like anxiety, depression is thought to be more prevalent among individuals with intellectual disabilities. Also similar to the literature on anxiety, the prevalence estimates of depression within this population vary widely, ranging from 1.5% to 30% of all individuals. Though rates of depression are higher among individuals with (vs. without) intellectual disabilities, prevalence patterns mirror those of the general population: women are more prone to depression than men, and adolescents/adults are more likely to experience depression than children. Additionally, certain genetic disorders may be at a higher risk for depression. Thus, individuals with Down syndrome seem more vulnerable to depression, particularly during the adolescent and adult years.

Assessment

For several reasons, mental health professionals have difficulty in assessing psychopathology among individuals with intellectual disability. First, professionals have historically allowed the diagnosis of intellectual disability to overshadow a potential diagnosis of psychiatric disorders. For example, if an individual with intellectual disabilities displays symptoms of depression, anxiety, or a behavioral disorder, a clinician might simply attribute these behaviors to the person's intellectual disabilities, rather than assessing the individual for a psychiatric diagnosis. In this way, diagnostic overshadowing can lead to the lack of appropriate assessments and diagnoses for individuals with intellectual disabilities.

A second issue concerns the degree to which traditional diagnoses apply to individuals with intellectual disabilities. As described in the DSM-IV-TR and the ninth or tenth edition of the International Classification of Diseases (ICD), diagnoses are often based on information gathered during psychiatric interviews. When interviewing persons with intellectual disabilities, professionals have raised concerns about the validity of such interview responses for several reasons. First, persons with intellectual disabilities often display an acquiescence bias, telling the interviewer what he or she wants to hear. Second, some individuals with intellectual disabilities have difficulty with expressive language and with communicating abstract thoughts and feelings. Finally, some individuals may struggle with reporting accurate information about the nature and duration of their symptoms.

To address these problems, mental health professionals have developed alternatives to typical psychiatric interviews. For example, the Psychiatric Assessment Schedule for Adults with Developmental Disability was developed specifically to assess individuals with intellectual disabilities. Additionally, the National Association for the Dually Diagnosed (NADD) and American Psychiatric Association (APA) have recently adapted the criteria for diagnoses in the DSM-IV-TR, tailoring them for use with individuals with intellectual disabilities. These adapted criteria are detailed in the *Diagnostic Manual – Intellectual Disability* (DM-ID).

In addition to these assessment adaptations related to formal psychiatric diagnoses, other tools are available to assess the behavior of individuals with intellectual disabilities. Checklists and screeners developed expressly for this purpose include the Aberrant Behavior Checklist, the Reiss Screen, and the Developmental Behavior Checklist. In addition, conducting a Functional Behavioral Assessment (FBA) is an excellent way to observe the nature, duration, and functions of particular problem behaviors performed by an individual. Using the FBA, professionals can identify patterns in an individual's problem behavior, and identify interventions that may effectively decrease this behavior.

Interventions

To address areas of concern for individuals with intellectual disabilities, several interventions are available. These relate to academics, social and adaptive behavior, mental health, and family supports.

Academic Interventions

Prior to 1975, individuals with intellectual disabilities were either not educated at all or educated in segregated settings solely for individuals with intellectual disabilities. Since its passage in 1975, however, the Individuals with Disabilities Education Act (IDEA) has mandated that schools provide services to students with intellectual disabilities. Furthermore, IDEA requires that students with intellectual disabilities be educated in the least restrictive environment: to the maximum extent appropriate, these students are educated with their peers without disabilities. The most inclusive setting these students could participate in is the general education classroom with supports and modifications.

Research overwhelmingly supports the inclusion of students with intellectual disabilities in general education classrooms. When educated in inclusive settings (as opposed to segregated settings), students with disabilities have higher levels of academic achievement and social competence. Furthermore, there have been no negative effects upon the instructional time of students without disabilities; these students also benefit from inclusive schooling as it allows them to take on different academic roles (e.g., peer tutor) for their classmates with disabilities.

While prior to the 1997 reauthorization of IDEA most instruction for students with intellectual disabilities focused on functional skills, recently the instructional focus has been academic skills. Regarding reading, systematic prompting, and

fading have been found effective in teaching sight words to students with intellectual disabilities. These instructional developments have been critical to advancing the literacy of these students. To give one example, students with Down syndrome were historically not considered capable of learning to read, with many doubting that these students could gain phonemic awareness (i.e., the ability to break down words into sounds). Given appropriate instruction, however, many students with Down syndrome can acquire phonemic awareness and, eventually, literacy skills. Changes in instruction along with inclusive education have advanced both the academic achievement and community integration of individuals with intellectual disabilities.

Another intervention used to support the academic achievement of students with intellectual disabilities involves universal design. The purpose of universal design is to deliver instruction in multiple ways to ensure that all students can access the material. The curriculum is designed to give multiple representations of content, multiple options for expression, and multiple choices for engagement. Instruction using universal design principles could include using a lower reading level, using visual representation for words, and embedding auditory cues within text. These strategies can allow learners of all ability levels to access academic content.

Social and Adaptive Skill Interventions

In addition to academic interventions, there is also a need for interventions related to adaptive behavior and social skills. For example, an individual with an intellectual disability may have difficulty with self-determination: making choices and advocating for oneself. During childhood and into early adulthood, many choices are limited or unavailable to individuals with intellectual disabilities; instead of choices, these individuals are often given directives. For these reasons, it is important to explicitly teach individuals with intellectual disabilities about decision-making. One way to do this is through a task analysis. A task analysis breaks down the steps involved in a specific act into teachable units. By clearly delineating the steps needed to make a certain decision, the individual may be better able to make decisions.

Another issue related to self-determination among individuals with intellectual disabilities is safety and vulnerability. Compared to those without intellectual disabilities, individuals with intellectual disabilities are more likely to experience exploitation or victimization. During childhood, children with (vs. without) disabilities are four to ten times more likely to experience physical and sexual abuse, and neglect. Similarly, adults with intellectual disabilities are twice as likely to experience crimes committed against them. In response to such statistics, behavior skills training – teaching and modeling safety skills and then role-playing the learned skills – has proven an effective teaching method for this population. Such skills are further developed and generalized when behavior skills training sessions are combined with assessments in which the individual practices the safety skills in the community.

Related to their deficits in choice-making and higher likelihood of victimization, individuals with intellectual disabilities also have trouble with social adaptation. Specifically, some individuals with intellectual disabilities have poor

perspective-taking and poor social skills. Consequently, these individuals have difficulty recognizing and interpreting non-verbal and contextual cues. One way to address these social deficits is through social stories: by reading or hearing a story, the individual learns the social cues specific to a certain situation and the ways in which he or she should respond. By repeatedly reading the social story, the person with disabilities can learn the appropriate social response to a specific scenario.

Mental Health Interventions

Treatment of dually diagnosed individuals may include pharmacological interventions as well as cognitive and behavioral therapies. As with all patients, professionals should exercise caution in recommending pharmacological treatments for individuals with intellectual disabilities. There are, however, several issues of special relevance that must be considered.

First, many mental health professionals do not receive adequate training in working with individuals with intellectual disabilities; beyond their training years, most only work with this population occasionally. This lack of training and experience may result in diagnostic overshadowing, or in inappropriate diagnoses. Insufficient training and experience can also lead to inappropriate prescriptions for these individuals. Clearly, mental health professionals should exercise caution in diagnosing and treating persons with intellectual disabilities.

In addition to pharmacological interventions, individuals who are dually diagnosed may benefit from cognitive behavioral therapy. This type of therapy has been used to treat individuals with a variety of mental health issues, including depression and anxiety disorders. Using cognitive behavioral therapy to treat an individual with an anxiety disorder might involve relaxation and mindfulness training. Additionally, it might include gradual exposure to the object of fear or anxiety. Cognitive behavioral therapy alone, or paired with appropriate medication, offers potential for addressing the needs of individuals with intellectual disabilities.

Family Support

In earlier times, all families of individuals with disabilities were considered to have high levels of problems. Since the mid-1980s, however, researchers have appreciated that having a child with disabilities simply involves an added stressor on the family system. Like moving, changing jobs, having a child, or getting sick, such stressors can lead to either good or bad effects on the family overall and on each member. Following this realization, researchers changed in their perception that all of these families were in trouble, to the view that some families were doing well, others poorly. Henceforth, the emphasis shifted to identifying those characteristics – of the child with disabilities, the parents, siblings, or family as a whole – that might promote optimal family functioning and identifying those families in need of additional help.

In this vein, some supports seem needed by virtually all families, others by only a few. Faced with the birth and early development of a child with intellectual disabilities, all families require information about various social service systems, ranging from early intervention programs to medical services. Later, parents must learn about schools, individualized education

program (IEP) meetings and federally guaranteed rights. As the child reaches the end of their federally guaranteed public education, parents need to learn about their state's adult-service system, and how to negotiate for their offspring.

In addition to learning about the service system, parents and families also require specific knowledge of their child's condition. Such information is often provided by knowledgeable local professionals, as well as by national, state, and local chapters of various parent support groups. Increasingly, such information can be found via many different modalities, including federal, organizational, and parent-group websites.

In addition to education about services and their child's condition, many parents value the chance to meet and talk with parents of children with similar problems. Parent support groups are especially effective for new parents, who realize that they are not alone in parenting a child with a specific condition. Parents also begin to see older children with the condition and realize that their child may be capable of more than they had imagined. Parent groups may also empower parents to advocate for their child with school, medical, and social service personnel.

One also must consider the needs of siblings. In contrast to the thinking from earlier years, most siblings of individuals with intellectual disabilities fare well. Adverse outcomes are nonexistent, affect only a few nondisabled siblings, or show only 'small effects' in group-difference studies. Although positive outcomes have been less-often studied, many individuals benefit from being the sibling of a person with a disability. Such siblings consider themselves to have grown because of this experience, and siblings often remark that they now better appreciate differences among individuals, are open to new experiences, and appreciate life's true meanings.

A final issue relates to the longevity of individuals with intellectual disabilities. In most industrialized countries, individuals with intellectual disabilities are living increasingly longer lives, even as the majority (about 60%) of such individuals live their adult years in their parents' home. The presumed future caregiver for most aging adults with intellectual disabilities will thus be a nondisabled sibling, in most cases one of the female siblings. Many, maybe even most, of these women need information about the needs of their sibling with a disability and the various systems that might provide support. Unfortunately, most state service systems are ill-equipped to handle the growing numbers of aging individuals with disabilities; sibling caretakers need information about how best to navigate this system to secure needed services.

Conclusion

Historically an area of less interest or excitement, the population with intellectual disabilities is increasingly gaining in importance within a wide variety of fields. Much of this interest stems from connecting findings on those with different genetic disorders to specific cognitive-linguistic, medical, or other conditions. Those with genetic disorders are increasingly serving as models for how specific behavioral or medical outcomes might arise.

Persons with intellectual disabilities and their families also have characteristics and needs that are only now being understood. For example, over the past decade we are gradually

appreciating just how often intellectual disabilities and mental health problems co-occur. Likewise, only now are questions being asked about how best to match characteristics of these individuals and their families to current or future service-delivery systems.

We are, in short, at an exciting time in the field of intellectual disabilities. Over the past decade, growing numbers of diverse professionals – from neuropsychologists and developmental psycholinguists to pediatricians, cardiologists, and oncologists – have all been drawn to subgroups within this population. Service systems and training structures have also grown and become more sensitive to the characteristics and needs of these individuals. Although we clearly have a long way to go, individuals with intellectual disabilities and their families are increasingly the focus of research, clinical-outreach, and training efforts.

Glossary

Alien hand syndrome A neurological disorder in which individuals perceive their limb(s) as autonomous agents performing actions independent of their own conscious volition.

Faux pas The unintentional violation of cultural norms or etiquette rules.

Joint attention The process of drawing another person's attention to an object nonverbally, often by looking to the person, then to the object, then back to the person.

Mentalizing The ability to connect overt behavior to subjective mental states.

Phantom limb The illusory sensation that a body part that has been amputated is still attached to the body.

Readiness potential Neural activity occurring in the movement-related areas of cortex ~1 s prior to voluntary muscle movement, and ~350 ms before the conscious desire to move.

Theory of mind (ToM) One's construal of the mental states of others. The development of a ToM requires the understanding that others have subjective mental states (beliefs, desires, intentions) and that these unobservable mental states are linked to their observable behavior.

Introduction

As Justice Oliver Wendell Holmes famously put it, "even a dog knows the difference between being stumbled over and being kicked." Intentions, rather than actions, are most informative about the character and likely future behavior of others. Accordingly, intent comprises the primary determinant of legal culpability for common-law crimes, such as murder and theft, in many legal systems. The Supreme Court affirmed in *Morrisette v. United States*, "The contention that an injury can amount to a crime only when inflicted by intention is no provincial or transient notion. It is . . . universal and persistent in mature systems of law . . . [and] is almost as instinctive as the child's familiar exculpatory, 'But I didn't mean to.'" At the same time, scientific findings suggest that the relationship between intention and action is more complex than our intuitions might suggest. This article examines the study of intention from the developmental milestones that give rise to an understanding of intent to the nature of the relationship between intention and action.

Understanding the Intentions of Others: Developmental Milestones

Attending to Eyes

We come into the world hardwired to find other people interesting. From birth, newborns attend more to faces than to any other object. Within the face, newborns seem to find the eyes especially interesting, as they stare more at the eyes than at any other facial feature. Researchers have argued that this attentional bias occurs because the eyes are a useful source of information regarding what a person might do next. Indeed, at as young as 3 months of age, infants not only look preferentially at the eyes, but also track eye gaze direction. By the time they are 9 months old, infants will use their gaze to get another person to look at an object with them. This is accomplished by looking first at the person, then at the object, and then back

at the person. This form of communication, and the ability to respond in kind, is called 'joint attention.' Joint attention appears to be an early precursor to an understanding of intent. At this age, infants cannot fully understand intent, as they have not yet developed a concept of another mind, but they are beginning to learn that gaze and behavior are linked. That is, by 9 months of age, infants have learned that looking at an object often precedes acting on that object. Even if joint attention may not indicate a true understanding of other minds, it appears to be foundational to this ability. Impairments in joint attention are among the earliest signs of autism. Moreover, the degree of individual impairments in joint attention predicts the intensity of an individual's autistic symptoms, responsiveness to therapeutic interventions, and long-term social outcomes.

Understanding Action Goals

Within the second year of life, children begin to understand that other people have goals and desires. One study by Andrew Meltzoff showed 18-month-old infants' videos depicting unsuccessful actions. In one such video, an adult tried to separate a dumbbell but his hands slipped. The infants were then given the same dumbbell. The authors' empirical question concerned whether the infants would mimic the adult's actual movement by letting their hands slip off of the dumbbell or attempt to separate the dumbbell. Only attempting to separate the dumbbell would suggest that the infants had understood the actor's goal. The infants' behavior indicated that they did indeed understand the goal of the action. This finding was later replicated with 15- and 12-month-old infants but not with 9-month-old infants, indicating that an important developmental change in action understanding occurs at approximately 1 year of age.

Although understanding the goals of actions may seem tantamount to understanding intentions, psychologists have pointed out a key difference – the inference of another mind. Action goals can be ascertained without considering another mind using the simpler metric of object-directedness. In the dumbbell example, it is likely that the motions employed to

separate the dumbbell indicated effort and directedness while the slipping of the hands did not. Thus, the infants may have inferred which motions were related to the goal and which were not without having to represent the adult's mental state (i.e., his or her intention). An analogous process may occur when adults consider the actions of robots. The action goal of a Roomba, for example, is understood perfectly well from its observed action (vacuuming dirt). Inferring that the Roomba's action was mentally driven (intended) would be unnecessary and absurd. Inferences of intention go beyond understanding action goals, as they involve the attribution of an unobservable cause: a mind.

Mentalizing

Mind attribution is central to successful social functioning. The capacity to represent the contents of others' mental states is referred to as 'theory of mind' (ToM). An important component of ToM is the ability to understand that others have subjective desires. Wellman and Woolley demonstrated that 2-year-old boys possess this capacity using a 'Finds-Wanted' paradigm. Children in this study observed characters looking for target objects, and had to make judgments about the characters' feelings and subsequent actions in three conditions. The character either found what they were looking for in the first location ('Finds-Wanted'), found nothing ('Finds-Nothing') or found an attractive object that was not the particular object they had been searching for ('Finds-Substitute'). Children were asked to predict whether the character would continue to search, and how the character felt in each of the three conditions. By and large, the 2-year olds in this study performed well on the task. For instance, the children could infer that the character would continue to search for the desired object if he had not found it in the first location, and that the character would only be satisfied after finding the particular object he desired. These results suggest that children as young as 2 understand that the desires of others are subjective. The ability to understand desires that conflict with one's own, or to represent beliefs that conflict with reality, however, seems to arise later in development.

Children typically first demonstrate the ability to represent the beliefs of others as distinct from objective reality at around of 3 or 4 years of age. This developmental landmark has been delineated based on studies using false belief tasks. Success on such tasks often requires participants to solve an 'object transfer' problem in which the characters possess beliefs that differ from reality. A particularly popular false belief task is the Sally-Anne task (Figure 1), consisting of a simulated interaction between two dolls, Sally and Anne. Anne has a box, and Sally has a basket. Sally places a ball in her basket before leaving the scene briefly. While Sally is gone, Anne removes the ball from Sally's basket, and places it in her box. Then Sally returns. The participant observes all of this, and is then asked, "Where will Sally look for the ball?" Adults tend to respond that Sally will look in her basket, an answer that requires understanding that Sally holds a false belief. However, children younger than 4 years of age tend to predict that Sally will look in Anne's box, suggesting that prior to the age of 4, children lack the ability to understand that Sally has a belief that differs from physical reality. Developing a theory of mind is a critical

Figure 1 Illustration of the Sally-Anne paradigm. Drawing by Axel Scheffler reproduced from Frith and Frith (1999).

milestone toward understanding intention because it enables a child to model another mind; a mind that is privy to different information, has a different psychological history, and may desire different things than one's own.

Advanced Mentalizing

As any parent would agree, understanding other minds is not perfected by kindergarten. It is not until at least 5 years of age that children can consider second-order mental states such as 'what Billy thinks that Sally thinks.' It is not until the age of 8 that children begin to develop an understanding of faux pas, the unintentional violation of a social norm. One recent study followed children from the age of 3 to the age of 12, measuring their levels of social understanding. In one task, the researchers used clips from the TV comedy 'The Office.' As the lead researcher, Dr. Yuill, explained, the boss character "is a typical example of someone who is very insensitive and reads social situations incorrectly. We cringe to watch it because we are embarrassed by his complete lack of social understanding." It was not until age 8 that children in the study began to cringe, rating scenarios with faux pas as more embarrassing than those without. By the age of 12, children in the study demonstrated as sophisticated an understanding of faux pas as their mothers.

Thus, understanding the nuances of social errors requires cognitive mechanisms that are not fully developed until late childhood. By the time they are teenagers, children have developed the understanding that a person's intentions are often more informative than, and can be contrary to, a person's actions.

In summary, a full understanding of intention requires a protracted development. Early on, babies monitor eye gaze direction. Later in development, young children exploit this attentional cue in order to infer and communicate intention. At around 1 year of age, infants differentiate goal-directed action from hapless mistakes, imitating only the former. By 2, children understand that the desires of others are subjective, and by 4, children understand that people can have thoughts that are distinct both from one's own and from objective reality. Theory of mind increases in sophistication over the childhood years, culminating in the understanding that nuanced social offenses can be committed unintentionally. Thus, by the teenage years, people have learned that actions are usually, but not always, preceded by intentions. Importantly, teenagers are able to detect and understand exceptions to this imperfect rule (e.g., *Roombas*, *faux pas*). The belated learning of these few exceptions underlines the utility and strength of the widely held intuition that intentions precede actions. However, science suggests that this link may be more tenuous than it may seem.

Understanding Our Own Intentions

A Social Psychological Perspective

According to Wegner and Wheatley's theory of apparent mental causation, an action feels intentional to the extent that it satisfies three criteria referred to as priority, consistency, and exclusivity. Specifically, we perceive ourselves as having intended to do something if we previously entertained a thought (priority) in line with the ensuing action (consistency), and if that thought appears to be the sole likely cause of that action (exclusivity). According to this view, the feeling of will is argued to be an inference that relies on the very same principles that govern our perception of causality in the external world. This position is not entirely new. Hume argued long ago that the belief that our intentions cause our actions is a mere perception, possibly rooted in fallacious inductive logic:

Some have asserted, that we feel an energy, or power, in our own mind . . . But to convince us how fallacious this reasoning is, we need only consider, that the will being here consider'd as a cause, has no more a discoverable connexion with its effects, than any material cause has with its proper effect . . . In short, the actions of the mind are, in this respect, the same with those of matter. We perceive only their constant conjunction; nor can we ever reason beyond it. No internal impression has an apparent energy, more than external objects have. (1888: 400–401).

According to Hume and the theory of apparent mental causation, we perceive an action as intentional when we interpret a thought as the cause of that action.

If actions are interpreted as intentional based on the presence of a few key features, then manipulating those features should engender a false feeling of intent. Just such a manipulation was attempted in the following illustrative study. In this study (Figure 2), a participant and a confederate (a research assistant

Figure 2 Experimental setting from the 'I Spy' study. Image reproduced from Wegner DM and Wheatley TP (1999) Apparent mental causation: Sources of the experience of will. *American Psychologist* 54: 480–492.

posing as another participant) manipulated the location of an onscreen cursor by moving a computer mouse together in sweeping circles while watching various objects displayed on the same screen (taken from the children's book 'I Spy'). The task, as it was explained to the participants, was to move the mouse together, stopping approximately every thirty seconds. Both wore headphones. The participant heard words related to the objects depicted onscreen, ostensibly as a 'mild distraction.' The participant was led to believe that the other participant (the confederate) heard different words. In actuality, the confederate heard instructions to force the cursor to stop at certain times. These stops were engineered to occur on specific objects at specific time intervals after the participant had heard a word related to that stop. For example, if the participant heard 'swan' the confederate might be told to force the participant to stop the cursor on the swan depicted on the screen. Following every stop, participants rated how much they had intended to make the stop relative to their partner on a one hundred-point scale.

In line with the principle of consistency, when participants heard a given word a few moments before the confederate forced a stop on a related object, they perceived that they themselves had engineered the stop. Consistent with the principle of priority, this held true only if the related word was heard a few moments before the forced stop engineered by the confederate, and not if the related word was heard well in advance of, or following, the forced stop. These results suggest that we can erroneously interpret an externally engineered event as intentionally caused by ourselves if we are made to think about that event immediately before it occurs.

Just as the 'I Spy' experiment demonstrates that we can experience will without performing an action, reports from clinical studies demonstrate that it is also possible to perform an action without experiencing the sensation of will. The uncoupling of conscious intention and action is the unfortunate everyday reality for individuals suffering from many psychological and neurological conditions. Schizophrenic patients often perceive their own subvocal speech as externally generated, or as if they are 'hearing voices,' and perceive that their own thoughts have been 'inserted' or controlled by others. Consistent with the general principles of causality outlined above, it has been suggested that this perception is rooted in a mismatch between these patients' conscious goals for thinking and behavior and their actual

thoughts and behavior. Additionally, those suffering from alien hand syndrome perceive that their own 'alien' limb is in fact autonomous, acting according to a will of its own. The rogue limb is often perceived to be malicious, or possessed by an external force. Conversely, patients sometimes consciously will limbs lost to paralyzing injury or amputation to move to no avail in order to relieve unpleasant sensations in these 'phantom limbs.' Patients suffering from the later stages of Parkinson's disease also find their limbs frustratingly unresponsive to their motor intentions.

Anecdotal experiences from everyday life suggest that the uncoupling of action and intention does not only occur in specialized patient populations or in social psychology experiments. We often feel that we did not 'mean to' perform mindless gestures or habits, perhaps because we did not consciously hold a thought consistent with that behavior before engaging in that behavior. The fact that the perception of action and the sensation of intent can be carefully decoupled in experiments, are consistently dissociated in those suffering from a variety of medical disorders, and are imperfectly aligned in the behavioral minutiae of everyday life, suggests that Hume may have been correct. Intention and action may be merely correlated rather than causally linked.

A Neuroscientific Perspective

Neuropsychological research investigating the temporal relationship between brain activity and subjective conscious experience has also called the nature of the intention-action link into question. In a seminal study on this topic, Benjamin Libet asked participants to extend their right index finger whenever they 'felt the urge' to do so (his description of intent) while fixating on a rotating clock-hand. Participants were asked to note, and later report, the position of the clock-hand at the moment when they first felt the intention to move. Participants' reported feelings of conscious intention to move preceded the actual movement by approximately 200 ms. However, using electroencephalography (EEG) to measure event-related potentials (ERPs) on the scalp, Libet demonstrated that preparatory activity in movement-related brain areas precedes movement by a full second. Libet interpreted the finding that this preparatory neural activity – or 'readiness potential' – occurs well before the conscious experience of will as evidence that we may not consciously initiate our actions.

More recently, Chun Siong Soon and colleagues have suggested that the temporal relationship between brain activity and the conscious experience of intention may be even more remote than Libet's findings initially indicated. Reasoning that the readiness potential reflects activity in brain areas associated with relatively late stages of motor planning, these authors used functional magnetic resonance imaging (fMRI) to assess activity throughout the entire brain while participants completed a self-paced task with multiple possible behavioral outcomes. Participants watched a stream of letters that changed every 500 ms. Participants were told to press one of two buttons with either their left or right index fingers whenever they wanted to do so. Participants were then asked to report which letter was present on the screen when they had decided to move. Using statistical pattern recognition techniques to analyze fMRI data recorded throughout the whole brain, Soon and

colleagues were able to predict which button a participant was going to push based on distributed patterns of brain activity measured between 7 and 10 s prior to the participants' conscious awareness of that 'decision.'

These findings have been taken by some to constitute evidence that the brain 'decides' to move well before the decision to move enters awareness. That is, conscious awareness of the decision to act may not be causal to the decision to act. Others have maintained that conscious awareness is causal to the decision to act, pointing out that the early patterns of neural activity observed in these experiments could merely reflect general anticipation of performing the task, or the preconscious beginnings of intentions. The early neural firing that constitutes the readiness potential, for example, might simply initiate a cascade of brain activity that prepares the brain to make a free, conscious decision. No currently available data can settle which interpretation is correct, and thus, whether or not conscious intentions play a causal role in action execution. However, the observation that action-related neural activity precedes awareness of a desire to make an action is a robust finding that must be incorporated into any contemporary model of conscious intention.

The readiness potential reflects a specific intention to move a particular body part within the next few seconds. This is, of course, a very narrow definition of intention. Humans are deliberative creatures who often plan courses of action well beyond the next 7–10 s, and certainly beyond a few 100 ms in advance. We also plan courses of action at levels of description far more nuanced and abstract than raising an index finger. Sometimes we have purely propositional intentions that lack specific action plans. For example, we may intend to 'go to college one day' or to 'be a good person.' We may also intend to 'get a cup of coffee,' an intermediate intention that launches a series of more specific motor plans toward that goal. Although neuroscientific research has focused largely on intentions to perform specific movements (e.g., finger raises) and associated cortical activity, recent evidence suggests that parietal and frontal regions may subserve intermediate and long-term plans, respectively.

A long-term, propositional intention, such as 'intending to retire early' requires imagining a time in the future when that intention will be realized. This ability to mentally time travel may be unique to human beings. While other animals are focused on here and now, as human beings, we spend much of our time remembering the past and wondering about the future. Consistent with the relative uniqueness to humans of mental time travel, long-range intentions are thought to be subserved by a region of the brain that is disproportionately larger in humans than other animals: the prefrontal cortex. Summarizing the evidence for the expansion and reorganization of prefrontal cortex in the course of human evolution, Flinn and colleagues suggest that this brain region is associated with self-awareness and the ability to project oneself into the future. This brain region also supports executive processes, such as reasoning and working memory, which may be critical to this kind of counterfactual thinking. Developmental evidence also points to the maturation of prefrontal cortex between the ages of 3 and 5 years as critical for the cognitive development of the ability to make plans, delay gratification, and understand intent.

A neural circuit that links the prefrontal cortex with the inferior parietal cortex may help translate propositional intentions in the prefrontal cortex into action plans in the parietal cortex. Activation of this prefrontal-parietal circuit may underlie the feeling of agency for a particular course of action. When Desmurget and colleagues stimulated the parietal cortex of epilepsy patients, they experienced an endogenously generated wish to move. That is, patients felt that they had spontaneously desired to create a movement. This phenomenology stands in contrast to stimulations of supplementary motor area (SMA), a region associated with the readiness potential. Stimulation of subdural electrodes in SMA causes an 'urge' to move that may also be described as the feeling of being 'about to move.' A strong stimulation of SMA, but not parietal cortex, will lead to actual movement. This suggests that SMA may play a key role in the feeling of being about to move while parietal cortex may play a key role in the feeling of generating an intention. Clearly, the word 'intention' belies its diversity. There are multiple levels of intention that range from long-term plans ('go to college') to specific motor plans ('pick up the cup'), which are subserved by distinct but interacting brain regions.

Failures of Intention

Try as hard as you can to not think of a white bear for the next 5 min. Go ahead. Were you successful? If you are anything like the participants in thought suppression experiments, you were dramatically unsuccessful, with thoughts of white bears popping into your mind every few seconds. Intending not to think or do 'x' can have the ironic effect of making 'x' more likely to occur. This is particularly true when we are tired or distracted. Wegner's ironic process theory accounts for this phenomenon by proposing that intentional control of the mind employs two processes: an operating process that directs conscious attention to whatever thought or action is intended and an automatic monitoring process that looks for failures of that intention. Stress, fatigue, and distraction have a disproportionate effect on one's ability to attend to something consciously, thereby disabling the operating process more than the monitoring process. The result is an unchecked monitoring system continues to search for failures of intention, continually bringing to mind the most unwanted thought. This ironic process has been used to explain the obsessive nature of unwanted thoughts and the tendency of athletes to 'choke' in a big game.

This article has focused on how intentions relate to actions and how an understanding of this relationship develops. However, most budding intentions never become actionable for good reason. Failures to inhibit intentions are just as damaging as failed intentions. Consider how much time people spend daydreaming; musing about everything from the motivational (e.g., wanting to advance in a career) to the wicked (e.g., wanting to hurt one's spouse). Not only do humans mentally time travel, they also wonder counterfactually what it would be like to do something different than whatever it is they are doing now. Playing out an intentional course of action in the mind's eye can be useful. It can help one realize, for example, that the long-term consequences of hitting one's boss would outweigh any ensuing short-term satisfaction.

Inhibition at this early stage of intention affords a reasoned decision about which intentions become actionable and which should stay in the realm of fantasy. This requires considerable inhibitory control from the frontal cortex.

Patients with damage to orbitofrontal cortex (OFC) lack this inhibitory control. To these patients, having the thought to act and acting on that thought are largely synonymous. No lesion is as damaging to social behavior. The personality changes of OFC patients have been described by many writers. Perhaps the earliest account was by Dr. John Harlow in 1868. Harlow was the doctor who attended to Phineas Gage after Mr. Gage was involved in an accident that sent a metal tamping iron of the size of a walking stick through one eye and out of the top of his head. The accident did not kill him but decimated his OFC, giving scientists the first window into the function of this brain region. The accident did not compromise Phineas Gage's memory, sensory perception or language, leading to early reports that he survived mentally unscathed. However, Gage's friends noticed that his personality had changed radically. His lesion resulted in massively disinhibited behavior, allowing instinctual urges and transient impulses to become realized in action. The Country and Western song that thanks God for 'unanswered prayers' should add 'unrealized intentions.' The ability to quell 'bad' or inappropriate intentions is as beneficial to social relationships as realizing 'good' and appropriate intentions.

Summary

Intentions are good predictors of behavior most of the time. While simple intentions and actions have been decoupled within the context of carefully controlled experiments, they are strongly correlated. Further, it is unclear how this decoupling in the lab generalizes to the way we think about intention in everyday life.

Whether or not intentions are perfectly causal to our actions, they are consistently correlated with our own and others' behavior, and thus, are useful markers of what we might do next. Therefore, it is no wonder that a nuanced understanding of intention receives a prioritized, protracted development. The intuition that intentions cause behavior is an extremely useful heuristic in most circumstances. In sum, a thorough understanding of intention requires two things: (1) an appreciation of the general rule that conscious intention predicts behavior, and the concomitant pragmatic and legal uses of that rule and (2) a recognition of the empirical and neurological examples that show that this relationship is far from simple.

Glossary

Avatar A digital representation of an individual that he or she can manipulate within a virtual world, online community, simulation, computer game, or other online environments.

Blog Contraction of 'web log,' in which an individual or organization regularly posts comments about various subjects with links to other blogs or web pages. Posts appear in reverse chronological order.

Global positioning system (GPS) Allows small receivers embedded in mobile devices to determine and report the device's physical location by interpreting signals transmitted from orbiting satellites.

Microblogging A type of blogging in which the content of the posts is much shorter with very small file size. Twitter is an example of a site that supports microblogging.

Multiuser dungeon (or dimension) (MUD) These were real-time text-based virtual worlds for role-playing games and online chat.

Social network A set of social entities that can include people and organizations connected by meaningful relationships, and who interact with one another online, face-to-face, or both.

Social networking site A Web site in which individuals create profiles of themselves with posts, photos, and videos, and link to profiles of friends and colleagues to form interlinked social networks.

Spoofing Forging an email header to make it appear to the recipient that the email came from a different source.

Virtual world A type of online community in which members create avatars to interact with other people and objects in the graphical environment.

Introduction

Launched as a distributed computer network for the government and academia in the 1960s, the Internet has become a fundamental part of people's lives. The net's open architecture and standard technical protocols support countless innovations, most of which were never imagined by its designers. Collaborative features and quick communication underlie the growth of the Internet as an environment for social interaction with family, friends, acquaintances, colleagues, and total strangers. Indeed, for a growing number of people, online interaction plays some role in almost every human relationship.

The Internet's capacity to facilitate interaction, participation, and contribution has exploded with Web 2.0 technologies and approaches. It has been transformed well beyond an information source, a shopping outlet, publishing platform, or text-based communication venue. Web sites supporting social networking or other collaborative venues offer an array of new tools to manage impressions, interact with other people, form friendships, and work in teams. With mobile technologies, in particular, people can engage in technology-mediated social interactions anywhere, anytime, and not just when they are sitting in front of a computer. The social interaction environments now encompass smartphones, wireless devices, netbooks, video consoles, and more.

Together, these varied devices, transmission media, and the applications they support comprise information and communications technologies (ICT), which collectively open many new avenues for social interaction. For the purposes of this article, online environments are broadly defined to include any ICT-supported environment in which the interactions are not face-to-face, but mediated by technology. They offer people a dazzling array of choices when they want to interact with others, from a

one-line text message to a live interactive video conference, and much more.

Demographics and Social Use of ICT

Worldwide, access to the Internet is available to at least one-fourth of the population, with much higher rates in the developed countries. The fastest growth rates, however, are in the Middle East and Africa, where wireless communications technologies are playing a major role in building up the infrastructure in cost-effective ways. Mobile phones, both as a communication device in their own right and as a means to access Internet services, are playing an increasingly important role in technology-mediated social behavior. While low-cost versions support voice and text messaging, more capable smartphones support email, web browsing, global positioning system (GPS), and a growing variety of applications, many of which are oriented toward social interaction. The use of these devices to access Internet services is not generally captured by studies on net access, so statistics on Internet usage are probably underestimates, particularly in the case of developing countries in which ownership of mobile phones far outpaces computer purchases.

Who actually engages in online social interaction? Although worldwide statistics are not easily available, the Pew Internet and American Life Project conducts surveys on the US population, charting the ways in which Americans use technologies by age, gender, ethnicity, and other demographic variables. The trends show that the young lead the way, both in the extent to which they depend on ICT for social interaction and the variety of tools they use. For example, teens flock to the social networking sites such as Facebook or MySpace, where they connect with friendship networks. In 2009, 73% of teens who had access to

the net used an online social networking site. Teens and young adults are often the primary early adopters of other innovations that support social interaction, from online gaming and micro-blogging to wikis and virtual worlds. Nevertheless, people of all ages use these sites and older adults are the fastest growing population on Facebook.

With respect to personality measures, studies generally confirm a relationship between extraversion and online social interaction. Outgoing people tend to use email, text messaging, social networks, and other online tools more frequently, largely to enrich their existing friendships and relationships. Shy or socially anxious people, however, also take advantage of the online world. Research indicates they are more likely to prefer technology-mediated communications as a substitute for face-to-face interactions.

Early research suggested that high levels of Internet use may be associated with social isolation and depression, partly because the people using the net in such circumstances were mainly interacting with people they had never met in person. But the net continues to evolve, along with how people choose to use it for social interaction. Online social environments are widely used to maintain and extend existing relationships, even when those relationships already have a strong face-to-face component. The environments continue to support interactions not only with distant and unknown strangers, but also among working groups, virtual teams, friendship networks, family ties, virtual communities, online classes, and romantic connections. Many online settings support anchored relationships, in which people are easily identified, well known, and often not geographically distant.

Types of Online Social Environments and Tools

The range of technology-mediated social environments has expanded considerably since the 1990s, when the primary venues were email, discussion forums, MUDs, and text-based chat networks. These early systems, most of which continue to exist in some form, primarily support text-based communications, either synchronous or asynchronous. Interactions rely heavily on the written (typed) contributions of the participants – an important element in the way these environments affect behavior and group dynamics. Much research has been conducted to better understand how social behavior unfolds in such settings. The findings have helped identify areas for technological improvements, especially to reduce or eliminate some of the most troublesome features that hinder smooth social interaction. Current systems incorporate images, video clips, interactive audio and video, networking tools, awareness of presence indicators, location indicators, rating systems, abuse reporting tools, reputation systems, shared whiteboards, avatar-based interactions, virtual classrooms, collaborative document editing, and many other features that greatly improve the ways in which people can work and play together online.

Technological tools to support more fluid synchronous social interaction are improving considerably. For example, some environments include awareness of presence icons that users can control, indicating whether they are currently available for real-time interaction. Others add collaborative features such as shared whiteboards, making it possible for people at a

distance to view, discuss, and annotate the same document, as though they were all standing in front of an actual whiteboard. Although text-based chat systems are still widely used, interactive video and audio add to the media richness of social interactions.

Within the social networking sites, new tools are emerging constantly to help people manage their self-presentations, and build, maintain, and extend their social networks. Sending a request to join someone's network involves a simple click, for example. The sites provide many innovative incentives to encourage people to stay in touch via the network and invite others to join. Some, for instance, offer to invite everyone in your email address book to join your social network.

The ratings and reputation systems are especially important to the explosive growth in user-generated content, in which social interactions revolve around evaluations of particular products or services. People engage in brief social interactions as they rate and share their views on hotels, books, editorials, news items, contractors, or other services. The more useful comments that people contribute, the more valuable the site becomes for everyone, attracting more users.

Location-aware technologies add another dimension to technology-mediated social behavior, one that overcomes the lack of geographic placement. In many online social interactions, the participants do not know one another's physical location, a factor that can affect the way they interact. However, location data is available and is being added to many social tools, such as Twitter. Smartphones equipped with GPS can pinpoint the sender's location, and include that as part of the message.

Avatar-based environments such as Second Life add a sense of physical presence in the shared space, especially when people can customize the avatar to their liking to better manage the impression it makes. Gathering with other people's avatars in the same virtual world is another step that enriches the online social environment.

These technologies continue to improve, not only with engineering advances, but also with more research on the nature of online social behavior. As we learn more about how people prefer to use these technologies, how their behavior is affected by them, and what kinds of risks they present to privacy or human relationships, we will see a better match with what humans actually need for rich, technology-mediated social interaction.

Psychological Aspects of Online Social Environments

Online social environments differ from face-to-face environments in several important psychological dimensions that affect social interactions. They also differ from one another, given the enormous range of tools available and the wide variety of online social environments. This section summarizes those characteristics and the following sections explore how they affect different kinds of online interactions.

One critical variable is anonymity, that is, the extent to which people can identify others with whom they are interacting. People who participate in ongoing discussion forums or online games, for instance, may have little or no knowledge about the identity of other members of the group. A nickname,

such as 'MaryTheMom,' might indicate gender or other characteristics the participant cares to share. But in many of these environments, the perception of anonymity can be high, especially compared to face-to-face interactions.

The degree of anonymity for people in online social environments can vary widely. Regarding sites designed to support a working group, for instance, the members often meet in person and are fully identified online. On eBay, the buyers and sellers use nicknames, but once an auction is over they must have accurate information about one another in order to complete the transaction. In the comment section for an online newspaper, a person who wishes to comment may have no idea about who else is joining the discussion, other than nicknames.

A closely related characteristic is identifiability, which refers to the participant's sense of how anonymous he or she feels, and whether others will be able to individually identify him or her. Depending on the environment, identifiability may be low but rarely zero. For the newspaper comments, for example, the others who comment may not know who the poster is, but the news agency may require more detailed information. From a technical perspective, the identity of a person who participates in an online social environment can usually be determined, or at least the identity of the device they use.

Physical isolation is the third characteristic that typically distinguishes online social interaction from face-to-face interaction. Although there are occasions in which people gather in the same physical space to engage in online social interactions – to play multiuser computer games, for example – most online social interactions involve people who are not physically present in the same space.

Other characteristics are becoming increasingly important as the tools become more powerful. For example, these environments offer opportunities to control self-presentation in ways that are far beyond what an individual might do in any face-to-face setting. For text-based environments, swapping genders or changing professions involves little more than typing a new nickname, switching 'PhilosopherBob' to 'AnnietheActress.' But social networking sites add rich multimedia features, controlled by the user, who can select and tweak the images. These sites also display information about a person's friendship networks. Self-presentation thus includes not just information you release about yourself, but about whom you know and have friendship ties with. This feature adds a new psychological dimension to online social interactions as the people with whom you interact form impressions of you in the context of your social ties.

Microblogging sites such as Twitter, while lacking rich multimedia capabilities, allow users to send out frequent, short text messages to their followers' cell phones, creating a kind of ongoing connectedness that transcends distance. Avatar technology adds yet another level to self-presentation. The ability to construct highly detailed avatars that enter online social worlds adds many more possibilities to the way people choose to present themselves to others.

Knowledge about the nature and size of the audience or group is another characteristic that differentiates online and face-to-face settings. In a public discussion forum, for example, participants may have an idea of how many people are engaged in the discussion, but not of how many are viewing it or

forwarding favorable posts to their colleagues. Even in social networks, in which individuals choose their 'friends' and thus know their own audience, they know far less about their friends' network of friends. Without knowing the details of a friend's privacy settings, a person might post a humorous note on a friend's wall which could be visible to that person's entire network. There may be individuals in that audience, like parents, employers, or old girlfriends, who might not expect or appreciate that humor.

Effects of Online Social Environments on Behavior

People do behave differently online, and social interactions are affected in subtle ways by the differences between online and face-to-face settings. For example, in text-based environments people often become disinhibited, expressing themselves more bluntly, abruptly, or aggressively compared to what they might say in person. In many discussions, they can be more task-oriented, and their messages often lack nonverbal cues or those verbal softeners that smooth conversations. Instead of 'I'm not certain I agree with that,' they might simply say, 'I disagree.' Tenser and more controversial interactions, especially ones in which people are relatively anonymous, lead to heated discussions. Participants who would never think of themselves as particularly aggressive engage in furious 'shouting' matches, name-calling, foul language, and sarcasm. Attitudes can become polarized and people can take quite extreme positions.

The online social environment can also bring out another side of disinhibition: intimacy and self-disclosure. In certain circumstances, people are not necessarily abrupt or blunt. Instead, they are more intimate and disclose more personal details about themselves than they would in person. They also reveal information more quickly, without necessarily waiting for the communicating partner to reciprocate.

These seemingly contradictory findings show that the effects of the online social worlds on human interaction and behavior are certainly real, but they are not straightforward. Drawing especially on research in social psychology and communications, various models have been proposed to account for these nuances and better understand how these effects play out in different circumstances.

One early proposal emphasized the impoverished of text-based interfaces, and their inability to support much transmission of nonverbal and paralinguistic cues. With just the ASCII keyboard to work with, people lacked social presence and their partners had little to go on. People could add a smiley face emoticon to hint at a joke, but even these are quite easily misinterpreted without knowledge about the tone of voice, volume, vocal patterns, body posture, facial expression, and physical distance. Effective communication, according to this 'cues filtered out' approach, requires verbal and nonverbal cues, the richer the better. The fewer cues available, the more difficult it would be to develop any meaningful relationship.

As it became clear that people did indeed develop strong social ties online despite the sparse social presence, other proposals were offered. The hyperpersonal model explains how the paucity of cues, especially visual and nonverbal ones, could actually contribute to the creation of strong social bonds between people who interact online. With the tools they

have, people selectively craft their presentations with a minimum of cues and the partner idealizes and imagines the rest. This relative lack of information makes whatever is available more valuable. Selective presentation, combined with imagined and exaggerated perceptions, acts together over time, making it possible for people who interact online to feel quite close.

Another model that focuses particularly on the role of anonymity in online social influence is SIDE, which stands for social identity model of deindividuation effects. Drawing on research on how people tend to become depersonalized in crowds, SIDE predicts that online behavior depends partly on how anonymous people are and also whether the setting tends to promote greater salience for the social or personal identity. Under anonymity, people who identify with a social group are more likely to adhere to the group's norms and agree with its positions. SIDE also helps explain why intergroup differences can grow larger and more contentious when people from two groups interact online and the anonymity is high.

These models were initially developed to explain some of the surprising findings on how social behavior unfolds in text-based environments, particularly among people who had not met in person. However, online social behavior now encompasses a much wider range of activities, locales, and group memberships. For example, over 90 million people use social networking sites with their rich multimedia tools, photo and video albums, social games, group memberships, and wall postings. In most cases, a social network includes only people the individual knows in person or those who are known to one of the individual's friends. Nevertheless, many of the psychological characteristics that affect text-based interactions are still important in these environments, though they play out in somewhat different ways.

Managing Impressions

Just as people try to put their best foot forward in face-to-face settings, they devote some effort to the impression they make when they go online to interact. The difference is that instead of focusing on fine grooming, clothes, a smile, and a firm handshake, people use keyboards, mice, cameras, and camcorders. For the most part, people use the tools they have to create a persona that is not too distant from their true selves, but they do try to refine and polish it to highlight the positive.

Impressions can be quite difficult to manage online. People can easily miscalculate the impression they make and also make mistakes as they form impressions of others. One reason for online impressions going awry involves social cognition and social categories. People tend to use a short list of categories to form impressions quickly, relying especially on age, gender, and ethnicity. The stranger's actual behavior is less important and more time consuming to unravel as a means to form an impression. In a face-to-face interaction, those three characteristics are normally quite easy to discern. But online, especially in a text-only environment, they could be far less apparent. For some, this characteristic of the online world is liberating as it frees people from the overwhelming influence of the usual social categories and facilitates interactions based

on the communications themselves. A very bright high school student might engage in online interactions with scientists, for example, whose responses would be based on the student's actual remarks, not his or her age.

As multimedia tools are added to social environments, the most important feature people use to form an impression in face-to-face settings returns to online interaction. This is physical appearance, from which age, gender, ethnicity, physical attractiveness, and much more can be ascertained instantly. The impression people make, when they post photos on their Facebook profile, for example, is dominated by the photo, just as physical attractiveness dominates impressions in real life. Attractive people are perceived as more likable, more confident, and as possessing a number of positive characteristics compared to unattractive people. Showing an attractive photo makes it more likely that Facebook visitors will be interested in meeting you. But displaying an unattractive photo turns people away, even more so than showing no photo at all. This conforms to the hyperpersonal model, as visitors exaggerate positive qualities of the person showing the attractive photo, or the negative qualities of the less attractive person. A profile with no photo at all leaves room for imagination, and exaggeration as well.

Online worlds let users craft an appearance with avatars, and these tools offer much broader opportunities to reinvent the persona and manage an impression. The new avatars can affect social interactions in subtle ways, not only because of their effects on the others in the virtual world, but also by virtue of their effects on the person behind the avatar.

As expected, an attractive avatar is perceived more favorably. The positive response of others can then affect the behavior of the person who is behind that avatar as social interactions take place in real time. He or she may become more confident and assertive in a process called behavioral confirmation. The person may behave in ways that conform to the expectations of others about how an attractive person typically acts. Indeed, just donning an attractive avatar heightens the person's own self-perception and affects behavior. As though the person is looking at himself or herself from the outside, expectations about how an attractive person would act can influence the way the person behaves.

Adjusting the avatar's height also affects social interactions. In face-to-face settings, taller people are perceived to be more confident and powerful, and they often come out ahead in negotiations. But a short person can become a tall avatar in a virtual world, and the new appearance may affect the way that person behaves. In experiments that manipulate the avatars' heights, the people behind those avatars behaved as expected. Regardless of the participants' real height, short avatars tended to lose the negotiation. These height effects also appear in interactions using video chat and webcams. People who appear shorter because of camera position also tend to be in a disadvantageous position.

These transformed social interactions may have longer lasting effects on behavior and social interactions, even after people leave the virtual world and resume the management of their real-world impressions. Controlling a tall or attractive avatar for a while may indeed help build confidence in some circumstances, but more research is needed to clarify what happens if the virtual world spills over into other social contexts.

Online Deceptions

Online, especially when identifiability is low and the perception of anonymity high, it is easier to deceive. One might craft a deceptive persona that is quite far afield from a person's true self or misrepresent the facts in an attempt to deliberately mislead. The individual may swap genders, alter his or her appearance, make up new personality traits, change professions, or lie about age, location, citizenship, income, nationality, or anything else. Many high-profile cases in which people succeeded in elaborate online masquerades, often becoming deeply involved in relationships under the cloak of their false persona have been documented.

Several types of deceptive tactics play out online. Masking, for example, involves the elimination of cues to erase crucial information, something that is quite easy to do online. A profile photo might show the person from the neck up only, failing to disclose other physical characteristics. Photos can also be easily edited to eliminate scars, wrinkles, and other flaws.

The reasons people engage in online deception are complex and varied. Some experiment with their identities to find out how people react to them if they present themselves quite differently. Many others slip into deception in an effort to best manage their impression, greatly exaggerating or lying about their positive qualities and masking negative ones. Much of the increasing online deception, however, involves fraud and other kinds of criminal activity, with greed being the primary motive. The most common deceptions occur in online auctions in which sellers try to sell merchandise they do not have or buyers receive goods they have no intention of paying for.

The psychological characteristics of the online world greatly amplify the scope of fraudulent deceptions and facilitate new types as well. They influence human behavior such as the truth bias, which is the tendency to overestimate others' truthfulness. In most situations, people presume that incoming information is truthful unless they have evidence to the contrary, which is partly why online scams can be so effective. For example, scammers can spoof valid email addresses of a person's trusted associates and send messages that appear to come from them to obtain private information. Few question the source of an email without specific alerts.

More sophisticated technology opens up new avenues for deception. Photo and video editing software, for instance, is widely available and used to enhance online impressions as well as deceive. Different manipulations can have various effects on social behavior. For example, people tend to be attracted to others perceived to be similar to themselves, and digital tools can simulate this effect by morphing one person's photo with another, subtly blending their features. People tend to prefer images of strangers made to look more like them because of morphing. Researchers find that voter attitudes can even be influenced by such digital manipulations. When a political candidate's image is morphed with an undecided voter's image without the person's knowledge, the voter begins to prefer that candidate.

Deception has taken on new forms online because of the psychological characteristics of the Internet, with its heightened sense of anonymity and lower identifiability, and its reduced sense of physical presence. It is further enabled by growing technological capabilities, such as the ability to edit

or fake images, Web sites, videos, or email. Together, these features interact with aspects of human behavior to amplify the risks. People are not particularly expert at spotting deceptions in person and they appear to be even less so online.

Online Group Dynamics

When a group of people with a common purpose conducts some or all of its activities online, the characteristics of the online world can affect group dynamics, often in surprising ways. The features that affect other aspects of interactions also influence the way online groups develop norms, establish a group identity, discuss topics, air arguments, achieve consensus, and carry out tasks.

Group norms, for example, are important to establish a group identity and expectations for group members. Yet developing those norms and finding ways to encourage conformity are challenging in online social settings. The physical distance associated with online interactions can reduce the effects of group pressure, and higher levels of anonymity would reduce them further. Nevertheless, groups do establish norms, often by using more explicit statements about what is expected, such as terms of use agreements.

Members also learn norms from one another, just as they do in person, by watching what others do. For example, in social networks, the choice of privacy settings is affected by what an individual believes other members of his or her network are choosing. If it appears most friends are revealing their cell phone numbers to their networks, that same privacy setting is more likely.

Enforcing norms can be more difficult without the benefit of immediate feedback, both verbal and nonverbal. An arched brow or a deep sigh might be a clear signal that norms are violated in person, but online, other tactics prevail. Often they involve more explicit statements of reproach or warning, either privately or in public. Virtual teams, for instance, often develop teamwork plans that include very specific conflict resolution agreements that spell out the consequences for noncompliance.

Online groups sometimes show a status equalization effect, in which people with lower status are able to contribute equally with higher status members. In most face-to-face settings, status will be apparent in a group, based on characteristics such as company position, expertise, age, wealth, fame, tenure, or athletic prowess. High-status individuals do more talking and have the most influence on group decisions. Online, a person's real-world status may be less apparent and sometimes not visible at all. In such groups, contribution levels and influence tend to be more equalized. The online decision support tools used to brainstorm new ideas rely on this effect. The software hides the origin of each contribution and even as the ideas appear on the screen, visible to all group members, the source is unknown. This feature encourages lower status members to contribute candidly and minimizes the dominance of the boss. When anonymity is low or absent, however, status effects creep back and higher status members have more influence.

Another aspect of group dynamics that touches on status involves settings in which status is earned online and real-world status has little meaning. The reputation systems used in many discussion forums or product review sites display

this effect, as people earn social recognition through their contributions. On Amazon, for example, book reviewers gain reputation as shoppers rate the quality and usefulness of their reviews and Amazon's software make each reviewer's status quite apparent. On the massive multiplayer games, players earn their status by gaining levels and experience; so, a 10-year-old with a powerful, high-level avatar and extensive knowledge of the game will have higher status than a 30-year-old newcomer with a Ph.D.

Disinhibition effects are particularly important in the group dynamics of online support groups. Many of these are still text-based and they provide people with a venue to discuss very personal issues with others who are in similar situations. Support groups exist for almost any kind of problem, from HIV/AIDS, to knee surgery, parenting, divorce, and depression. These groups are especially valuable to people whose problem is stigmatizing in some way, making it more difficult for them to discuss issues with people they know in real life. The disinhibiting effects that support self-disclosure, combined with higher anonymity, increase the value of these support groups.

As the SIDE theory suggests, online group settings can facilitate polarization, particularly if the setting promotes group identification and anonymity is relatively high. This is to some extent the reason why there appear to be few moderate voices in many online text-based forums with high anonymity, particularly in forums dealing with controversial subjects. The discussants reinforce one another in a kind of echo chamber, and views that might contradict or moderate their conclusions are ignored, vilified, or driven out of the group. An 'us' against 'them' approach can arise easily in such settings. This characteristic of online group dynamics, combined with the ease with which people can find others of like mind on the net, helps explain why online extremism is a major concern.

Mobile phones offer capabilities that affect online group dynamics in new ways. As a mobile is a device that is constantly on and available, it is widely used to micro-coordinate activities, depending on text messages or Twitter feeds. During a social protest in Iran, for example, people used Twitter to broadcast messages and coordinate group movements. The location-sharing capabilities of smartphones also heighten identifiability, so that group members not only receive messages from one another but also see each person's precise location. The effects these features have on group dynamics is not yet well understood and is still evolving, though they appear to strengthen group identity by increasing the sense of connectedness.

Conclusions and Looking Ahead

The Internet has become a fundamental part of human relationships, supporting interactions that could not have existed in the past and enriching connections with those we see frequently in real life. The devices that connect to it, from computers and laptops to smartphones, video game controllers, and televisions, continue to increase, making online interaction available anytime, anywhere. ICT offers countless new tools people can use to manage the impressions they convey and interact with others, such that choosing among them is no simple task. A wall posting on a social network site carries a meaning that is different from a tweet, and both are quite different from an email or an interactive video session.

Deciding where to set the webcam to conduct a video chat, or whether to turn it on at all, is another choice confronting people who interact online. The characteristics of all these environments affect how we behave and how people perceive and interpret our behavior.

While early online social environments were awkward to use and primarily text-based, current ones offer rich features that better support social interactions. The early environments offered little commercial potential. But as the value of large, loyal communities grows, developers launch feature-rich, engaging social sites in the hope of attracting large numbers, both to increase advertising revenue and to gain access to data that can be used for targeted marketing. Sites such as YouTube, Facebook, Yahoo, eBay, Baidu, Foursquare, Yelp, and many others compete for people's attention and participation, driving even more innovations designed to encourage people to stay active in the community and bring their friends along.

For example, a wildly popular application on Facebook called Farmville engages over 80 million players and the developers draw heavily on social psychology to make it a compelling environment that promotes socializing. The game continuously provides incentives, not just for advancing in levels, but also for sending gifts and inviting friends to participate. A lost digital kitten might suddenly appear and the player is encouraged to invite real-world friends to the game to help find her a home.

While increased commercial value has led to the development of many free, lively social venues offering a breathtaking array of communication tools, it also presents greater risks to privacy. Default privacy settings on these sites lean heavily toward making each individual's contributions widely available. Although users can change settings, many do not take the time, leading to numerous cases in which information intended only for a small group of friends was made available to a much wider audience. Combined with disinhibition and the tendency to self-disclose online, the failure to attend to privacy settings and consider the audience poses very serious risks.

What will tomorrow's Internet look like and how will it affect human behavior? Privacy issues are emerging as a major theme as technologies advance to track even the faintest digital footprints. Mobility will be another theme and the pros and cons of having a device that connects you to the net at all times will become clearer. Virtual reality will blossom and we will learn far more about transformed social interactions among cleverly crafted avatars. Beyond these, tomorrow's Internet no doubt holds many surprises ahead for human behavior and our social lives.

Glossary

Account-making The development of a story-like narrative about a life event in order to gain a sense of control or meaning around the event.

Attribution The process of inferring causality or responsibility for events observed in the social or physical world.

Empathic accuracy The ability to accurately interpret another's mood or emotion based on nonverbal behaviors observed.

Implicit personality theory A set of beliefs that an individual holds about how personality traits are manifested in behaviors or about how personality traits predict behavior.

Impression management The selection of certain appearance, behaviors, and messages intended to portray a desired image to others.

Interpersonal perception The process by which people form judgments of others and interpret their verbal and nonverbal behaviors.

Self-disclosure Communicating personal information about oneself to another person.

Self-monitoring The extent to which someone monitors social cues in the environment and is able to adjust the presentation of self to match those cues.

Stereotype threat The fear of being perceived by observers as someone who fulfills a negative stereotype.

Nonverbal Communication

Nonverbal behavior conveys information about another's intentions, moods, and sincerity. One of the most powerful and obvious forms of nonverbal behavior is facial expression. Theories about how people interpret facial expression go back to Charles Darwin, and research into the intricacies of facial movements continues today.

Scholars agree that facial expression of emotion is a universally recognized form of nonverbal communication. There appear to be six major emotional expressions that are displayed similarly across cultures: anger, happiness, surprise, fear, disgust, and sadness. It is easy to recognize these facial expressions in others, regardless of background or culture. Very young children also begin displaying these recognizable expressions quite early in their development, even before they are fluent in language. Behavioral scientists hypothesize that recognizable displays of these six emotions must have been particularly adaptive for humans; they must have helped us to communicate urgent needs in ways that enabled us to survive and thrive. Contemporary emotion research suggests that there may be individual and cultural differences, however, in the perception of more complicated expressions that blend two or more emotional states or of more subtle emotions, such as anxiety or contempt.

Other than providing information about mood and emotion, nonverbal behavior also helps to regulate interpersonal communication and demonstrate the level of intimacy in relationships with others. For example, gestures can help illustrate communications, change the pace of interactions, or show understanding of another. Eye contact can signal beginnings or endings of interactions, communicate intimacy, or signal dominance. Other nonverbal cues, such as interpersonal distance or posture, also inform us about the nature of interaction.

Empathic accuracy describes the ongoing ability to assess a communication partner's emotions accurately and spontaneously.

The level of accuracy a perceiver can achieve in any situation is dependent on two things: how clearly the communication partner reveals cues to mood and emotion, and how much empathic skill the perceiver has. In general, empathic accuracy tends to be higher with people we know than with strangers, probably for two reasons. First, people know more about their family and friends and have observed their responses in different types of situations. Second, when interacting, people tend to be more open in communication with those they know than they would be with strangers. Thus, they reveal more unambiguous nonverbal and verbal cues to their emotions, making it easier to be accurate in judging them.

Empathic accuracy also improves when the perceiver is highly motivated. For example, if the observer desires to develop a positive relationship with a communication partner, empathic accuracy is likely to increase, probably due to increased effort and attention. On the other hand, people are also sometimes less motivated to be accurate, and may even prefer to be inaccurate in empathetic judgments. For example, if a romantic partner's inattention or annoyance threatens the stability of a relationship, this may be easier to ignore than to acknowledge. This motivated inaccuracy can usually only persist as long as the partner's emotional cues are somewhat ambiguous.

Regardless of motivation, some people tend to be more sensitive to nonverbal cues than are others. Many studies indicate, for example, that women are better at noticing and interpreting nonverbal behavior than men. However, research has also demonstrated that people are generally poor judges of their own empathic abilities. This blindness to empathic deficits can be especially problematic in situations where one person is oblivious to signals that he or she is hurting another person because of the inability to read signs of distress or displeasure.

While facial expression is obviously one of the more powerful types of nonverbal communication, studied in terms of its

universal qualities, people use other nonverbal cues as well to communicate a variety of emotions and responses to others. The ability to empathize and read others' nonverbal signals seems to be due partly to individual skill, but it may also be affected by motivational factors. Using nonverbal information well, though, depends also on the ability to communicate empathy. People not only read nonverbal signals, but use nonverbal behavior to express empathy for another. Matching another's facial expression, leaning toward someone in sympathy, winking to express mutual amusement across a room, all these are ways in which we can communicate shared understanding of a moment or emotion using nonverbal behavior.

Attributions for Others' Behaviors

People routinely observe the behavior of others and have a need to explain the reasons for what they observe. Attributions are these explanations or reasons we create for events or behaviors we observe in the world around us. Making attributions sometimes involves a great deal of critical thought and analysis, as when trying to explain another's behavior that is confusing or hurtful. Other times, when the behavior has relatively little impact, the attributions may be almost automatic. How people create attributions has been one of the most actively pursued questions in interpersonal perception research.

Attributions can be roughly broken down into two types: dispositional or situational. In other words, we have a tendency to explain others' behaviors as arising either from their own personalities (dispositional attribution) or from the pressures of the situation (situational attribution.) For example, when waiting for someone who is late to an appointment, one might make a dispositional attribution by thinking the latecomer to be irresponsible or disrespectful. Thinking that the person must be caught in traffic or held up at work would be making a situational attribution for the same behavior.

Whether we attribute causality to dispositional or situational influences may depend in part on whether we are the actors or the observers of a behavior. When we observe our own behaviors, we have a tendency to attribute more of our actions to the influence of the situation, especially if those actions are somewhat negative. We lost the game because the referee was unfair. I was late to the meeting because there was no place to park. The opposite is true for attributions of observed behavior. We have a tendency to attribute the behavior of others to their personalities or dispositions. He lost the game because he is not very good at it; she was late to the meeting because she is unorganized.

One explanation for this actor/observer difference is that when we are acting as observers, our attention is captured more by the people in the scene rather than the environment surrounding them. So, making a dispositional attribution for another's behavior is simpler than searching for a situational explanation. When we ourselves are the actors, however, our attention is consumed by the factors in the environment around us. Therefore, it is far easier for us to come up with situational attributions for our own behavior. This tendency to make correspondent inferences, assuming that a person's actions correspond to his or her personal qualities, is so prevalent that it is sometimes called a correspondence bias.

Psychologists also often refer to this tendency as a fundamental attribution error because it can cause us to make inaccurate judgments about others.

Correspondent inference allows us to make attributions quickly. But with time to process another's behavior, we may be more likely to use logical deduction in making attributions. When given the time and information, observers might make attributions based on the covariation of three factors: consistency, consensus, and distinctiveness. If your business associate was late to a meeting, for example, this model assumes that you would ask yourself three questions: Has this person been late to meetings before (consistency)? Are other people also late to this meeting (consensus)? Is this person late to other kinds of events as well (distinctiveness)? If the answers to the above questions are yes, no, and yes, then you might comment on how unreliable your associate is (dispositional attribution). If, on the other hand, this person has never been late before (less consistency), or if many others are also late to this meeting (greater consensus), you might be more inclined to wonder what had happened to delay everyone's arrival (situational attribution). Covariation and correspondent inference models of attribution continue to resonate in social psychological research.

Logical analysis of another's behavior often requires more time, cognitive effort, and attention than people have to spare. As a result, individuals often rely on cognitive shortcuts in order to make judgments quickly. The exploration of these shortcuts or biases is part of social cognition, the study of how thought processes, such as memory or attention, affect our perceptions of other people and social interactions.

Several of these cognitive shortcuts are worth mentioning here, however, because they have powerful effects on interpersonal communication. One of the most common is the correspondence bias described above. A related bias is our tendency to ignore the importance of base rates, or the real-world probabilities of events. We are largely unaware of how often certain behaviors or attitudes occur. This also leads us to assume that others are more similar to us than they actually are: a false consensus effect. For example, a busy working mother sees another woman looking rushed. The first woman may assume the other is a mother trying to balance work and home life, just as she is. The observing woman is also likely to assume the stranger shares her own opinions and has similar concerns.

We are also biased by our need to make sense of the world and to believe that it operates in a just manner. This, combined with the fundamental attribution error and our lack of base rate knowledge, can lead us to blame others for events which may be out of their control. For example, we often assume victims of crimes have been incautious or provocative in some way. This quick judgment of others' suffering allows us to continue to believe that the world is fair and also affords us the comforting belief that we can avoid being victims of these kinds of unfortunate events ourselves. We sometimes use communications with others to further confirm these beliefs. If I experience a trauma of some kind, an acquaintance might ask what I could have done to prevent it. Our cognitive biases can lead us to sometimes directly accuse injured people of negligence, or speculate on why a sick person did not take better care of himself or herself.

An additional and important form of attributional bias involves stereotyping. Stereotyping is the process of making

assumptions about others' behaviors based on their presumed membership in a particular group. Stereotypes allow us to ignore individual differences between people and make attributions about their behaviors with little effort. Like other forms of attributional bias, stereotyping can lead to inaccurate judgments about others.

Attributions have a direct effect on interpersonal communication. Our attributions for others' behaviors affect the way we may subsequently interact with them. If I interpret a sales clerk's smile as a genuine wish to help me, I may be friendlier and spend more money than if I attribute it to a desire for a higher commission. Secondly, our very purpose in communicating with another may be to clarify our attributions. For example, I may confront someone to demand an explanation for a behavior, accuse him or her of a particular motivation for a behavior, or raise a question about why the behavior occurred. Finally, people communicate excuses for committing various social errors, like being late or not returning a phone call, in order to control the attributions that others might make for those behaviors.

Social scientists have examined the interplay between attribution and communication most frequently in close relationships, especially marital relationships. Partners in stable, positive relationships tend to make dispositional attributions for behaviors that enhance the relationship, and situational attributions for behaviors that are more negative. The reverse appears to be true for partners in distressed relationships. Both verbal and nonverbal communication between partners is affected by the partners' attributional patterns. Couples with relationship-enhancing attributional patterns are likely to reinforce those patterns with positive nonverbal behaviors and open discussions about problems. A more negative attributional pattern is more likely to lead to negative communication between partners, such as blaming, rejection, and refusal to accept responsibility for problems. The kinds of attributions made by interaction partners can thus lead to an overall pattern of communication that can strengthen or weaken the relationship.

In brief, people make attributions for the events they see around them, but often make them quickly and under the influence of preconceptions or cognitive biases. These attributional complications affect the way in which we communicate and interact with others around us. A wife may interpret a husband's comment as a criticism and withdraw in resentment. A teacher can misinterpret a child's confusion as lack of attention and scold him or her. Two coworkers might each form different impressions of a supervisor's offer of assistance and respond positively or negatively. The tone, manner, and intimacy with which we approach and communicate with others can be directly affected by the attributions we make about their behaviors.

Person Perception and Communication

When people form judgments about others, they draw conclusions not only about others' behaviors but also about personalities. Some research has shown that people reach conclusions about another's personality even when they have seen that person's face for only a fraction of a second. What we believe about another person will affect the way we choose to

communicate with that person; therefore, our judgments about personality have consequences.

Early research into personality perception examined how accurate people were in their judgments of others' personalities. This work was problematic, however, because of the nature of accuracy in personality assessment. Making an accurate evaluation of another's personality depends in part on comparing that person's personality characteristics to the norms for those personality traits in the general population. For example, it is difficult to judge how extroverted someone is without comparing him or her to others. Because most people do not have that kind of broad knowledge about personality norms in the population, those who generally make more conservative judgments of others appear to be more accurate in their evaluations than those who are more extreme in their opinions of others. Thus, it is hard to separate accuracy from natural caution in judgments. Because of this difficulty, much research into person perception has focused less on the accuracy of judgment than it has on the process of how we develop theories about others' personalities.

One theory of person perception hypothesizes that people collect pieces of different information about someone in order to form an overall impression. In this model, people sum or average another person's favorable versus unfavorable traits in order to calculate an overall impression. Though there is evidence that people weigh the value of various traits in reaching an opinion, the process appears to be more complex than simply averaging impressions.

Considerable research demonstrates that one unifying characteristic or trait can shape someone's overall impression of another. These central traits are characteristics that seem so important that they overwhelm or color other information about another person. An example is the personality trait of being warm versus cold. Research has demonstrated that if we hear someone described as a warm person, we then have a strong positive impression of that person that influences everything else we subsequently hear about him or her. The reverse is true if we hear the person described as cold.

These initial conclusions about certain central personality characteristics can lead to other assumptions about a person's overall personality. For example, I might associate warmth with honesty or helpfulness. If I meet a person who appears warm, or has been described to me as being a warm person, I might be more inclined to trust him or her, based on my automatic association of warmth with honesty. These networks of assumptions we have about people's personalities are implicit personality theories. Each individual probably has a unique implicit personality theory, based on his or her own previous experiences, but there seem to be some commonalities. Two central traits appear to be crucial to most people's implicit theories: warmth and competence. We seem to evaluate people first on the dimension of warmth by assessing aspects of their personality like friendliness, humor, and sincerity. Then we look for traits related to competence, like intelligence, persistence, and reliability.

There are other personal and situational factors that affect what we pay attention to about others when we are seeking to form an impression of them. For example, research has demonstrated that membership in a specific population group (e.g., ethnic background, gender, age) influences our

evaluations of another. This research has had significant effects on theories of prejudice and stereotyping. Our recent pasts also bias our evaluations of others. When we have recently been exposed to very unpleasant behavior, for example, we may judge people who are neutral as more positive in contrast. This contrast effect works in reverse as well, making us more critical of Allen when we have been recently exposed to extremely pleasing or positive behavior by Barry.

Our judgments of others' personalities are also biased by their physical attractiveness. Specifically, we have a tendency to assume that attractive people are happier, more successful, and warmer than are less attractive people. In this way, physical attractiveness may operate much like a central trait in affecting our subsequent judgments.

Given all the factors affecting our impressions, can we possibly be accurate in these personality judgments? Some contemporary research into person perception has circled back to examine this question. Researchers have compared people's first impressions of strangers to the personality descriptions given by the strangers' friends and family members. These first impressions often correlate with the ratings made by those who knew the targets well. Although this work is complicated by the factors mentioned earlier, it seems to indicate that people can be fairly reliable at judging some basic characteristics of personality, even after a relatively short exposure to another's actions.

This process of impression formation affects the way we communicate with other people. As individuals interact, they attend to cues and form impressions of each other. Physical attraction affects our responses to others. Social interactions with others will also be affected by the social cues we receive, like those related to gender or authority. Next, an individual might look for nonverbal clues as to the other's personality, such as facial expression or posture. Finally, any attributions made about the person's personality characteristics are factored into the equation. The summary of these perceptions affects not only the observer's interpretation of the person and the world but also his or her subsequent verbal and nonverbal responses.

The ability to make these assessments affects one's skill at appropriate social interactions. Communication competence is expressed in the ability to display sensitivity to an interaction partner while also achieving one's own goals for the interaction. Various factors affect communication competence, including aptitude for reading others' nonverbal behaviors, various biases in making attributions, and judgments of the other's personality. We are more likely to achieve our communication goals if we are attentive to others' responses and accurate in judging them.

Because communication competence in part depends on knowledge of others, we are less secure communicating with partners about whom we know very little. Uncertainty reduction theory considers how people strive to gather this kind of information in a new interpersonal situation. Communication scholars interested in uncertainty reduction explore how people probe for information when interacting with others, test out their new conclusions in subsequent interactions, and make decisions about further communication.

But when we interact with others, we are not just observing them. We are influencing them as well. As we form impressions

of others and then strive to reduce our uncertainty about them, we may inadvertently cause them to produce reactions that confirm our initial impressions. A man who is told a particular woman is extroverted will ask questions of her and engage her in conversation that assumes her to be outgoing and social. He is thus more likely to elicit responses from her that confirm this initial expectation. His communication style has influenced hers and strengthened the first impression of her personality.

In summary, we often make very quick judgments not only about others' behaviors, but also about their personalities. These judgments might be based on an analysis of various actions we have seen others display, but they are likely heavily affected by our impressions of central traits like warmth and competence. Our initial impressions may be biased by another's membership in a particular group or level of physical attractiveness, and they are influenced by the implicit theories of personality that we have developed through time and previous experience. These initial judgments of personality are powerful because they may affect the way we choose to communicate with others. Those communication choices may influence others' responses. This creates an interaction spiral of initial perceptions, attributions, subsequent communication, other's response, and confirmation or revision of the initial judgments. It is through a continuing series of these interactions that we build relationships and intimacy with others.

Communicating About Oneself to Others

Sharing information about oneself, or self-disclosure, is a central avenue of interpersonal communication and another way to create intimacy in relationships. Self-disclosure is defined as personal information about oneself that is communicated to another. Disclosure differs in terms of its breadth, depth, and duration. Breadth refers to how many different topics are covered in the disclosure, depth to how personal or intimate the level of disclosure is, and duration to the length of the actual disclosure.

A common way for people to disclose information about themselves is to construct an account. An account is a package of impressions, perceptions, attributions, emotions, and description, formed into a story. Someone would develop an account about an event in his or her life in order to gain a sense of control and meaning around the event. Sharing that account with others is a way of giving out information about yourself, helping others to understand you, or influencing others' impressions of you. People may construct accounts about other people's behavior as well and share those accounts for the same reasons: to give out information about the leading players in those accounts or to influence others' impressions of either the account maker or the actors in the story.

Self-disclosure is a key concept in social penetration theory. Social penetration theory describes the process by which people develop relationships. As two people get to know each other, there is usually a social exchange as people take turns disclosing. One person's mild disclosure often triggers this exchange. The second person in the interaction can then choose to disclose in return or not. If so, there may be a continuing spiral of increasing intimacy between the two people. These disclosures gradually become more intimate and

involve more depth. Through this process, the communication partners uncover information about each other, developing a multilayered understanding of the other that serves as a foundation for the relationship. Thus, one major purpose of disclosing personal information is establishing friendship or intimacy with another.

A second use of self-disclosure is as a social strategy, revealing or withholding information in order to obtain a goal. For example, you might share a sympathetic story about yourself in order to get someone to assist you in a task or to talk your way out of a negative consequence of some kind. In contrast, you might disclose your pride in a success in order to make a good impression at a job interview.

Disclosure can also be used as a catharsis, or a venting of emotion. There is research demonstrating that disclosure of this kind can be therapeutic, if an empathetic listener receives it. Early theories of self-disclosure assumed that this type of disclosure was always beneficial and that the willingness to self-disclose was a sign of mental health. Now, however, it is clear that disclosure is more complex than this, and that there are several risks involved in the decision to self-disclose. There is a risk of rejection by the listener, loss of personal control over the information shared, and of embarrassing the listener.

Self-disclosure is a discretionary behavior; that is, people control how much, to whom, and when they wish to disclose. Self-disclosure can also be a goal-oriented behavior; it can be used for different purposes in different situations. There is risk attached to self-disclosure. For all of these reasons, perceptions of others are crucial to decisions about disclosure. The impressions and attributions we have formed regarding others affect the extent of our willingness to disclose to them and the circumstances under which we are willing to disclose. We may be more likely to disclose to people who appear warm, receptive, and trustworthy. We may also disclose more to those who appear to have advantages to offer us in return for our disclosures. For example, someone is likely to self-disclose more readily to a prospective romantic partner who is both attractive and congenial than to one who appears to be either cold or personally unappealing.

Individuals manage their communication and disclosure with others to further their social goals. A major theoretical perspective related to this idea is that of self-presentation or impression management. This research assumes that people take on different roles in their daily lives, much like actors on a stage. Individuals select certain appearances or behaviors intended to convey a particular image for others.

One person may have a variety of roles or images he or she can portray, depending on the situation or the social goal of the moment. Some strategic methods of self-presentation that have been identified by researchers include emphasizing one's strengths or accomplishments, advertising one's moral superiority, portraying oneself as a helpless victim, ingratiating oneself through flattery and admiration, and appearing aggressive or intimidating. Individuals may rely on one particular self-presentation method in most of their interactions with others, or may vary their self-presentation based on the needs of the situation.

Different people are more or less motivated to change their self-presentation to suit the social requirements of different situations. Self-monitoring is a term used to describe the

awareness of changes in social situations and the desire to alter one's self-presentation in order to better fit into those situations. People who are high self-monitors have many different images they are able and willing to present; people who are low self-monitors are more consistent in their self-presentation across many different situations. People also vary in how anxious they are in social situations; this can affect how well they manage their self-presentation. Extroverted people are generally more at ease with self-presentation strategies than are introverts; however, this appears to be mainly due to some introverts' anxiety over social interactions rather than a lack of skill in impression management.

The growing use of technology as a communication medium creates new questions about person perception and self-disclosure. In the past decade, much research has focused on the increasing use of the Internet as a medium for interpersonal communication. Because these types of communications tend to be relatively brief and made at a distance, communication partners often do not have the benefit of nonverbal or emotional expression in order to reduce uncertainty or help form judgments about the other. Early studies seemed to confirm that communicating through media such as e-mail, chat rooms, or cell phone text messages had the expected negative effect on communication effectiveness and social intimacy.

However, newer research findings are more equivocal. Some research indicates that communication via Internet increases openness in self-disclosure, promotes positive feelings about communication partners, and allows frequent interaction with friends and family. It is possible that as these technologies have become more established and accepted as useful communication tools, people have adapted their patterns of communications and social judgments as well. One hypothesis is that people who suffer from anxiety in face-to-face social encounters may be more at ease communicating by computer and thus able to have more satisfying social interactions. Social scientists have only begun to explore the effects of technology on interpersonal perceptions and communication. It is not clear as yet what the full impact of newer technologies will be on patterns of interpersonal communication.

How much one communicates to others about oneself is a complex social decision. This self-disclosure may serve several purposes: social penetration, social manipulation, or emotional catharsis. People often build accounts about themselves to use specifically in telling their stories to others. They may also strategically balance how much they reveal in order to maximize social benefits through self-presentation while minimizing the inherent risks in disclosing personal information. To do this well, people must make judgments about the receptivity, trustworthiness, or helpfulness of others. Thus, disclosure decisions are linked to the process of interpersonal perception.

Expectancy Effects

People form initial impressions of others rapidly and these impressions can be important influences on subsequent interactions with those others. The judgments or attributions made about another's actions lead to expectations about that person's subsequent actions. These expectations about others

affect interactions, regardless of whether those expectations are based on accurate or inaccurate judgments.

Once we have formed a judgment about someone else, we are vulnerable to a confirmation bias. This is a tendency to notice only information that will confirm our previous judgment. For example, if we have previously concluded that Susan is a bad parent, we will tend to notice her children's behaviors that confirm that belief but ignore those that do not. This bias in what we attend to will strengthen our previous expectations. If we have judged John to be an impatient and angry person, we will interpret his every fidget as a sign of that impatience; this will further confirm our previous assessment of him. Our beliefs about others then are likely to persevere, even in the face of contradictory evidence, because we are unlikely to take notice of that evidence.

We increase our confidence in our own judgments, not only by ignoring conflicting information but also by acting in ways that support our previous conclusions. We avoid people with whom we have had negative interactions, which can lead to few opportunities to change our impressions. If we must interact with them, we may view the situation as unpleasant, which again reinforces our opinions of them. If we enjoy our initial interactions with someone, however, we may seek him or her out. Moreover, we will seek that person out with positive intentions and expectations and treat him or her as though we expect a pleasant interaction.

Positive or negative expectations of someone can lead to a self-fulfilling prophecy. This occurs when a perceiver forms a strong expectation about another that affects the perceiver's behavior. The target of this behavior responds in a way that reinforces the expectation. If that cycle continues, the target begins to fulfill the expectation, regardless of whether or not the perceiver's initial beliefs were accurate. For example, if Allen has a negative expectation about his interaction with Barbara, he may approach her defensively. Barbara is annoyed by Allen's defensive behavior and responds aggressively. This reinforces Allen's opinion of her and he continues to treat her in a negative way. If this interaction pattern persists, Barbara may become consistently as unpleasant as Allen always expected her to be.

The initial and most influential work on self-fulfilling prophecies was originally done in educational settings. Research seemed to demonstrate, for example, that if teachers were led to believe that certain children were more capable of improvement than others, those children would in fact show greater performance improvements. The teachers' expectations appeared to be responsible for the children's successes. Evidence over the years seems to indicate that these types of specific expectations in the classroom may not have as big an impact as originally thought, but do exist.

Other important research in this area involves whether or not people are aware of the expectations that others have of them. Stereotype threat is the fear that others have expectations of you related to your membership in a stereotyped group. One example might be a fear that others expect that you would struggle with certain academic subjects because of your gender or race. Research has documented that when students are made aware that teachers or test administrators know the negative stereotypes pertaining to their racial or

gender group, those students suffer anxiety about confirming those stereotypes. This anxiety interferes with their academic performance.

Stereotype threat is most likely to occur when someone feels that he or she will be compared with others who are not members of the stereotyped group. One method of countering stereotype threat is to remind people of positive attributes they share with all the others in the situation, for example reminding them that they were all selected because they were the best applicants for a job. Some research shows that reducing anxiety in general also reduces the negative effects of stereotype threat. Other researchers have found that simply explaining what stereotype threat is and how it might affect members of stigmatized groups can reduce its impact on individuals.

Some people may be less susceptible to expectancy effects than are others. People who generally have a clear sense of self, and those who are less anxious about social evaluation may be more resistant. When someone is very confident and also has considerable experience regarding a personal ability or characteristic, he or she may be less likely to be influenced by a perceiver's expectations.

In conclusion, the processes of interpersonal perception and interpersonal communication directly affect each other. Both processes also affect our personal interactions and relationships in everyday life. People form impressions of others rapidly, making judgments and attributions about their personalities and behaviors. These perceptions influence the way people then choose to communicate with others and what they choose to disclose about themselves. As people's expectations and perceptions change their behaviors and communications toward others, they may produce self-fulfilling sequences that actually create change in others' subsequent behaviors. The relationships that people build with each other are therefore based on these structures of perception and communication. The ongoing dynamics between perception and communication is the foundation for interpersonal relations.

Glossary

Anhedonia A marked decrease in interest or satisfaction from participating in once pleasurable or rewarding activities.

Complicated grief A deviation from the normal or typical response to loss such that the grief reaction is prolonged, more complex, and profoundly disrupts healthy functioning. Particularly difficult or tragic manners of death of significant others (e.g., suicide, homicide, and accidents) may pose a significant barrier to healthy resolution or acceptance of the death.

Depressive episode The (potentially recurrent) experience of a severely depressed mood state, and/or anhedonia, which is manifested by several of the following over a 2-week period: disturbances in sleep, appetite, concentration, psychomotor activity, energy, feelings of self worth, and/or thoughts of death, suicide, with or without a suicide plan or attempt.

Grief The normal (and typically transient) response to the loss of someone or something loved or prized, which incorporates a range of reactions and adjustments across several dimensions (i.e., social, cognitive, and emotional).

Internal working model (IWM) From early-life experiences with a primary caregiver and close others, children develop a set of expectations about how they should be treated, the responsiveness and sensitivity of others, as well the likely outcomes of various interpersonal interactions. The IWM is theorized to be formative in the development of self-esteem and other self-views.

Interpersonal deficits The lack of effective or healthy relationship building or maintaining skills, which may result in boredom or loneliness in the absence of a supportive social network.

Interpersonal disputes Conflicts with significant others while in stages of renegotiation or dissolution, or when a conflict reaches an impasse.

Role transitions A marked change in an individual's life or relationship status in response to the beginning, end, or passage from one life or relationship stage to another.

Selective serotonin reuptake inhibitors (SSRIs) Individuals suffering from psychiatric disorders, particularly mood and anxiety disorders, may be prescribed antidepressants alone or in combination with psychotherapy. Selective serotonin reuptake inhibitors (SSRIs) are a class of commonly prescribed antidepressants which are often preferred over monoamine oxidase inhibitors (MAOIs) and other classes of antidepressants. SSRIs such as Fluoxetine, Citalopram, and Fluvoxamine help regulate levels of serotonin, a neurotransmitter implicated in the development of depression and other mental illnesses.

Treatment phases Stages in the therapeutic process that build upon one another and may focus on different issues or problem areas as a patient progresses with treatment. Specific strategies or tools may be implemented during these stages to help achieve therapeutic goals and reduce symptoms of psychopathology.

Interpersonal psychotherapy (IPT) is a time-limited, diagnosis-specific psychotherapy originally developed for the treatment of major depressive disorder (MDD). It was initially developed for a clinical trial, testing the maintenance treatment of MDD using drugs and psychotherapy alone and in combination. In 2007, a simplified guide for clinicians was released, based on the original book which describes the basic techniques and strategies. This guide and an updated version of the original book presents scripts for carrying out the procedures, provides case material, and includes updated efficacy data. IPT draws its principles from interpersonal and attachment theories, which hypothesize the connection between life events, interpersonal interactions, and the development of psychopathology. Empirical evidence has since demonstrated the close association between the onset of depression in biologically vulnerable individuals as a function of interpersonal events.

IPT has been tested in comparison and in combination with medication for the treatment of MDD. It is designated by the American Psychiatric Association and Primary Care Practice Guidelines in 1993 as a recommended treatment for adult

depression. It is included in evidence-based practice guidelines of depression by the Royal College of Psychiatrists and the National Institute of Clinical Excellence (NICE) for residency training. IPT is also part of the clinical practice guidelines for depression in the Netherlands. The IPT manual has been translated into French, German, Japanese, Spanish, Italian, Danish, and Portuguese.

This article delineates the theoretical substrates which contribute to the nature, onset, and maintenance of depression according to IPT and supporting research. It also describes the treatment techniques and session content of IPT. An illustrative rather than exhaustive review of international IPT adaptations is included. A comprehensive description of IPT concepts and procedures is available in the current IPT published manual.

Depression

Depression is classified as a mood disorder by the *Diagnostic and Statistical Manual of Mental Disorders* (4th edition) and the

International Classification of Impairments, Disabilities, and Handicaps (10th revision). It is a prevalent, yet treatable psychiatric illness with a lifetime prevalence of ~10% for men, and 25% for women. Depression poses significant costs to society in terms of productivity loss and healthcare costs, with a mortality rate of 10–15%. The Hamilton Depression Rating Scale and the Beck Depression Inventory are valid measures used to assist diagnosis as well as monitor depressive symptoms. Diagnosis of depression must include either depressed mood or loss of interest (anhedonia) for most of the day for more than half the days in a 2-week period. Appetite changes (weight gain or loss), sleep problems (insomnia or hypersomnia), loss of energy, poor concentration, psychomotor retardation, feelings of worthlessness or guilt, and/or recurrent thoughts of death or suicidality, may also be present. At least four of these symptoms in the same 2-week period are required for a diagnosis of depression.

Theoretical and Empirical Background

Sullivan's Interpersonal Theory

The principles of IPT are based in part on Sullivan's interpersonal theory, which connects the development of psychopathology to the quality of interpersonal contexts, with special focus on the formative years. Sullivan suggested that individuals, particularly those suffering from mental disorders, were less aware of patterns involved in their interpersonal experience, known by the process of selective attention. Selective attention was integral to his investigation of psychopathology, such that information regarding patients' unique interactional and affectual patterns were necessary for diagnosis and designing a therapeutic strategy. The emphasis on the relational approach to case conceptualization and its usefulness for elucidating processes behind psychopathology have endured as influential aspects of interpersonal theory. IPT, however, focuses on current interpersonal difficulties and significant life events, rather than early formative experiences.

Bowlby's Attachment Theory

Another important theoretical source of IPT is Bowlby's attachment theory, which explains that the primary caregiver and child dyad represents the most elementary of human relationships. The charge of the caregiver, therefore, is to provide the child with the necessities for surviving and adapting to an environment, while shielding from harm. Ainsworth and colleagues discussed this dynamic process wherein the caregiver functions as a secure base for the child to explore his or her environment. This concept was developed in response to the strange situation research which explored children's reactions to several experimental manipulations involving the disappearance and return of their caregivers. From these studies emerged two main styles of attachment behavior: secure, and insecure (anxious and anxious-avoidant).

Bowlby incorporated his theory of internal working models (IWMs) to explain the centrality of early relationships and their influence on relational expectations. Some of the most integral adaptational processes, such as predicting outcomes in one's environment and engaging in survival techniques (e.g., seeking

social support), are guided by the IWM formed by early attachment. Bowlby suggested that disruption in the development of a healthy IWM, due to neglectful or inconsistent caregiver behavior, may lead to vulnerability to psychopathology in later years. Adult attachment style has been delineated by Bartholomew and colleagues to resemble four main prototypes as a function of high or low relationship avoidance and anxiety: secure (low avoidance and anxiety), preoccupied (low avoidance and high anxiety), dismissing (high avoidance and low anxiety), and fearful (high avoidance and anxiety). Insecure attachment in adulthood has been linked to depression and substance abuse, highlighting the vulnerability of adults with dysfunctional IWMs. However, research suggests that attachment style in adulthood is malleable in response to newly incorporated information into the IWM. This process may ameliorate relational problems and ultimately reduce risk for psychopathology. Preliminary research suggests that attachment style may help predict important aspects of the therapeutic relationship, including time necessary to form a patient–therapist alliance, treatment response, diagnostic features, and treatment course.

Life Events

IPT addresses current episodes of illness by relating mood states to present interpersonal problems. Research on depression and its psychosocial triggers have guided the conceptualization of relational issues into four main categories: role transitions (e.g., motherhood and marriage), interpersonal disputes (e.g., conflict-driven marriages), grief (i.e., complicated bereavement), and interpersonal deficits (e.g., social isolation and loneliness). In IPT, each domain is addressed by a range of therapeutic strategies designed to foster positive interpersonal interactions and elevate mood.

Depression literature has long suggested that life events affect the onset of a depressive episode. Yet, recent theories propose that different types of life events make the relationship with depression more complex. The psychological impact of events originating from sheer coincidence (e.g., natural disaster and automobile accidents) is contrasted with events that involve a severed relationship (e.g., divorce and job loss). Consistent with psychosocial research, depression associated with stressful relationship-oriented events has been associated with the onset of a future depressive episode. When events of sheer coincidence are implicated in the onset of a depressive episode, they have failed to show an association to future episodes. Events that involve humiliation or strong social disapproval are closely linked to the development of a depressive episode. Similarly, neuroticism (the tendency to interpret events through a negative or emotional lens) influences the perceived impact of an event before a depressive episode. This illustrates the role of personality and outcome expectation on the development of an illness episode. This notion is demonstrated in studies of recurrent depression in which the development of a depressive episode after two or more episodes was found to be unrelated to life events. The techniques of IPT adapted as a maintenance therapy are amenable to treating recurrent episodes of depression.

Life events may be subjectively interpreted and appraised. Therefore, the reaction to life events varies between individuals. Selye differentiated between negative stress (i.e., distress) and

positive stress (i.e., eustress). The concept of eustress delineates the nature of stress such that positive life events may also cause significant disruption in individuals' lives. The challenges of life transitions typically assumed to be positive (e.g., marriage and childbirth) have the potential to be as problematic as negative life events (e.g., death of a loved one). Some individuals may suffer a depressive episode in response to such life events, whereas others may be relatively unaffected by their influence.

Recent genetics research has demonstrated a possible biological interaction between life events, genes, and psychopathology, highlighting individual differences in vulnerability to depression. Caspi and colleagues conducted a prospective-longitudinal investigation in which the experience of stressful life events and depressive episode were linked by genetic variability. The serotonin transporter gene, 5-HTT, affected by a functional polymorphism was isolated as a moderator of the influence of stress from life events on the onset of a depressive episode. That is, experience of stressful life events is causally related to the onset of a depressive episode in vulnerable individuals. Individuals with two or more copies of a short allele affected by the 5-HTT polymorphism comprise 60% of the population. Of these individuals, those who experience a stressful life event(s) may compose the bulk of patients seeking treatment for depression. Undoubtedly, in the future, other genes and their pathways and interactions will be identified. This study conveys the need to address current life stressors as a facet of treatment for depression in biologically vulnerable individuals. These empirical findings validate IPT's focus on present life events and current stressors as a method of reducing depression symptoms.

Focus and Techniques of IPT

IPT assumes the patient is not responsible for the onset of a depressive episode. In this way, a diagnosis of depression removes guilt. In the first sessions of IPT, the therapist educates the patient about the nature of depression, explains that it is ego-dystonic, and defines its symptoms. Patient assumptions about personal weakness or failure are absolved by educating patients about the symptom course of depression, as well as treatment availability. This perspective also assists therapists with instilling hope in patients and demystifying depression. To help achieve its goals and foster a collaborative therapeutic alliance, IPT utilizes the sick role concept. Sociologist Talcott Parsons defined the sick role as a formal excusal from normal duties while undergoing medical treatment. In IPT, the sick role fosters the motivation necessary for patients to take steps to restore their former social roles and healthy functioning.

Therapeutic Strategies

IPT is principally concerned with the current triggers of a depressive episode. Therefore, IPT's main strategy involves linking stressful life events and interpersonal problems to changes in mood. By helping the patient recognize and understand the interaction between symptom onset (i.e., depressed mood) and interpersonal triggers, action can be taken to reduce its maintaining factors. In active collaboration with the IPT therapist, the patient can work to resolve issues and improve their situation, leading to depressive symptom reduction.

In IPT, interpersonal difficulties are conceptualized as the main activating factors of a depressive episode, which generally fall under four categories: grief, interpersonal disputes, role transitions, and interpersonal deficits. Typically, the therapist and patient work jointly in an effort to determine the most impactful life event and/or the main problem area triggering the depressive episode. This integral step is completed in the first phase of treatment and may be revised or refined as necessary as progress is made. In the middle phase of IPT treatment, the therapist implements therapeutic strategies designed specifically for the isolated problem area.

Techniques

IPT relies on techniques that are common to psychotherapy. When focusing on interpersonal disputes or deficits, the therapist needs to acquire a sense of the problem and the communication styles of the patient and their significant others. Therefore, a communication analysis is accomplished by recreating an interaction that has caused distress for a patient or has affected their emotional state. Mainly, this strategy is used to determine problematic content.

In order to work collaboratively toward a defined and realistic goal in IPT, the therapist helps the patient reconcile the wishes and actual options for his/her interpersonal problems. The patient is encouraged to reveal his/her hopes for the most desired outcome for his/her interpersonal situations. The therapist and patient discuss how to achieve the patient's wishes within the context of realistic options offered by his/her interpersonal relationships.

After defining the goals of treatment, it is crucial to explore and determine the best options for reducing depressive symptoms. To work toward these goals, it is necessary to navigate interpersonal issues as they arise. A decision analysis is implemented to help the patient generate possible options and determine the solution most likely to foster his/her larger goal(s).

An important therapeutic strategy of IPT is the use of role play. This technique is employed when a patient learns a new skill or tactic for solving interpersonal problems and rehearses its implementation. This is a valuable strategy for treating patients with interpersonal deficits who may gain comfort from practicing new skills before introducing them in real-world situations.

The diversity of tools in IPT, in contrast with psychodynamic therapies, primarily focuses on the present, namely the here and now, rather than early-life experiences, dreams, or instances of transference. IPT also assumes that patients can be taught to recognize their emotions in connection to events, rather than unearthing suppressed emotions or unconscious conflicts. Moreover, IPT invokes the medical model perspective which eliminates patient guilt or responsibility for illness while instilling hope in the patient as an agent for change.

Comparison of IPT to cognitive-behavioral therapy (CBT) demonstrates that IPT sessions are less structured than CBT sessions and rely less on specific homework tasks. Furthermore, CBT fosters the recognition of dysfunctional or unrealistic cognitions as they relate to mood or action. However, IPT's strategies focus on linking mood to event as the essential mechanism for depressive symptom alleviation. In IPT, several overlapping goals within the four major problem areas may be addressed

simultaneously. Despite these theoretical differences, both approaches utilize the concept of the here and now and strategies such as role play to promote reduction in the syndromal constellation.

Treatment Phases

In acute treatment form, IPT comprises three phases in a 12–16-week schedule. However, length of IPT treatment is not standardized and can vary considerably. The time-limited nature of treatment is explained and the time span is defined in the initial phases, which can be renegotiated later, but with specific goals for an extension of treatment. The following is a delineation of the typical IPT treatment phases for MDD. As described earlier, IPT has been modified for several mood and nonmood disorders, as well as a maintenance therapy for depression, all of which would deviate to some extent from this clinical illustration. In these cases, the appropriate diagnosis would be substituted and explicated by the therapist in the first phase. The content and therapeutic strategies during the middle phase would be adapted to the presenting diagnosis and appropriate symptomology, with additional modifications based on developmental concerns or culture.

The main focus of the IPT intervention is the patients' current interpersonal context rather than past relationships or experiences. Therefore, IPT does not address issues of personality during treatment. Personality issues are difficult to tease apart in the presence of an Axis I disorder and require further work beyond this time-limited therapy.

Initial Phase

The first phase of IPT typically covers the first session through the third session. The necessary standardized diagnostic evaluations are completed at this stage. In addition, a complete psychiatric history is collected which includes the interpersonal inventory. This schedule compiles information about the patients' current social context, significant others, as well as their level of social functioning. Information regarding the most closely linked interpersonal event to the onset of the depressive episode begins to emerge at this stage. The therapist gathers data on changes (e.g., relocation) or conflicts (i.e., marital strife) in the patients' relationships and is keen to developing themes of emotional content. The interpersonal inventory also includes information about both the therapist and patients' outcome expectations for treatment. Thus, a crucial aspect of the first phase is setting the appropriate framework of treatment based on the information garnered by these tests and inventories. After a diagnosis of depression is confirmed, the therapist reviews with the patient the symptomology and typical illness course to demystify the diagnosis.

An integral aspect of the first phase of treatment is the conferring of the sick role. This symbolically excuses the depressed patient from performing duties they find difficult as a result of the challenges presented by the depressive episode. The sick role further serves as a verbal contract ensuring that the patient will take the necessary steps agreed upon during the sessions to restore their healthy functioning.

It is crucial in the first phase to assess for patient suicidality based on ideation, plans, or recent attempts. Referral to an

intensive level of care at a psychiatric hospital or clinic equipped to handle issues of suicidality may be necessary. The need for medication should also be considered at this stage with reference to symptom severity, psychiatric and medication histories, and response to previous treatments, if any. After thorough psychoeducation about the diagnosis, IPT treatment, and medication, the patient is encouraged to discuss his/her preference for adopting a medication regimen, if suggested. Before the treatment moves to the next phase, the patient chooses from the four problem areas on which he/she wants to focus. This choice is a careful consideration of the proximal interpersonal issues that were developing around the time of symptom onset. It is imperative that the most pertinent issues are clearly and coherently defined. Treatment begins on a weekly basis, which may shift to once every 2 weeks. This determination should be based on symptom improvement and must be agreed upon by both the therapist and patient.

Middle Phase

In the middle phase of IPT treatment, the therapist begins the implementation of the therapeutic strategies suited for the patients' interpersonal problems, as previously described. As the therapist and patient work toward the mutual goals, symptom improvement begins to occur as a function of interpersonal progress. Goals can be altered as necessary as new information is gathered.

Grief

Patients whose depression is triggered from the death of a loved one must focus on facilitating grief. Also known as complicated bereavement, abnormal reactions to the death of a significant other precludes patients from experiencing the normal phases of the mourning process. The therapist assists the patient in accepting the loss while exploring both positive and negative feelings about the deceased. Facilitation of the delayed grieving process is guided by the therapist while methods of breaking social isolation are discussed and implemented. An adaptation of IPT for depression occurring during the normal grief process is underway.

Interpersonal disputes

If the focus area is interpersonal disputes, problems stem from overt or covert conflicts with significant others (e.g., spouses, friends, family members, or coworkers). These conflicts usually relate to situations in which one or more persons involved have nonreciprocal expectations about the relationship. Significant distress may be felt from loss of perceived control over the future of the relationship, diminishing hope for improvement or reconciliation, and/or lowered self-esteem. In many cases, lack of productive communication habits may perpetuate disputes. Here, the therapist helps the patient examine the relationship and the phase of the dispute with possible options for resolution. In the instance that reconciliation reaches an impasse, renegotiating the problem or ending the relationship is considered.

Role transitions

The problem area of role transitions references Selye's conceptualization of stress such that both positive and negative life changes and personal growth may cause significant disruption.

Patients in whom depression is related to life status changes can include milestones such as marriage, graduation, and childbirth, as well as job promotion, career change, or diagnosis of an illness. In these cases, the therapist assists the patient in mourning the loss of a previous role and accepting the challenges or life changes posed by the transition. A realistic perspective on past and future roles is fostered through exploring the positive and negative aspects of each experience. Additionally, patients may benefit from developing new interpersonal skills which may assist them in the new role.

Interpersonal deficits

Some patients presenting for treatment for depression, particularly those with recurrent depressive episodes, are likely to have chronic problems relating to the initiation or maintenance of healthy relationships. Lack of social skills often thwarts the development of healthy social functioning, as well as maintaining an optimal level of social contact. Issues of boredom, loneliness, low self-esteem, or lack of relationship skills are likely indicators of patients with interpersonal deficits. For patients who exhibit problems initiating or sustaining relationships, the goal of IPT is to reduce social isolation and promote the generation of new relationships. It is important to relate the patient's depressive symptoms to social isolation and to discuss the adaptive benefit of social support. The therapeutic relationship can be used to demonstrate how the patient typically relates to others, and the use of role play can assist in the development of social skills.

In IPT, patients' experience of stressful life events affects negative mood states and the onset and maintenance of depression. IPT's goal of helping patients recognize the connection between mood and current life events is crucial for the alleviation of depression symptoms. Therefore, the focus on the here and now is paramount to discussing problems suffered in childhood or other developmental issues. To this end, the therapist serves as a supportive guide in fostering understanding of the mood-event link. IPT therapists begin sessions with the question: "How have things been since we last met?" This opening question directs the patients' attention to recent events and their impact on their experience of positive and negative affect. This technique also teaches patients to mentally catalog a short history of events that have affected their mood states to discuss in an upcoming session.

The role of the therapist in these discussions is to serve as a source of hope and strength in the face of pessimism or perceived helplessness on part of the patient. In IPT, it is understood that patients' hopelessness about life clouds the exploration of possible options for change. Therefore, another major goal of the therapist is to help the patient generate these possibilities for positive change in a nonjudgemental manner. It is important for the patient to try different options for change with significant others to determine the best methods of increasing mood and reducing depression-maintaining situations.

Final Phase

The last few weeks of IPT treatment for acute depression is considered the final phase, or termination. This phase should be discussed throughout treatment. Positive and negative feelings about treatment end are fully explored at this stage.

Sadness about ending treatment is contrasted with the experience of depressed mood. A major objective for termination is that the patient and therapist comprehensively review the gains made during treatment. The changes made in the patients' interpersonal domains are identified as they relate to their depression remission. The independence and sense of control which develops in the patient is recognized. In an effort to sustain these changes, the therapist and patient anticipate events that may potentially trigger depressive symptoms in the future. In these instances, a plan is created and steps are outlined that would help the patient problem-solve in the face of future stressors. There is an option for maintenance therapy sessions based on patient preference. For continuation therapy, sessions are usually conducted weekly for ~8 months, or as needed. Sessions for maintenance therapy have been conducted monthly for up to 3 years. In the instance that the patient has not significantly improved, the therapist helps the patient understand that the treatment has not fully addressed his or her issues and that the patient is not responsible for failing at treatment. A disclosure of other effective treatment methods is made for the patient to consider at this stage.

Efficacy Review

Numerous controlled clinical trials have demonstrated that IPT is efficacious as a treatment for both acute and recurrent MDD. Indications for the utility of IPT have been shown for its modifications, including: depressed adolescents, ante and postpartum women, HIV/AIDS patients, geriatric patients, primary care patients, as well as depressed patients in developing countries. A few contraindications have been found for IPT in clinical trials, including a study which investigated treatment for patients with psychotic depression. Never intended as a treatment for psychotic disorders, this study found that IPT was not effective for patients in the absence of a medication regimen.

Generally, patients presenting for depression treatment with comorbid acute drug use do not receive additional benefit from IPT. This is due to the insight and cognitive focus necessary to fully participate and collaborate with the therapist. Thus, patients with acute drug use disorders are encouraged to seek treatment for these conditions before beginning IPT or another depression treatment. Three clinical trials have failed to show IPT's benefit for depressed patients receiving methadone maintenance therapy or during cocaine abstinence.

IPT trials as well as recent novel applications have been included in the following presentation. However, the following is not a comprehensive report of all the studies of IPT. Yet, it is a selective review of several IPT adaptations. A complete review of studies and their associated authors can be found in the current IPT manual.

Acute Major Depression

The robust effectiveness of IPT was first shown in a randomized 16-week trial comparing IPT and the medication, amitriptyline, for acute MDD. Eighty-one outpatients received IPT alone or in combination with pharmacotherapy, compared against a nonscheduled control treatment. IPT and medication groups

did not differ at treatment end and all monotherapeutic and combination treatments were superior to the control condition. Results demonstrated that the combination treatment (IPT-amitriptyline) was most effective overall. At a 1-year follow-up, patients in IPT condition maintained the benefits of treatment (i.e., improved psychosocial functioning). These results were not observed in the medication condition or at the time of treatment end. This study highlighted the necessity of further IPT treatment following the initial treatment, which was addressed by maintenance therapy, discussed later.

Another study comparing IPT to other therapies was conducted by the National Institute of Mental Health's Treatment of Depression Collaborative Research Program (NIMH-TDCRP). Two-hundred and fifty outpatients with depression were randomized into four groups for a 16-week treatment. Patients received weekly sessions of either IPT or CBT, or were placed on an imipramine regimen. Treatment groups were compared against a clinical management and placebo control condition. At the end of treatment, all patients with less severe depressive symptoms (defined by the Hamilton Depression Scale) improved across all the four conditions. However, patients on a medication regimen benefited from a more rapid improvement in depressive symptoms compared to placebo. IPT and medication were most effective in treating patients whose symptoms were more pronounced. Relapse rates collected at an 18-month follow-up showed that patients who remitted by the end of treatment and were treated with IPT or placebo experienced the fewest recurrences. However, these findings suggest that monotherapies with maintenance treatment may be insufficient for long-lasting recovery.

Maintenance Treatment for Recurrent MDD

IPT was originally developed for a maintenance trial for MDD. A sample of 150 women previously treated for acute MDD with an amitriptyline regimen were randomized into three conditions. Over the course of 8 months, patients received either IPT alone, IPT with amitriptyline, or placebo. After 6–8 months, the benefits varied such that IPT most comprehensively increased social functioning, yet medication most reliably prevented recurrence of a depressive episode. The greatest outcomes were observed from the IPT-amitriptyline condition, which highlighted the benefits of combined treatment for maintenance therapy.

In the longest maintenance trial of MDD to date, 128 outpatients who previously suffered at least three acute depressive episodes were placed in a 3-year treatment study. The patients were randomized into monthly IPT maintenance sessions with or without high-dose imipramine (20 mg), placebo, or regular clinic visits. Results showed that the imipramine dosage proved highly effective in preventing relapse. A significant effect of IPT in preventing recurrence at 1 and 3 years was also observed. These findings demonstrated that monthly IPT sessions were effective in prolonging onset of a new depressive episode in patients with recurrent depression not following a medication regimen.

Depressed Adolescents

When considering treatments for adolescent depression, there is significant concern surrounding the use of medication in

youth. In response, an adapted version of the IPT intervention for MDD in adolescents was created. This modification incorporates parent and school teacher involvement as the therapist sees fit. This adaptation also accounts for salient developmental issues pertinent in the lives of adolescents which may serve to maintain depression (e.g., peer pressure). Practice of skills and interpersonal techniques acquired during therapy are framed as work-at-home, which is contrasted with homework (which may have negative connotations for adolescents).

The IPT intervention for depressed adolescents was investigated in a trial of 63 patients randomized to either 12-weekly IPT sessions or treatment as usual (TAU) in school-affiliated clinics in low-income urban neighborhoods. Supervised social workers who had no prior psychotherapeutic experience administered the IPT after a didactic course. Results demonstrated that patients in the IPT condition experienced the greatest improvements in depressive symptoms and social functioning, as well as significant improvements in problem-solving, evident at 8 and 12 weeks posttreatment.

Late-Life Depression

Patients with late-life, or geriatric, depression have a tendency to report more physical complaints (e.g., pain, bowel problems). It has been estimated that mood disorders are the most prevalent psychiatric disorders in elderly populations, with a staggering suicide rate. To address this growing problem, a 3-year maintenance study was conducted with a sample of geriatric-depressed patients receiving IPT, IPT-nortriptyline, or nortriptyline alone. A number of modifications were instituted, including shortened sessions to optimize attention and comfort of the elderly patients. The inclusion of early-life issues as discussion topics was implemented due to patient interest in addressing lifelong issues. Therapists also used techniques that fostered the acceptance of issues that were not likely solved by psychotherapy (i.e., lifelong experiences of psychopathology). Findings demonstrated that patients' whose quality of sleep improved near the beginning of treatment had an 80% reliability of maintaining symptom improvement for the first year of treatment, across all conditions. The researchers suggested that the greatest gains for functioning were found in the combination treatment group, IPT-nortriptyline, highlighting the benefit of a comprehensive approach to late-life depression.

Depressed Primary Care Patients

In this study of depressed primary care patients, no major modifications of the IPT intervention were necessary. The efficacy of IPT was compared with pharmacotherapy for ambulatory medical patients with MDD. Two-hundred and seventy-six patients were randomized to receive 16-weekly treatments followed by 4-monthly maintenance sessions of IPT, nortriptyline, or regular physician care. Results demonstrated that compared to TAU, patients in the IPT and nortriptyline conditions experienced more rapid improvement in depressive symptoms. At the end of treatment, more patients in the IPT intervention group met recovery criteria compared to patients who received clinical management only. This application found efficacy for IPT in a primary care setting, yet management of symptoms by a psychiatrist in primary care settings

may not be cost-effective. This study supports some recent international efforts to train nurses and other primary care professionals in IPT to address depression in patients receiving ambulatory treatment.

A recent study evaluated the effects of IPT and a selective serotonin reuptake inhibitor (SSRI; Citalopram) with patients with coronary artery disease and concurrent MDD. Five hundred and sixty-eight participants were randomized to 12-weekly IPT sessions and clinical management or clinical management alone and then to either a 12-week regimen of citalopram or placebo. Results demonstrated that IPT did not offer a clinical advantage over clinical management with or without the addition of citalopram.

Ante- and Postpartum Depression

Addressing ante- and postpartum depression with psychotherapy may be an important alternative to a medication regimen. A flexible adaptation for this population was developed which adjusted the time course and session duration of IPT treatment. These modifications allowed for the consideration of child care issues, doctor visits, bed rest, and other logistical concerns. In addition, sessions were able to accommodate breast-feeding with hospital visits and telephone sessions completed as required.

Depressed HIV/AIDS Patients

A modification of the IPT intervention was developed to address the unique needs of HIV/AIDS patients, with special emphasis on issues of death, grief, and role transition. In a 16-week trial, patients were randomized to the modified IPT intervention, a similarly modified CBT intervention, supportive counseling, or supportive counseling with an imipramine regimen. Results showed that, regardless of condition, depressive symptoms were significantly reduced. However, IPT and imipramine alone produced the greatest improvements in depressive symptoms when compared to the other treatments. The focus on the mourning process and navigating life stresses might have been the mechanisms for the robust effectiveness of IPT in HIV/AIDS patients.

Depression in Developing Countries

An adaptation of the IPT intervention was conducted in rural Uganda with depressed community members. Traditional healers expressed that they were not equipped to treat depression where medication is costly and there is an extreme paucity of medical doctors. The adaptation required a 2-week training of local practitioners in a simplified version of the IPT intervention. Treatment length was extended to 18 weekly sessions of 90 min. Maintaining cultural norms, treatment was segregated by gender and completed in groups. Two initial sessions were conducted individually and used to describe the treatment and diagnosis.

One-hundred thirty-seven patients were recruited from 30 villages and allocated to either the IPT condition or TAU (hospitalization for severe cases which involved psychosis or suicidality). At the end of treatment, as well as at a 6-month follow-up, patients in the IPT condition exhibited greater

improvements in social functioning and experienced extensive symptom reduction compared to the TAU. Adaptations of the IPT manual and training of health care workers have been undertaken in Romania, China, Goa, and Japan.

Practical Training in IPT

Several IPT training programs have been assembled across Europe and bring IPT to clinical practice. Accreditation programs recognized by local societies, which incorporate a 3-day workshop and require supervision for at least two treatment cases, have been established in the Netherlands and the United Kingdom.

IPT can be taught through manualized treatments, didactic courses, videotapes, and even telephone supervision. Clinicians with previous experience using psychotherapy can utilize these resources to implement IPT in their individual practices (training media available through verdelih@childpsych.columbia.edu). Yet, supervision is strongly recommended, especially in the context of credentialing programs.

A gap still exists between research evidence and clinical practice for psychotherapy in the United States as only a few training programs in psychiatry, psychology, or social work offer training in IPT.

Jealousy

P N Stearns, George Mason University, Fairfax, VA, USA

© 2012 Elsevier Inc. All rights reserved.

Glossary

Constructivism Theory of emotion that argues all emotions are constructed by society according to its fundamental needs at a time.

Courtly love Literary praise for platonic love, in the fourteenth to fifteenth centuries.

Darwinian psychology Study of emotions from perspective of evolutionary utility.

Dating Informal courtship associated with entertainment outside the home; began to become common, particularly in the United States, after about 1918.

Early modern period Sixteenth to eighteenth centuries in European history.

Freudian psychology Psychology based on the theories of Freud, emphasizing unconscious impulses and their conscious control.

Honor Code of conduct demanded of worthy people.

Open marriage Marriage with approval of multiple sexual partners.

Prescriptive literature Books or articles written to advise people on proper standards of behavior, family life, etc.

Siblings Brothers and/or sisters.

Spock, Dr. Benjamin The leading popular writer on child-rearing in the second half of the twentieth century.

Unwritten law Idea that a man has a right to attack a wife's or fiancée's lover.

Victorian Middle-class culture in nineteenth century Europe and the United States.

Jealousy constitutes the emotional reaction to a real or imagined loss or threat of loss of a valued object, quality or person, to a rival. It is most commonly seen, in modern West European and United States society, in terms of sexual or love relationships, when individuals become jealous of a partner's interest in or involvement with someone else. Jealousy can also arise simply because such interest and involvement are imagined, in which case the emotion helps cause perceptions as well as results from them. Another common instance of jealousy involves relationships among children. At least some forms of sibling rivalry stem from a child's jealous response to the attentions lavished on a new baby, which seem to constitute a loss of parental love for the child himself or herself. A great deal of the scholarly work on jealousy applies primarily to a Western context, including comparisons within the West; but developments associated with globalization are raising new jealousy issues in other societies as well, which amplify the possibilities for comparative work and suggest strong emotional responses to change in gender relations.

Definitions of jealousy in current scholarly literature, at least in the West, routinely emphasize the negativity of the emotion and its relationship to personal insecurities. Other cultures, however, evaluate somewhat differently; so the assessment is best kept more open. Strong emphasis also rests on sexual jealousy, which again may be a culturally limited focus. A larger assessment of jealousy must not only embrace important recent scholarships, but also a wide cultural approach that allows for sometimes unexpected comparisons.

Sociobiologists have hypothesized that jealousy serves a basic function in assuring the paternity of one's offspring, but this tends again to narrow jealousy to a limited focus and to stress male over female jealousy though the latter is quite common; above all, it founders on the fact that many cultures

do not place a high valuation on identifying paternity. Debates over issues of this sort call attention to the continued scholarly tensions in assessing what jealousy is all about.

Problems in Defining Jealousy

Jealous responses vary greatly among individuals in a given culture. Many studies of jealousy, for example, among American college students, reveal such variations. Clinicians, such as marriage counselors dealing with jealousy as a problem in couples, note such variations as well, not only in the United States but also in Germany and elsewhere. A lover's flirtation may be easily tolerated by one partner, while provoking an intensely jealous reaction in another. Some psychological studies in the 1930s hypothesized that variations in jealousy stemmed from different childhood experiences, depending on whether earlier threats of loss were cushioned by emotional support. Many psychoanalysts continue to argue that jealousy experiences in childhood are absolutely unavoidable, but that many individuals suffer losses without support while others learn that loss – for example, a parent's death or a separation from a close friend or relative – may be compensated by other fruitful relationships. Individuals in this second category, according to this argument, will be able to deal with adult threats to affection with little or no jealousy. The explanation is plausible, and many therapists do explore childhood background in dealing with intense jealousy. But no rigorous or systematic correlations have been demonstrated.

Recent psychological research, paying renewed attention to jealousy, has discounted the explicit childhood origins of jealousy. Differences among individuals are vitally important, and indeed new categories extend the differentiation. Thus 'suspicious jealousy,' provoking jealous reactions because of internal

pressures within an individual, is distinguished from 'reactive jealousy,' which responds to a definite threat. But why some individuals are suspicious, and why some react more than others to the same threat, is attributed to broader personality factors and to an overall emotional style that is not easy to explain. Jealousy often results from a larger sense of personal insecurity, an older belief reemphasized in recent research, but here too the ultimate causation problem is pushed back more than accounted for save insofar as it clearly depends on more general traits.

Jealousy is a social emotion. That is, it arises in interactions among people and it affects the way people operate in social situations. Jealousy also depends to some degree on social sanctions. Some cultures tolerate or even encourage jealousy, while other cultures disapprove. The social aspects of jealousy and its dependence on particular cultural contexts have determined much recent research on the emotion, bent on determining jealousy's results in interpersonal relationships and on understanding why jealousy varies and changes depending on place and time. Even psychologists who assume fairly standard emotional reactions thus note different triggers and different responses (jealous Frenchmen get angry, jealous Dutch get sad) depending on cultures.

The most obvious difficulties in pinpointing jealousy, however, arise from the fact that it is an amalgam of a number of emotions, or as one psychologist puts it, serves as a 'blended emotion.' Only a few recent definitions argue that it is a basic emotion. While animals may display something like jealousy – for example, the pet that mopes at the arrival of a new baby or another pet in the household because of a resentment against deprivation of attention, or the male animal that displays aggression against a sexual rival – it is not clear how useful it is to perceive jealousy in humans as an innate response. Again, the considerable variations among individuals and differences in cultural guidelines complicate the issue. Jealousy, when it is intensely experienced, expresses a sense of grief at loss plus anger at the individual seen as responsible for the loss (a lover's lover, for example). It may involve not only anger but also aggression, when the cause of jealousy is attacked either outright or in imagination. Or, like grief, it may occasion passivity, sadness, and self-doubt. Perceived or anticipated jealousy may also embody fear or impending loss. The mixture of emotions and responses involved complicates any easy definition of jealousy itself.

Jealousy is also close to envy. Technically, to be sure, the two emotions are quite different: jealousy involves reactions to loss or threat of loss, and envy a desire to have what someone else has. Envy may lead someone to take something belonging to another, thus causing jealousy. In practice, jealousy and envy are not always distinguishable, and some scholars have found in the twentieth century United States a growing confusion of the two terms. Most Americans, thus, while able to define envy, rarely use the word, terming themselves jealous instead. Teenagers who say they are jealous of so-and-so's hairdo are in fact envious. Their use of the term jealous, however, may be revealing of some new emotional configurations, and thus may be open to explanation. Both envy and jealousy involve hostility, and one major study finds the only emotional difference between them is that jealousy is more intense. The proximity between the terms and the experiences of

jealousy and envy unquestionably add another complication to any definition; again, jealousy is an amalgamated emotional experience.

Jealousy is normally defined as an unpleasant emotion. Certainly it is so regarded in contemporary Western culture. A German therapist writes in the 1980s of "how agonizing, how galling, how unbearable even 'completely normal' jealousy can be. Anxiety, disquiet, and an incessant compulsion to brood about the immediate situation endanger, even prevent, one's ability to conduct one's life as usual." Most commentators on jealousy have similarly noted its potentially consuming qualities. In some cultures, however, jealousy's pain is accompanied by a feeling of invigoration, and jealousy is not regarded simply as disagreeable. This is true in some honor-based cultures, for example. Recent psychological research, turning to the coping mechanisms jealousy generates, begins to turn from the dysfunctional, often violent results of the emotion in certain instances, to potentially constructive translations. Thus jealous individuals have more stable marriages on average than less jealous because they learn how to win the commitment that will allow them to avoid emotional pain. Here too, basic definitions are complex.

Meanings of Jealousy and Methods for Its Study

Some of the complexity of jealousy as an emotional response and potential spur to behavior emerges from consideration of its various meanings. The word in English derived from the same Greek stem as the word for zeal, and at least until recently elements of this definitional linkage persisted. The Christian God, in the West European language versions of the Bible, was a jealous god, which implied resentment of any threats to position – worship of false idols, for example – but also a vigorous defense of legitimate prerogatives. Attached to the divinity, jealousy has obvious positive connotations. Similarly, references to a jealous defense of rights, suggested a commendable and justifiable energy, not a narrow unwillingness to share. Jealousy as a goad to righteous and useful action enters into the usage of the word in many circumstances, although it no longer forms the dominant evaluation.

Jealousy also early acquired its more common meaning, of possessive alertness and response to threat. Jealousy in love was a prominent theme in the courtly literature of late-medieval Europe. Part of the enthrallment with a highly stylized love, according to the troubadours, involved subjection to the woes of jealousy, as suitors (by implication usually male) fended off rivals and coped with the flirtations of their adored.

Jealousy's meaning has also embraced implications of both strength and weakness. Jealous defense of rights, honor, or property – including God's jealous wrath against impure worship – generated strength. Jealousy in these areas was indeed a motivation for forceful action and could be associated with larger virtues of manhood. Jealousy played a considerable role in inspiring defenses of family honor, when men sought to avenge an insult or sexual transgression against a wife or sister which caused the family to lose its appropriate control over female virtue. On the other hand, jealousy has often been associated with pettiness and weakness. Here, the emotion can appear as a last-ditch attempt by enfeebled

people to cling to some object or relationship. Natalie Davis, a historian of France in the sixteenth century, has noted that in appeals for official pardon after a conviction of crime men often argued that they had acted in anger – a clearly aggressive emotion associated with power – whereas women more commonly pleaded that they had been overwhelmed by jealousy, a reaction more suitable for the less powerful gender. In this category too, word usages suggest a considerable range for jealousy's interpretation by individuals invoking the emotion and by other people observing a jealous response.

Jealousy has long served as a literary theme because of its relations to honor and love and because of its capacity to consume those who experience it and on occasion drive them to extreme acts. The dramatic quality of the emotion, in Western culture, extends from the Old Testament to contemporary American films. A mixture of jealousy and envy frequently turned brothers against each other in the stories of the ancient Jews. Shakespeare's *Othello* focused entirely on the insane frenzy generated by groundless jealousy, a cautionary tale against the uncontrollable qualities of the emotion in those whose folly made them susceptible. Some of the same qualities made jealousy a frequent subject for comment by moral philosophers. Thus, the French aphorist La Rochefoucauld opined, in discussing the links between jealousy and love: "It resembles hate more than friendship." Alexander Pope termed the emotion 'hateful,' following the much earlier lead of St. Paul who condemned the effects of selfish jealousy in his comments on marriage.

Other, more scientific vantagepoints for examining jealousy began to emerge only in the later nineteenth century, as an outgrowth of Darwinian interest in considering the evolutionary implications of common emotions. A number of Darwinian psychologists, including G. Stanley Hall in the United States, studied jealous reactions among children or adolescents. The studies generated significant data on jealous responses. They also produced some general claims about jealousy's functions. Most evolutionary theorists argued that jealousy served a purpose in helping to form and defend families, converting romantic or sexual interests into definite commitment because of a fear of rivals or because of reaction to a partner's expressions of jealous concern. Some popularizers added that jealousy helped turn love into marriage. This evolutionary school generally contended that women displayed more jealousy than men because of their role in forming and protecting families from outside threat and because of their own dependence on family for survival.

The rise of Freudian psychology created a second general approach to jealousy, though relatively few Freudians directly commented on the emotion. Freudian beliefs in inevitable competition for parental affection, including the famous Oedipal conflict between a child and his same-sex parent, called attention mainly to aggression and withdrawal. Freudian concern for the early stages of childhood did encourage more direct studies of jealous interactions among young children themselves, though not cast in an explicitly Freudian mold. Further, one writer, Melanie Klein, wrote about the inherent envy of infants toward the mother as giver or withdrawer of breast, formulating a generalized psychological dynamic relevant to presumably universal manifestations of

jealousy. Other scattered psychological research has studied displays of childhood jealousy, seeking to define inherent components across cultures.

The rise of sibling studies in the 1920s and 1930s formed the next major empirical approach to jealousy, focused of course on jealous disputes among young children over parental attention and related material possessions provided by adults. A large number of observations on interactions among siblings and young children piled up empirical evidence about the frequency of sibling jealousy, though one study argued that it was far from normal; more general findings indicated a slight preponderance of girls over boys in sibling strife. The sibling studies related to a larger psychological literature that assumed the necessity of successful management of sibling disputes, on the assumption that these disputes were dangerous to young children themselves and, if unresolved, could produce distorted jealous personalities in later life, incapable of successful personal or work relationships. These extensions of the sibling studies were not, however, scientifically researched. Finally, while sibling research trailed off after the 1930s, a renewed set of studies in the 1980s disputed many earlier findings, calling the research into question methodologically and contesting the findings of frequency. Recent sibling research argues that severe jealousy is far from common among siblings, who often bond quite positively. According to some recent research, the relationship that most regularly produces sibling rivalry (though technically envy more than jealousy) occurs when the oldest child is a boy. Otherwise patterns are quite random and unpredictable and, as noted earlier, not necessarily significant in the late adult response.

After the more concentrated spate of sibling studies in the 1930s, jealousy research has become increasingly fragmented, with few clear lines of inquiry and relatively little theoretical structure. Essays on jealousy have reemerged, particularly from scattered feminists ruminating over their tense relationships with mother or lovers.

These aside, the most frequent inquiries into jealousy in the past 30 years have emphasized its social context or its psychological components, with insufficient bridging between the two approaches. On the social side, some anthropologists have inquired into jealousy patterns in different cultures, though this has not been a major emphasis. Several social psychologists have compared jealousy reactions in various societies on the basis of questionnaire research. Questionnaire research also figured strongly, even before the 1970s, in inquiries into male and female jealousy in dating contexts, particularly among American college students. In the 1970s, when jealousy standards were undergoing considerable revision, both social psychologists and a new breed of sociologists of emotion looked into standard definitions of jealousy through questionnaires and also inquiries in special settings such as communes and other centers of experimental sexuality. The result of this research has been a considerable exploration of widely accepted norms concerning jealousy and also the tensions these norms can produce in cotemporary settings. Finally, two publications in recent years have explored jealousy from a historical standpoint – another largely social and cultural context – and problems of jealousy as a vital theme in modern marriage counseling.

Psychological research has reflected concern for social context; recognizing jealousy as a genuine, if blended, emotion brings attention to cognitive appraisals of jealousy-producing situations, which in turn involves cultural standards. The surge of psychological interest involves more attention to how jealousy fits with other models of emotion, why and how individuals differ, and what strategies are used to deal with jealousy when experienced. Psychological studies of jealousy focus almost exclusively on romance, which raises questions about the emotion's broader scope. They rely heavily on questionnaires administered in laboratory settings, which produce replicable results but also raise questions about actual experience in lived relationships. Some follow-ups on correlations between jealous personalities and marital history begin to bridge the gap in part. In addition to distinguishing among types of jealousy and insisting on the links between jealousy and other emotional responses in an individual personality, the psychological research traces the emotional channels jealousy may take once aroused – anger, withdrawal, embarrassment – and the overall intensities involved. As they move beyond classification schemes, recent studies particularly emphasize the importance of jealousy in producing coping strategies and the potentially fruitful nature of some of the strategies. Jealousy, in other words, remains an active emotion, shaping individual lives and contacts with others. While some responses can be quite dysfunctional, leading to violence or to devastating emotional collapse, others work well in causing individuals to reassess problems, including lack of self-confidence, or in inducing their partners to provide needed reassurance.

Jealousy, in sum, is only beginning to command the kind of scientific interest devoted to a number of other emotions. It has been part of several theoretical frameworks, and research has generated important (though sometimes also disputed) data. The current emphasis on jealousy as part of social interactions lacks grand claims about jealousy's theoretical place in a larger emotional arsenal, but it has produced growing understanding about the evolution of contemporary standards in relation to functional results of jealousy in interpersonal contacts – particularly, in terms of recent literature, among adult lovers, married, or otherwise.

Less attention has been paid to reactions to jealousy, but logically these form an important part of the topic, dependent both on cultural and on personal proclivities. Some cultures encourage signs of jealousy as part of a demonstration of true love – this was part of the courtly love culture of medieval Europe. Modern American culture tends to denigrate jealousy not only as a sign of immaturity but also an attempt to interfere unduly in someone else's relationships or past relationships. The cues for reception of jealousy deserve exploration in their own right and lead logically to comparative analysis.

Jealousy in Comparative Perspective

One of the huge gaps in current knowledge involves any systematic sense of differences in evaluation and uses of jealousy from one culture to another. Yet the fact of such variation is well established, and several larger possibilities invite

attention. Jealousy seems particularly attached to cultures that place strong emphasis on possession of property and, by extension, on women treated as property (and also to identifications of paternity). Less property-conscious societies, such as certain Eskimo groups or the Tahitians, manifest a willingness to share possessions, children (as in common adoption practices with parental consent), even sexual partners (before and sometimes after marriage), in ways that reflect either an unusual absence or jealousy or a distinctive targeting of the emotion. The connection between jealousy and possessiveness is obvious, but the cultural and historical circumstances that generated a rather low level of both have not been probed. Possibly jealousy, for all its potential intensity, is a culturally constructed emotional amalgam that developed rather late in human prehistory – a line of argument that, though speculative, would bear some interesting relationship to a larger constructive approach to emotions.

Among propertied societies, cultures that generate a particular attachment to personal honor also generate unusually fierce versions of jealousy. Jealousy serves as an emotion that motivates defense of honor against threat and also revenge when honor has been violated. In some instances, it seems more freely indulged in upper classes, where honor codes may relate to family power and military prowess, than in the population at large. In other instances, however, jealousy and honor concepts alike spread widely. This seems particularly true in Mediterranean cultures (both Muslim and Christian) and in some of the American cultures heavily influenced by Spain. Thus, a jealous response to affronts to honor or to the sexual purity of a family's women remains particularly vivid in these cultural areas. The quick jealousy of Arab men has often been noted (though not systematically studied), and the frequency of jealousy-derived crimes of passion, directed against sexual rivals, contributes to unusually high murder rates in a number of Latin American and Caribbean societies. Though slightly less marked, a disproportionate rate of jealousy-induced murders in the American South (compared to other regions of the United States, in the nineteenth and twentieth centuries alike) reflects a similar cultural complex. Emphasis on honor generates particular social utility for jealousy. Jealousy, in turn, helps create both the emotional vividness often associated with attacks on rivals and the sustained grievance essential to longer-term campaigns for revenge. Some of these same cultures that elevate jealousy also attempt particular arrangements of controlled seclusion for women, as in traditional Arab cities, in order to express not only the legitimacy of possessiveness in social habits, but also to reduce the occasions for active exercise of jealousy in day-to-day routine.

Recent concerns about the impact of rapid social change and globalization in certain regions create other opportunities for examination of jealousy in comparative context. The significant increase in accusations of infidelity or outright violence against a presumably errant partner (almost always a woman) seem to result from jealous reactions not just to real or entirely imagined actions, but to a broader shift in the economic and educational opportunities for women and to international gender imagery. Jealousy here results from a sense of threat to established gender norms, but it can be deeply experienced by individuals. Even knowingly false accusations,

by involving legal problems and social shunning for women, serve to express this diffuse by intense jealousy. There may be some correspondence here to justifications of violence in the later nineteenth century United States, also the scene of rapid social change and unusually open uses of jealousy in courts of law.

Opportunities for more extensive and focused comparative research, that would more fully explain cross-cultural differences in promptings toward jealousy while also exploring jealousy's role in motivating social patterns, are obviously considerable. A wide-ranging anthropology of jealousy has yet to be offered.

Jealousy and the Law

One point of focus, relevant to comparative analysis of jealousy's social functions, has already attracted some attention. Legal treatment of jealousy, closely related to jealousy's presumed role in actual crime, is an important variable. Informal notions that jealousy's consuming qualities might excuse certain crimes seem to have developed early in Western culture; the link between jealousy and weakness also might have legal relevance.

French courts long accepted jealousy as an excuse for what would otherwise be murder, on the part of men and women alike. The American legal culture of jealousy was slightly different. In the United States, formal allowance for jealousy in the law emerged after 1850. Between 1859 and 1900, about 30 homicide cases invoked what was called the 'unwritten law' in defense of a jealousy-inspired murder of the lover of a fiancée or wife. With urbanization, community sanctions against adultery declined. This provided a context for ingenious lawyers to argue that jealous outrage so legitimately and intensely consumed an offended husband that he was rendered temporarily insane and so not responsible for his acts. As one attorney argued in 1870, "For jealousy is the rage of a man; therefore he will not spare in the day of vengeance . . . Those who dishonor husbands are here warned of their doom . . . Jealousy . . . enslaves the injured husband, and vents itself in one result, which seems to be inevitable and unavoidable." Several trials invoking this new defense were highly publicized, and acquittals often produced extensive popular approval from men and women alike. Women were not allowed the defense; only men could be swept away by this uncontrollable passion in the eyes of the law. Nevertheless, the new interest in jealousy as a legal excuse shows an important connection between law and emotional norms, in a society that was developing new concerns about appropriate sexual behavior particularly for women.

Equally important, however, was the fact that this connection did not prove permanent. By 1900, many state courts were rejecting unwritten law defenses, on grounds that they merely encouraged violence. Jealousy could and should be restrained, according to this new thinking. Some states experimented with compromises between old and new, holding that killings committed in the 'heat of passion' should be regarded as manslaughter, not murder. Several southern states, particularly, continued to grant some tolerance to murders resulting from

momentary but blinding jealousy. But by the 1970s, even southern states were moving away from this thinking. A 1977 Georgia ruling argued that

In this day of no-fault, on-demand divorce, when adultery is merely a misdemeanor . . . any idea that a spouse is ever justified in taking the life of another – adulterous spouse or illicit lover – to prevent adultery is uncivilized. This is murder; and henceforth, nothing more appearing, an instruction on justifiable homicide may not be given.

Clearly, in less than a century, jealousy in the United States had moved from serving as a logical response to sexual infidelity on the part of women, to becoming (if not suitably restrained) uncivilized. This example shows the potential importance of jealousy in influencing not only social norms but also criminal jurisprudence; it also demonstrates the possibility of substantial change, with jealousy open to redefinition depending on larger cultural norms.

Jealousy in Social History: Traditional to Victorian

Much recent work on jealousy, by sociologists, social psychologists, and historians, uses changes in social standards concerning jealousy as a basic frame of reference for dealing with the emotion. Particular attention rivets on the widespread disavowal of the legitimacy of jealousy by the vast majority of middle-class Americans by the 1970s. This disavowal was important, even if a number of the people questioned admitted problems in living up to the standards they believed in. The disavowal was also new, which meant that its emergence requires some essentially historical treatment and explanation.

The earlier history of jealousy in Western society is by no means entirely clear. The emotion had acknowledged function, in relationship to defense of honor and of rights. Its danger was also widely noted, for the potential intensity of jealous passion was extensively criticized. The result, studied most clearly in work on French literature in the early modern period, was a definite ambivalence. While many authors and essayists highlighted the risks of jealousy, others noted its importance to love. As a French courtly love author put it: "Real jealousy always increases the feelings of love . . . Jealousy, and therefore love, are increased when one suspects his beloved." For many West European dramatists in the seventeenth and eighteenth centuries, jealous wives formed an uncomfortable but diverting thread in romance, so long as they were kept within bounds. A few religious writers, finally, tried to reconcile the ambivalence: "There is a just and an unjust jealousy. Just, is with married partners, who mutually love each other; there is with them a just and prudent zeal lest their conjugal love be violated." Unjust love, in contrast, involved loss of control or a suspiciousness totally out of the proportion to any real threat.

The standards of nineteenth century middle-class society in Western Europe and the United States were more clear-cut, though the existence of legal allowance for jealous crimes indicates some ongoing ambivalence. Because concepts of honor declined in middle-class culture, and because greater emphasis was placed on romantic love, jealousy was rethought – and in principle condemned. True love was not supposed to involve

jealousy, for the latter was a selfish and obsessive passion that would only sully the high ground of real romance. Women, particularly, were warned against jealousy, not only of other people but of their husband's work. At the same time, however, jealousy was not seen as a major problem in most instances, and some prescriptive literature recognized that modest expressions of jealousy (mainly from women, now assumed to be particularly liable to jealous reactions) could usefully recall men to their proper attentiveness. Women's focus on domesticity, part of Victorian emphases on 'respectability,' also reduced concern about jealousy.

The Twentieth Century Dynamic: The Sibling Jealousy Crisis

Jealousy began to assume problem proportions early in the twentieth century, and it was at this point that the essential background to contemporary Western standards started to take shape. The outpouring of concern about sibling rivalry that emerged by around 1920 was one index of the new identification of jealousy as a major emotional issue. The leading child-rearing manuals routinely advised that "Few emotions are experienced ... which from a social point of view are more important than jealousy ... The jealous person becomes an object of dislike." A few advice manuals retained a vestige of older attitudes, in urging that a bit of jealousy could be useful as motivation for children. In general, however, the overwhelming message stressed dire warning. "Unless the parents recognize that jealousy will normally appear, and are prepared for it, strong feelings of hostility often develop which continue to make life miserable for both [rivalrous] children over many years," one popular pamphlet intoned.

The same child-rearing materials recommended a number of remedies. Dr. Spock's 1945 bestseller, urging that 'a lot of effort' was essential, summed up the standard advice. Prepare a child for a new baby carefully. Spend extra money on a separate room for each child, and on separate toys and clothes, to reduce jealous potential. Teach grandparents and other visitors not to make a fuss over a new baby, but rather to pay greater attention to the older, jealous sibling. Above all, in various ways, reassure of love, while conveying understanding of any feelings of hostility. "I know how you feel, dear. Come on over and I'll give you a hug and we'll see if that doesn't help." Or, in a similar recommended parental antidote: "I know how you feel; you wish there were no baby; I love you just as always." The goals of these strategies were to prevent outright conflict among children themselves, now assumed to be natural enemies because of inevitable jealousy, and to use wise management of sibling jealousy to prevent jealous personalities in adulthood. These twin goals, regarded as difficult but essential, gave urgency to the parental task. Large numbers of American parents, by the 1930s, dutifully listed their concern about sibling rivalry as one of their chief worries.

The rise of the sibling jealousy campaign is a fascinating chapter in the history of jealousy. The emotion was hardly new, but it had never before been identified with such anxious fervor. Two factors prompted the change in outlook. First, shifts in family life may actually have heightened jealousy among young children. The decline in the birth rate, the

disappearance of adults other than parents from the normal household, and emphasis on intense maternal affection may well have created more childish anxiety about the arrival of a new sibling than had been common before. Even more obviously, adults grew more hostile to the potential impacts of jealousy in their lives and more impatient with signs of the emotion in their children; hence, the acceptance of a major socialization effort. The sibling campaign itself became more routine by about the 1940s in the United States. The inevitability of traumatic jealousy among young children was downplayed, but at the same time, more parents took for granted the need for some of the reassurances that their own parents needed to be taught. Efforts to prevent jealous personalities through careful child-rearing on the whole continued.

The sibling jealousy crisis forms a vital link in examinations of jealousy that blend an understanding of common emotional tensions with cultural context. Although contemporary psychological experts are confident that their more relaxed view of sibling jealousy is more accurate than the near-hysteria of the 1930s, full exploration of sibling interactions remains to be accomplished. Also important, and as yet undone, is comparative work. There is evidence that large families generate less sibling rivalry than small, because in the former, children band together against parents rather than competing with each other for parental favor. This finding has both cross-cultural and historical significance, given changes and variations in birth rates and family size.

Adult Jealousy: New Standards

In the United States and Western Europe, concern about sibling jealousy was closely linked to an unprecedented attack on the emotion in adult relationships. Marriage counselors, for example, almost uniformly urged against jealousy by the 1920s. "Jealousy kills love. It is a symptom of weakness and of selfishness. Wanting a suitor, or a wife, or a husband to pay exclusive attention to one has nothing in common with real devotion." Or in another marriage-expert sally: "We may even blight and blacken our happiness by jealousy, which is really an admission of our own inferiority, of our own cowardice and conceit." Accepted wisdom now held that adult jealousy, almost exclusively defined from the 1920s onward in terms of love relationships, resulted from inadequate childhood socialization: jealousy was immature.

These new standards had two major sources. First, while their intensity of concern and the attribution of immaturity were new in the twentieth century, the idea that jealousy marred love had developed in the nineteenth century, with some roots even earlier in Western culture. Second, the growing attention paid to jealousy followed from a decline in the domestic seclusion of women. With women participating increasingly in coeducational schools, politics, work (albeit as inferiors to men in most respects), and leisure activities, jealousy reactions almost had to relax in Western Europe and the United States. Add to the increasing interaction between men and women a growing interest in sexual expression – another development taking shape in the 1920s – the need to encourage adults to play down jealousy became virtually essential from a functional standpoint. Young men and women who

began to date fairly regularly, with a considerable variety of partners, were thus urged to avoid jealousy or to conceal it if avoidance broke down. Married couples who began to socialize more informally, with more interactions with the spouses of others, earned the same advice. Here was the context for the considerable outpouring of popularized advice, in books directed toward young people and in popular magazines: "Jealousy is a terrible emotion, one of the extreme forms of psychological cruelty." This was the context, also, for the shifts in criminal law, which assumed that jealousy could and should be controlled even in extreme provocation.

The general trend toward firm prescriptions against jealousy gained additional ground in the 1960s, when sexual standards in Western society loosened further. Many experimental sexual situations, including 'open marriage,' were predicated explicitly on an ability to keep jealousy under wraps. Urging a variety of sexual partners, advocates of open marriages noted that "Jealousy has no place in open marriage. The fact that it is so prevalent in closed marriage does not mean that love and sex must always be accompanied by this dark shadow." Couples in open marriages or visiting promiscuous reports – couples interested in what 1960s Americans called 'swinging' – were taught strategies to deal with unwanted jealous impulses, including wishing their partner a good time as he or she went off for an evening with someone else. Jealousy workshops opened in several American cities, directed to the upper middle class and designed, according to their founders, for "those who are strongly motivated to outgrow jealousy."

Most adults in the West did not, of course, participate in the most extreme sexual experiments. Some of those who did found themselves sorely tested, caught between their cognitive belief that jealousy was immature and the fact that they felt very uncomfortable with a partner's 'swinging.' Jealousy increasingly produced shame: one woman told a sociologist, "I think it comes from possessiveness and I'm trying to grow away from that." Most middle-class Americans, if they felt jealousy at all – and polls taken in the 1970s suggested that about a third really did not experience much sexual jealousy – sought to minimize it or to deny it. A comparative study revealed that Americans were far more likely to try to conceal jealousy than were West Indians, Asians, or Africans. Women were a bit franker than men in discussing jealousy problems that cropped up despite good intentions. American male culture urged at least a claim of superiority to jealousy, along with vigorous resentment against jealous, nagging women. Women's culture was a bit more ambivalent, and concern about men's infidelity was correspondingly considerable. The vast majority of middle-class Americans, both male and female, professed to find jealousy uncivilized and unacceptable. There was no significant gap between the standards urged in emotional advice literature and those disclosed by adults. And while American jealousy was particularly examined in this regard, every indication suggests that a similar middle-class culture had developed in Britain, Germany, and elsewhere. Indeed, the proscriptions against admitting jealousy even in cases of outright adultery may have been even greater in European society than in the United States, in the wake of the sexual revolution of the 1960s.

The development of new and strongly disapproving standards for jealousy, and indications that many people internalized these standards, color most of the research and comment

on jealousy in recent years. The historical approach permits some understanding not just of what the current standards are, but also of how they developed and what caused them. The current standards themselves, however, raise at least four additional questions essential to a wider understanding of jealousy as a social emotion:

1. Has the evolution of jealousy standards in the West been matched by changes in other cultures? The scant comparative work available suggests that contemporary Western efforts to evade jealousy are unusual, but no full exploration has been ventured. The rise of jealous outbursts in some contemporary societies suggests the impact of differential timing in social change and its emotional impact. A few psychologists claim to find basic uniformities in sexual jealousy across culture, but the data are limited.
2. Within Western society itself, have the jealousy standards been as widely accepted in fact as in principle? Here the answer is clearly negative. Groups outside the middle class may not fully accept the disapproval of jealousy in the first place – though subculture differentiation has not been explored systematically. Gender differences are also salient. American women use jealousy to terminate a relationship more often than men do, and they (surprisingly) more commonly seek to reinforce loyalties to deal with their jealousy. A variety of evidence suggests that if middle-class people themselves of both genders experience a jealousy of which they disapprove, their guilt or embarrassment in some instances actually complicates their reaction, making constructive adjustments more difficult. This is an important theme in marriage therapy, and it is a struggle that a number of individual writers (mainly women) have also documented, in dealing with their extremely complex reactions to what is even by itself a troubling emotion. It is probable that fewer people feel intense jealousy than was the case a century ago, at least in comparable behavioral circumstances; altered standards do correspond in part to altered emotional experience. Nevertheless, the very disapproval of jealousy makes reactions to it – always somewhat diverse – both subtle and difficult.
3. Has the twentieth century culture persisted since the 1970s? Some popularized literature by the 1980s, at least in the United States where fear of AIDS and correspondingly enhanced sexual conservatism ran particularly strong, suggested that jealousy might again become more acceptable as an emotion useful in defending sexual fidelity. Psychological research on jealous personalities and on successful coping strategies returns attention to the important role jealousy can play in mature relationships. It is certainly possible, given what we know about the frequent oscillations in cultural standards applied to jealousy and their dependence on larger social functions, that more public acknowledgement of at least limited utility for jealousy is developing. But the prospect, however logical, remains uncertain.
4. What has happened to jealousy in other contexts? Modern Western culture, beginning in the nineteenth century, increasingly associated jealousy with love – love for parent and expectation of parental love in return, love of suitor or spouse. The decline of explicit recognition of jealousy in

relation to wider concepts such as honor paralleled this narrower definition. But jealousy relates to other relationships as well, and here scattered findings suggest some interesting manifestations in recent decades. It is, further, possible (though not proved) that as jealousy was combated in romance, individuals who experienced it might seek other outlets. Jealous children, for example, were urged explicitly to turn their attention to a new toy or some other material possession. This could serve as the basis for later jealous competitiveness in consumer interests, with individuals relieving an unacknowledged jealousy by trying to surpass others through acquisitions. Jealousy in school and work formed other expressions, providing emotional spur to a sense of rivalry. Many school children, eager to claim in interviews that they had outgrown sibling jealousy at home, more freely expressed jealousy of classmates' looks, athletic prowess, or good grades. Work authorities generally urged that jealousy be downplayed in the interests of smooth bureaucratic functioning, but jealous rivalries were common.

None of this was necessarily novel, and again a full exploration of contemporary jealousy outside romance has not been attempted. The apparently growing confusion, in normal speech, between envy and jealousy was nevertheless significant in this context. The jealousy that was most freely admitted – of school or work rivals – was in fact primarily envy – that is, resentment of something someone else possessed. But perhaps because Americans sought outlets for jealousy, perhaps because they viewed certain expectations as such an intimate part of their person that another's achievement provoked a sense of threat or loss, and hence real jealousy, the increasing confusion of envy with jealousy was exceedingly suggestive. Here, evaluation of the meaning of jealousy may be a central ingredient in understanding contemporary emotional life and definitions of self. In using the term jealousy for their reactions, some Americans may have heightened the emotional charge of their reactions to other people's possessions or attributions.

Conclusion

Jealousy is a complex emotional amalgam. It can be overpoweringly intense, even compulsive in some instances, particularly in societies that find some jealousy functional and that value emotional intensity generally. It plays a direct role in motivating certain behaviors, including violence, and several forms of rivalry. It may also motivate a desire to excel competitively, though this is not clearly acknowledged in contemporary American culture. The emotion is social, in that it takes shape in social relationships. It is also social in its dependence on social or cultural norms for its frequency, its vigor, and its manifestations. Variations in jealousy, ranging from qualified approval to blanket hostility form a vital part of understanding the emotion in terms of particular cultures and also in terms of significant changes over time. It is also true, however, that within any given culture jealousy is clearly variable from one individual to the next. Societies that encourage some

jealousy encounter diverse response, with some individuals being less jealous and more forgiving than they are 'supposed' to be. Contemporary Western society, that rigorously discounts the emotion at least in love relationships, certainly generates variety, from individuals who apparently experience no sexual jealousy, to people who experience jealousy but manage to conceal or displace it, to people profoundly troubled by their inability to live up to what they recognize is a widely shared emotional norm. The same standards often influence researchers' assumptions about the motives and causes of jealousy.

Clearly an emotional variable, jealousy can be understood in large part through the various social functions it serves, and the disadvantages it entails. Cultural divergences and significant changes in these social formulas provide the most explicit entry to jealousy's meaning beyond their purely individual level. Jealousy's obvious mixture of several discrete emotions helps explain the different roles it can provide, and the different kinds of action – from dire revenge to embarrassed self-doubt to a recementing of a threatened relationship – it can generate.

Glossary

Availability heuristic The tendency to judge the likelihood of an event based on the ease with which exemplars of the event are accessed in memory.

Framing effects A situation where the perceived value of an outcome is influenced by details associated with, but not directly related to, the outcome.

Gain-loss asymmetry The tendency for the psychological value of a loss to be perceived as greater than the value of gaining exactly the same amount (the absolute value of losing \$100 is greater than the value of winning \$100).

Heuristics Quick mental shortcuts used in problem solving that simplify processing of complex information, but can produce cognitive errors due to oversimplification.

Psychophysics Techniques and tools intended to reveal the relationship between the size or intensity of physical stimuli and the resulting mental representation.

Representativeness heuristic The tendency to judge the likelihood of an event based on the degree of similarity between the event and internal exemplars of the event.

Signal detection theory A widely used model describing the mechanisms underlying our judgments, based on signal and noise distributions that are represented by bell curves and a decision criterion.

Temporal discounting The tendency for delayed outcomes to be viewed as psychologically less valuable than if they were to occur immediately.

Making judgments about stimuli and events is a critical component of mental life. Whether we are judging the speed with which we are approaching the car in front of us or attempting to judge the likelihood that the defendant in a murder trial is guilty, making a judgment requires that we collect information, evaluate it, and make a decision about how to respond to this new information. For example, a person who hears an unexpected noise while walking home on a dark night must judge whether the sound was threatening or simply unexpected. The psychological interpretation of this event is dependent both on the characteristics of the stimulus and the context surrounding the event. A person walking home from a relaxing dinner party with friends will react differently to an unexpected noise than will an individual returning home from watching a thriller/horror movie. This process of input-and-evaluate information within the current context occurs across all levels of human cognition.

Experimental psychologists interested in mental information processing (cognition) commonly distinguish between lower level processing that includes such things as sensation, perception, and attention, and higher level processing mechanisms that include decision making and problem solving. Quite often, principles that constrain lower level mechanisms are also relevant for higher level mechanisms. This similarity across levels is particularly relevant to our understanding of judgments about events. To illustrate this point, consider the well-known Ebbinghaus illusion depicted in [Figure 1](#). The disk surrounded by smaller disks (upper left) is *physically* the same size as the disk surrounded by larger disks (lower right), but *perceptually* their sizes are different. The Ebbinghaus illusion compels us to conclude that perceived size is a function not just of physical size, but the stimuli surrounding the target item (context).

The role of surrounding stimuli can be extended from lower level perception to describe such higher level concepts as the perceived size of monetary rewards. For example, how would

you feel about a 1% raise in salary? Before deciding, you might first investigate the raises given to your colleagues. You would probably feel slighted if most of them were given a 2% raise. However, if you later discover that a friend from the neighborhood did not receive any raise at all, you might suddenly feel better about your 1% raise. Just as with the Ebbinghaus illusion, the perceived size of the raise depends not just on its actual magnitude, but on additional surrounding information. The remainder of this article will consider the mechanisms involved in lower level perceptual judgments and then move on to higher level judgment heuristics.

Psychophysics

Imagine that you were helping a friend move from one office to another, during which you were straining to hold up one end of a heavy desk. Would you notice any difference in weight if someone dropped a stick of gum on the desk? On the other hand, would you notice the extra weight if the stick of gum were dropped onto an exam booklet you were holding? Although the weight change is the same in both cases, you would be less likely to notice it when added to the desk than when added to the exam booklet. In the late nineteenth century, Ernst Weber looked at whether people could distinguish between the weight of one object and another that weighed about the same. Small weight differences were undetectable if the magnitude was less than what Weber called a just noticeable difference (JND). As can be seen in the example of the desk and exam booklet, JND varies along with context; a weight change that is unnoticeable when added to a heavy object might be noticeable when added to another, lighter object. Thus, JND does not have a single fixed value, but is better expressed as a ratio. When holding one object, an addition of about 1/40 of the original object's weight is just noticeable.

Figure 1 In the well-known Ebbinghaus illusion, the disk surrounded by smaller disks and the disk surrounded by large disks are physically of the same size, but they appear to be of different sizes.

A contemporary of Weber's, Gustav Fechner was working in the tradition of René DesCartes, the mathematician and philosopher who had proposed that body and mind are composed of two different kinds of stuff. Whereas physical things can be felt and measured, it seems incoherent to ask how big or how heavy is a mental entity such as the idea of a chair. While Fechner agreed with DesCartes' assertion that the physical and mental worlds are distinct, he sought to discover the relationship between the two, and referred to the science that he inaugurated as 'psychophysics.' Fechner recognized Weber's work as a key contribution to his project, and formalized Weber's findings into a mathematical equation that has become known as Fechner's law: $S = k \log R$. Here S represents the sensation, R represents the strength of the physical stimulus, and k represents a constant. In other words, perceived intensity does not increase linearly with the intensity of the physical stimulus, but increases less quickly (the law of diminishing returns).

Upon becoming acquainted with psychophysics, it is tempting to think of JNDs as sharp boundaries such that we either sense a stimulus or we do not. In fact, the boundary between those stimuli that are easily sensed and those that are never sensed is surprisingly fuzzy. In an experiment, a psychophysicist will select several levels of a stimulus that lie very near participants' JND threshold. For example, participants might be asked whether they sense a dim light, hear a quiet sound, feel a flower petal falling on their skin, taste any sugar in a weak solution, or smell a drop of perfume. Some levels of the stimulus will reliably induce a sensation and others will reliably fail to induce a sensation. In between these extremes, the tendency to sense the stimulus typically increases smoothly along an S-curve, as depicted in Figure 2. Because there is no sharp break-point along this curve, threshold is often defined arbitrarily as the intensity of stimulus that was sensed 50% of the time.

Signal Detection Theory

One way to think about this fuzzy boundary might be to imagine carrying on a conversation at a crowded cocktail party. While concentrating on your own conversation, would you notice if someone in another conversation said your name? The background noise would mask the sound of your

Figure 2 The likelihood of detection between stimuli that are never sensed and stimuli that are easily sensed increases smoothly along an S-curve; the threshold of detection is often defined arbitrarily as the stimulus intensity that is sensed in 50% of trials.

name so that you would not always notice it. In the cocktail party example, 'noise' refers specifically to random auditory information, but to someone interested in signal transmission 'noise' refers more generally to any random activity. Because some neural activity will always be spontaneous, there will always be uncertainty in our sensory judgments. Nevertheless, in some cases we are more sensitive than others. During the Second World War, radar engineers developed methods for determining the sensitivity of signal transmission devices. After the war, psychophysicists realized that these tools and techniques could profitably be used to describe sensory judgments.

To see how signal detection theory applies to sensory judgments, consider the case in which someone at the cocktail party has actually said your name, creating a signal to be detected among the chatter. In this case, sometimes your name clearly pops out from the background, and at other times it is obscured. If we could count the number of times that a signal is easily detected, the number of times that it is obscured, and the number of times that it comes somewhere between the two extremes, a resulting frequency plot would look like a bell curve; extreme values are relatively infrequent and moderate values are relatively frequent. What about if nobody has said your name, so that there is not actually a signal to be detected? Even in the absence of a signal you might feel as if you hear your name embedded among the chatter (most people have experienced thinking they were called or heard their name when it was not actually spoken). As with the signal case, sometimes you can clearly hear your name among the noise, sometimes you cannot, and sometimes the sound of your name lies between the two extremes so a resulting plot also generates a bell curve. In Figure 3(a), the x-axis represents how clearly your name can be discerned so that at high values your name is clearly heard and at low values it is not heard at all, and the y-axis represents the proportion of times when a given level of clarity occurs. Because the mean of the signal distribution is higher than the mean of the noise distribution, your name is more often heard when someone actually did say your name (signal) than when nobody said your name (noise). The means of the signal and noise distributions depend on the strength of the signal relative to the strength of the noise. Thus, at a rowdy party, the mean of the signal distribution just slightly exceeds the mean of the noise distribution (Figure 3(b)), but at a quiet dinner party the mean of the

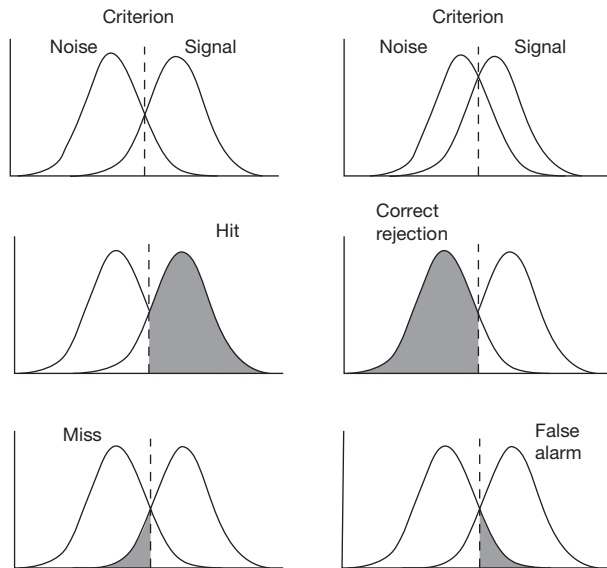

Figure 3 Signal and noise distributions, and a criterion set halfway between the means of the signal and noise distributions. When signal and noise distributions overlap slightly (a), sensitivity is relatively high, but when there is more overlap (b), sensitivity is relatively low. (c, d) The sensation matches the physical stimulus, so that a signal is detected (hit), or the lack of a signal is not detected (correct rejection). (e, f) The sensation does not match the physical stimulus, resulting in an error. Either a signal is not detected when one is present (miss), or is detected when none is present (false alarm).

signal distribution greatly exceeds the mean of the noise distribution (Figure 3(a)). The amount of overlap between signal and noise represents how sensitive you are to the stimulus: as the overlap between signal and noise increases, sensitivity decreases. These distributions represent how your ears transmit a signal to your mind, but how do you decide whether anyone has said your name?

To make this judgment, you need to set a decision cutoff or criterion along the x -axis so that you will respond as if you heard your name in all cases that exceed the criterion, and respond as if you did not hear your name in all cases that fall below the criterion. While the distributions are determined by factors outside your control (e.g., the strength of signal relative to noise), you get to decide where to set the criterion. Where should you place it? A reasonable place to start might be halfway between the means of signal and noise, but a more prudent method for determining where to place the criterion must acknowledge the fact that every criterion will cause errors and that some errors are more costly than others. If we set the criterion halfway between the means of signal and noise as in Figure 3, notice that generally, but not always, the criterion will allow you to make the right decision. That is, most of the signal distribution exceeds the criterion and most of the noise distribution falls below the criterion. Noticing a signal when it is present is called a hit (Figure 3(c)) and failing to notice a signal when it is absent is called a correct rejection (Figure 3(d)). Unfortunately, sometimes you will make an error. Failing to hear your name when it has been said is called a miss (Figure 3(e)) and hearing your name when it has not actually been said is called a false alarm (Figure 3(f)). If signal

and noise overlap at all, it will be impossible to eliminate both sources of error. Because the costs of errors are often not equal to each other, a judicious placement of the criterion will reduce the more costly type error while allowing the less costly error to occur more frequently. In everyday life, the effect of changing criteria can be seen when an individual anxiously awaiting news of an upcoming promotion reacts to every occurrence of words sounding similar to his/her name (high false alarm rate) while a coworker anxiously engaged in conversation with a coworker fails to hear another colleague calling his/her name (high miss rate).

A vivid example of differential criteria can be seen in the criminal justice system in the United States. Police officers often gather evidence that leads them to suspect that some person was the perpetrator of some crime. Because no piece of evidence is perfectly reliable, even in the face of apparently iron-clad evidence a suspect may be innocent. Nevertheless, a police officer would likely think that a guilty person evading capture (i.e., a miss) would be much worse than arresting an innocent suspect (i.e., a false alarm). Police are typically reputed to set their criteria accordingly low. In contrast to police officers, the judicial system is built on the assumption that falsely incarcerating an innocent person is much worse than letting a guilty person free. That is, the courts have an opposite view of the relative cost of errors such that false alarms are worse than misses. For the courts, the relatively high criterion is enshrined in the well-known maxim that people are presumed innocent until proven guilty beyond a reasonable doubt. By this example, we can see that, while signal detection theory is most commonly associated with low-level cognition, it also describes our most exalted and important judgments.

Higher Order Judgments

The preceding sections discussed the process of making psychophysical judgments about sensory events. The processes of making judgments about sensory information frequently take place on an automatic, subconscious level. For example, it is difficult to describe how a baseball player correctly judges the angle and speed of an incoming ball, but the high level of accuracy with which the ball is caught indicates the ability to make these decisions. However, judgment also plays a significant role in higher level cognition for subjective outcomes such as monetary gains or losses, social interactions (who would make a good friend or mate), and physical activities. Economists often refer to the values calculated through judgments concerning these types of subjective outcomes as *utilities*. The process of calculating utilities for possible outcomes is a critical step in the decision-making process.

Similar to the workings of Fechner's Law of Psychophysics, Kahneman and Tversky's Prospect Theory demonstrates that the law of diminishing returns applies to utilities. According to their model, as the absolute magnitude of the outcome increases, the rate of change in psychological value decreases. For example, consider the change in perceived value (utility) as a monetary gain changes from \$0 to \$10 compared to the change in value from \$1 000 000 to \$1 000 010. In both cases the value changes by \$10, but the change seems more

Figure 4 Kahneman and Tversky's utility function demonstrates that both gains and losses show decreasing rates of gain in psychological value as the absolute magnitude increases. The gray box demonstrates that the loss function in the lower-left quadrant has a steeper slope than gains (upper-right quadrant).

significant when going from \$0 to \$10 (see the top section of Figure 4).

The negatively accelerating shape of the value function has two important implications. First, the larger the outcome being evaluated, the greater the change that is needed to produce a similar psychological change in value to that seen for smaller outcomes. To best understand this, consider the following choice situation:

- (a) A TV costs \$500 at a store 1 mile from your home.
- (b) The same TV costs \$450 at a store 5 miles from your home.

Given the choice between (a) and (b), would you be willing to drive the extra distance to save \$50? Most people would be willing to do so. Now consider the following:

- (c) A computer you want is advertised for \$1500 at a store 1 mile from your home.
- (d) The same computer is advertised for \$1450 at a store 5 miles from your home.

Would you drive the extra four miles to save \$50 on the computer? While the savings for driving farther is the same in both scenarios, more people are willing to drive further to save \$50 in the first scenario than in the second scenario. The observed shift in preference is due to the difference in relative value between the outcomes; that is, in the first scenario the discount is a larger percentage of the overall cost of the item. In order for the two scenarios to be viewed as similar, the difference in price between (c) and (d) would have to be greater (say \$1500 and \$1350).

A consequence of the shape of the value function is that the presentation of 'bundled' outcomes is viewed as more valuable than presenting the same absolute magnitude as a single outcome. Imagine the choice between receiving two \$500 checks or a single \$1000 payment. While both options result in a net gain of \$1000, due to the shape of the value function, the summed value of the two \$500 outcomes is perceived as greater than that of the single payment.

A second characteristic of the typical value function (as shown in Figure 4) is that a similar value function describes negative utilities (losses). Similar to the curve for gains, the value function for losses is negatively accelerating such that the difference in perceived change between a loss of \$10 compared to no loss is greater than the change experienced between a loss of \$1 000 000 to a loss of \$1 000 010 (see the bottom-left section of Figure 4). As with gains, the bundling of losses produces larger perceived losses than a single loss (receiving two \$500 fines is perceived as worse than a single \$1000 ticket). However, while the gains and losses curves are similar in shape, they are not symmetrical. A critical difference is that the absolute value of losses is typically about two times greater than for gains (this difference is illustrated by the shaded gray box in Figure 4). The asymmetry in the valuation functions for gains and losses is often summarized as: losses loom larger than gains (or gain-loss asymmetry).

The principle of gain-loss asymmetry is illustrated in the following gamble: Imagine that a fair coin is flipped into the air. If the coin falls on heads, the player wins \$100. If the coin lands on tails, the player loses \$100. Would you play this game? You would be in the majority if you declined. However, according to standard economic theory, the outcome of this gamble should be viewed as neutral, producing a feeling of indifference toward the gamble. Indifference is predicted because the chance of the coin landing on heads, and thus paying \$100, is the same (50%) as the chance of the coin landing on tails, thus costing \$100. Most people, however, do not view the gamble as neutral. Rather, due to the increased psychological attention paid to losses, the possibility of losing \$100 outweighs the potential benefits of winning \$100. As losses are typically viewed as twice as significant as gains, the outcomes in the 'coin-flipping' procedure described would have to be around \$200 for a heads compared to \$100 for a tails before preference would start shifting in favor of the gamble.

A third major characteristic of utility judgments is that they are strongly influenced by a reference point. When asked to judge the magnitude of an outcome, the process does not start from 0 and move up or down accordingly, but rather participants start from their current perceived wealth and adjust from this point. To illustrate this, consider the following two situations:

- (i) You are originally told that you were selected to win a \$1000 prize, only to learn later that the actual value of the prize is \$500.
- (ii) You are originally told that you were selected to win a \$250 prize, only to learn later that the actual value of the prize is \$500.

Note that in both (i) and (ii) you are experiencing a gain of \$500. However, the reference point for the two situations is very different. For (i), your reference point is set at \$1000 so that the actual \$500 prize is perceived not as a gain, but rather as a loss. In (ii), your reference point was set at \$250 so that the change to \$500 represents a financial gain. In practice, people would write in protest to the sweepstakes over (i) while bragging to friends about their good fortune in (ii).

The role of reference points in making psychological judgments is best understood through the *framing effect*. Framing

occurs when information associated with, but not directly relevant to, an outcome influences its perceived value. For example, choices (i) and (ii) above should be viewed as identical, as both produce a financial gain of \$500. However, due to the information surrounding the outcomes, the \$500 outcome is viewed differently. Similarly, a medical procedure that is 97% successful is not viewed as identical to one that is 3% unsuccessful, despite the fact that the two are mathematically identical (the use of success rates focuses attention on positive outcomes while talking about the number of unsuccessful surgeries puts the emphasis on possible losses).

In summary, the three major characteristics of Kahneman and Tversky's *utility curve* are (1) negatively accelerating curves, (2) the slope of the losses curve is steeper than the curve for gains, and (3) judgments start from subjective rather than absolute reference points.

Judgments and Decision Making

Determining the value, or utility, of an outcome is the first step in decision making. When evaluating between two possible outcomes, the active decision-maker has to form a judgment of the value of each choice items before a comparison can be made between the items. When the items are similar along all but one dimension, this process requires very little effort. For example, if deciding between two vehicles that are completely identical (same price, financing, features, color, and so forth), except one is held by a dealer that is 5 miles away and the other is 10 miles away, it is easy to choose which to purchase: the vehicle that is held by a nearby dealer. Unfortunately, it is rare that choice outcomes vary along a single dimension. Instead, most decisions require some form of integration across multiple dimensions. When we seek to purchase a new vehicle, the available vehicles typically differ in cost, financing, color, options, and so forth.

In order to compare outcomes that differ across multiple dimensions, the decision-maker must simplify the elements into a single value judgment. Judgments of value across commodities that differ along multiple dimensions often involve two processes: (1) reducing cognitive load by ignoring highly similar or subjectively less important dimensions and (2) weighting the remaining dimensions and computing a 'value' estimate.

When computing the value of a multidimensional outcome, those characteristics that are shared across choice outcomes and/or those that are viewed as personally unimportant are ignored. For example, most modern cars come with floor mats, power steering, and a heater, so these shared characteristics are not considered when evaluating possible auto purchases. Modern vehicles also come with many different engine sizes and characteristics. As many consumers are unfamiliar with the role of torque and horsepower, they frequently ignore this information as they focus on better understood features such as fuel efficiency. The process of ignoring shared or subjectively irrelevant information can be viewed as a form of mental economy. Unfortunately, this gain in mental efficiency may be offset by losses in quality due to undervaluing important dimensions; the consumer who lives in a mountainous area may find they made a poor choice in automobiles

when they select a vehicle with a small, light engine over a more powerful, heavier engine, despite getting better fuel economy than the smaller vehicle.

After selecting which information is deemed relevant to determining the value of the outcome, the value (or utility) is calculated. While several theories (prospect theory, expected utility theories) present detailed mathematical models for calculating the utility of an outcome, they all take the general form of:

$$V = \sum (w \times v)$$

In this equation, V is the value of the outcome after summing across the perceived value, v , of each outcome times the weight, w , attached to each of the possible outcomes. The product of this mental arithmetic is the psychological value of the outcome. This process is repeated for each exemplar in the choice situation (each car under consideration for purchase) and then a decision is made after comparing these values. Like most psychophysical judgments, the weighting of characteristics and calculation of value often occur outside of conscious awareness. Often a decision-maker can identify which exemplar they prefer, but is unable to identify the 'why' behind this preference.

Judgments Concerning Probabilities

While decision weights are often subjective, studies using risky choices (situations where both the outcome and the probability of the outcomes are known) demonstrate how decision weights, like value judgments, are often nonlinear. When making risky-choice judgments, the expected value of the outcome is equal to the absolute value of the outcome multiplied by the probability of the outcomes occurrence. If decision-makers weighted probabilities linearly, the outcome of the probability weighting decision would be equal to the outcome's expected value. However, the actual decision weights assigned to outcomes differ significantly from the mathematical prediction of the expected value due to nonlinear weighting of probabilities.

When evaluating probability, decision-makers tend to overweigh the extremes while changes in value for mid-range probabilities are underweighted (see [Figure 5](#)). For example, people are willing to engage in very low probability behaviors, such as purchasing lottery tickets, due to the fact that the small chance of winning is overvalued. At the other end of the spectrum, people are hesitant to select an option that involves a small risk over a less preferred option that comes with a guarantee.

Judgments Concerning Delays

Just as changing the likelihood of an event's occurrence changes the judgment weights attached to the outcome, so does changing the time until the outcome's occurrence. In general, increasing the delay to the occurrence of an outcome decreases the perceived value of the event, a phenomenon known as temporal discounting. For example, a \$100 check you receive today is worth more to you than a \$100 check you are scheduled to receive in a month. A frequently used model (though it is important to note that both economics and

Figure 5 When determining the value of probabilistic outcomes, the weight given to probabilities is not linear, as shown in the black S-curve shown here. The straight gray line shows the expected change if probabilities were evaluated linearly. Note that the curve is sharpest at the low and high end of the x-axis, indicating greater weight for these probabilities compared to the relatively flat middle of the curve.

psychology include other mathematical models of the relationship between delay and value) that describes this relation is

$$V_p = \frac{A}{1 + kD}$$

In this model, the current value, V_p , of a commodity is a function of the absolute value of the commodity, A , divided by the number 1 plus the free parameter, k , times the delay to the outcome's availability, D . The number 1 in the denominator allows the delayed value of the commodity to approach the absolute value of the commodity as the delay approaches 0. The free parameter k is included as an individual index of temporal sensitivity. The larger the value of k , the greater the reduction in value as the delay is increased. The k parameter is typically referred to as the discount rate.

A unique characteristic of the hyperbolic discounting model is that the rate at which the commodity loses value decreases as the length of the delay increases. For example, with a discount parameter of $k = 0.1$, a commodity that is worth \$100 today would lose 9.1% of its value after a delay of 1 day, 8.3% between day 1 and day 2, and 7.7% between day 2 and 3. The decreasing rate of discounting as delay increases can help provide a logical explanation to seemingly irrational preference reversals often seen in human choice (such as preferring not to order dessert before arriving at the restaurant but actually ordering dessert at the end of the meal, and preferring the long-term results of good grades but choosing to attend parties rather than study).

In order to understand the role of discounting in preference reversals, consider the following two choice options:

- (a) \$100 available in 100 days
 - (b) \$80 available in 80 days
- and
- (c) \$100 available in 20 days
 - (d) \$80 available now.

Figure 6 Hypothetical discounting curves. The hyperbolic discount curves predict that, when the delay to outcomes is long (T_1), the discounted value of the larger outcome will be greater than that of the smaller but more immediate outcome. However, when the delay is relatively short, the discounted value of the sooner outcome is greater than that of the larger outcome. The shift in preference occurs at the point where the discounted value of the outcomes is the same, which is the indifference point (T_3).

These two choice pairs present identical monetary outcomes (\$100 compared to \$80) with the same delay between the outcomes (20 days), but with a different shared delay between the two outcomes (80 days and no delay). What impact does the extra 80-day delay have on preference across these situations? Typically, option (a) is selected over choice (b) while option (d) is preferred to option (c), indicating a reversal in preference across these choice pairs. The differences in preference across the choice pairs can be described as follows: when the delay to both outcomes is large, participants prefer 'more,' but as the outcomes become temporally closer, preference shifts to 'sooner.'

But why does preference shift across these choice situations? To understand this, consider the hypothetical discounting curves shown in **Figure 6**. When the delay to both outcomes is large such as in (a) and (b) (marked as T_1 in **Figure 6**), the value of the larger outcome is greater than that of the smaller, more immediate, outcome, producing a preference for outcome (a). However, due to the hyperbolic shape of the discounting curves, as we move closer to the occurrence of the two outcomes (right along the x-axis), the value of the sooner of the two outcomes gains faster than the value of the delayed outcome. At some point in time (marked as T_2 in **Figure 6**), the two discounting curves cross. When the smaller outcome is immediate, as in choice pair (c) and (d), the value of the small immediate outcome is greater than the value of the delayed larger outcome (as seen at T_3 in **Figure 6**), producing preference for outcome (d).

An important implication of the hyperbolic discounting function is that there is an indifference point (T_2 on **Figure 6**) where the psychological (discounted) values of the sooner smaller and later larger outcomes are the same. Increasing the delay to both outcomes beyond the indifference point will produce preference for the larger later outcome (self-control). Decreasing the delays to both outcomes ahead of this

indifference point produces preference for the smaller sooner outcome (impulsivity). The predicted shift in preference from the larger delayed outcome to the smaller immediate outcomes is seen in human behavior. A real-world preference reversal is evident in human behavior when dieters and problem drinkers make commitments to avoid the dessert table or the bar before arriving at dinner, but show a strong preference for dessert/drinks once in the restaurant. When the 'temptation' to engage in problem behavior is in the future, the rewards of the dessert/drink are small compared to the larger but more delayed rewards of controlled weight or sobriety. However, once in the immediate context of the restaurant (delay to dessert/drinks is near 0), the immediate outcomes loom larger than the still more delayed rewards of health and sobriety. Consistent with this example, observed discount rates (the speed with which the value of delayed outcomes decreases) are greater in substance abusers than in non-substance-abusing controls.

Heuristics

Unfortunately, evaluating uncertain outcomes, even when the probability of the outcome can be accurately estimated, is cognitively expensive. To best understand this, imagine a contestant on the game show *Deal or No Deal*TM. The participant is considering an offer from the banker of \$10 000 or playing for the chance of winning a case containing \$1, \$50, or \$35 000. Which should the contestant choose? The rational decision-maker would calculate the expected cost of the gamble (\$11 566.84) and the value of the banker's offer (\$10 000) and select the option with the higher value. This calculation, though, requires significant cognitive effort. Rather than invest the effort needed to make these decisions, people frequently rely on rules of thumb, or heuristics. The game show participant might think, 'A bird in the hand is worth more than two in the bush' or 'it's better safe than sorry' and take the banker's offer (and many in the audience would applaud the decision!).

Heuristics are simple rules that aid in decision making under uncertainty. Uncertainty occurs when the probability of an event's occurrence is unknown, requiring the decision-maker to estimate these probabilities before calculating the value of the event. While the probabilities of many events can be accurately determined, the search for accurate information is costly. Under these conditions of uncertainty and demands, decision-makers often turn to their memory to develop the needed likelihood estimates. To better understand the role of heuristics in developing likelihood estimates from memory, consider the functioning of two well-known heuristics: representativeness and availability.

Representativeness Heuristic

The example that is most often used by experimental psychologists to illustrate the representativeness heuristic is so well known that it has become known simply as the Linda problem. A hypothetical woman named Linda is described as being 31 years old, single, outspoken, and very bright. In college, she majored in philosophy, was deeply concerned with issues of social justice, and participated in antinuclear demonstrations. Given all this information, which of the following do you think is more likely:

- (A) Linda is a bank teller
- (B) Linda is a feminist and a bank teller.

To find the correct answer, you would first decide how likely it is for Linda to be a feminist, how likely she is to be a bank teller, and then multiply the two to find the likelihood that she is both a bank teller and feminist. Given the fact that the probability that Linda is a bank teller is less than 1 (i.e., not every woman is a bank teller) and likewise for feminism, the product of two numbers less than 1 will be less than either of the original numbers. Thus, a simple multiplication will yield the answer that B is less likely than A. In practice, however, most people believe that B is *more* likely than A (a cognitive error known as the conjunction fallacy), indicating that they must not be carrying out this simple calculation. Instead, when asked to consider whether A or B is likelier, we first form mental images of Linda, a bank teller, and a feminist bank teller. After building these mental images, we compare Linda's image to the other two images, and then decide that the third image better resembles Linda than the second image; in other words, Linda is more representative of feminist bank tellers than she is of bank tellers in general.

Whereas the Linda problem seems to show how poorly our minds work, in fact it shows that we tend to prefer strategies that are quick and that yield the correct answer under most circumstances. For example, you might hear about two women, one of whom has two children, both sons, and another that has 20 children, all boys. Which is more surprising? Most people would correctly say that having 20 all-male children is more surprising. In this example, two boys is more representative of pairs of children (one out of four possible pairs) than 20 boys is of 20-children groups.

Availability Heuristic

A second automatic judgment occurs when the likelihood of an event is determined by how easily exemplars of the event are drawn from memory. The easier the event is to recall from memory, the greater the perceived likelihood of the event's occurrence. For example, which is more dangerous to have in a home: a pool or a handgun? As most people do not know accident statistics, they reference their memory with the simple query of, 'Do I remember any deaths/accidents involving pools? What about handguns?' Most people find it easier to recall information concerning handguns, gun control, gun safety, and so forth, than to recall information concerning pool safety (when was the last time a group launched a campaign for a constitutional amendment on pool control?). Given the ease of recall for gun-related information, the frequent, yet incorrect, answer is that guns are more dangerous to have in homes than in-ground pools (although in actuality more child deaths each year are the result of drowning than shootings).

Similar to the representativeness heuristic, the availability heuristic is partially a by-product of the brain's normal and correct functioning. The brain is designed to respond to novelty in the environment. Stimuli/events that are predictable and consistent do not typically signal danger. Novel and unexpected events are frequently signs of upcoming trouble. Accordingly, the brain is wired to pay particular attention to

low-frequency events. When asked to make likelihood judgments about these events, the brain then errs on the side of caution and overestimates the likelihood of the infrequent event's occurrence.

Conclusion

Judgment is the process of making rapid decisions concerning stimulation or information from the environment. Whether focusing on low-level sensory processing or higher order decision making, the brain extracts information from the world and determines the likelihood of the information being important. As illustrated by the representativeness and availability heuristics, while the brain is extremely well suited for its general tasks, occasional systematic and predictable errors occur in the judgment process.

Glossary

Availability heuristic The tendency to answer a question of probability by asking whether examples come readily to mind. What we recall becomes what we believe will be likely.

Belief perseverance The tendency to prefer and shield personal or preexisting beliefs despite irrefutable evidence that they are incorrect.

Challenges for cause Challenges that occur when jurors do not meet specific statutory qualifications.

Confirmation bias Seeking out only those sources of information that support preexisting beliefs or theories and actively neglecting all contrary evidence or sources of information.

Exempt Jurors on the venire who are unable to serve.

Exhibits Evidence, records, or testimony shown to the jury in court.

Jury A group of men and women lawfully selected, convened, and sworn to inquire into a legal dispute and render an impartial finding of legal fact.

Jury consultant Someone who works with legal professionals, mainly attorneys, to assist in various aspects of case preparation, including jury

selection, development of case strategy, and witness preparation.

Peremptory challenges Challenges that are exercised by attorneys where they see fit.

The CSI effect A particular set of biases caused by the portrayal of forensic science on fictional and pseudodocumentary programs like CSI, Forensic Detectives, and Forensic Files.

The primacy effect A cognitive bias in which those ideas or arguments that come first are given more credibility than those that come later.

The recency effect A cognitive bias in which those items, ideas, or arguments that come last are remembered more clearly than those that came first.

Venire A list of potential jurors within a particular jurisdiction created by drawing individuals from voter registration lists, driving license lists, and supplemental lists when necessary, including public phone directories and those on welfare.

Voire dire An in-depth examination to determine the suitability of jurors for service on a particular case. This process allows attorneys to ask specific and often personal questions about individual juror backgrounds, lifestyle choices, relationships, and views.

Rendering the Venire

In an adversarial justice system, the burden of proof is on the prosecution. The prosecutor must prove the defendant's guilt beyond a reasonable doubt rather than the defense being required to prove any degree of innocence. However, the defense must demonstrate a reasonable doubt with respect to the prosecution's theories regarding their client's guilt. Ironically, these controversial legal standards are commonly left to the subjective interpretation of regular citizens serving on a jury.

A *jury* is a group of men and women lawfully selected, convened, and sworn to inquire into a legal dispute and render an impartial finding of legal fact (adapted from Black, 1990). Trial by jury is the constitutional right of US citizens, preserved by the Sixth Amendment to the US Constitution (Starr and McCormick, 2001).

Preserving the right to an impartial jury involves the assumption that juries are capable of impartiality or objectivity. This assumption is problematic at best. There are many elements that work against the formation of an impartial jury and its subsequent objective efforts. As discussed subsequently, most of them hinge on an understanding of those circumstances that affect jury psychology and cognition.

The Jury Pool

The initial makeup of the 'jury pool' in a given legal jurisdiction and how it is subsequently molded by the courts in

individual courtrooms has a bearing on the capabilities and biases of those who are ultimately allowed to serve.

Jurors are meant to be selected in an impartial and random manner from a representative cross-section of the community. In the United States, a *venire* (also known as jury panel: a list of potential jurors within a particular jurisdiction) is created by drawing individuals from voter registration lists, driving license lists, and supplemental lists when necessary, including public phone directories and those on welfare. This master list is then pared down, as not all citizens are able to serve.

Those jurors on the venire who are unable to serve are referred to as *exempt*. The nature of these exemptions creates a final jury pool with a particular ethos, a character that is defined by those who are allowed to sit as well as by those who are excluded and why. Prospective jurors are commonly exempt from service for the following reasons:

1. They are not citizens.
2. They are not old enough (e.g., under 18).
3. They are too old (e.g., well beyond retirement age and unwilling to serve).
4. They have not lived in their current judicial district long enough to establish residency (e.g., less than a year).
5. They do not speak English or lack sufficient literacy to complete a juror qualification form.
6. They are not mentally or physically capable of the requirements of jury duty.

7. They have been charged with, or previously been convicted of, a felony.

It should be noted that in many instances, jurors serve despite the existence of one or more of these disqualifiers, as background checks are not standard. Prospective jurors are often simply taken at their word that they meet the requisite qualifications and possess none of the automatic disqualifiers. Even in cases where they are honest about a disqualifier, the presiding judge may simply choose to ignore it. This means that felons, the illiterate, and the mentally infirm can and have served on juries in criminal trials – sometimes with the court's full understanding and approval.

Other hardship and occupation-related exemptions exist that can further shape the character of the jury pool, including the following:

1. Jury service would create a financial hardship.
2. Recent injury or illness prevents capable service.
3. Jury service creates a child-care hardship, especially with mothers of children who are still breast feeding.
4. Active military service or deployment prevents service.
5. The prospective juror is out of town attending college.
6. The prospective juror is a licensed, practicing attorney.
7. The prospective juror is a current or former law enforcement officer.
8. The prospective juror is related to, or friends with, one or more of the parties involved in either side of the trial.
9. The prospective juror is a violent crime victim, especially those involving attempted murder, sex crimes, or domestic violence.
10. The prospective juror has a history of negative experiences with one side or the other that creates bias (e.g., prior false arrest, prior wrongful conviction, general dislike for defense attorneys).

Applying such exemptions fairly and consistently is a task that every court is charged with. Imposing jury service on those with hardships creates animosity toward the justice system, as well as distracting the attention of the juror well away from their appointed court-related tasks. Allowing the service of those with a clear bias toward or against either side of the case reduces the overall impartiality of the jury that they ultimately serve on. The failure of the court to properly exempt or disqualify jurors when building the jury pool can allow bias to enter the legal system before the facts of any case are heard.

The strong cultural bias that exists when allowing a former or active law enforcement employee to serve on any jury where law enforcement sits in alignment with either side should be self-evident. Though it should be sufficient cause for automatic exemption, this is not the case in every jurisdiction. As discussed in [Gershman \(1997\)](#), the issue of law enforcement testimony weighed too heavily by those jurors who are prolaw enforcement in their orientation is cause for judicial concern (p. 259):

When the prosecution's case rests heavily on the testimony of law enforcement agents, the refusal to inquire at the defendant's request whether prospective jurors would give added credence to the testimony of a law enforcement agent simply because of his position may be an abuse of discretion. The error is not cured by a court's extensive inquiry concerning a prospective juror's acquaintance or relationship with law enforcement personnel.

However, an extraordinary and undeniable bias against the accused is inherent among those law enforcement officers employed by the arresting police agency, let alone those officers specifically charged with building the ongoing court case. Impaneling such a juror is therefore fraught with ethical peril.

Judges have great discretion on matters related to jury selection and therefore a duty to ensure that both sides receive a fair hearing of their case. The authors are aware of many instances involving judges who have no problem taking the time to discharge these duties fairly and reasonably. Similarly, there is no shortage of examples where judges have failed outright.

Consider an extraordinary instance of impromptu jury selection in Lane County, OR. Judge Mary Ann Bearden faced the start of three major felony trials along with a juror shortage brought on by two converging circumstances: the failure of some citizens to show up for jury duty (summonses for jury duty are routinely ignored by even the most law-abiding citizens) and the nature of the crimes themselves, involving sexual assault and domestic violence. Not enough prospective jurors showed up, and some that did were disqualified by virtue of experiencing domestic violence, sexual abuse, or child abuse personally or in their families. In order to make up the difference, Judge Bearden invoked *Oregon Revised Statute 1.235 (4)*, which reads: "If there is an immediate need for additional jurors, a judge of the circuit court for the county may direct the clerk of court, sheriff or other officer to summon a sufficient number of eligible persons to meet that need. Those persons shall be summoned as directed by the judge." In accordance, she directed deputies to go out onto the street in front of the courthouse, grab the first 12 US citizens over the age of 18, and put them in the jury pool – which they did ([Rillos, 2008](#)).

Pretrial Publicity

Some events and related courtroom matters achieve a high level of media coverage and even an undeniable celebrity all their own because they involve bizarre or salacious facts, a victim or defendant of some celebrity, or because of the pretrial tactics of attorneys on either side. Pretrial publicity can be so intense and overwhelming that it taints prospective or empaneled jurors in favor of the emotional tones being drummed. Historically, the media has been quite capable of exerting this kind of inappropriate influence over the pool of prospective jurors in a given community, as was demonstrated by the defense in the infamous case of *Sam Sheppard v. Maxwell* (1966):

Petitioner's wife was bludgeoned to death July 4, 1954. . . . His trial began October 18 and terminated with his conviction December 21, 1954. During the entire pretrial period virulent and incriminating publicity about petitioner and the murder made the case notorious, and the news media frequently aired charges and countercharges besides those for which petitioner was tried. Three months before trial he was examined for more than five hours without counsel in a televised three-day inquest conducted before an audience of several hundred spectators in a gymnasium. Over three weeks before trial the newspapers published the names and addresses of prospective jurors causing them to receive letters and telephone calls about the case. The trial began two weeks before a hotly contested election at which the chief prosecutor and the trial judge were candidates for judgeships. Newsmen were allowed to take over almost the entire

small courtroom, hounding petitioner, and most of the participants. Twenty reporters were assigned seats by the court within the bar and in close proximity to the jury and counsel, precluding privacy between petitioner and his counsel. The movement of the reporters in the courtroom caused frequent confusion and disrupted the trial; and in the corridors and elsewhere in and around the courthouse they were allowed free rein by the trial judge. A broadcasting station was assigned space next to the jury room. . . . Despite his awareness of the excessive pretrial publicity, the trial judge failed to take effective measures against the massive publicity which continued throughout the trial or to take adequate steps to control the conduct of the trial.

The defense appealed their case all the way to the US Supreme Court and, on June 6, 1966, Sam Sheppard's initial murder conviction was reversed and his case remanded for a new trial.

In keeping with this decision, the US Supreme Court has continued to argue that (*Patton v. Yount*, 1984): "adverse pretrial publicity can create such a presumption of prejudice in a community that jurors' claims that they can be impartial should not be believed." So not only can pretrial publicity shape the opinions of jurors, the impact is intellectually and emotionally overwhelming to the point that they may be incapable of being truthful about it. This is something that cognitive psychologists have known for years: people cannot be relied upon to objectively observe and assess their own bias. As the Federal Court explained in *US v. Davis* (1978): "The juror is poorly placed to make a determination as to his own impartiality."

With the advent of the Internet, social networking sites, and the 24-h news cycle, what is said about a criminal prosecution in the morning may be heard around the world within minutes. Prosecutors and defense attorneys alike are well aware of this reality and of the influence such media exert over public opinion and respective jury pools. This can be felt every time an attorney for either side issues a press release or even provides interviews to the media – in many cases before charges have even been filed. There can be no mistake that such conduct by legal advocates is an overt attempt to influence eventual jurors through the manipulation of public opinion toward their point of view. This is true whether it is a series of heartfelt denials by the representative of a soon-to-be defendant or the release of police documents directly to the media along with inflammatory accusations by a zealous prosecutor.

These collective circumstances, with lawyers, pundits, and even judges giving interviews on every major case that catches the public eye, serve to compound the possibility of inappropriate media influence over potential jurors. However, with all sides benefiting from the press and the exposure, it is rare that any party remains far enough above the fray to complain without appearing hypocritical. We would do well to remember the warning provided in *Gershman (1997)*: "...where a prosecution may be the subject of widespread media attention, trial courts have been admonished to conduct their *voir dire* carefully, to strongly consider questioning jurors individually."

A Jury of One's Peers

Those unfamiliar with the law will no doubt take notice of the absence of the phrase 'Jury of One's Peers' in the preceding discussion. This is not a mistake. Culturally, we have been

generally misled by fictionalized accounts of courtroom 'drama' which bear limited resemblance to the real thing. Among the many myths propagated by the entertainment industry is that of the accused's right to a trial by a jury of one's peers. This is not precisely correct.

In *Lockhart v. McCree* (1986), the US Supreme Court held that an individual jury need not be a truly representative cross-section of the community. As explained in *Cooley (2004)*, in a discussion of *Lockhart* (p. 299):

The Supreme Court discarded the Eighth Circuit's cross-section analysis by holding that the cross-section requirement applies only to venires and not petit juries. The Court held that the "point at which an accused is entitled to a fair cross section of the community is when the names are put in the box from which the panels are drawn." Moreover, the Court expressed that providing a truly representative petit jury to every criminal defendant would be nearly, if not entirely, impossible.

Subsequently, while the final result of sampling the venire may not be a jury that is demographically representative of a particular community, the representative standard is argued to have been met if the *venire* itself is drawn from initially representative sources. Moreover, the diversity of the venire is argued to help foster overall impartiality, as multiple views and voices will be represented and, hopefully, even each other out (*Cooley, 2004*).

The initial formation and subsequent molding of the 'master' jury pool have an undeniable and cumulative impact on the character, capacity, and overt bias that can be present in a final jury that is empanelled for service. Ideally, it is meant to be free from prejudice and predisposition; it is meant to be representative of the community it serves; and it is meant to discharge its duties without fear of undue influence. In order to serve as a check against such concerns when the court has not adequately addressed them, attorneys from each side are afforded an opportunity to participate in the final process of jury selection. However, this awesome power is not always wielded ethically.

Jury Selection

The intended goal of the jury selection process is to render a qualified jury that is free of prejudice and bias (*Frederick, 2005*). However, most jury pools will be populated with unqualified or biased individuals that the court has failed to screen. It subsequently falls upon attorneys from both sides to interview and challenge the suitability of the juror for service.

Voir Dire

Citizens who respond to a summons for jury duty, and who are not exempted from service by the court, must submit to more in-depth examination to determine their suitability for service on a particular case. This process, known as the jury *voir dire*, allows attorneys to ask specific and often personal questions about individual juror backgrounds, lifestyle choices, relationships, and views. Attorneys may interview jurors individually or in groups, as dictated by the rules in a given court. This presents attorneys with their first chance to probe individual

juror bias and also to make a first impression with jurors who will eventually serve on their case. The judge both presides over and participates in this process.

Challenges to Juror Service

Federal statutes provide that “no citizen shall be excluded from jury duty because of race, color, religion, sex, national origin or economic status” (O’Malley et al., 2009: 1). However, jurors may still be stricken from service during or subsequent to voir dire. This filtering process consists of exercising *challenges for cause* and *peremptory challenges*.

Challenges for cause occur when a juror does not meet specific statutory qualifications. Because the failure of a judge to remove a juror for cause may result in a reversible error, attorneys are allowed an unlimited number of such challenges.

Peremptory challenges are distinct because they give attorneys the freedom to exercise challenges where they see fit – and without a stated cause (Frederick, 2005). The number of such challenges is limited, depending on legal statutes and the seriousness of the crime (Gershman, 1997: 248). As explained in Cooley (2004: 287): “After questioning prospective jurors, counsel may then attempt to exclude those individuals who have expressed views unfavorable to their client’s case.” In these instances, when attorneys fail to find cause, they may use one of their peremptory challenges to have a juror excused.

The peremptory challenge is considered vital to the overall fairness of jury selection, allowing attorneys on either side to eliminate those with extreme views. However, it may also be argued that such challenges are open to abuse, allowing attorneys to strike jurors for ‘race, color, religion, sex, national origin, or economic status’ in violation of the law. Additionally, the court’s recognition of the need for challenges without cause suggests a corresponding admission that the jury pool itself is not a representative cross-section of the community.

Jury ‘Profiling’

Although jurors are selected to give their verdict according to the evidence, it is widely understood that some jurors enter the courtroom with preexisting biases or characteristics that influence their ability to vote objectively. The predisposition to vote a certain way and for inflexible personal reasons supports the growing industry of jury consultants. They are meant to assist in the strategic use of peremptory challenges as well as with the development of trial strategy that may be effective with manipulating or influencing the personalities on a given jury.

A *trial consultant* or *jury consultant* is a broad term that can be defined as “someone who works with legal professionals, mainly attorneys, to assist in various aspects of case preparation including jury selection, development of case strategy, and witness preparation” (Roesch et al., 2010: 324). Those who specialize in jury selection “attempt to determine who among potential jurors will be most and least receptive to a client’s case, and devise strategies to pick and challenge those jurors” (Jonakait, 2003: 159). They focus on the scope of potentially influential factors, such as personality traits, and demographics, including race, gender, education, and socioeconomic status (Donner and Gabriel, 2009; Strier and Shestowsky, 1999).

The demographic characteristics of jurors have been studied largely because they are easily observed. Socioeconomic status and sex are two examples of demographic characteristics that are associated with juror bias in favor of defendants, when those traits are also present in the defendant (Donner and Gabriel, 2009).

Socioeconomic Status

According to a rather dated study by Adler (1973), when the difference between juror and defendant socioeconomic status increased, so did the likelihood of conviction (as cited in Donner and Gabriel, 2009). That is to say, jurors were more likely to convict those who they felt were more or less advantaged than themselves. This suggests an historical class bias in jury decision making.

Sex

Another rather dated study conducted by Nagel and Weitzman (1972) found that sex influenced the verdicts of jurors. In civil cases, male-dominated juries tended to award higher damages to male plaintiffs, whereas female-majority juries tended to award larger sums to female plaintiffs (as cited in Devine et al., 2001). This suggests a same-sex bias once harm has been established and the need for damages is deemed appropriate.

A more contemporary study of rape trials by Fischer (1997) found that juries composed mostly or entirely of women tended to convict male defendants more often than juries with a low proportion of women (as cited in Devine et al., 2001). This study contradicts conventional rape-trial wisdom that suggests female jurors are actually less sympathetic to female complainants (often second-guessing their role in events), while male jurors are more quick to convict male defendants for fear of seeming tolerant or accepting of rape in general.

In general, Devine et al. (2001), a meta-analysis of multiple demographic studies, noted that when the evidence against the defendant was weak or ambiguous, juries that were demographically similar to the defendant tended to be lenient; however, when the defendant’s culpability was clear, juries tend to be harsher. This suggests a bias against like defendants, with juries desiring to make an example of those among their own who are found guilty.

While the aforementioned research suggests that jurors with specific characteristics are predisposed to voting a certain way, it is impossible to suggest that these general propensities will apply to specific jurors. Jury consultants have published almost no data to support that jury verdicts are predictable under any conditions, and social science studies have consistently found that the overwhelming determinant of verdicts is the evidence presented to the jury (Jonakait, 2003). Moreover, according to Strier and Shestowsky (1999), there appears to be no way to assert with certainty that a successful verdict in an actual trial is directly attributable to jury selection. This may be because “the client who can afford a trial consultant is usually the same client who can afford the best attorneys, and the best expert witnesses and the best investigators” (Strier and Shestowsky, 1999: 12).

The involvement of jury consultants in the process of jury selection also presents ethical concerns, as their role is to purposefully manipulate the outcome of the jury's decisions. In fact, trial consultants have even been known to help deliberately lead to a mistrial or delay the goals of the legal system (Posey and Weightsman, 2005). Additionally, jury consultants are expensive. The minimum fee for meaningful work has been put at around \$50 000, with higher-end services going for around \$500 000. As a result, only those with sufficient resources can afford them, which in effect may be said to at least help buy a favorable verdict when the facts alone do not merit it (Jonakait, 2003).

Courtroom Influences

Once the jury and their alternates have been empanelled for a particular case, the court's influence over their behavior and emotions focus sharply. They are generally ordered to refrain from forming opinions until they have heard all the facts, to avoid any media coverage of the trial, not to research the trial independently, and not to discuss the trial among themselves or with anyone else. In short, they are required to conduct themselves, and to reason, in a way that is generally foreign to their everyday experience. In extreme cases, they may be sequestered to avoid any contact with the outside world throughout the trial.

While the number of influences over the jury is reduced during trial, their imposed isolation necessarily causes those influences to have an increased importance on their perceptions, emotions, judgments, and decision making. As a consequence, the jury sees events unfold from a very unique perspective. It is fair to say that the trial they are watching is not the same trial that anyone else is watching – it is filtered.

The Judge

During trial, the judge is the single greatest influence over the jury. The judge makes the rules and doles out any sanctions for infractions. Beyond the controls already mentioned, the judge also dictates when jurors must arrive, where and when they must wait, when they should take breaks and eat, whether and when they may have contact with friends and family, and how late they must stay in court every evening. This can create internal pressure and stress on jurors in a situation that is already going to have too much of both from everyone else involved.

The judge also rules on the admissibility of facts, evidence, witness testimony, and permissible case theory. In essence, he/she has the power to direct the narrative or 'story' that either attorney may use when arguing his/her side of the case. By the time the jury hears arguments and testimony, or sees evidence, the volume has been greatly reduced and reshaped from its original form. This profoundly changes the character of the trial that the jury sees and is allowed to consider, as opposed to the facts that are generally or publicly known.

The judge further controls the jury by deciding whether jurors may take written notes, and which evidence, records, or testimony they may take with them into their deliberations (referred to as *exhibits*). Human memory is frail and

imprecise. In cases where jurors are not allowed to take notes, they must rely on that memory when forming arguments to support their vote. In cases where note taking is permitted, those jurors who take the most complete set of notes have an inordinate sway over others. And jurors tend to take more notes in the beginning and less over time as the trial progresses. This issue becomes increasingly important in lengthy trials that involve complex fact patterns and relationships or require an understanding of how to interpret complex physical evidence. The judge ultimately controls whether and how the jury is allowed to recall what they have experienced during the trial and the mechanism by which they may refresh their memory when important details become a matter of dispute.

Apart from imposing many procedural influences over the jury that affect their capability and temperament, the judge also wields tremendous influence over the emotional content of the courtroom by virtue of his/her own professional conduct. The judge is the only person in court who can speak to anyone and everyone at any time and often in any manner that he/she sees fit. A judge's manner and tone, intentional and otherwise, can improperly telegraph his/her personal agenda or preferences to the jury. This can be the result of general intolerance and impatience with attorneys resulting from a strained relationship, as he/she tends to see the same legal players playing the same legal games despite numerous advisements from the bench. This can also be the result of an improper prosecution bias, as many judges are former prosecutors themselves.

Judges may conduct themselves improperly toward the defendant or defense witnesses. This includes assuming the role of the advocate (acting as a backup prosecutor); openly conveying skepticism or disbelief, active disinterest (such as sleeping through or otherwise ignoring testimony); or disparaging remarks; and obvious character attacks. This also includes improper remarks that disparage witness credibility; the use of sarcasm and ridicule; and racial, ethnic, or other derogatory remarks (Gershman, 1997). When this kind of judicial behavior takes place in front of the jury, the message is undeniable: the defense and their witnesses are deserving of the court's admonitions and hostility and are therefore less credible. If the judge treats the defense and its case as less credible, then the jury may find it difficult to perceive them in any other way.

The judge may also engage in improper conduct toward the prosecution and its witnesses by virtue of eliciting favorable proofs, acts of advocacy for the prosecution, vouching for character or testimony, or any other form of obvious favoritism (Gershman, 1997). If this type of judicial behavior takes place in front of the jury, the message, again, is all too clear: the prosecution is deserving of favor and therefore is deserving of preferential treatment, which equates to greater credibility. If the judge treats the prosecution as more credible, then it will likely be viewed by the jury in the same fashion because of the power structure inherent in their relationship.

These examples of improper judicial conduct are prejudicial in nature. In some cases they are almost impossible for even the most objective jury to ignore. Such misconduct from the bench consequently subverts the defendant's right to a fair trial and an impartial verdict. These are just some of the

many examples of how a judge can influence and even subvert the behavior, emotions, attitudes, and ultimate decision making engaged in by jurors.

The Prosecution

Adversarial justice systems are premised on a presumption of innocence, where the state has the burden of proving a defendant's guilt. In reality, however, the prosecution often enters the courtroom with a tremendous amount of bias in their favor.

First, the fact that a criminal defendant has been investigated and arrested by law enforcement creates a 'guilty bias.' This is because a majority of the public maintains the false belief that law enforcement only arrests guilty individuals. This can extend to the flawed reasoning that even if the defendant is not guilty of the charges at hand, they must be guilty of something, and therefore a guilty verdict of some kind is warranted despite any holes or weaknesses in the evidence being presented. This is often referred to as 'the prosecutor's fallacy.'

Next, there is a 'moral bias' present. We the people regularly experience cultural and institutional pressure to view law enforcement and the prosecution as the morally 'right' side of any argument and the defense as the morally 'dark side.'

Additionally, some in the general public do not want to believe that law enforcement or prosecutors are capable of anything other than professionalism, competence, and truthfulness. Therefore, whatever they present in court must be believed. If what they present cannot be believed, then the justice system cannot be trusted and nobody is safe from wrongful prosecution. Such a reality is undesirable for many to contemplate. This inability to view law enforcement and the prosecution in a negative fashion creates a proauthority bias stemming from fear or apathy.

It is important to acknowledge that in some legal jurisdictions, and among some groups, these prosecution biases have been upended. This can result from highly publicized or systemic patterns of police and prosecutorial misconduct and abuse. It can also result from certain groups or communities experiencing a consistent history of negative contact with law enforcement in the lawful performance of their sworn duties. Any of these circumstances can create a collective animosity against law enforcement and the criminal justice system in general. This may provide for a local jury pool that is skeptical if not completely biased against local authorities, and some among them may even be looking for payback through jury service.

The prosecution often seeks to influence the jury through emotional appeals. This is especially effective with cases involving sympathetic victims or horrific fact patterns. Depending on the nature of the crimes charged, members of the jury may feel the strain of psychological or moral imperatives to hold someone responsible and prevent an injustice. The prosecution may feel a corresponding need to meet perceived umbrage and outcry on an equal footing.

Common prosecutorial appeals to emotion include repeated focus on sensational or grotesque details of crime, to the point of distortion if not exaggeration and falsity; focus on victim suffering and innocence, again to the point of distortion; inappropriate attacks on defendant character, including the misuse of prior conduct, arrests, or convictions;

and inappropriate attacks on the character of the defense and their witnesses, referring to them as criminals or liars (Gershman, 1997). Prosecutorial appeals to emotion can also be found in inflammatory conduct, including name-calling; appeals to 'law-and-order' and public safety issues; insinuations of violent threats against witness; appeals to racial prejudice; appeals to nationalism or religion; appeals to wealth or class prejudice; and appeals to jurors as parents (Gershman, 1997). Prosecutors may also warn the jury regarding what might happen if they fail to convict – the consequences to the community, and future victims, of an acquittal.

Less commonly known is that many prosecutors, keenly aware that their manner of dress is carefully scrutinized by members of the jury, adopt a very particular courtroom 'uniform.' Rather than consistently dressing according to their means, some will dress up or down in their professional attire depending on the jury. This panders to the jury's perceived class, creating the false impression that they share common socioeconomic origins and values.

These examples are but a few of the many ways that prosecutors can influence the behavior, emotions, attitudes, and ultimate decision making engaged in by jurors. In many cases, they are a form of prosecutorial misconduct and must be objected to by the defense to preserve their right to appeal. Such misconduct from the prosecution can subvert the defendant's right to a fair trial and an impartial verdict from the jury.

The Defense

Unless prosecution biases have been upended in a particular legal jurisdiction, as discussed in the previous section, the defense enters the courtroom under the weight of tremendous prejudice. They are, in general, considered to be on the wrong moral and legal side of any courtroom. This circumstance alone provides a tremendous jury bias against any case theories that the defense seeks to advance. In some jurisdictions, this will be made worse by the arrangement of the courtroom, where the defense must sit at a long distance from the bench, subordinate to its bailiffs and well away from the jury. Under extreme circumstances, the judge may even require the defendant to wear handcuffs, shackles, or even prison clothing – telegraphing a context of guilt for all to see.

The way defendants look and conduct themselves in court is also among those subjective measures used by the jury to gauge a defendant's character and subsequent guilt, whether conscious or not. This involves observing how the defendant dresses and grooms, and whether this seems too contrived or vain. It also involves a subjective assessment of the defendant's reactions to court proceedings, to the point where the smallest look or gesture, even note taking, may be interpreted as a sign of guilt. Nothing is overlooked, when looking is all that the jury can do. Experienced defense attorneys know this, and commonly advise their clients to sit still, react to nothing, and take no notes. Ironically, this advice may backfire, as many jurors have claimed that the absence of defendant emotion or reaction weighed in their mind as evidence of bad character, general criminality, or even direct wrongdoing.

The character of the defense attorney is also on trial before the jury, as likeability and trustworthiness are always important factors. If the jury does not trust the messenger, they will

not trust the message. Trust is gained through professionalism, honesty (being forthcoming), and sincerity. Any attorney, defense or otherwise, can lose the trust or support of the jury by misstating evidence; harassing victims or witnesses; putting on an insincere show or a spectacle; making rude, derogatory, or offensive remarks; or withholding evidence. Some defense attorneys confuse this with dressing for success in high-end suits that telegraph financial success. While this may cause some jurors to perceive increased competence and professionalism, others may perceive this as evidence of success at being deceptive and getting off 'bad guys.' As with any subjective criterion, it merely tends to be used for reinforcing views that are already formed rather than creating new impressions.

Jury Psychodynamics

There are many psychological facets and relationships that have influence over decision making, and we have shown that jurors deliberating as to guilt or innocence are not especially immune to their complexities.

The Availability Heuristic

As defined in Tury (2008), the *availability heuristic* refers to the (p. 76): "tendency to answer a question of probability by asking whether examples come readily to mind. What we recall becomes what we believe will be likely." This is how many people reason – including many jurors. They do not actively listen, they do not try to learn, and they have no interest in reaching beyond what they already know so they tune out when required to try. Their first point of reference for understanding and solving any problem is going to be experience or movies or television, and not necessarily in that order. When explanations go beyond their experience, they tend to be cynical and even mistrustful. The less education, intelligence, and critical thinking possessed by individual jurors, the more their decision making is influenced by their own subjective availability heuristic.

The Primacy Effect

The *primacy effect* is a cognitive bias in which those ideas or arguments that come first are given more credibility than those that come later. In other words, whoever or whatever comes first is right: the first to present evidence and opinions, the first to make an argument, and the first to make their case. This creates a tremendous bias in favor of the side that presents their case to the jury first – namely, the prosecution.

The primacy effect is reduced when information is presented too quickly and is increased when information is presented slowly. This would seem to be highly relevant to how evidence arguments should be presented to the jury, depending on the desired outcome.

The Recency Effect

The *recency effect* is a cognitive bias in which those items, ideas, or arguments that came last are remembered more clearly than those that came first. The more recently heard, the clearer

something may exist in a juror's memory. This is common when information is given in lists – the last thing heard is recalled, while those at the beginning and in the middle may be forgotten. As a result, the party delivering the final closing argument – the defense – has an advantage.

The recency effect is increased when too much information is presented too quickly, and it is reduced when coupled with other tasks. With respect to jury memory, allowing note taking could also reduce both primacy and recency effects.

Belief Perseverance

Belief perseverance is the tendency to prefer and shield personal or preexisting beliefs despite irrefutable evidence that they are incorrect. This is related to *confirmation bias*, which involves seeking out only those sources of information that support preexisting beliefs or theories and actively neglecting all contrary evidence or sources of information. This means that when someone has strongly held personal beliefs, it is likely that he/she will be immune to facts or evidence that disprove him/her. Jurors are no different, and it is therefore important for those beliefs to be revealed during the *voir dire* process when they are relevant to issues at trial.

The 'CSI' Effect

All of the previously mentioned biases and influences contribute strongly to what has been referred to as *the CSI effect* and its impact on juror expectations and decision making. Named after the popular television franchise, this particular set of biases is caused by the portrayal of forensic science on such fictional and pseudodocumentary programs as CSI, Forensic Detectives, and Forensic Files. In these programs, forensic evidence is gathered, examined, and interpreted quickly by armed police investigators who convey moral umbrage and confront criminals directly with laboratory findings. As explained in Cooley (2007), religious viewers of such programs (p. 471) "come to believe or blindly assume three broad themes regarding the forensic science community: (1) crime labs are pristine scientific sanctuaries, which always have the most up-to-date forensic technology; (2) crime labs only employ the most skilled and imaginative 'scientists' who make few, if any, errors; and (3) forensic scientists are actually practicing and engaging in legitimate science." The reality is that forensic evidence examination, testing, and interpretation is a lengthy process involving scientists, not police officers, many of whom work in less than ideal conditions with limited budgets and training, and are surrounded by many biasing influences – to say nothing of error rates for evidence testing being generally unknown. This means that, too often, there is no science in forensic science (see generally The NAS Report – Edwards and Gotsonis, 2009).

The CSI effect can impact the juror in two ways. First, it can create unreasonable expectations for the prosecution – that physical evidence will always be collected, tested, and examined in every case, even when the resources do not permit it or the facts of the case do not require it. Second, it can create an unreasonable bias against the defense, as the evidence that is presented by the state's forensic examiners may be presumed

infallible or more certain than it actually is. This is especially problematic when attorneys and forensic scientists intentionally distort their arguments and testimony to meet the expectations created by the CSI effect, in essence leaving false impressions behind in the minds of jurors.

Jury Deliberation

When both sides have closed their arguments, the jury is sent back to deliberate and render a verdict in accordance with the instructions provided by the court. It is rarely as simple as finding the defendant 'guilty' or 'not guilty.' The court decides the charges that may be considered, and jurors are also given rules, referred to as jury instructions, relating to legal issues that have been raised throughout the trial. They are admonished to follow these carefully.

Jury deliberations are conducted in secrecy, under guard by the court's bailiffs, and without outside intrusion. The only exception is that the jury can ask questions of the judge, passed through the bailiff in the form of written notes. They may want to look at particular exhibits, to read particular testimony, or to have a matter of law clarified. The judge has broad discretion to grant or deny these requests.

Jurors are not allowed to consider anything outside of the trial as fact or evidence in their deliberation. They may not conduct their own research or their own investigations. They must rely only on what has been presented in the courtroom to make their decisions. Jurors who violate this covenant may be removed from service and replaced with one of the several alternatives that will have been serving simultaneously. Outside communication may also result in a mistrial, where the entire case must be tried again with a new jury.

Jury deliberations may take hours or they may take weeks, as there is no set time limit to this process. Experienced jurists believe that the longer the jury is out, the better it is for the defendant. This indicates that their findings are not certain and debate is ongoing. Similarly, a speedy verdict is said to be bad for the defendant as is sending a case to the jury on a Friday, as some feel that the jury may rush to judgment to avoid deliberating over a weekend. In truth, this is all just speculation. Every jury in every jurisdiction is different; each deliberates in accordance with the composition of their members. There is no predicting how long they will take or what that means for either side.

If a jury is deadlocked or unable to reach a verdict, they must inform the judge. In turn, the judge may refuse to accept their lack of a verdict and send them back to deliberate further, advising them of the cost of a new trial. If a jury is hopelessly deadlocked, with insufficient votes to meet the threshold of guilt or innocence, then a hung jury is declared and the case must be retried in front of a new one.

Conclusion

Individual juries do not represent an unbiased cross-section from a given community. They are carefully screened for service, first by the court and then by the attorneys involved. They are exempted from service based on who they are, what they believe, and whether they are perceived as helpful or

threatening to the arguments and evidence that may be presented.

Once empanelled, jurors are caught in a three-way tug-of-war between the court, the prosecution, and the defense. Each side plays to its biases, prejudices, and frailties for its own advantage. Jurors are manipulated with respect to the facts and evidence they see, how they feel, and ultimately how they may reason.

Despite the persistence of these many biases, frailties, and other psychological influences, there remains no reliable predictor of jury outcomes. They think the way that they do, and judge the way that they do, in a manner those observing from outside have yet to fully understand or reliably anticipate. This includes those of us who have served on a jury ourselves.

Glossary

Alliance theory The theory that a key to understanding kinship systems is how they distribute marital alliances by dividing kin into marriageable and unmarried.

Coefficient of inbreeding The probability that maternally and paternally derived copies of a gene are identical by descent in their offspring (measured relative to a background population).

Coefficient of relatedness The probability that a gene at a given locus is identical by descent in two organisms (measured relative to a background population).

Descent theory The theory that a key to understanding kinship systems is how they assign individuals to groups based on descent from a common ancestor (sometimes limited to descent through the male line – patrilineality – or the female line – matrilineality).

Generalized reciprocity Distribution of goods without definite expectation of balanced return. The common mode of distribution in families and many larger kin groups.

Kin selection A form of natural selection in which a trait is selected not just because of its consequences for the bearer of the trait, but because of its consequences for the bearer's genetic relatives.

Kin terminology (vs. kin terms) How kin types are split or merged (vs. the actual words used for kin types). For example, it is a fact about English kin *terminology* that the words for father's sister and mother's sister are the same; it is a fact about English kin *terms* that the word for father's sister is 'aunt.'

Westermarck effect A lack of erotic interest in adulthood resulting from coresidence in childhood. A proposed evolved mechanism for avoiding inbreeding.

Two disciplines have, more or less independently, taken up the study of kinship: evolutionary behavioral biology and cultural anthropology. Evolutionary biologists argue that much animal social behavior tracks genetic kinship, while cultural anthropologists from the beginnings of the discipline have found kinship to be central to human social organization.

However, there are deep disagreements between evolutionary and cultural approaches to kinship – disagreements regarding the relationship, if any, between nonhuman and human kinship, and between biological and cultural dimensions of kinship among humans. There are further disagreements within cultural anthropology itself: some anthropologists nowadays are skeptical about whether kinship is really important or even well defined for many societies. As a result, it is impossible to present a consensus view of this subject. This article follows a different path. The following sections compare and contrast evolutionary and cultural approaches to three bundles of topics in the field of kinship: (1) altruism and amity, (2) mating and marriage, and (3) the recognition and categorization of kin. Each section begins with a summary of theories and findings from biology. It then introduces anthropological approaches, and considers arguments that humans are special in ways that may require modification or even rejection of evolutionary approaches. A final paragraph considers the prospects of reconciliation.

Kinship and Kindness

It is no accident that 'kin' and 'kindness' are etymologically related; the association of kinship with altruistic behaviors, sentiments, and norms is a commonplace observation. It is also a major topic for both evolutionary biologists and anthropologists.

Kin Selection and Altruism

When Darwin began exploring the logic of natural selection, he was struck by "one special difficulty, which at first . . . appeared insuperable." Members of sterile worker castes among ants, bees, and other social insects have instincts and physical structures that differ from those of their fertile conspecifics but are still fine-tuned to their environments. How could natural selection, which depends on differences in reproductive fitness, produce adaptations limited to sterile organisms? How could natural selection favor sterility itself? Darwin eventually realized that plant and animal breeders had already supplied the answer to these questions. Breeders face the problem that some desirable traits, like vegetable flavor and meat quality, can only be assessed post mortem. Because breeders cannot select these traits directly, by selecting from the plants or animals set on the table, they must work indirectly, breeding from surviving family members, who are likely to be correlated on the selected traits. As Darwin put it, "selection may be applied to the family, as well as to the individual."

This insight anticipated what would come to be called the theory of *kin selection*. A trait associated with reduced fitness in one organism can be favored by selection if it is associated with sufficiently increased fitness among relatives likely to share the trait.

The behavior of social insects in provisioning and protecting their nests is a particularly extreme example of biological *altruism*. From an evolutionary perspective, an animal is behaving altruistically if its behavior is adapted to raise the fitness of other organisms, while lowering its own. For example, in many species, giving an alarm call in the face of a predator is altruistic: neighboring animals are warned, but the caller is more likely to be attacked by the predator. The commonest variety of altruism is parental care, with parents promoting the

survival and reproduction of existing offspring at the cost of producing fewer offspring.

The development of population genetics in the twentieth century allowed a more precise formulation of the relationship between kinship and altruism. The foundational work dates to the 1960s. William Hamilton demonstrated that, given some simplifying assumptions, altruism toward genetic kin is favored by natural selection as long as the condition $c < rb$ is satisfied. In this inequality, c stands for the cost of a behavior to the organism performing it and b for the benefit of that behavior to a relative of the first organism, with costs and benefits measured in terms of fitness – expected reproductive success. The term r is called the *coefficient of relatedness*. The coefficient of relatedness is a measure of the genetic similarity between two organisms resulting from common descent (over and above any genes the two have in common simply by virtue of belonging to the same wider population). The coefficient of relatedness is a regression coefficient. Given the presence of an allele in Organism 1, the expected number of copies of that allele in Organism 2 is $r(1-p) + p$, where r is the relatedness of Organism 2 to Organism 1, and p is the frequency of the allele in the population as a whole.

The coefficient of relatedness of an individual to a parent, child, or full sibling is $1/2$. Relatedness to a half-sibling, parent's sibling, sibling's child, grandparent, or grandchild is $1/4$. Relatedness to a first cousin is $1/8$, to a second cousin $1/32$. These coefficients assume the standard Mendelian rules for inheritance of autosomal genes. They may not work for genes on sex chromosomes, or for non-Mendelian inheritance. For Mendelian inheritance, in the absence of inbreeding, the relatedness of B to A equals the relatedness of A to B. In some other systems of inheritance, such as those found in some social insects, this symmetry does not hold.

The coefficient of relatedness can be used to define a quantity called *inclusive fitness*. Take the individual fitness of an organism – its expected reproductive success. For each relative whose fitness is raised or lowered by that organism, take the resulting change in fitness and multiply it by r . Sum these quantities. The result is called inclusive fitness. Inclusive fitness is a measure of an organism's success in getting copies of its genes into the next generation, either through its own reproduction or through assisting the reproduction of relatives sharing its genes. Under a wide range of conditions, natural selection favors genes that raise the inclusive fitness of their carriers.

In the inclusive fitness approach, fitness is divided into two components: the individual fitness of an organism and its effects on the fitness of its relatives. There are other ways of partitioning fitness that provide an alternative perspective on kin selection. The *multilevel selection* approach, pioneered by George Price, divides fitness into within-family and between-family components. The within-family component of fitness is the fitness of an organism relative to the mean fitness of its family. The between-family component is the fitness of the organism's family relative to the mean fitness of the population. In the case of kin selection, an altruist has lower fitness than the nonaltruist members of her family, but the increased fitness of her family relative to other families is enough to allow the spread of genes for altruism. This framework draws attention to the fact that kin selection requires selection

between families to operate, because the coefficient of relatedness is defined relative to a background population. In a population consisting of only one family – Adam and Eve and their children, say – selection would favor spite rather than altruism toward kin. It is important to note that inclusive fitness and multilevel selection approaches are two different ways of doing the bookkeeping, not two rival theories.

Kin selection is the subject of an enormous literature in animal behavior. This work demonstrates the importance of kinship to affiliation and altruism, and shows how kinship interacts with other factors in the evolution of a wide range of phenomena, including cooperative breeding, conflict within families, communication, group formation, and population structure.

The Axiom of Amity

In the mid-nineteenth century the study of kinship by scholars like Henry Lewis Morgan and Henry Maine helped to inaugurate the establishment of anthropology as a scholarly discipline. The rise of anthropology marked a break with earlier philosophical speculation about the origin of society from a state of nature. Anthropologists investigating social organization in nonstate societies did not find autonomous individuals creating order by drawing up a social contract. Instead, they found themselves in a world where relations among kin were central to social organization, a world of lineages and clans, cross-cousins and parallel cousins, genealogical and classificatory kin. Sorting out the principles underlying variation in kinship both in tribal and state societies became a major occupation in anthropology over the next century and a half. This section introduces some of the basics of human kinship by comparing and contrasting it with kinship as understood in the theory of kin selection.

The connection between kinship and altruism has been noted by a number of anthropologists. Meyer Fortes argued that an *axiom of amity* is a central presumption of kinship: kin are expected to share with one another simply because they are kin, without necessarily expecting an exact return. A similar observation was made by Marshall Sahlins, who documented an association between kinship and a principle of *generalized reciprocity*. In generalized reciprocity, goods, and favors are distributed to a large extent on the basis of need. (With *balanced reciprocity*, by contrast, which commonly prevails among nonkin, a quid pro quo is expected.) The principle of generalized reciprocity may be expressed through *demand sharing*, in which individuals are allowed to demand goods or favors from others, or through *pooling*, in which goods are pooled and then redistributed by a representative of the group. Generalized reciprocity is universally familiar as the chief mode of distribution within families; in many societies it also applies to wider groups. Generalized reciprocity is widely, but not exclusively, tied to kinship.

It is tempting to suppose that the anthropologist's axiom of amity is just the biologists's kin-selected altruism in another guise, but the two seem to be different in important respects. Many cultural anthropologists argue that culturally defined kinship often does not map well onto genetic relatedness. Discrepancies between cultural and biological kinship take several forms. In some cases individuals known to be

biologically unrelated, including adopted or adulterine children, are incorporated into kin groups and counted as kin when genealogies are reckoned. In some cases, individuals are assigned places in the kinship system based on *classificatory kinship*, which may be different from genealogical kinship. For example, if a man is classified as 'brother' to my mother, I may know that his child should be classified as my 'cousin' without being sure about the actual genealogical connection between the two parents. And in some cases, relatives at equal genealogical distance are distinguished based on the sex of connecting relatives: a mother's brother may be classified and treated as a different type of relation than a father's brother.

How serious a problem these discrepancies pose for an evolutionary account of human kinship is a matter of dispute. On the one hand, considerable evidence, amassed by both mainstream cultural anthropologists and evolutionary anthropologists, shows that adoptive and classificatory kinship do not simply erase consciousness of genealogical connections. Adoptive, step, and foster children are commonly treated differently from biological offspring, and in most premodern societies they keep up some connections with their birth parents. And natives will generally treat a 'real' sister differently than a classificatory one. On the other hand, current evidence does not support the view that these varieties of culturally defined kinship are just window dressing which people ignore in favor of biological kinship; they can be shown to have observable and measurable effects on behavior. For example, in many societies, principles of generalized reciprocity are extended to a culturally defined kin whose actual genetic relatedness is too low for much altruism to be expected on the grounds of inclusive fitness.

A further difference between 'kin altruism' governed by the axiom of amity and 'kin-selected altruism' concerns the motives for altruism. Anthropologists often note a distinction between the *domestic* and *jural* spheres of kinship. Kinship in the domestic sphere operates mainly in smaller social units, and especially among family members. In the domestic sphere, altruism toward a kin is an individual choice, motivated by the sentiments of the donor toward the recipient. Kinship in the jural sphere operates among more distant relations. In the jural sphere, altruism toward a kin is a duty, motivated by a concern for proper behavior and for reputation among a larger circle: how one person treats his or her kin is everybody's business. This normative aspect of kinship is a complication usually missing from standard kin selectionist accounts.

Many of the discrepancies between biological and cultural kinship seem to reflect the fact, often noted by cultural anthropologists, that human kinship is not just about relationships between individuals, but about relationships between groups. Membership in a group often entails obligations that run counter to personal inclinations. The group side of kinship is the focus of *descent theory*, pioneered by Robert Lowie, A. R. Radcliffe-Brown, E. E. Evans Pritchard, and others. Descent theory begins with the observation that, although the genealogical connections established by biparental reproduction – so-called *bilateral kinship* – can be used to situate each individual in the middle of a network of near and distant kin, they do not, barring close inbreeding, divide a population into bounded, nonoverlapping groups or categories. Constructing groups out of the network of kin requires that some of an

individual's closest genealogical links, but not others, be used to assign group membership. For example, in *patrilineal descent*, a child belongs to his or her father's – but not mother's – descent group or category. *Matrilineal descent* is the sex-reversed version of patrilineal descent, with group membership following the female line.

Groups defined by *unilineal* (patrilineal or matrilineal) *descent* play a variety of social roles in many societies (although bilateral kinship is always important as well). These groups may have proper names. Their members may share property rights. They may have common social obligations: to share with one another, avenge attacks on group members, or refrain from fighting with one another. They may have common rituals, gathering to commemorate or worship their founding ancestor, for example.

Descent groups as conceptual entities often do not match up perfectly with effective social groups. Groups that conceptualize themselves as matrilineal or patrilineal may in practice recruit members in other ways as well, and those entitled by descent to claim membership in a group may not exercise that claim. Also, some societies have groups based on *cognatic descent*, allowing an individual to claim membership in *either* father's or mother's group. These societies generally need some mechanism for deciding conflicting membership claims when mother and father belong to different groups, although this problem is lessened to the extent that individuals marry within the cognatic group.

Most, but not all, of the tribal societies studied by anthropologists attach some importance to unilineal descent, rather than treating kin connections through males and females as interchangeable. The mode of descent – patrilineal, matrilineal, other, or neither – shows some correlation with mode of subsistence: both patrilineality and matrilineality are common among tropical horticulturalists, while herding peoples are overwhelmingly patrilineal. But kinship organization is a conservative trait, and also has a strong historical component. Unilineal descent groups are important to this day over large areas of Africa, Asia, and Oceania.

Kinship, Mating, and Marriage

Kindness to kin need not extend to copulating with them. Animals, including humans, commonly avoid inbreeding with close kin, and humans often elaborate incest taboos and marriage proscriptions and prescriptions to cover more distant kin.

Inbreeding Avoidance

Genetic relatedness (see previous section) and genetic *inbreeding* are related concepts. Genetic relatedness implies that genes are identical by descent in two different organisms. Genetic inbreeding implies that genes are identical by descent in one organism, as a result of mother and father being related. If mother and father are not themselves inbred, but are related with a coefficient of relatedness of r , then the *coefficient of inbreeding* – the probability that maternally and paternally derived copies of a gene are identical by descent in their offspring – is $F = r/2$. F is smaller than r because not all genes shared by parents are passed on to their offspring.

Inbreeding may have both immediate and long-term disadvantages. Some alleles, called deleterious recessives, are harmless in a heterozygous condition (one copy of the allele from one parent), but harmful when homozygous (two copies of the allele, one from each parent). The immediate disadvantage of inbreeding is that inbred organisms stand an elevated chance of having two copies of deleterious recessive alleles. Two related parents are no more likely to carry deleterious recessives than unrelated parents, but they are more likely to carry *the same* deleterious recessives, and to produce offspring homozygous for those recessives.

There are also long-term disadvantages to inbreeding stemming from reduced genetic variation consequent on accelerated genetic drift. Inbreeding negates the advantages of sexual reproduction in producing varied offspring.

The short-term disadvantage of inbreeding can be measured by the number of *lethal gene equivalents* per individual. For example, if an individual is carrying 20 deleterious recessives, each of which, in a homozygous state, would reduce fitness by 10%, then the number of lethal equivalents is $20 \times 0.1 = 2$. Estimates of this number for human populations vary widely depending on the population and the research methods, ranging anywhere from 0.4 to 5 according to one review.

Given the likely fitness costs of inbreeding, one might expect that natural selection would favor inbreeding avoidance, and there is considerable evidence that animals in the wild commonly avoid potentially fertile matings with close relatives. In primates for example, there is strong evidence of avoidance of parent–offspring and maternal half-sibling matings. Evidence is weaker for inbreeding avoidance between paternal half-siblings, presumably because of the difficulty of assessing paternity. Inbreeding avoidance plays a major role in shaping mammalian social organization. In many species, one sex or the other or both typically leave their natal group upon reaching sexual maturity to avoid mating with close relatives.

Incest Taboos and Marriage Rules

If incest is defined as full sexual relations between closely related adults – parents and offspring, or full brothers and sisters – then incest is quite uncommon relative to nonincestuous sex in the great majority of human societies. (This conclusion might be different if incest were defined more broadly, to include sexual acts short of adult intercourse, and/or more distant relations or step-relations.) Of the varieties of heterosexual nuclear family incest, mother–son incest is least common and father–daughter incest probably most common.

Nuclear family incest has been an accepted practice in a few societies. In some cases, including Pharaonic Egypt, Inca Peru, and traditional Hawaii, dynastic politics led to high frequencies of brother–sister marriage among royal families. In Zoroastrian Persia, father–daughter, brother–sister, and mother–son marriages were encouraged for religious reasons, and seem to have been moderately common. Among Greeks in Roman Egypt, census returns show that brother–sister marriage was an accepted and common practice for several centuries. These cases are unusual, but sexual relations and marriage involving more distant relations are not so uncommon. Marriage between uncles and nieces and between paternal

half-siblings are acceptable in some societies; marriage between cousins is widely allowed or encouraged.

Incest avoidance has to be distinguished from incest taboos. In many societies where incest is uncommon, the possibility is regarded as bizarre or ridiculous, not disgusting and immoral.

Social scientists have proposed a number of theories to account for incest avoidance and taboos. Incest might be tabooed in societies where people have observed its deleterious genetic consequences. Incest might have undesirable social consequences, encouraging fighting and sexual jealousy within families, or limiting friendly connections between them. This last factor might contribute to explaining the extension of incest taboos outside the nuclear family (see below on alliance theory). But the likeliest explanation for nuclear family incest avoidance – and a partial explanation for incest taboos – was proposed almost a century ago, by the anthropologist Edward Westermarck. While conducting fieldwork in Morocco, Westermarck observed that cousins brought up as children in the same extended family household were often reluctant to marry even when encouraged to do so. He proposed that a kind of negative sexual imprinting takes place in childhood, resulting in “a marked lack of erotic feeling between children raised together from infancy.” This has come to be called the *Westermarck effect*.

As Westermarck realized, there is a likely evolutionary basis to this effect. Natural selection will favor avoidance of sexual relationships among children raised together as long as children raised together are usually close genetic kin. The result will be inbreeding avoidance even if the individuals involved are unaware of the genetic costs of inbreeding.

There is overwhelming evidence from many nonhuman animal species that the Westermarck effect affects mate choice. With humans, there are obvious practical and ethical barriers to testing Westermarck’s hypothesis, but it is strongly supported by several natural experiments. In early Israeli kibbutzes, children were raised together in communal nurseries. Sexual relations and marriages between children raised in the same nursery groups turned out to be relatively infrequent. There was no social pressure against such relationships, but limited sexual interest. In early twentieth century Taiwan, a common marriage arrangement involved a girl being adopted at a young age into the family of a prospective groom. The subsequent marriages had high failure rates, with low levels of sexual interest between partners, low fertility, frequent extramarital relationships, and high divorce rates. These effects were stronger when girls were adopted at younger ages.

A common objection to Westermarck’s hypothesis has been that it explains incest avoidance but not incest taboos. Why taboo something people do not want to do anyway? Westermarck addressed this issue, in the course of developing a more comprehensive theory of human moral development. He argued that the incest taboo was part of a more general pattern in which people have an aversion not just to performing disgusting or polluting acts but to others performing them as well.

Many cultures extend incest taboos, by custom or law, to kin outside the nuclear family. There is a great variation across cultures in how incest taboos are extended, and in related marriage rules. In one common pattern, taboos extend bilaterally to kin out to a certain genealogical distance. In most states in the United States, for example, marriages between first

cousins are illegal or invalid. In other societies, the sex of a linking relative is important, and principles of unilineal descent – instead of or in addition to bilateral kinship – govern the extension of incest taboos. In traditional Chinese society, for example, where patrilineal extended families and clans were important institutions, members of one's father's clan were off-limits for marriage, while equally close nonpatrilineal relatives could be acceptable. Incest taboos may thus cover varying combinations of relatives – bilateral kin, or kin having patrilineal or matrilineal connections with self, father, mother, or more distant relations. Incest taboos also sometimes cover step-kin and in-laws. They can also cover more exotic 'relations,' such as those who are linked through a wet nurse, a godparent, a natal village, a surname, or a guru.

Societies that proscribe marriage to one class of kin (negative marriage rules) may encourage or prescribe marriage to other classes of kin (positive marriage rules). Thus one common family of marriage rules, found in many of the native societies of Oceania, Southeast Asia, South India, and the Americas, bars marriages between parallel cousins (linked through same sex parents, father's brother's child, or mother's sister's child) while treating cross-cousins (linked through opposite sex parents, mother's brother's child, or father's sister's child) as allowed or preferred marriage partners. At its simplest, cross cousin marriage may result from sister exchange, in which two men marry one another's sisters. If sister exchange is repeated in the next generation, with the sons and daughters of one couple marrying the daughters and sons of the other, the result is symmetrical cross cousin marriage or *direct exchange*.

Many permutations are possible. In asymmetrical cross cousin marriage or *indirect exchange*, if men from family or marriage class A marry women from B, then men from B cannot marry into A, but must find wives in another family or marriage class. Some versions of cross cousin marriage 'skip a generation' so that people marry into the same marriage sections as their grandparents rather than their parents. And cross cousin marriage is often marriage between distant relatives who can be classified as cross-cousins, but whose actual genealogical connections may be unknown.

The motives behind these marriage rules are disputed among anthropologists. According to *alliance theory*, pioneered by Claude Lévi-Strauss, Louis Dumont, and others, marriage rules establish exchange relations between families and other social segments. The Arapesh of New Guinea express the logic of alliance theory when they say that a man should not marry a woman of his own clan, just as he should not eat yams or pigs from his own garden: it is better to establish relations of reciprocity with others by exchanging women and food. Lévi-Strauss argued that the principle underlying the various rules of *exogamy* (out-marriage) across cultures is the disposition to establish social relations through exchange, which he called a 'fundamental structure of the human mind.' It is worth noting, however, that many tribal societies do not have positive marriage rules, and those that do tend to have high frequencies of *polygyny* (men with multiple wives), suggesting that these rules may serve as much to regulate conflict over marriageable women as to promote friendly relations between groups.

In stratified societies, other considerations come into play in rules and strategies of marriage. Marriages between close kin,

and *endogamy* (in-marriage) within lineages, castes, or classes may be a device for conserving and concentrating land and other physical capital, as well as the intangible social capital of honor. These considerations led to high levels of cousin marriage in some of the traditional societies of Eurasia. Lineage endogamy is particularly common in the Islamic Middle East. Today in many Middle Eastern countries, half or more of marriages are between first or second cousins. Conversely, political and religious institutions have often sought to increase their own power at the expense of extended kin groups by limiting close kin marriages. In parts of Europe, the Catholic Church's wide injunctions against cousin marriage, and its opposition to arranged marriage, helped to weaken the hold of larger kin groups on individuals and nuclear families.

Kinship in Mind

In order to help their kin, or avoid mating with them, organisms must have mechanisms that discriminate kin from non-kin. Some organisms go beyond recognizing their own kin to recognizing kin relations among others. And humans go even further, using kin concepts recursively (e.g., mother's brother's child) and devising theories of kinship.

Kin Recognition and Cognition

Work on kinship in nonhuman animals suggests four major mechanisms whereby animals might recognize their genetic relatives: the *green beard effect*, *spatial proximity*, association (especially *developmental association*), and *phenotype matching*.

Theoretically, a single gene or linked set of genes might code both for a phenotypic trait – a green beard, say – and for discriminating altruism toward carriers of that trait. However, most current evidence points to more indirect mechanisms, which depend on learning cues reliably associated with kinship. Spatial cues are important in some species: many birds follow a simple rule of feeding any offspring they find in their nest. This can have surprisingly maladaptive consequences, in some cases leading to birds feeding nest parasites of another species like their own offspring. Developmental association is probably the most important mechanism of kin recognition in mammals. Animals reared by the same mother will commonly show kin-related affiliative and other behaviors in adulthood (see discussion of Westermarck effect above). Finally, organisms may learn their own phenotype, or that of associated organisms, and treat those with similar phenotypes as kin. Such phenotype matching may be tied to visual, auditory, or olfactory cues. Phenotype matching may allow organisms to recognize kin they have never encountered before, and to discriminate coefficients of relatedness – between full and half-siblings, for example – where no associational cues are available. Evidence for phenotype matching has been harder to come by, but now exists for a number of animal species.

Members of intelligent social species may go beyond recognizing their own kin to recognizing the kinship relations of others. This has been studied in a number of species of Old World monkeys, including vervets, savannah baboons, and macaques. Consider, for example, the widespread phenomenon of redirected aggression. A monkey attacked by another

sometimes retaliates, not against her attacker, but against the attacker's sibling or other close relative. Fights between monkeys increase the probability that their relatives will fight. This would seem to require using mental representations corresponding to the proposition 'A is the sister/matrilateral relative of B.' Experiments on captive macaques also support the conclusion that monkeys may grasp that different mother-daughter pairs have something in common that distinguishes them from other female pairs. Apparently, monkeys keep track not only of the characteristics of other individuals, but of kin and rank relations between them, and use this relational knowledge in social inference.

Human Kin Cognition: Psychology, Conceptual Structure, and Culture

Turning to how humans recognize kin and conceive of kinship, we find more varied evidence but less agreement than for other animals. Below we consider three sources of evidence: psychology, anthropological linguistics, and ethnographic fieldwork.

In psychology, kinship is a relatively neglected topic. Psychologists who have studied kinship and cognition have often been more interested in concept formation than in kinship per se. But research to date does support some conclusions. Kin relationships rank with sex and age as fundamental social categories, durably encoded and relatively immune to forgetting or confusion. Kin terms are acquired early in development. Sex, relative generation, and family membership/nonmembership are the earliest dimensions along which children differentiate kin types, with other distinctions acquired later. Knowledge of kinship is abstract and not purely experience-driven: young children understand that their kin may include people they do not live with and seldom encounter, and children without siblings are not delayed in understanding sibling terms.

Several mechanisms may be at work in establishing connections to primary kin. Evidence from a number of species, including some nonhuman primates, suggests that the immediate postpartum period is a *sensitive period* for mother-infant bonding, mediated by neuroendocrine changes. Some evidence, albeit controversial, suggests this may be true in humans as well. For sibling recognition, two separate associational cues may be involved: duration of childhood coresidence and maternal perinatal association. The latter operates when older siblings witness infant siblings being cared for by their mothers. The first cue is available to siblings regardless of relative age; the second is only available to older siblings with respect to younger siblings. Each is independently associated with attachment to siblings, and aversion to incest. A role for visual phenotype matching in kin recognition is supported by research showing that facial images are perceived as more trustworthy, but less sexually attractive, when artificially manipulated to resemble subjects' faces. The role of olfactory phenotype matching in kin recognition is supported by research showing that humans prefer the odor of potential mates who differ at the major histocompatibility (MHC) locus.

Kinship linguistics is a universe of its own within kinship studies; some of the findings in this area have broader implications for how humans conceptualize kinship. The

linguistics of kinship can be subdivided into the study of *kin terms* (words for kin), *kinship semantics* (the meaning of kin terms), and *kin terminology* (how kin terms are related to one another).

Kin terms themselves are largely arbitrary, like the rest of the lexicon. There are a few exceptions: across cultures, the nursery words for mother or father – words used by children, and between children and adults – are often some version of 'ma' or 'mama' and 'pa/ta' or 'papa/tata.'

Semantically, kinship belongs to the wider semantic field of possession: consider the underlined English possessive constructions in 'your mother,' 'Wendy's sister,' 'father of the bride,' and 'she has a daughter.' Clearly each of these constructions applies to a far wider range of possessive relationships than just kinship. However, cross-linguistic comparison shows that, in the universe of possession, kinship is special. Many languages make a distinction between inalienable (intimate, inherent, inseparable) and alienable (accidental, acquired, transferable) possession; when these distinctions are made, kin terms and body-part terms are the two semantic classes of nouns most often treated as inalienable. Conceptually, having kin and having a body are the two most prototypical, inherent kinds of having.

Further information about the conceptual status of kinship comes from kin terminology. Kin terminologies are not the same kin terms. It is a fact about English kin *terminology* that the words for father's sister and mother's sister are the same, while the word for mother is different, but it is a fact about English kin *terms* that the word for father's sister is 'aunt.' Many languages (Japanese, for example) have the same terminology for parents' siblings as English, lumping, and splitting kin types in the same way, even though the words of course are different.

On the surface, kin terminology shows enormous variation across cultures. Taking just mother and aunt terminologies, there are four major variants: *lineal* (like English, father's sister = mother's sister ≠ mother), *generational* (father's sister = mother's sister = mother), *bifurcate collateral* (father's sister ≠ mother's sister ≠ mother), and *bifurcate merging* (father's sister ≠ mother's sister = mother). There are also subvariants, since some languages make further distinctions based on whether the sister is older or younger than the linking parent. Extending the analysis to more distant kin allows for even more exotic possibilities. In some languages, some types of cousin are equated with mother or father, in others, with grandparents and grandchildren.

Yet kin terminology is actually a highly structured domain. Some terminologies are repeatedly reinvented, while many more logical possibilities are rare or nonexistent. Different schools of analysis of kin terminology have zeroed in on some major conceptual/linguistic principles that seem to be involved. First, *componential analysis*, pioneered by Ward Goodenough, Kimball Romney, and others, has identified a modest number of distinctive features present in the world's kin terminologies. In English, these distinctions include sex (e.g., sister/brother), lineal versus collateral (mother/aunt), near versus distant generations (parent/grandparent), senior versus junior generations (mother/daughter), and consanguineal versus affinal (sister/sister-in-law). Additional distinctions, absent in English but common in other languages include relative age (older sibling/younger sibling), and several varieties of cross versus parallel distinction. Many important

social facts fall outside the conceptual universe of kinship and are seldom or never encoded in kin terms, like relative wealth (rich uncle/poor uncle).

Second, *markedness* theory, developed by Joseph Greenberg, Per Hage, and others, grows out of the observation that along several of the axes identified by componential analysis, kin terms may be divided into linguistically unmarked and marked, where unmarkedness is a linguistic indicator of cognitive prototypicality. This takes several forms. In English, for example, parents are unmarked relative to grandparents, since the latter are labeled with an extra morpheme, 'grand,' (a *mark*), rather than getting a word to themselves. Brothers and sisters are unmarked relative to cousins, since there is a sex distinction among the former which is neutralized among the latter. Both of these examples illustrate a generalization which holds across languages, that near kin are normally less marked than far kin, or at least not more marked.

Third, *reduction rules*, developed by Floyd Lounsbury, and *kinship algebra*, developed by Dwight Read, are two approaches reflecting the recursive nature of kin categories, in which a core set of close kin types can be recombined to generate categories covering more distant relations.

There are important differences between these approaches. Of note here is what, in combination, they suggest about the conceptual structure of kinship. Underlying the kaleidoscopic variation of kin terms, there seem to be a modest number of conceptual primitives of social organization, including genealogical distance, seniority, and social rank, and in-group and out-group status – a finding broadly consistent with the developmental evidence.

A final source of evidence regarding kinship and cognition, ethnographic fieldwork in cultural anthropology, is both the richest and the most contentious. Here we can do no more than briefly introduce a controversy that continues to roil cultural anthropology.

For most of the history of kinship studies, although anthropologists might note that native ideas about conception, generation, and paternity were at odds with the facts of life, they generally forged ahead studying kinship systems without worrying too much about what it was that they were studying. Recent decades, however, have seen a full scale attack on the idea that kinship even exists as a proper object for cross-cultural comparison. One of the most influential kinship skeptics was David Schneider. Schneider carried out research on kinship both in the United States and on the Micronesian island of Yap. He eventually concluded that the American idea of kinship as resting on shared biogenetic substance – shared blood or genes – is missing on Yap. He claimed, for example, that Yapese did not recognize the role of intercourse in paternity, and that the father–child relationship on Yap was based on economic interests – or, more provocatively, that there was no such thing as a father–child relationship in Yapese culture.

This line of argument has been taken up by a host of anthropologists, who have documented an enormous array of beliefs about what 'kin' have in common. In Malaysia, it has been claimed, sharing food and hearth are as important as pregnancy and parturition in establishing kinship. In New Guinea, coresidence and commensalism are said to turn even genealogically unrelated individuals into kin. In some

societies, pregnancy is said to be possible without insemination, in others, semen from multiple men may be helpful or necessary to make a fetus, so that a child can grow up with several fathers. This variation has led some anthropologists, including Janet Carsten, Jane Collier, and Sylvia Yanagisako, to suggest that the whole enterprise of kinship studies is defunct, or at least that the study of kinship needs to be recast as the study of *cultural relatedness*, where cultures may have widely differing ideas about how individuals come to be related. The attack on traditional kinship studies is part of a broader intellectual movement which has claimed that maleness and femaleness, reason and madness, and racial categories are *socially constructed*.

These claims about kinship have not gone unchallenged; however, some anthropologists have raised sharp questions about the quality of the ethnographic evidence said to undermine traditional approaches to kinship.

Even setting aside the skeptical attack on kinship studies, we find a deeply divided field, at least where humans are concerned. Resolving the disagreements will probably require both advances in theory and new kinds of evidence. On a theoretical level, the evolutionary approach to kinship has proven fruitful in investigating human altruism, inbreeding avoidance, and kin recognition in the domestic sphere. But theories devised for nonhuman animals may require significant elaboration and revision to handle some uniquely human aspects of kinship: the importance of socially enforced moral codes in regulating altruism, incest, and exogamy; the recursive character of kin categorization; the symbolic elaboration and cultural transmission of the theories of kinship. On an empirical level, perhaps the most underdeveloped area of kinship studies is the cross-cultural psychology of kinship. Some important work has been done in the area of kinship and developmental psychology by John and Beatrice Whiting and their students, but a lot more could be done. Growing this field and strengthening its connections with evolutionary and cultural approaches could be an important step in developing a unified account of evolved mechanisms of kin recognition, universal core concepts of kinship, and culturally specific theories of kinship.

Glossary

Grammar Is the component of language that contains the rules that dictate how words are combined into sentences to convey complex ideas and intentions.

Language Is a code with structural properties, characterized by a set of rules for producing and comprehending utterances through the use of arbitrary symbols.

Neurolinguistics Is the study of the manner and location of the processing of linguistic information in the brain.

Phonology Is the sound system of a language and involves the rules that govern the structure, distribution, and sequencing of speech sounds.

Plasticity Refers to the ability of the human brain to change and adapt in response to environmental stimuli.

Semantics Is a system of rules governing the meaning of words and word combinations.

Language is a code with structural properties, characterized by a set of rules for producing and comprehending utterances through the use of arbitrary symbols. Often assumed to be synonymous with language, speech is a specific type of motor output for the production of language. Language may also be produced through gestures and writing. Language and its various modes of production fall under the much broader concept of communication, which is the process of sharing or giving information, feelings, and attitudes. A large number of individuals from the behavioral and biological disciplines have spent decades attempting to study and understand the nature of language development. This brief overview of language outlines recent and historical attempts to study the origins and development of language.

The Components of Language

Language is a complex system that is generally divided into four primary components: phonology, semantics, grammar, and pragmatics. Phonology is the sound system of a language and involves the rules that govern the structure, distribution, and sequencing of speech sounds. There are approximately 3000 languages in the world that use 50 or fewer sounds produced by the human vocal tract called phonemes. Phonemes are the smallest units of sound that are significant to a native speaker of a particular language (i.e., consonant and vowel sounds).

Semantics is a system of rules governing the meaning of words and word combinations. Semantics is a system in which words of a specific language represent objects, actions, events, and concepts that exist in an individual's daily life, although words are not necessarily analogous to their referents. Word meanings, or vocabulary, are hierarchically structured and are linked to each other through a semantic network.

Grammar is the component of language that contains the rules that dictate how words are combined into sentences to convey complex ideas and intentions. Grammar is composed

of two smaller aspects called syntax and morphology. Syntax refers to the rules that govern the ordering of elements of phrases, clauses, and sentences, while morphology is concerned with the use of morphemes (i.e., the smallest units in language that convey meaning). For example, in English, plural endings vary according to the last sound of the word stem.

The final component of language, pragmatics, involves the rules that guide the use of language in a social context. Pragmatics is often referred to as communicative competence because it represents the ability to use language appropriately across different social situations for the purpose of expressing one's intent and accomplishing various ends.

While each of these components can be described in isolation, successful expression of each component relies on aspects of the others. Further, although these four components may develop at different rates throughout the life span, their development is continuous and interrelated.

Language Development Over the Life Span

Infancy

Language development is fascinating and complex. One of the reasons why language development is so remarkable is that it is never explicitly taught to young children. Language is learned primarily through immersion in a linguistic environment. Even before children are born, they are exposed to linguistic information and are learning in utero. As young as 4-day-old infants prefer listening to their own language to that of a foreign language. Young infants also show the ability to distinguish between phonetic elements of speech. By 6 months, infants evidence canonical babbling represented by repeated consonant/vowel combinations.

Even before children say their first word, they communicate their intentions through gestures, smiles, eye contacts, and vocalizations. At around 12 months of age, most children can produce 10 spoken words and can comprehend as many as 50. By their second birthday, children move from the use of one-word

utterances to communicate through the use of telegraphic speech which is characterized by two-word phrases that only contain important words.

Preschool Years

By 3 or 4 years, children acquire the major elements of their native language. During the preschool years, children learn two to four words a day. It is estimated that by the time a child is 5 years old, she will have learned approximately 6000 words. This amazing ability to learn words at such a fast rate is attributed largely to the idea of fast mapping. Fast mapping involves a child's ability to form a hypothesis about the meaning of a word after only hearing it once or twice.

At around 30 months of age, children's syntactic skills become more complex and they begin to put together simple, but grammatically correct sentences. Coupled with this, the understanding and use of language in a social situation develops dramatically. During this time, children develop appropriate requesting skills and the ability to adjust speech to different social contexts. Children's ability to carry on and contribute to extended conversations also improves significantly.

Language and Literacy in the School Years

During the school years, children develop metalinguistic awareness, or the ability to understand that language is an object that can be manipulated. A major hallmark of language development in the school years is the ability to use decontextualized language. Children increasingly develop the ability to talk about things that do not exist in the immediate context. They are able to share past experiences and talk about future events. It is not until adolescence that more figurative language concepts such as metaphors and sarcasm are fully developed.

By the time a child enters kindergarten, he or she will have mastered much of the pragmatic use of language. As a result, peer relationships become increasingly important and influential. Interactions with peers are frequent, represent extended discourse, and are charged with emotional content. These interactions are important because they are different from those entered into with adults and provide a developmental context that encourages the development of important communicative skills such as storytelling, social interaction competence, and turn taking.

The rate of vocabulary development during the school years slows, and the bulk of vocabulary knowledge is learned through literacy activities rather than exposure to the spoken language. Literacy instruction occurs long before the child enters the school setting. Children are exposed to a number of different activities that foster the development of print awareness and print use conventions. Further, literacy skills are based on early oral language skills. An important oral language skill necessary to successfully learn to read is phonological awareness. The ability to understand that words are composed of smaller phonetic elements is important when learning to understand that orthographic patterns represent the sounds of speech. Reading, however, is a complex, multicomponent process that involves a number of motor, cognitive, and

linguistic skills to coordinate simultaneously for the recognition and decoding of words and the comprehension of written sentences.

Language Development in the Adult Years

Opinions have changed concerning the age at which language learning is complete. It is now generally acknowledged that language development continues throughout the life span. The average adult with a high school education has a vocabulary store of approximately 60 000–80 000 words. In contrast, an adult who is an avid reader has a mental lexicon of approximately 120 000–160 000 words. It is clear that those individuals who are exposed to advanced educational experiences and are actively exposed to print continue to learn new words.

In addition to vocabulary development, the social use of language continues to change in the adult years. Gender-linked speech styles continue to develop and women use language more to establish rapport, while men use it more to convey factual information. Further, increased competence is seen in the area of adjusting speech and language characteristics to fit work and socially specific situations.

In older adults, linguistic abilities begin to diminish as a result of the natural aging process. Although this population may have a large mental lexicon, access to this vocabulary becomes more difficult, and many older adults report word retrieval difficulties. Further, the ability to understand complex linguistic utterances, and the ability to produce complex syntactic forms, decreases. These linguistic declines are often exacerbated by other physical and health declines that co-occur during the aging process. In fact, it may be difficult to differentiate between actual linguistic declines and declines in linguistic competence due to physical health complications. Comprehension of spoken language can be disrupted due to declines in memory, and hearing loss can contribute significantly to poor comprehension of spoken language. Older adults also may experience declines in the speed at which they can process linguistic information, which can lead to problems in comprehension.

While these linguistic declines in older age appear to be inevitable, research indicates that staying linguistically active can slow the decline of linguistic ability. Further, developing strategies such as writing notes as thoughts occur can help with accessing and using linguistic information.

Language in Special Populations

Given the central role that language plays in both an individual's development and his/her integration into a social world dependent on language, the impact of various forms of language impairment is significant. Studying the language behavior of individuals with language difficulties offers a unique view to our understanding of the key elements needed for language and its development. A number of congenital disabilities (e.g., autism, cerebral palsy, deafness, mental retardation) may result in language development that is described as delayed or disordered. Many factors, such as the child's age at identification, the severity of the disability, the child's environment and experiences, all combine and affect the child's language development.

In the past three decades, substantial progress has been made in creating and delivering services to children with significant language acquisition difficulties. Advances in computer technology, coupled with strong language teaching models, have resulted in significant language learning gains. One area of language intervention for individuals with complex communication needs is augmentative and alternative communication. Augmentative and alternative communication systems are designed to offer another route for communication by individuals who cannot speak. Alternative output modes, such as the use of voice technology, allow this interface with the auditory world. Children who use speech output systems, along with proven intervention strategies, can develop their language skills and use them for communication. Educational and later employment opportunities have also increased as a direct result of these language and communication gains.

Theories of Language Development

The study of language and language development extends as far back as seventh century BC. Formal theories concerning language acquisition, however, have not come into existence until relatively recently. A number of different theories have been put forth to try to explain language acquisition. For a theory to successfully explain language acquisition, it must not only describe language at different ages, but it must also generate testable hypotheses and put forth an effort to explain how children eventually talk like adults. These requirements, combined with the complexity of language behavior, have resulted in the failure to develop one theory that completely explains the nature of language acquisition. As a result, portions of competing theories are often used to explain language acquisition. Three of the most influential traditional theories are behavioral theory, linguistic theory, and cognitive developmental theory.

Behavioral Theory

Behavioral theory has its roots in classical conditioning that was formalized and applied to language development by B.F. Skinner in the late 1950s. Skinner believed that all behavior, including language, was a learned response. This theory minimized the influence of mentalistic explanations of language behavior. According to Skinner, behavior was modified or changed through forming associations with certain stimuli in the environment. A major tenet of behavioral theory is operant conditioning, which suggests that likelihood of a behavior occurring is increased or decreased as a result of reward and punishment. Behavioral theory assumed that language is a special case of behavior only because it is a behavior that is reinforced solely by other individuals. As children are learning language, they try to produce language that is similar to adult language because it is rewarded through praise and response, while inappropriate language is ignored or corrected.

Linguistic Theory

Linguistic theory was formed by Noam Chomsky who described language as having a grammar that is largely independent of language use. Unlike behavioral theory, linguistic theory argues

that language acquisition is governed by universal, underlying grammatical rules that are common to all typically developing humans. Across many different cultures, there are a number of linguistic developmental similarities. Chomsky argues that these similarities are due to the presence of an innate language acquisition mechanism housed in the brain called the language acquisition device (LAD). According to Chomsky, the LAD is a specialized language processor that contains universal underlying linguistic principles that provide children with the innate knowledge to speak and learn language. The environment only serves to activate the maturation of the LAD. Chomsky believed that only humans were born with the LAD and that language was species-specific and unique to humans.

Cognitive Developmental Theory

Falling in between the strictly environmental account of language acquisition posed by behavioral theory and the strictly innate account posed by linguistic theory, Jean Piaget's cognitive developmental theory represents a more interactionist approach to language development. Though Piaget's cognitive developmental theory emphasized internal structures as the primary determinants of language acquisition, it was the interaction with the environment that actually shaped the development of language. Unlike Chomsky, Piaget did not view language as a separate construct. Instead, he believed that language was one of the many symbolic functions that resulted from cognitive maturation. Thus, language acquisition was driven by the interaction between the child's level of cognitive functioning and the child's linguistic environment. Piaget argued that a child's cognitive functioning constrains language development because language is based on general cognitive functioning and changes in this functioning as a child matures. As a result, the sequence of linguistic developmental milestones is determined by the sequence of cognitive development.

Sociolinguistic Theory

More contemporary theories of language acquisition emphasize the interactive nature between cognitive and social factors originally proposed by Piaget. Recent theoretical debates concerning language acquisition no longer fall along lines of biological innateness versus environmental explanations. The debate is now confined to the degree of involvement of these two factors and the nature of the interaction between them. Sociolinguistic theory posits that children are born with certain biological capacities that facilitate language development, but it is the interaction with sensitive linguistic partners that allows the linguistic system to develop successfully. This theory emphasizes the importance of social interactions, especially early in the language acquisition process. A key component of this theory is child-directed speech (CDS). CDS is characterized by simple sentences combined with exaggerated speech sounds and is representative of how parents interact with infants and young children. Through repeated interactions, children are able to map meaning onto the linguistic code evidenced in the parents' speech. Thus, while the child brings important biological predispositions to the interaction, parents and more skilled linguistic partners provide the types of language experience necessary for development.

Connectionism

Connectionism is a set of approaches that attempt to represent mental or behavioral phenomena through the use of models that imitate the neural structures of the brain. It was originally known as parallel distributed processing and emphasizes that information processing in the brain occurs on multiple levels at the same time and across a number of different processing mechanisms. Further, the functions of the domains like language are not carried out by dedicated, innate, and domain-specific neural systems. Connectionism argues that we are born with certain innate processing constraints that result in specific areas of the brain being better at processing certain kinds of stimuli and negates the idea that we are born with brain structures that are innately specified to produce language. As the brain is exposed to environmental stimuli (speech for most language learners), those areas that can most efficiently process the information are activated. Over time, the interaction between these areas in the brain and exposure to linguistic stimuli in the environment leads to these brain areas becoming specialized for processing linguistic information.

According to connectionism, there are three types of innate processing constraints. The first are representational constraints. It is theorized that mental representations are patterns of activations across neurons. The form of these patterns is determined by the nature of the connection between the units (i.e., synapses). The second type of constraint is the architectural constraint, which includes the specific properties of neurons, the circuitry layout of the brain (e.g., the number of layers in the brain, the density of cells, the degree of interconnectivity), and connections at the larger level between brain areas and regions. The final constraint suggests that the timing of the development of different brain areas can be important in determining the specialization of brain regions for specific functions. This is often referred to as critical or sensitive periods in development when specific areas in the brain develop optimally when exposed to the appropriate environmental stimuli. Connectionism, therefore, uses the term innate to refer to aspects of brain structure rather than to genes or the genetic code.

The Biological Bases of Language

The uniqueness of the properties of human language has led many researchers to conclude that there is a biological base for language development. Two primary lines of inquiry that have emerged from this conclusion are the examination of the characteristics that distinguish human language from animal communication systems and the examination of the relationship between language and its correlates in the brain.

Animal Communication

When examining animal communication systems, it is important to specify what differentiates language from the broader concept of communication. Debate exists about what specific criteria must be met for a form of communication to be considered language. Three criteria, however, are generally agreed upon. The first is productivity and represents the ability to make new and unique utterances that have not been heard before.

The second is that communication must be symbolic in that it represents objects, ideas, and events. The final criterion is that the information being communicated does not have to be associated with the current situational context (i.e., displacement).

One line of research attempting to understand the communication systems of animals is examining the way different animals communicate under normal circumstances. Early ethologists attempted to study the communication system of insects, in particular, the communication of bees. It was discovered that bees returning to the hive after finding flowers bearing nectar will perform a 'dance' for other bees in the hive. This dance indicates the direction and distance of the flowers. The dance is a recreation of the route to the flowers and, therefore, is not a symbolic 'conversation' and is limited in its conversational topic (i.e., directions to the flowers). As a result, this dance fails to meet many of the requirements of human language.

Unlike bees, dolphins and birds use vocal calls to communicate intentions. Both birds and dolphins have been found to have signature calls that identify themselves. Further, it has been shown that dolphins can imitate the vocal calls of other dolphins. The exact purpose of this call matching is unclear, but it is thought to serve as a way to gain the attention of a certain dolphin in large groups. Some birds have evidenced a variety of calls that have specific meanings. For example, it has been shown that a bird in the crow family has courting calls, calls that initiate flight and calls signaling to fly home. Again, while these communication systems resemble human language in many ways, they lack aspects of productivity, symbolism, and displacement.

A second line of research examining animal communication systems involves attempting to teach animals human language. Research with gray parrots has produced some intriguing results. Gray parrots have demonstrated that they can learn to label objects with explicit instruction. Further, one gray parrot has shown evidence of learning to recognize objects, colors, and shapes. He even has been successful at answering questions about these objects, colors, and shapes posed to him with spoken language. Though these studies suggest that gray parrots are able to learn to symbolically represent ideas, they are not able to learn in a passive environment or communicate about ideas that are not in the immediate context.

Research that has shown the most promise in teaching animals human language involves the study of nonhuman primates like great apes. Early nonhuman primate studies failed because of their effort to teach chimpanzees to speak. Chimpanzees do not have the vocal mechanisms necessary to produce speech. Later primate research focused on teaching apes (i.e., gorillas, orangutans, chimpanzees, and bonobos) to produce complex manual signs or use visual-graphic symbols.

Apes who have been taught American sign language have demonstrated the ability to learn hundreds of signs and combine them into meaningful communications. Further, there is evidence that some apes have generalized known words to unfamiliar objects in their environment (e.g., labeling a dog they have never seen before as a dog). The primary critique of these studies is that it is unclear whether the apes were able to spontaneously generate communicative signs or whether their signs were due to prompts from their trainers. Research utilizing visual-graphic symbols as a mode of communication, however, has produced some convincing evidence that

chimpanzees and bonobos are capable of acquiring word meanings and use this visual-graphic symbol system to communicate with each other and with humans. Currently, the best example of apes demonstrating the capacity to learn human language comes from research conducted with bonobos. One young male bonobo was found to learn symbols solely through observation with no direct instruction or external reward. Most striking, however, is that he demonstrated the ability to understand spoken words and novel word combinations. Subsequent studies with other bonobos have replicated these original findings and suggest that humans may not be the only species that is capable of spoken language comprehension. Overall, results from studies with bonobos suggest that they have the ability to learn language skills that are equivalent to those of a 3- or 4-year-old child.

Results from research on animal communication have led to two general conclusions concerning language development. The first is that although many different species appear to have developed systems that allow them to communicate ideas and concepts, humans are the only species to develop the complex system of language without specific instruction. The second general conclusion is that given specific instruction, certain animal species have shown the ability to learn some components of language to varying degrees of competency.

Neurolinguistics

In contrast to the nonhuman animal population, human brains have areas that are specialized for the production and comprehension of language. The study of the manner and location of the processing of linguistic information in the brain is called neurolinguistics. It is estimated that 98% of the human population is left-lateralized for language, that is, language processes are located in the left hemisphere of the brain. This percentage encompasses almost all right-handed people and 60% of the left-handed population (only about 10% of the population is left-handed). For most people then, the left side of the brain is responsible for most of the processing of linguistic information. This does not mean that the right hemisphere is not involved in language processing. For example, the right hemisphere is responsible for processing the emotional content of speech and is activated when the left hemisphere processing capacity is taxed. In addition to this hemispheric specialization, evidence from autopsies on individuals with brain insults (e.g., stroke, brain injury) and studies using functional magnetic resonance imaging (fMRI) techniques have identified specific areas of the brain that are related to specific language behaviors.

Broca's area is located in the frontal region of the brain near the part of the motor strip that is responsible for controlling the tongue and lips. This area of the brain is associated with language production, and damage to this area results in Broca's aphasia. In general, aphasia refers to the loss of previously acquired language skills because of damage to the brain. There are different types of aphasia that are based on the location of the brain damage and the skills retained by the individual. Broca's aphasia is characterized by naming difficulties, telegraphic speech (i.e., speech that contains only important words), and pronunciation difficulties. Comprehension of language, however, is retained.

Wernicke's area is found in the posterior temporal lobe and is associated with the comprehension of language. Damage to this area results in poor comprehension of speech and neologisms (nonsense words) combined with fluent and grammatically correct speech.

While specific areas of the brain have been shown to be related to specific language behaviors, there is debate as to how directly these brain structures are related to language behavior. It is possible for damage to occur in the areas and result in no discernable linguistic problems. Additionally, the brain is a large interconnected network with many cortical and subcortical areas involved in the processing of linguistic information.

Plasticity

Plasticity refers to the ability of the human brain to change and adapt in response to environmental stimuli. This ability is important not only for general development, but also for intervening with populations with language disabilities. It was previously thought that the brain lacked the ability to adapt or change after the onset of puberty and that if language was not acquired by this event, it would never be acquired. While there is evidence that the brain becomes less plastic as we age, these critical periods of development are now conceptualized as sensitive periods in which there are optimal times during development for key linguistic skills to develop.

It is estimated that 8–10% of the school age population evidences some type of developmental language difficulty that can be considered a language disability. Some of the major causes and patterns of language disabilities include hearing impairment, mental retardation, autism spectrum disorder, speech and articulation disorders, and reading disabilities. Research across a number of these areas is consistent in indicating that early intervention efforts are associated with better language development outcomes. The ability of the brain to change in response to intervention techniques intended to remediate language difficulties is believed to be responsible for these positive outcomes. Supporting this belief are studies that use imaging techniques like fMRI to compare the brains of atypically developing children with their typically developing peers. For example, brain imaging studies conducted with children with reading disabilities have shown that the brain anatomy of these children is different from that of children without reading problems. When exposed to a reading intervention, however, the brain structures of these children change to become similar to those of children who do not evidence difficulties with learning to read.

Brain plasticity has also been observed in individuals who have acquired language disabilities. Such language impairments may result from stroke, traumatic brain injury (TBI), or progressive neurological diseases. As with individuals with congenital language disabilities, positive outcomes have resulted from intervention and rehabilitation efforts. Individuals who have experienced a stroke may completely lose the ability to produce speech. Through intensive rehabilitation efforts, many of these individuals learn to speak again.

The most striking example of brain plasticity, however, comes from individuals who have undergone a complete hemispherectomy. There are rare cases of people who experience numerous epileptic seizures in a day. These repeated seizures

are so debilitating to daily life that it may become necessary to remove an entire hemisphere of the brain to stop the electrical imbalance causing the seizures. After the removal of the problematic hemisphere, the remaining hemisphere must take over all of the functions previously served by the removed hemisphere. Even individuals who are left-lateralized for language and who have had the left hemisphere removed can relearn and functionally use and understand language.

The concept of plasticity has two important implications for language development. The first implication is that the brain develops in response to experience with the environment. Thus, the more enriched the linguistic environment a child is exposed to during language development, the better a child's later linguistic outcomes. The second implication is that language difficulties that result because of biological (e.g., developmental disabilities) or environmental (e.g., TBI) reasons can be remediated, at least partially, through appropriate intervention efforts.

Genetics

Recent research on the genetic makeup of humans has led to the identification of a specific gene, FOXP2, that appears to be related to language. The complexities of acquiring language skills, along with the clear requirement that infants must be immersed within interactions that give them experience with spoken language, indicate that a single gene is not solely responsible for the development of language skills. More recent research that studies language and reading disorders has focused on identifying other candidate genes and offers a possible multiple gene model to explain the problems seen in those disorders.

Conclusion

In conclusion, the development of language is a highly complex process that continues throughout our life span. Our understanding and knowledge of the biological bases of language and its lifelong developmental phases continue to increase. The use of sophisticated methodologies and cutting-edge techniques has yielded important sources of information about language behavior, its origins, development, and use. Future scientific research will continue to explore, and explain, the intricate processes of human language acquisition.

Glossary

Leadership A multilevel leader–follower interaction process that occurs in a particular situation where the leader and followers share a purpose and jointly accomplish things willingly.

Leadership antecedents Precursors or predictors of leadership; fundamental human processes underlying leadership approaches.

Leadership consequences Outcomes or criteria of leadership; leadership effectiveness resulting from leadership approaches.

Levels of analysis Entities or objects of study; persons/individuals, dyads, groups/teams, and collectives involved in leadership.

Multilevel leadership approaches Leadership views (theories, models, styles) that include multiple levels of analysis in theory building (conceptualization) and theory testing (methodology).

Introduction

Leadership is one of the most widely discussed and researched topics in all of human behavior, cutting across the social, behavioral, and physical sciences and the disciplines of psychology, management, political science, anthropology, sociology, and biology as well as evolutionary studies. Leadership is a key topic in the popular media and the managerial and practice world, and what is sought in corporate, government, military, and not-for-profit realms. While it is one of the most studied topics in human behavior, leadership is also one of the least agreed upon, with literally thousands of definitions of and approaches to leadership in existence. As such, leadership is both a broad and deep field of study.

The purpose here is to present a multilevel overview of the leadership literature. To accomplish this, first, a working definition of leadership – one that encompasses multiple levels of analysis (person, dyad, group, and collective) involved in leadership – is developed and elaborated. Then, general and foundational notions about leadership processes that are incorporated in most approaches to leadership are discussed. Next, organized around four general categories of leadership approaches – classical, contemporary, alternative, and new wave views – numerous multilevel leadership views are described in detail to highlight the breath and depth of the field. Finally, some implications of these approaches for leadership practice and application are presented to enhance understanding of leadership in organizations.

What Is Leadership?

A working definition of leadership that includes multiple levels of analysis and encompasses the leadership approaches described here is: leadership is a multilevel (person, dyad, group, collective) leader–follower interaction process that occurs in a particular situation (context) where the leader (e.g., superior, supervisor) and followers (e.g., subordinates, direct reports) share a purpose (vision, mission) and jointly accomplish things (e.g., goals, objectives, tasks) willingly.

Leadership is one of the most important things in the realm of human behavior because literally nothing gets accomplished without it. Leadership may be formal and occurs at all levels of management or organization and not just at the top; and it may be informal, so it is not solely bestowed by title or position. Leaders can be appointed (or hired), anointed (by connections), elected (by stakeholders), and emergent (by acclamation).

Are leaders born or made? Yes, all leaders are born and all leaders are made! Leaders typically have a base level of skills with which they begin, generally linked to heredity and early life experiences (born), and they then add to or enhance those skills throughout their later lifetimes and experiences in various realms (made). In short, regardless of where leadership skills begin, leadership can be learned, developed, trained, and coached.

Leadership and Levels of Analysis

To more fully comprehend leadership and various leadership approaches, however, an understanding of levels of analysis and multilevel notions is necessary. In much leadership work, interest is in human beings (entities) in work organizations. Levels of analysis are the entities or objects of study. Entities are typically arranged in hierarchical order such that higher levels (e.g., groups) include lower levels (e.g., individuals) and lower levels are embedded in higher levels. Four levels of analysis of human beings are relevant for leadership approaches that are examined here. First, human beings in organizations can be viewed as individuals or persons, independent of one another. In this case, focus can be on a leader or a follower/subordinate, or how leaders or followers differ from one another. Individual differences are of interest. At the individual/person level, the focus is primarily on focal leaders' traits or characteristics, leadership style, vision, charisma, and the ability to transform others (followers) for the greater good.

Second, human beings in organizations can be viewed as dyads or two individuals who are interdependent on a one-to-one basis. Dyads are a special case of groups, a two-person

group. In this case, focus can be on superior-subordinate dyads, leader-follower dyads, or interpersonal relationships, independent of the formal work group. At the dyad level, the focus is primarily on leader-follower exchanges or transactions and the empowerment and development of followers.

Third, human beings in organizations can be viewed as groups or teams. While there are some potential differences between groups and teams, they are viewed similarly here, as a collection of individuals who are interdependent and interact on a face-to-face or virtual (non-co-located) basis with one another. Formal work groups or teams generally consist of a leader and his/her immediate direct reports. At the group/team level, the focus is primarily on leadership styles displayed toward the group or team as a whole. Tasks (initiating structure and concern for work) and relationships (consideration and concern for people) are the central notions here, with participation, delegation, sharing of duties, and interdependence as key issues.

Fourth, human beings in organizations can be viewed as collectives. In this case, the focus is on clusterings of individuals that are larger than groups or teams and who are interdependent based on a hierarchical structuring or a set of common or shared expectations. Collectives can include groups of groups, departments, functional areas, strategic business units, networks, and organizations. Collectives often do not involve direct interaction among people (as in groups and teams), but are held together by echelons or hierarchies. At the collective level, the focus is primarily on management, including managerial philosophy, and supervision as well as setting the strategic mission and goals and energizing the collective effort overall.

Beyond these single levels of analysis (i.e., individuals/persons, dyads, groups/teams, or collectives viewed separately), a key issue is that of multiple levels of analysis. In other words, levels can be viewed in combination or simultaneously. In these cases, concern is with multilevel or cross-level effects, as well as mixed determinants and mixed effects. Multilevel models depict relationships between independent (predictor, e.g., antecedents of leadership) and dependent (criterion, e.g., consequences of leadership) variables that operate at different levels of analyses. Cross-level models are those where patterns of relationships are replicated across multiple levels of analysis (e.g., hold or occur for both individuals and groups). Mixed effects models are those in which a single variable of interest (e.g., leadership style) may have effects at multiple levels with multiple criteria of interest (e.g., performance of both individuals and groups). Mixed determinants models are those where multiple predictor variables at various levels of analysis (e.g., leader personality traits, leader-follower interpersonal relationships) affect a single criterion at a single level of analysis (e.g., leadership effectiveness in a group). The leadership approaches described here have these multilevel characteristics.

Leadership Antecedents and Consequences

In addition, the leadership approaches highlighted below often include similar or analogous antecedents and consequences. As such, a general way to view the leadership process, summarized in the aforementioned working definition and

typically endorsed by the leadership approaches described here, is antecedents → leadership → consequences.

Most approaches and views consider similar antecedents or precursors of leadership which are essentially underlying fundamental human processes. At the person level, affect and cognition are important fundamental human processes. Affective processes include rapid formation of general liking or disliking of leaders and followers. Cognitive processes include how leaders and followers think about things – obtain, store, retrieve, categorize, and use information. There also are some linkages among personality – especially represented by the Big Five of neuroticism, extraversion, or surgency, openness to experience, agreeableness, and conscientiousness – and various forms and aspects of leadership.

At the dyad level, attraction and exchange are important fundamental human processes. For example, similarity or a match on a mutual interest or characteristic can lead to mutual liking of one another. At the group and team level, climate and norms are important fundamental human processes. A key group or team norm is that leaders are predetermined or emerge and fulfill certain functions and create positive climates. At the collective level, organizational culture and values are important fundamental human processes. Various elements of culture and values can impact or influence the appointment and emergence of various types of leaders and the organizational leadership philosophy and approach. In terms of multiple levels of analysis, communication is an important fundamental human process that cuts across levels. The methods, media, and technology of communication are critical to the formation, development, and use of leadership.

Most leadership approaches and views are interested in similar multilevel consequences or outcomes of leadership which are essentially aspects of leadership effectiveness (e.g., team building, performance, satisfaction, commitment, attachment, loyalty, absenteeism, turnover, stress, safety). At the individual level, high degrees of satisfaction, commitment, and loyalty (soft performance criteria) as well as effective and higher individual performance, lower absenteeism, and less turnover (hard performance criteria) are relevant factors. These variables can have conceptual linkages with various individual-level aspects of the leadership approaches.

At the group level, high degrees of cohesion, high morale, and positive climate (soft performance criteria) as well as objective, effective, and higher group/team performance and lower group absenteeism (hard performance criteria) are important. Team members' perceptions of the team cohesiveness and the nature of the climate are as important as the cohesiveness and climate *per se*. These variables can have conceptual linkages with various group- and team-level aspects of the leadership approaches.

At the organizational level, a positive culture, recognition of internal and external stakeholders, and a multifaceted mission (soft performance criteria) as well as objective, effective, and higher organizational performance (e.g., stock prices, sales, return on assets, return on equity – hard performance criteria) are important. These variables can have conceptual linkages with various organizational-level aspects of the leadership approaches.

At multiple levels, performance – including quantity and quality of performance as well as general and specific

performance – is perhaps the most crucial dependent (outcome) variable in leadership research. Leader performance, team performance, and, ultimately, the performance of the entire organization via multiple individuals and teams are a central concern. Affect and emotional contagion at both the individual and group/team levels can also be a key outcome for leadership. Stress also is relevant at both the individual and team levels and can be an outcome of various leadership approaches. Though some degree of stress may actually enhance performance, excessive degrees can have debilitating consequences. Conflict, both intraentities and interentities (e.g., groups) conflict, is relevant at both the team and organization levels and can be a consequence of leadership. Some degree of conflict may actually improve performance, but excessive amounts of conflict can be stifling and have dire consequences. Also, team members' perceptions of conflicts are as important as the conflicts themselves.

With these foundational and integrative notions of leadership (working definition, levels of analysis, antecedents, and consequences) in mind, five classical, five contemporary, four alternative, and four new wave views about leadership are considered in more detail. For each leadership approach, the primary level(s) of analysis, key ideas and constructs, and main multilevel effects are elaborated to highlight the range and richness of the leadership field for understanding human behavior.

Classical Leadership Views

The first classical view, *Ohio State* approach to leadership, includes two leadership styles, initiating structure (task-oriented and directive supervisory behavior) and consideration (friendly and interpersonally supportive supervisory behavior), that are predicted to differentially impact subordinate satisfaction and performance, given various situational moderators (e.g., unit size, job anxiety, role clarity, supervisory control). Initiating structure and consideration, as typically measured by the Leader Behavior Description Questionnaire, are relatively independent leadership styles, such that leaders can be placed on a continuum from low to high on each dimension. The effectiveness of low-low, low-high, high-low, and high-high consideration and initiating structure styles depends greatly on the type of performance assessed and various situational or contextual factors.

The second classical view, *contingency model* of leadership effectiveness, was an early multiple-level approach to leadership and one of the first models that was tested with multi-source data from leaders, followers, and the organization. The model predicts that two main factors determine a leader's effectiveness: a task or relationship style (motivational orientation), which is a leader attribute, and a leader's situational favorability (situational control). Leaders who have a task motivational orientation compared to those who have a relationship orientation are predicted to be more successful in high- and low-control situations. In contrast, relationship-oriented leaders, as compared to task-oriented leaders, are predicted to be more effective in moderate-control situations. Leaders are said to be in match in situations where the model predicts high group performance and are referred as out of match in situations of low group performance.

In the ideal contingency model approach, a leader's style or motivational orientation is measured at the individual (leader) level by the Least Preferred Coworker scale. Situational control or favorability comprises group climate, task structure, and authority, which are assessed via the group – or individual-level measures of group atmosphere or leader-member relations, task structure or type of job, and position power, respectively. Typical measures of leadership effectiveness, at the group, dyad, or individual level, include satisfaction, stress, and performance. Overall, the three situational control variables, with each rated as low or high ($2 \times 2 \times 2$), comprise the classic eight-cell view of moderators of the relationship between leader attribute/style and end result/performance.

A third classical view, *participative leadership*, is a normative model of leader decision-making to understand a leader's choice of autocratic versus participative behaviors. The model guides the leader's choice among five decision processes (two autocratic, two consultative, one joint or group) on the basis of 11 decision heuristics that are grouped around the notions of improving decision quality, improving decision commitment, reducing decision costs and time, and increasing subordinate development. Overall, the appropriate decision styles that result in effective leadership are autocratic, consultative, and collaborative sharing (either joint or delegative), but the choice of these styles differs from situation to situation.

A fourth classical view, *path-goal leadership*, is a means-end motivation explanation of the effects of leader behavior on subordinate satisfaction, motivation, and performance. Dimensions of leader behavior such as leader initiating structure, consideration, authoritarianism, hierarchical influence, and closeness of supervision are analyzed in terms of path-goal notions such as expectancy (probability that effort will lead to performance), instrumentality (probability that performance will lead to outcomes), and valence (value of outcomes). The approach also specifies some of the situational moderators on which the effects of specific leader behaviors are contingent. There are two legacies of path-goal leadership – substitutes for leadership and charismatic leadership – and a reformulated path-goal approach specifies eight classes of leader behavior that enhance subordinate empowerment and satisfaction as well as work unit and subordinate effectiveness, subject to several contingency moderators. The essence of path-goal leadership is a meta-proposition that leaders, to be effective, engage in behaviors that complement subordinates' environments and abilities in a way that compensates for deficiencies and is instrumental in subordinate satisfaction and individual and work group unit performance.

A fifth classical view, *vertical dyad linkage* approach to leadership, was the first one to recognize that leaders treat subordinates within the same work group differently. This notion was radical when introduced, as prior approaches to leadership assumed that leaders treated all followers or subordinates in a group similarly. Using the key variable of negotiating latitude, leaders can create differentiated dyads within work groups, such that some subordinates are members of the in-group (cadre) while others are members of the out-group (hired hands). Two legacies of the vertical dyad linkage approach are the leader-member exchange and individualized leadership approaches, both of which are described in the following paragraphs and involve different variables, constructs, and alternative levels of analysis.

Contemporary Leadership Views

A first contemporary view, *charismatic leadership*, in the management and psychology literature, is generally defined in terms of the leader's influence over followers and the nature of the leader–follower relationship. Key leader behaviors include articulating an appealing vision, communicating high performance expectations, displaying self-confidence, role-modeling exemplary behavior, expressing confidence in followers' abilities to achieve goals, and emphasizing ideological aspects of work and collective identity. Other key aspects of charismatic leader behavior are articulating an innovative strategic vision, displaying unconventional or creative behaviors, taking personal risks, and showing sensitivity to follower needs and environmental constraints, opportunities, and threats. The effects of these charismatic behaviors are numerous: followers develop trust in, respect for, devotion to, loyalty to, unquestioned obedience to, commitment to, and identification with the leader; develop confidence in their ability to achieve goals and exceed expectations; and develop radical changes in their beliefs and values.

Socialized charismatic leadership includes the development and empowerment of others, a basis for egalitarian behavior, and indicates that the leader disregards his/her self-interest in favor of the collective interest. Socialized charismatic leaders are characterized by a high need for power with high activity inhibition (restraint), low Machiavellianism, non-authoritarianism, strong internal beliefs, and high self-esteem. Such leaders are also called authentic transformational leaders. Personalized charismatic leadership, in contrast, includes exploitation of others, personal dominance and authoritarian behavior, and serving the leader's self-interest and self-aggrandizement. Personalized charismatic leaders are characterized by a high need for power with low activity inhibition (restraint), high Machiavellianism, high narcissism, external beliefs, and low self-esteem. Such leaders are also called pseudo-transformational leaders.

Charismatic leaders form a unique emotional and value-based bond with their followers. They achieve their charismatic effects by engaging and implicating followers' self-concepts. Through role-modeling behaviors and frame alignment, charismatic leaders develop followers' values and beliefs to be congruent and complementary with the leaders' ideology, goals, and activities. In particular, charismatic leaders are able to increase followers' intrinsic valence of effort and goal accomplishment, effort-accomplishment expectancies, and prospects and hopes for a better future state. Charisma is often viewed as a unique, distinct element and the only aspect of leadership that is extraordinary.

A second contemporary view, *transformational leadership*, in management and psychology research, is generally defined in terms of the leader's behaviors and effect on followers. Different from transactional leadership (defined as an exchange process to motivate follower compliance with a leader's requests and organizational role requirements), transformational leadership involves an underlying influence process that motivates followers by encouraging them to transcend their self-interests for the sake of the organization and goal accomplishment. Followers, through transformational leadership, are motivated to do more than originally expected and feel trust, loyalty, respect, and admiration toward the leader.

Transformational leaders raise followers' levels of awareness and consciousness about the value and importance of key outcomes and their accomplishments. They alter followers' portfolios of needs and wants, expanding and raising these in terms of the need hierarchy. Moreover, transformational leaders encourage and help followers transcend their self-interests for the enhancement of the group, team, organization, or larger interests of society.

There is a generally, though not universally, endorsed distinction between transformational and charismatic leadership: A leader may be charismatic without being transformational in that little or no influence to change followers is exerted. As such, charismatic leadership is viewed as only one component of transformational leadership, along with inspirational motivation, intellectual stimulation, and individualized consideration. While charismatic leadership is perhaps the key component of transformational leadership, charisma is a necessary but not sufficient element of transformational leadership. Very closely related views to transformational leadership are labeled authentic, ethical, and servant leadership; all of which are essentially transformational-like in orientation, description, and application.

A third contemporary view, *leader–member exchange*, is a relationship-based approach to leadership that developed from the vertical dyad linkage approach to leadership. The leader–member exchange literature is quite extensive and has evolved through four research stages. In stage one, research found that leaders developed differentiated relationships with their subordinates. In stage two, research focused on these differentiated relationships of the leader within the work unit and the nomological network of leader–member exchange-related constructs. In stage three, the focus of research was on how leaders work with each person/subordinate on a one-to-one basis to develop a partnership with each of them. In stage four, dyadic relationships are expressed in terms of how they are organized into larger collectives within and beyond the organizational system.

At the core, leader–member exchange is a transaction-based relationship between a leader and a follower. More specifically, leader–member exchange is a system of components and their relationship involving both members and interdependent patterns of behavior as well as sharing mutual outcomes. It differs from vertical dyad linkage (which focuses on negotiating latitude) and individualized leadership (which focuses on support for self-worth), both of which seem to have a clear level of analysis focus. In leader–member exchange, a leader and an individual follower develop a relationship as they influence each other and negotiate the follower's role. This exchange relationship takes one of the two general forms: the in-group is a special exchange relationship with a small number of trusted subordinates who serve as assistants or advisors; the out-group is the remaining subordinates with whom the exchange relationship is more formalized and based on role requirements and job descriptions. Over time, leader–member exchange relationships can develop from stranger (low exchange) to acquaintance (medium exchange) to maturity (high exchange) in a life cycle of leadership making.

A fourth contemporary view, *shared leadership* approach, focuses on the entire team or group and how they operate collectively and share responsibility. Especially in high-performing

teams, there is a strong reliance on shared mental models (shared knowledge and cognitions) within the team. In shared leadership, no one member of a team stands out always and everywhere as a leader; rather, leadership roles and responsibilities are shared and distributed throughout the team depending on the issue, circumstance, expertise needed, and time constraints. The need for shared leadership is driven by the new, complex demands of work situations, technology, and new patterns of interdependence and coordination required among team members. No one person can likely have all the knowledge, expertise, and skills needed to meet goals and accomplish tasks successfully in cross-functional and multi-functional situations.

Through team processes of communication, face-to-face interaction, and collaboration, there is considerable knowledge acquisition and sharing in teams. Knowledge and information sharing lead to cognitive elaboration where new knowledge structures are created and old structures are modified. Over time, cognitive convergence occurs where team members gradually acquire enhanced overlap among their cognitive structures. Shared cognitive structures and knowledge (shared mental models) then can reduce variance in team performance, enhance cohesiveness, build a positive team climate, and promote successful goal accomplishment. These shared mental models are similar, overlapping, compatible, or complementary knowledge or belief structures that represent features of the context (such as task-specific knowledge, task-related knowledge, knowledge of team members, and attitudes and beliefs). Shared and overlapping knowledge and belief structures support the alignment of expectations that permit rapid and smooth coordination of behavior, availability, and access to a larger pool of information for problem solving and task completion, enhance the creation of new knowledge, enable team innovation and learning, and foster faster agreement on problem definition and strategic decisions.

These elements result in enhanced team effectiveness and efficiency based on teamwork with high levels of expended collective effort and high-quality interpersonal relationships. Highly effective teams are characterized as having a clear focus or vision when members are willing to sacrifice individual goals and accomplishments for team mission fulfillment. Team members identify so well with the team purpose and mission that they are willing to make individual sacrifices for the team and to enhance other team members' potential and capabilities. By developing a shared belief structure, teams develop a shared climate and culture that includes understanding of their behaviors, values, and ideas, and that develops a sense of cohesiveness and a set of expectations that facilitate learning and the ability of the team to lead itself.

A fifth contemporary view, *strategic leadership*, attempts to infuse a philosophy, set of values, mission, goals, and objectives throughout the entire organization. This may signal the influence of a CEO, top management team, and/or various department or unit leaders. Strategic leadership focuses on executives who have overall responsibility for an organization. The characteristics, behaviors, and impact on organizational outcomes of top individuals (e.g., CEOs) and top groups (e.g., top management teams, boards of directors) are considered to be of prime importance. The strategic leadership approach is concerned with strategic leadership per se, organizational form

or conduct (strategy, structure, and processes), environment or stimuli external to the organization (such as industry structure), and organizational effectiveness or firm performance.

Strategic leadership occurs at the highest levels of management, and regardless of the level of analysis or focus (e.g., CEO as an individual, top management team, philosophy, and values for the organization), involves dealing with organizational culture and effectiveness, the highest degrees of cognitive and behavioral complexity and decision-making, critical tasks that include strategy, vision, and organizational design, and the longest time spans (often 20 years and beyond). Strategy is the means-end package of the organization, typically expressed in terms of the vision of the CEO and/or top management team. Organizational design includes an overall configurational characterization (e.g., tall vs. flat) and various combinations of dimensions such as size, formalization, and centralization.

For organizations to be effective, there should be a consistency between the organization's strategy and structure. Behavioral and cognitive complexity, another aspect of strategic leadership, is essentially an individual's (e.g., CEO's) cognitive power, the sophistication of organizing processes, the skill to differentiate and integrate multiple cognitive elements, and the ability to engage in and effectively perform multiple roles and wide-ranging behaviors required by an organization in its environment. This includes creating, defining, and managing the organizational culture. Culture is multilayered (i.e., visible artifacts, deeper shared values and beliefs, and even deeper shared basic assumptions), with potentially numerous subcultures, and dimensions of culture that may vary both within units (intensity or agreement within) and between units (integration or agreement between). All strategic leadership elements impact numerous indicators of organizational performance and effectiveness, as valued by various internal and external stakeholders.

Alternative Leadership Views

A first alternative view, *substitutes for leadership* model, differs from previous leadership approaches that suggested that leadership styles will be effective regardless of the situation. Rather, it posited that particular individual, task, and organizational variables could substitute for or neutralize leadership, thereby negating a leader's ability to positively or negatively influence subordinate attitudes and effectiveness. Neutralizers create an influence vacuum and reflect characteristics that make leadership effects impossible. On the other hand, substitutes not only can affect which leader behaviors are influential, but also will tend to impact criteria.

A subordinate's need for independence, professional orientation, and indifference toward organizational rewards would tend to neutralize relationship-oriented leadership. Similarly, intrinsically satisfying tasks, cohesive work groups, no control over rewards, and the spatial distance between the subordinate and the superior also would neutralize relationship-oriented leadership. Subordinate characteristics such as the need for independence, professional orientation, indifference toward rewards, and ability and experience tend to neutralize task-oriented leadership. Similarly, routine tasks, highly standardized tasks, tasks that provide their own outcome feedback, cohesive

work groups, no control over rewards, the spatial distance between the subordinate and the superior, highly specified staff functions, and organizational formalization and inflexibility also would neutralize task-oriented leadership. Thus, substitutes can moderate the leader behavior–outcome relationship for all categories of substitutes, that is, person knowledge, skills, and abilities; dyadic informal relations; group and team cohesion and potency; and collective structure, formalization, job descriptions, and standard operating procedures.

A second alternative view, *influence tactics approach*, examines specific types of behavior used to exercise influence, rather than focusing solely on power as a potential source of influence. Influence attempts, based on legitimate power, that are reasonable, relevant to the mission, and the target person knows how to do, tend to be the most successful. The key categories of influence tactics, or proactive influence behaviors, are rational persuasion, inspirational appeals, consultation, ingratiation, personal appeals, exchange, coalition tactics, legitimacy tactics, and pressure. The directional use (up, down, or lateral) and effectiveness of these tactics varies across situations and targets (subordinates, peers, or supervisor).

A third alternative view, *information-processing and implicit leadership*, is a person-perception based approach that relies on both affective and cognitive processing strategies. These mechanisms determine followers' perceptions of leaders and play an important role in the formation, often rapidly, of liking or disliking of a leader. Follower affect and cognitions result in leadership perceptions that can be recognition-based or inference-based. Stereotypes and implicit theories of followers or subordinates about effective leadership determine the perceived relevance of various types of leader behavior. Followers and subordinates also use information about the situation and past events to draw conclusions about effective leadership and judge a leader's intentions.

A fourth alternative view, *pragmatic leadership*, focuses on the leader and his/her style and also on the style of others in a group or team who have some form of leadership responsibility. Sometimes labeled as functional and problem-solving leadership, this is leadership where influence is exercised by identifying and communicating solutions to significant social problems, working through elites (e.g., authorities) in solution generation, creating structures to support solution implementation, and demonstrating the feasibility of these solutions. The pragmatic leadership approach asserts that effective leadership behavior fundamentally depends upon the leader's ability to solve the kinds of complex social problems that arise in teams and organizations.

Leaders begin to address complex issues by defining the problem and formulating a solution framework or set of ideas to understand the problem and develop initial solution strategies. The focus here for leaders is on the problem per se, its significance, origin, and potential solutions. Experience, knowledge of the job/tasks, and understanding of the environment shape the way the leader represents the problem, the kinds of information sought, and the type of concepts applied. Capabilities such as wisdom and knowledge, perspective-taking, creative problem solving, and social judgment skills enable leaders to go beyond themselves to assess how others react to a solution, identify restrictions, develop plans, and build support for implementation.

Performance ultimately depends on the implementation of a plan which occurs in a social context where the leader depends on the efforts of others for making proposed solutions happen. Social cognition and knowledge of peers, subordinates, and superiors are critical for solution implementation. Flexibility and adjusting plans as dictated by the changing social environment and the ability to communicate a vision, establish clear and achievable goals, monitor progress, and motivate others to implement a given solution, also are seen as critical skills. General cognitive abilities, crystallized cognitive abilities, motivation, personality, and prior career experiences – all influence a leader's problem-solving skills, social judgment and social skills, and knowledge. Pragmatic leadership requires careful observation of people and social systems to identify needs, objective analysis of the situation to identify restrictions and intervention points, and development and implementation of solution strategies designed to maximize benefits at low cost.

New Wave Leadership Views

A first new wave view, *multiple linkage* model, builds on prior models of leadership and group effectiveness. Using four types of variables – leader behaviors, intervening variables, situational variables, and criteria – the model proposes interacting effects of leader behavior and situational variables on intervening variables that determine work unit performance. In this model, leader behaviors include various managerial behaviors such as supervising, planning, organizing, controlling, coordinating, consulting, and administering. The intervening variables include subordinate effort, role clarity and task skills, organization of work, cohesiveness and cooperation, resources and support services, and external coordination. Situational variables include neutralizers, substitutes, and various other factors. The model proposes that leaders institute short-term actions to deal with deficiencies in the intervening variables and positively impact group performance in the long term.

A second new wave view, *multilevel and leaderplex* approach, is the integration of behavioral complexity, cognitive capacity, and social intelligence. Behavioral complexity is represented by roles (mentor and facilitator, innovator and broker, producer and director, monitor and coordinator) based on competing values (collaborate, create, compete, control). Cognitive complexity or capacity assumes that cognitively complex individuals process information differently from and perform selected tasks better than cognitively less complex people because they use more categories to discriminate among stimuli and see more commonalities among these categories. Relatedly, cognitive capacity or cognitive power connotes those mental processes that tap the scale and complexity of the world one is able to pattern and construe. This is the raw mental power enabling one to sustain increasingly complex mental processes. Social intelligence, another leader characteristic, is the ability to notice and make distinctions among other individuals; in particular, among their moods, temperaments, motivations, and intentions. Beyond this ability is managerial wisdom and the skill to act based on an understanding of others.

In multilevel leadership, the focus is on conceptualizing hierarchical organization levels in terms of the amount of

cognitive capacity/power required at each of these levels, or groupings of levels, into domains: systems leadership, the very highest organizational levels; organizational leadership, middle to upper middle levels; and production leadership, lower levels. Thus, at increasing hierarchical levels or domains, the time span of decision-making increases until these time spans can be 10–20 years or more. As the time span requirements increase, a higher level of cognitive capacity/power is needed. Leadership is considered more effective the closer the match between time spans required and the leader's cognitive capacity to deal with the time span requirements.

A third new wave view, *individualized leadership* approach, focuses on the unique one-to-one dyadic relationship between a superior and a specific subordinate. Each relationship involves the superior's investments in and returns from the subordinates, and the subordinate's investments in and returns from the superior. Investments are what one party gives to another party. Returns are what one party receives from another party. Key variables involved in this dyadic exchange process are providing support for a subordinate's feelings of self-worth by a superior and providing satisfying performance to a superior by a subordinate.

The leadership process is individualized in the sense that each superior–subordinate dyad can be in agreement with regard to the degree of giving and receiving of these exchanged commodities. Leadership in this approach is defined as occurring when a superior is able to secure satisfying performance from a subordinate. One mechanism for securing leadership is for a superior to provide support for a subordinate's feelings of self-worth. A likely source of the initiation of individualized leadership is the leader's investment in a follower, as perceived by that follower, to enhance the follower's self-worth.

A fourth new wave view, *collective leadership*, focuses on units, teams, and networks, rather than solely on the skills of individual leaders, and draws on expertise from multiple sources in a timely fashion to arrive at an effective resolution of unique, rapidly emerging problems. Such leadership requires adaptability and the pooling of information and skills to accomplish missions; leadership becomes a collective or team- and network-based organization-wide enterprise. Collective leadership is a dynamic leadership process in which a defined leader, or set of leaders, selectively utilize skills and expertise within a network, and across levels of analysis and hierarchical levels, effectively distributing elements of the leadership role as the situation or problem at hand requires. In complex environments subject to rapid change, multiple leaders operating in a collective fashion and with team- and network-based approaches are critical to unit and organizational performance.

Beyond merely multiple individuals taking on different roles, sharing responsibilities and behavioral integration (including information exchange, collaboration, and joint decision-making which ultimately lead to some degree of attitudinal and/or behavioral influence) based on selective use of expertise within a broader network are important components of collective leadership. The collective leadership model includes key collective leadership constructs (i.e., leader skills, leader network, leader–team exchange, communication, problem setting, team performance parameters, team affective climate, and team network), baseline leadership and team processes (i.e., leader structuring and maintenance of group, mission, and team processes),

outcomes (i.e., team performance capabilities, immediate outcomes, and long-term outcomes), and the organizational setting and context (e.g., professionalism and expertise of the workforce, organizational structure, and work flow).

Communication is the currency of collective leadership. Leaders exchange information with their teams and networks, which helps to develop team and network parameters and affective climate and performance. Leaders involved could be formal or informal; teams involved may be formal or ad hoc; networks identified could be official (professional) or unofficial (personal or social). In collective leadership, there is meaning in the way information flows through specific patterns of team and network members; and it is conceivable that a team, network, or organization could develop their collective leadership capabilities such that the appropriate collective could be assembled rapidly in various situations.

Applications for Effective Leadership

Consideration of these numerous multilevel leadership approaches, while illustrating the breadth and depth of the leadership field, also leads to a general set of applications and guidelines for effective leadership practice in organizations regardless of whether the leader is a CEO, first-line manager, or an informal one. First, as leadership is multilevel in nature, leaders need to be cognizant of persons/individuals, dyads, groups/teams, and collectives in organizations. Ignoring any of these perspectives on human beings could create leadership problems and inappropriate solutions. Second, as leadership is multidimensional in nature, various elements and aspects must be implemented and practiced at multiple levels of analysis to be successful and effective.

In particular, at the individual/person level, leaders need to inspire followers, treat followers as individuals, spark followers intellectually, help followers become committed and interpret the meaning of events for them, pick a good person as second in charge, and try to eliminate their own job, thereby giving others a chance to develop and freeing the leaders to tackle new challenges. At the dyad level, depending on each follower's needs and wants, leaders ought to provide support, attention, time, resources, and challenging work to followers, encourage high follower performance, and develop and empower them one on one. At the group/team levels, leaders need to share responsibility, authority, and tasks to be completed; build cohesion and a welcoming climate; and foster cooperation and mutual trust among team members. At the collective level, leaders need to provide vision and direction; set the mission, goals, and objectives; be the moral and ethical compass and a model of integrity; and think long term (not only short term) for the entire organization. Finally, at multiple levels of analysis, because leadership titles create and set expectations for followers, leaders need to meet these expectations at the individual/person, dyad, group/team, and collective levels of analysis in organizations.

Conclusion

To summarize and integrate a vast and growing leadership literature, a broad-based working definition of leadership was presented at the outset. This integrative definition led to a

discussion of the foundational levels of analysis issues related to leadership and general leadership processes and ideas, including antecedents and consequences of leadership, which cut across a variety of leadership approaches. Numerous leadership approaches were then highlighted and detailed within the categories of classical, contemporary, alternative, and new wave leadership views. Lastly, a set of integrative applications and principles for effective leadership in organizations were presented. Regardless of the leadership approach that is considered or endorsed, the future of leadership research and application that takes a multilevel perspective on human beings holds great promise for a better understanding of human behavior related to leadership processes and practices in organizations.

Learned Helplessness

Glossary

Attribution theory A theory concerned with how one attributes causes to events and behaviors. In the original attribution theory, individuals may determine that the cause of an event was due to factors within themselves or outside of themselves. Key attributions include whether the cause was within an individual's control versus outside an individual's control, whether the cause is likely to be stable over time or not, and whether the cause can be applied only to the specific situation or can be applied broadly.

Depression A mood state characterized by feelings of sadness, hopelessness, being discouraged, and in many cases, greater irritability. In addition, other symptoms are often present such as loss of interest in a variety of activities, weight changes, insomnia, and fatigue. Cognitive deficits may appear as well in terms of inability to concentrate. Its worst cases warrant a clinical diagnosis with treatment.

Explanatory style Often also referred to as attributional styles, this is the type of causal attributions an individual commonly makes to an event. Individuals who typically attribute internal, stable, and global causes to an event have been described as having a pessimistic explanatory style that has been linked to learned helplessness and depression.

Learned optimism Representing the opposite of a pessimistic explanatory style, learned optimism describes individuals who have learned to employ an optimistic explanatory style (external, unstable, and specific attributions) to events. This manner of attributing causality appears to buffer against symptoms that often arise from a negative or stressful event.

Posttraumatic stress disorder (PTSD) Characteristic symptoms that often arise following exposure to an extreme stressor or traumatic event involving threat to oneself or others and in which the response involved fear or horror. These symptoms are present in the long term and often include reexperiencing the event in a variety of ways, emotional numbing and avoidance of stimuli related to the event, as well as increased physiological arousal.

Shuttlebox An experimental apparatus used in many of the first experiments on learned helplessness. It typically consists of a rectangular box with a series of metal bars on the bottom that serve as a platform for an animal to stand on and through which an electronic current can be passed to shock the animal. A small platform is placed in the middle of the box that the animal must jump over to relieve the shocks.

Definition

Learned helplessness is a theory that explains a particular response pattern that an organism has after experiencing stressful events for which there is no control. When an organism learns that it does not have control over a stressor, three primary behavior patterns can be observed. First, the organism will engage in fewer voluntary problem-focused behaviors. It will give up trying to resolve the situation. Second, the organism will display cognitive deficits. It will take a longer time for the organism to engage in an effective behavioral response, even if the organism has successfully performed the behavior previously. Third, because these effects can dissipate over time, the behavioral changes are influenced by emotional responses to the lack of control. If the organism learns the appropriate response to the stressor prior to loss of control, motivational and cognitive deficits do not occur. Modifications have been made to this theory, but these three response patterns remain defining hallmarks of learned helplessness.

Initial Findings

The theory of learned helplessness stemmed from studies in the 1960s and 1970s. In the first experiments, some dogs were restrained (in what is called a Pavlovian hammock) and then

shocked. The shocks occurred at unpredictable times and the restraint ensured that the dog could not escape or avoid the shock. One day afterward, the dogs were placed in a box with two compartments separated by a short barrier (a shuttlebox). While in the shuttlebox, the dogs were given light signals that indicated that the shocks would commence and 10 s later, the dog would be shocked until it jumped over the barrier. Dogs that jumped the barrier within those 10 s would not receive the shock. While most dogs that were not shocked prior to the shuttlebox trials jumped to the other side and quickly learned to do so in subsequent trials, the majority of dogs that had previously received shocks while under restraint did not jump to the other side. Furthermore, when these restrained dogs did jump across, they were slower to learn that jumping across relieved the shocks. Importantly, all dogs were able to effectively respond to other events (such as running out of the shuttlebox door once it was opened), indicating that these effects did not occur due to physical symptoms produced by the study procedure.

To test whether these deficits occurred due to a lack of control over the shock or due to the shock itself, a control group was added in which the restrained dog could press a bar to stop the shock. The unavoidable shock group was able to press the bar but this would not stop the shock. In this case, the dogs that experienced controllable shock did not show the same level of deficit (they were able to learn to jump over the barrier). Other variations on the experimental procedures

[†]Deceased.

demonstrated that the intensity, frequency, and duration of shocks could be varied with the same result. The same results could be obtained whether shocks were induced with a restraint or simply within the shuttlebox. Further experiments confirmed that, with few caveats, these effects were reproducible with other animals, including cats, rats, mice, birds, primates, humans, and even fish. These effects could also be produced using relatively innocuous stimuli (e.g., college students being asked to solve an unsolvable problem) and could generalize to other tasks (e.g., college students presented with uncontrollable noise subsequently having problems solving Anagrams).

The Initial Learned Helplessness Theory

In 1976, Maier and Seligman published a seminal paper in which they summarized this evidence and proposed the theory of learned helplessness to explain it. Essentially, the experimenters theorized that this response pattern arose specifically from the animal learning that behaviors are not paired with or otherwise do not produce expected outcomes. The resulting learned helplessness has three effects: First, the animal has a reduced motivation to perform later behaviors. Normally, the animal expects that its behavioral responses would produce relief from a stressor, but the animal has learned that this is not the case and therefore is not as motivated to perform behaviors. Second, the animal shows a cognitive deficit in the form of impaired ability to learn behaviors, even after it had performed the required behavior and observed the beneficial outcome. This was because the animal had already learned that the outcome was independent of their responses, and having this knowledge interferes with the possibility of arriving at the conclusion that the behavioral response actually did have an effect on the outcome. Third, a change in emotion occurs, characterized by behaviors indicating frustration, changes in appetite, and depressed affect, all of which were resolved after uncontrollable stimulus was removed. The characteristics required to produce these behavioral effects are (1) that the information the animal has at its disposal indicates that its behavioral responses cannot change the outcome and (2) that the animal has undergone some form of cognitive process to decide that this is the case. In the initial reports, researchers demonstrated that among a number of alternative explanations, learned helplessness was the best theory to explain these findings in both humans and animals.

Critique and Reformulation

Although the initial theory had explained much of the behaviors in animals, it quickly became apparent that the original learned helplessness theory was not able to fully explain human learning behavior. First, the theory as it was originally presented could not distinguish between responses that occurred when an individual decided that an outcome could not be changed versus it was possible to change the outcome but the individual was not able to do so. Such a person was described as having a low level of self-efficacy for changing the outcome. This distinction highlighted a limitation of the original theory in predicting actual responses: If an individual were

to decide that the current outcome was not controllable, then the only valid response would be one that changed the nature of the outcome (e.g., a change to the environment that gave the individual resources to control the outcome). However, if an individual were to decide that the outcome was controllable but that they cannot do so (such as an individual who believed that he or she was not competent enough to perform the required behavior), then the valid response would be to give the individual the tools needed to change the outcome. Such a distinction had important implications not only in predicting the ultimate response, but also in clinical settings in which different mechanisms of treatment would be employed based on the individual's beliefs. Second, although research indicated that learned helplessness from a stressor was often applied to further situations, the theory had little to say regarding how generalizable the response was or even in what situations that it would be broadly versus specifically applied. If a participant had undergone an experiment in which he or she was asked to solve an unsolvable problem and then was told during the debriefing that the problem was unsolvable, the original theory would have not predicted the result: Despite knowing that the problem was not solvable, the participant would not demonstrate learned helplessness to other events. Again, this distinction had important clinical implications because some situations would predictably produce a greater amount of learned helplessness and changes could be made to reduce learned helplessness. Finally, the theory did little to predict the degree of learned helplessness that an individual experienced when confronted with an uncontrollable stressor.

Researchers of learned helplessness resolved these discrepancies by using a modified form of attribution theory. When an individual was confronted with a situation in which he or she had no control, a number of attributions (i.e., decisions or judgments) were made regarding the level of control over the outcome. The individual essentially asked himself or herself why that uncontrollable situation happened. If an individual decided that as a whole, the situation was controllable but that he or she could not control it (analogous to low self-efficacy for changing the situation), then that individual was making an internal attribution or one of personal helplessness. Conversely, if an individual decided that nobody could have control over the situation, then that individual was making an external attribution or one of universal helplessness. Next, if an individual attributed the situation to uncontrollable factors, which may have been controllable in the future or given other circumstances, then that attribution was said to be unstable. However, if an individual attributed the situation to broadly uncontrollable factors that would not be controllable in the future, then that attribution was said to be stable. Last, if an individual decided that the factors involved in the uncontrollable situation were only really applicable to that situation, then the individual was making a specific attribution. However, if an individual decided that the factors were applicable to a wide variety of situations, then the individual is making a global attribution. Finally, the degree of learned helplessness was proposed to be based on the level of importance of the situation as well as the certainty that an individual had in his or her attributions. Through these attributions, an individual may have responded to learned helplessness in a variety of ways and across a variety of situations.

This revised model of learned helplessness allowed for prediction of situations in which individuals would respond more broadly and for longer periods of time. Consider an individual who attended a job interview but did not get hired. If that individual were to determine that he or she did not get the job because the position required a greater than normal degree of specialization (external attribution), the particular job was not a good fit compared to others (unstable attribution), and because he or she did not answer one interview question very well (specific attribution), then the individual may not have applied for another job at the same company but would probably not be discouraged from finding and applying for other jobs. Conversely, this same individual could have determined that he or she did not get the job because he or she was particularly unqualified (internal attribution), because he or she was not a good fit for any job (stable attribution) and because he or she was unable to answer interview questions well (global attribution). This individual would be more likely to have learned helplessness for a variety of jobs and over a variety of situations, thus causing that individual to drop out of the job hunt.

Researchers have developed the theory of learned helplessness further. In many cases, people have previous experiences available that allow them to make accurate attributions regarding an event. Sometimes, people do not have this, and must instead rely on their knowledge and response patterns. Therefore, in addition to the effect of attributions individuals have regarding specific uncontrollable situations, considerable research has been devoted to general response patterns individuals have toward a variety of uncontrollable situations. These attributional explanatory styles generally take the shape of optimistic attribution styles versus pessimistic attribution styles: Optimistic individuals generally attribute uncontrollable stressful events as external, unstable, and specific, while pessimistic individuals generally attribute uncontrollable stressful events as internal, stable, and general. Importantly, this is different from locus of control because this case deals with specific explanations made for past events, whereas locus of control involves expectations made toward future events.

In a natural extension of the attributional reformulation of learned helplessness, Seligman has coined the phrase learned optimism to explain the beneficial response that can occur when individuals make external, unstable, and specific attributions to events and therefore do not learn to be helpless. Instead, the individual is better able to cope with a wide variety of seemingly uncontrollable situations. In 1990, Seligman reviewed evidence on the protective effects that such an attribution and attributional style has on the individual compared to pessimism. In sum, the optimistic individual still experiences the negative situation, but the optimistic attributions allow the individual to bounce back faster or to be more resilient toward the various things that happen to the individual. Seligman asserts that individuals can learn to adopt a more optimistic attributional style through examining the evidence and disputing negative internal thoughts.

The Neurobiology of Learned Helplessness

Since the initial findings, a considerable amount of research has been devoted to finding the specific physiological

responses that were associated with the behavioral patterns seen in learned helplessness. Although some human studies exist, this research has primarily been conducted using mice and rats. Many use the learned helplessness paradigm as an animal model for depression or posttraumatic stress disorder (PTSD), and the vast majority of these studies focus on the original learned helplessness theory as opposed to the attributional reformulation. The information presented here is not comprehensive, and interested readers are directed to a 1995 book chapter by Peterson et al. devoted to this topic.

Rather than operating independently, a complex, interacting network of biological responses is involved to produce the behavioral response of learned helplessness. Researchers have found that induction of the paradigm (i.e., experiencing the inescapable stressor) produced an initial increase in catecholamine release, followed by a subsequent reduction in catecholamine (particularly norepinephrine) and a release in endogenous opioids throughout the body. Additionally, induction of learned helplessness produced decreases in the inhibitory neurotransmitter gamma-aminobutyric acid within the hippocampus that was related to the altered behavioral response and poorer learning produced by learned helplessness.

Recent studies have indicated that the responses exhibited during learned helplessness trials were of conditioned fear stemming from activation of the basolateral amygdala. Lesioning in this area prevented the conditioned fear response, resulting in a complete loss of response to learned helplessness trials: rats in the experimental group learned to escape just as readily as either of the control groups. At the neuronal level, a study showed that learned helplessness trials caused an acute reduction in synaptic activity at the hippocampus. It appeared that this at least partially controlled the behavioral response to learned helplessness because not only did injection of corticosteroids to the hippocampus produce the same reduction in synaptic activity and the same learned helplessness behavioral response, but blocking this synapse loss through use of a catecholamine reuptake inhibitor also prevented the learned helplessness behavioral response. In sum, the biological effect of inducing learned helplessness was varied and involved at least all of the following situations working in concert to produce the behavioral response: First, there was an overall reduction in catecholamine release. Second, there was a reduction in the inhibitory transmitter gamma-aminobutyric acid. Third, there was a release of endogenous opioids. Fourth, there was activation of the conditioned fear response within the basolateral amygdala. Last, there was inhibition of synaptic activity within the hippocampus.

Effects of Learned Helplessness

Although there has been a copious amount of research on the effects of learned helplessness in a number of different scenarios, the majority of the findings can be reduced to three main areas of research: physical health, depression, and posttraumatic stress. For physical health and depression, the majority of the research centers on the attribution reformulation of learned helplessness. However for posttraumatic stress, the majority of research focuses on the original theory. A brief summary of the findings follows:

Physical Health

Research on the health effects of learned helplessness has focused on the main component of lack of control, the behavioral aftereffects of lack of motivation, and the cognitive deficits. Human research has focused primarily on correlational studies using stressful life events and perceived daily hassles. The premise was that the degree of distress from life events (such as being involved in a car accident) and daily hassles (such as distractions from work) resulted from a perceived lack of control over the situations that caused those events. It has proved difficult to establish a direct link of health effects due to lack of control, but evidence supported the notion that worse health outcomes resulted when individuals employed a pessimistic explanatory style to determine the cause of stressful events. Employing an optimistic explanatory style, on the other hand, appeared to protect against the negative health effects of stressful events.

Lack of motivation resulting from learned helplessness has also been linked to decrements in physical health. Individuals with higher levels of learned helplessness fail to invest the time and make the required behavioral changes to prevent health issues. In one study, smokers who believed they would get sick by continuing smoking (had a high perceived susceptibility) were much less likely to quit if they did not believe that they could actually quit smoking. This relationship is especially problematic because the majority of deaths today are due to preventable lifestyle behaviors. Fortunately, many of these effects due to lack of motivation are readily treatable. Interventions have been designed to combat negative thoughts and perceptions that result in learned helplessness, thereby increasing motivation to make the lifestyle changes needed to improve.

A wider body of research is available to support the notion that differences in cognition serve to influence health. Specifically, the employment of optimistic or pessimistic explanatory styles has a direct influence on health. In one long-term longitudinal study, researchers tracked the influence of explanatory style on healthy men over the long term starting from college. They then analyzed participants' original open-ended responses to a question asking them to give specific details about things that had happened to them recently, looking for negative events combined with causal explanations for the events. The responses were coded to determine whether the individual employed overall optimistic versus pessimistic explanatory styles. The researchers found that individuals with an optimistic explanatory style had better health and individuals with a pessimistic explanatory style had worse health over 20 years after the explanatory style was measured. These psychological variables seemed to have their largest effect on health while individuals were between 35 and 50 years of age. Researchers have also assessed this relationship among a college population, using explanatory style to predict differences in the amount of time spent ill and visiting the doctor. Again, it was found that having an optimistic explanatory style was better than having a pessimistic explanatory style. Those who employed a pessimistic explanatory style spent more time ill and visited the doctor more than those who employed an optimistic explanatory style. In addition, the beneficial effects of an optimistic explanatory style have been demonstrated in an increased ability to survive and recover after a heart attack and in more favorable markers of immune system functioning.

Depression

Early in the development of the learned helplessness literature, it became apparent that the effects of learned helplessness mimicked depressive symptoms. The direct behavioral effects, a sort of maladaptive passiveness, were present in both. Furthermore, it had previously been known that a key symptom of depression was the feeling that the individual had no response available to overcome failure. It was therefore theorized that the symptoms of depression arose from such experiences, and some of the initial studies on learned helplessness in humans corroborated the theory. For example in an early study, participants were exposed to an uncontrollable noise and then asked to move their hand to the other side of a shuttlebox to stop the noise. These individuals experienced many of the same behavioral symptoms as those exhibiting depression. They were more likely to sit passively and listen to the noise than both those who were not exposed to uncontrollable noise and those who were exposed but could stop it.

However, it was also apparent to researchers that the theory was not completely adequate to serve as a model of depression in humans. One glaring example was that when individuals in this study were debriefed, symptoms of learned helplessness did not appear. The attributional reformulation was done, in part, to more effectively address the nuances in depression. Most of the research focusing on depression in humans has subsequently focused on the reformulated theory and, in particular, the attributional style subset of that theory. Research on this topic is abundant. In a recent meta-analysis, researchers found that among college students and psychiatric patients, having a pessimistic explanatory style in making causal attributions predicted greater symptoms of depression. This evidence was extended with a second meta-analysis in which researchers found that having a pessimistic explanatory style predicted symptoms of depression among children and adolescents as well. A number of correlational, longitudinal, and experimental studies have provided clear support that having a pessimistic explanatory style produced greater amounts of depression.

Some of the literature concerned with the effects of learned helplessness on depression has encompassed the construct of anxiety. It should be noted that anxiety is not necessarily the same as depression, especially in regard to expectancies. In anxiety, the individual was typically more concerned about the threat of future loss, whereas in depression, the individual was typically more concerned about the loss that had already happened. However, when considering that the main issue is lack of control, there was often little difference. Individuals who made internal, global, and stable attributions toward an event (i.e., made pessimistic attributions) were using information they had available to them to explain the event but were simultaneously extrapolating this information toward expectations to the future. Because of these shared effects, the anxiety literature has often been incorporated within depression.

Posttraumatic Stress Symptoms

Unlike for depression, the original model of learned helplessness has been used extensively to examine the occurrence of past traumatic stress symptoms. Experiencing a traumatic event over which the victim has little control is very similar to the inescapable shock paradigm. In addition, researchers have

noted similarities between animal models of learned helplessness and the human experience of posttraumatic stress. Many of the physiological and behavioral alterations seen in response to a traumatic or cataclysmic event closely mimic the effects of learned helplessness. The typical behavioral response involving hyperarousal and hyperreactivity, combined with a reduced capacity for responding effectively to surrounding events, is almost identical to the behavioral responses to learned helplessness seen in animal studies. Similarly, the physiological response of increased endogenous opioids and depletion of catecholamines is the same. Because of these similarities, the majority of research has progressed with the original model of learned helplessness.

However, learned helplessness may not be analogous to posttraumatic stress. Rather, it is possible that learned helplessness may play a mediating role in the development of symptoms of posttraumatic stress. In one study, researchers examined this role among those exposed to partner violence. The researchers found that displaying symptoms of learned helplessness increased the likelihood of exhibiting symptoms of posttraumatic stress. The attributional reformulation model is also important to consider because having a pessimistic explanatory style may contribute to further symptoms of posttraumatic stress. Researchers have shown that among individuals addicted to alcohol and gambling, having a pessimistic explanatory style predicted more symptoms of posttraumatic stress. Some researchers have found that learned helplessness can play roles through both mediation and attributions. For example, researchers have found a mediating role of coping styles between attributions and symptoms of posttraumatic stress among combat veterans, whereby when the veteran made pessimistic attributions, subsequently employing negative coping mechanisms as a result of these attributions predicted posttraumatic stress. Though the field has traditionally focused on the traditional model of learned helplessness for posttraumatic stress symptoms, evidence for alternative explanations has been increasing.

Assessing Learned Helplessness

There have been a variety of mechanisms to assess learned helplessness, but only a few are widely employed. The traditional learned helplessness paradigm is more typically assessed using experimental methods among animals in the laboratory. A shuttlebox is used paired with shocks as described in the initial studies. In animals, this box typically consists of a floor through which an electric current can be passed to shock the animal and a short wall or platform that the animal can jump across to stop the shock. For humans, the shock is typically replaced by a loud or unsettling audio tone. Many variations have been developed for use in specific samples. In rats, for example, the traditional shuttlebox mechanism does not adequately assess learned helplessness. For rats, learned helplessness is instead shown by creating more complex mechanisms for the rats to learn in order to stop the shock (e.g., pressing a bar 3 times).

In humans, there are two primary ways to assess learned helplessness through the attributional reformulation model. Both ways focus on attributional styles rather than attributions to specific events; there is no standard method to assess

attributions toward specific events. First, the Attributional Style Questionnaire is the most widely used method of assessing overall cognitive attribution styles. The self-report scale provides six positive and six negative hypothetical events and asks the individual to write down a major cause of the event. Then, the individual is asked to rate the cause that was written down along seven-point scales from internal to external, stable to unstable, and global to specific. In addition to the individual dimensions, the Attributional Style Questionnaire provides an overall assessment of optimistic to pessimistic attribution style.

In order to assess explanatory style in population samples that are either not able to fill out questionnaires or that has previously given written accounts of the event, another technique was developed. In this technique, called content analysis of verbatim questionnaires, trained coders extract identified events from written accounts. Like the Attributional Style Questionnaire, the content analysis of verbatim questionnaires was designed to assess attributions for both positive and negative events (the coder simply indicates whether the event was positive or negative). Then, the causal explanation for the event is extracted. Finally, the coder rates each cause along the same dimensions as in the Attributional Style Questionnaire.

Summary

Learned helplessness describes a particular response to an uncontrollable stressor that is characterized by a lack of motivation and behavioral responses, cognitive deficits in the ability to learn the correct responses, and an emotional response. This theory was initially formed to describe the seeming lack of ability that animals exhibited in solving simple puzzles to avoid being shocked after they had received uncontrollable shocks. Typical physiological responses involve decreases in catecholamine release and gamma-aminobutyric acid, increases in endogenous opioid release, activation of the basolateral amygdala, and inhibition of synaptic activity at the hippocampus. Taken together, these response patterns of learned helplessness have been shown to negatively impact physical and mental health. The theory and its reformulation have subsequently been used as the basis for several human conditions, particularly depression and PTSD. According to the attributional reformulation of the theory, individuals come to feel helpless through learning to attribute internal, stable, and global causes to a variety of events. This theory provides important implications for treatment especially for mental health problems such as depression. The phrase 'learned optimism' is used to describe the opposite explanatory styles as a way to buffer against negative symptoms. The Attributional Style Questionnaire and content analysis of verbatim questionnaires are the two most widely employed ways of measuring learned helplessness in humans. In animals, learned helplessness is typically induced experimentally through variations of the original procedure in which the animal is exposed to an uncontrollable stressor and then placed in a situation where the same stressor is controllable by performing some simple behavior. Based on these findings, Seligman and other researchers have developed a number of effective interventions designed to prevent the effects of learned helplessness. Interventions such as those designed to promote resilience among school children and among soldiers in combat have shown promise in

increasing physical health as well as reducing symptoms of depression and posttraumatic stress subsequent to being confronted with uncontrollable stressors.

Glossary

Enjoyment The experience of satisfaction and achieving something important.

Freedom Having the opportunity and ability to choose what one wants to do. All freedom, however, is perceived and generally relative, given that along with the freedom to choose also come responsibilities to self and to others.

Leisure Meanings that people attach to enjoyable activities freely chosen generally during their unobligated time.

Leisure education Helping individuals, families, communities, and societies to achieve a suitable quality of life and good health and to use leisure time intelligently and develop and cultivate physical, emotional, spiritual, mental, and social aspects related to the aims of education.

Leisure industry The agencies, organizations, and businesses that provide facilities, programs, services, or areas for people's enjoyment in their free time.

Play Activity undertaken by children and adults that includes characteristics of spontaneity, purposelessness, and the creation of an imaginary world. Play is almost always pleasurable, self-expressive, and can range from disorganized activity to structured involvements.

Quality of life The degree to which a person enjoys the important possibilities of life that reflect the interaction of personal and environmental factors.

Recreation Activities undertaken because of conscious or unconscious enjoyable end results.

State of being/state of mind A psychological experience whereby leisure is perceived as having characteristics including being freely chosen, not compulsory, and done for its own sake.

Work Activity undertaken for economic gain or social redeeming value.

Everyone knows what leisure is. All people have a notion of what it means and whether or not individuals feel they have enough leisure. Sometimes the idea results in laughter, when someone, like the author herself, says they do research about leisure. Leisure, however, is a huge industry across the globe. Further, many individuals find great meaning in their lives with people's self-identity often revolving around their leisure. For some people, however, leisure is illusive and they never have enough of it. Others sometimes experience boredom when they have too much *free* time. The term is sometimes associated with recreation, although recreation tends to have a specific activity focus such as sports, arts, outdoor activities, or hobbies. Play is also associated with leisure for both children and adults. Playing sports, going to plays, and other forms of play behavior are all a part of leisure. Leisure, recreation, and play are ubiquitous and the terms are sometimes used interchangeably.

Leisure obviously can be bountiful for some people and quite illusive on many levels for others. Further, leisure can be seen as a frivolous undertaking (e.g., when juxtaposed to work or other 'productive' activity) or it can be regarded as highly serious (e.g., individuals who define themselves by a leisure activity such as running or being an amateur musician). Leisure activities are important and when most people look back at their lives, they talk about wishing they had spent more time in activity (alone or with friends and family) rather than worked more. If you ask people what is on their 'bucket list' for their lives, almost everything mentioned is about leisure.

Thus, as an idea, leisure is both mysterious and powerful. It has many meanings generally associated with positive outcomes, but not always.

A *leisure age* was forecast over 40 years ago by the French sociologist Joffre Dumazedier as well as the American leisure studies pioneer, Charles Brightbill. At that time, leisure with all its possibilities was also seen as a potential problem or challenge if people had too much leisure. Concerns were raised in the mid twentieth century about whether people could handle leisure for their own good and for the good of their communities. The idea that leisure was becoming a commodity accessible for everyone was positive and yet problematic at the same time. Would people know how to use their leisure wisely? Would leisure have positive meanings for them? Can leisure be universally understood? What does, or what should, leisure mean?

Scholars who have studied dimensions of leisure over the years have lamented its definitional confusion. Definitions and meanings are not necessarily the same, but they are important dimensions of leisure. This realization of years of discourse without coming to universal agreement seems both disheartening and heartening at the same time. The definition and meaning of leisure may be just as misunderstood today as in the past. However, because leisure continues to have many meanings and interpretations, perhaps it has escaped the chains of modernity and as Rojek suggested:

In struggling to achieve that longed-for state of freedom, choice, and life-satisfaction, we find ourselves trapped in new, unanticipated obligations and chains . . . Things always seem less than they could be. It is the fate of modernism to regard these responses as subjects to be remedied; and it is the condition of postmodernism to perceive the remedy as the problem. By committing ourselves to decentering leisure we emancipate leisure from the modernist burden of *necessarily* connoting freedom, choice, life-satisfaction, and escape with

*Portions of this entry are used by permission from an article by the author appearing in *Loisir et Societe* (2009, Volume 31, No. 1, pp. 15–30) entitled, "Expanding the Meanings of Leisure in a Both/And World".

leisure [original italics]. We recover what the illusions of modernism have concealed. (p. 192)

Perhaps a uniqueness of leisure is that it always has been a postmodern notion that never could fit well into the modern age. Further, in abandoning a mandate to find a single meaning, leisure has been liberating for many groups of people. Uncovering *meanings* is more appropriate than articulating single definitions. For many individuals, especially in industrialized societies, 'finding' leisure is much more important than 'defining' it.

This encyclopedia entry describes meanings of leisure by illustrating discussions that have evolved over the years. Abandoning the search for a meaning in favor of multiple meanings provides challenges but also a plethora of opportunities for understanding the potential of leisure both as a subject of research and a way to enjoy life. After briefly examining the ubiquity of leisure throughout history, ways of explaining the meanings of leisure will be examined from five nonmutually exclusive frameworks that seem evident in the latter half of the twentieth century and into the twenty-first century: time, activity/recreation, state of mind, places and spaces, and cultural contexts. The variety of meanings of leisure offers many ways to understand broadly how leisure does (and sometimes does not) contribute to the quality of life of individuals, communities, societies, and the world.

A Brief History of Leisure

The history of leisure is also the history of informal education. Broadly defined, education is the process of giving instruction to impart knowledge, build skills, and develop character in humans. The outcomes of leisure often include learning, expressing oneself, and experiencing enjoyment. The history of leisure is often begun with a discussion of the Greek philosophers with explicit empirical demarcation evident with the beginning of the industrial age. Leisure, however, has been omnipresent in all cultures since people first began to inhabit the earth. Certainly notions about 'play' exist in many contexts including among animals. Further, leisure has not necessarily been learned but has been embodied in culture.

Adam and Eve in the Garden of Eden surely had all the leisure they wanted. The 'curse' that God put on them was to toil instead of to leisure. Hunting preserves and gardens were evidenced in ancient Egypt and China, and in historical Europe. Primitive cultures around the world have left evidence of games and 'sports' played. Certainly, traveling has been common throughout history. The Eastern cultures in the Tao Te Ching also talk about a notion of leisure:

There is a time for being ahead,
a time for being behind;
a time for being in motion,
a time for being at rest;
a time for being vigorous,
a time for being exhausted;
a time for being safe,
a time for being in danger . . . Mitchell. (trans., 1992, selection 29)

All religions emphasize elements of leisure and recreation in their teachings. For example, from Judaism the concept of

'Sabbath' is emphasized in letting the body rest. Christians stress notions of right action in *all* that people undertake. Islam focuses on remembrance and the importance of work and play experiences within the moral law. Hindus teach the value of karma and the law of cause and effect regarding any action. Buddhism focuses on the interdependence (i.e., yin-yang) of what people do (e.g., leisure-work). The World Leisure International Centre of Excellence advocated that even though the leisure is understood differently around the world, leisure is a part of all time periods, places, and societies.

Westerners usually point to the Greek philosophers with their first written discussions of leisure as the aristocratic ideal of human activity. Aristotle is credited as being the first Western philosopher to describe the relationship between leisure, education, and work, and he asked the question whether the end of education is culture or whether it is to fit people for the business of life. From Aristotle's perspective, leisure did not denote rest or recreation but was meant to be engaged with highest capacities of the soul.

The value of leisure is usually focused on the 'good' that it provides and how leisure contributes to the quality of individual and community life. Nevertheless, leisure has been and continues to be a site where both positive and negative social, political, educational, and cultural relations are visible. Recreation and leisure are learned experiences within cultural environments. Leisure has been described in many ways but most often related to time, activity, state of mind, places and spaces, and cultural context.

Time

The definition of leisure as time has been most evident in an industrial modern society that dichotomizes work and leisure. Time was initially defined simply as free time that typically meant nonwork time or unobligated time. This definition tends to define leisure as what it is NOT rather than what it is. Within the notion of time, leisure has also been described as unobligated time. Unobligated time denotes nonpaid work as well as other obligations one has in life such as personal care, social support, and other activities that are not necessarily 'free.'

Time dichotomized between paid work and nonpaid work is relatively easy to measure. Some feminists including me and my colleagues have objected to the definition of leisure as nonwork time because it assumes paid work. Some women, as well as some men, are not part of the work force; so considering leisure only as the opposite of paid work negates the important activity that is unpaid such as maintaining a household, childrearing, community volunteer activities, and personal care. Unpaid activities that are obligatory are not done in free time. Increasingly, however, work is defined as having both economic and social benefits suggesting that not all work is paid in monetary terms.

Time-use studies have been conducted regarding how people use their time. They have been coded primarily related to work and nonwork efforts and were focused on ascertaining the amount of leisure time people have. In the United States, the amount of work Americans do has been an ongoing debate. Some people believe that Americans work more

hours than ever before, and therefore, have less free time. Others argue that people have a good deal of free time, but because they are always tethered to technology and have dwindling amounts of large blocks of time, they do not perceive that they have more leisure time.

Leisure as free time continues to be an important definition given that time is often a prerequisite for any activity. However, free time as a simple measurable way to describe leisure raises questions that should be considered in understanding the meanings of leisure. Some questions relate to the distribution of work and leisure. People with higher levels of education often work longer than those with less education. Yet, evidence suggests that people with higher education make more money and spend more money and time on leisure. Further, how much time is spent working related to 'at work' is also an issue to consider. Sometimes work and leisure are hard to separate, since they may offer some of the same states of mind. Changes in the workplace such as flexible work schedules as well as electronic communications that both offer work as well as personal play experiences in the workplace blur the lines. Although individuals in some jobs may spend 8 h at work, the amount of time they are actually working sans personal internet time, breaks, and office interaction may not constitute work. Numerous examples exist today in large companies of work time spent in purposeful 'fun' activities among (mainly pink and white collar) workers to increase morale (i.e., food functions, birthday parties, and casual Fridays) and make workers more productive. These activities also blend work and leisure.

Nevertheless, time will continue to be an important meaning attached to leisure, since many people feel they never have enough time. However, only examining hours attached to leisure leaves out the meanings associated with priorities for time use, opportunities available, the perceived and actual amount of time available, how an individual feels about the value of his/her time, and social mores (e.g., guilt) that may play into the enjoyment of free time. Leisure as time is a necessary element in understanding other dimensions of leisure.

Activity/Recreation

Defining leisure as activity, which can be synonymous with defining it as recreation and play, is another common meaning associated with leisure. This activity generally is pursued for its own sake and for fun and enjoyment, although many activities that might be considered leisure also have secondary health benefits. Leisure activities have typically been categorized into activity sets with particular characteristics such as competitive sports, outdoor pursuits, cultural endeavors, and social interactions. Defining leisure as activity assumes that time is available and that these types of opportunities exist.

Leisure as activity has been commonly examined regarding participation and frequency of involvement in specific activities. These findings have been largely applied to recreation programmers, managers, and businesses to determine what people want to do, or what activities can be consumed or commodified, and therefore, marketed. Many of the common meanings of recreation activities connote physical movement or some type of external environment such as a ballfield, an

arts center, or a park. Research about recreation has moved from broad examinations of types of recreation activities to focusing on what particular activities contribute such as in the benefits based management approach, which today also relates more specifically to the outcomes of participation in activities.

Leisure as activity can be examined in terms of being an end or a means. An activity can be undertaken for its own sake or it can have intentional instrumental value. Activity such as fitness can be a means to an end if the goal is better health or perhaps weight reduction. When leisure activities serve as both ends and means simultaneously they are often perceived as being the most enjoyable.

The scope of leisure as activity has expanded as new activities have been added and meaningful activities have been redefined. For example, the focus on extreme sports has added more opportunities for this sports and outdoor specialization. Further, the recognition that nontraditional recreation activities such as texting on the phone, shopping, surfing the internet, or participating in religious endeavors may be leisure for many people is important.

Play is an area that has been studied in and of itself as well as for a foundation for leisure activity. Play is linked most to children, and yet adults play when play is defined as spontaneous and expressive activity done for its own sake. According to one of the first play theorists, Huizinga, play has common characteristics such as spontaneity, self-expression, and enjoyment. He described the elements of play related to purposelessness as well, which may make it somewhat different from some recreation activities such as competitive sports. Another play theorist, Michael Ellis, explained why people play from the perspective of physiological, psychological, sociological, and contemporary theories. Ellis seemed to lay the groundwork for play as a postmodern interpretation in that it has numerous elements that contribute to its value.

Another particular element of activity that relates to recreation as well as other fields is the focus on recreation and physical activity as a means to promote health. Because many people are not physically active, numerous chronic health issues have emerged. Although physical activity can be found in nonrecreation activities, recreation activities are generally an enjoyable and purposeful way to maintain health and well-being. Research shows and it makes intuitive sense that people generally continue to do (healthy) activities that they enjoy.

Leisure as activity is fairly easy to measure when checklists of activities are used and when people consider a particular activity to have outcomes that are enjoyable. However, what some people consider to be leisure activities may not be how others would define them. For example, some people love to run and gain great value from this activity, while other people find no enjoyment in a recreation activity such as running or jogging. Further, the personal, social, economic, and environmental outcomes of certain types of activities for individuals as well as communities may vary greatly. Nevertheless, leisure as play or involvement in particular recreation activities is highly important whether these activities are casual, serious, or somewhere in between. The recognition of the range of recreation activities and other less-structured activities that constitute leisure continues to expand in the twenty-first century.

State of Mind

Sebastian DeGrazia wrote about leisure during the early 1960s when the idea was gaining great momentum. He is most often associated with espousing the contemporary idea that leisure is a state of mind. Psychologists such as John Neulinger further measured this state of mind in the form of examining perceived freedom and intrinsic motivation. When leisure is described as time or activity, psychological outcomes emerge such as motivation, freedom, and enjoyment. Leisure from a state-of-mind perspective includes free choice, something done for its own sake, and a sense of control. Csikszentmihalyi's idea of flow or the autotelic experience, which has been used relative to both leisure and work, is another example of the notion of state of mind focused on individual motivations and perceptions. With the idea that leisure is a state of mind, almost anything could be considered leisure depending how individuals interpret their experiences.

Neulinger underlined, however, that freedom is never complete and is always relative. Further, some type of intrinsic outcome is necessary for a 'true' leisure experience. In most ways, leisure like other elements of life is a relative freedom. People are never completely unobligated or free to do anything anytime they wish. Nevertheless, the idea of state of mind is central for the enjoyment of leisure.

Although a number of leisure scholars describe the notion of a state of mind related to leisure, measuring these ideas has been complex as evidenced by the pioneering efforts of Neulinger and Csikszentmihalyi. Scales have been developed to try to capture the subjective meanings of leisure as a state of mind, but many of these scales have been inadequate in addressing the meanings of leisure. Nevertheless, these quantitative efforts have been useful in understanding the psychological dimensions of leisure as a state of mind.

Another way to understand how individuals find meanings in leisure for themselves have been uncovered in some of the research undertaken using qualitative approaches. When individuals can articulate leisure as more than free time or specific activities, they can describe the feelings and satisfactions associated with meaningful aspects of their lives. For example, when my colleagues and I asked women about their leisure, they said they had none. They also could not always name typical recreation activities that they defined as leisure. Yet, they could describe pausing to watch the beauty of a sunset or the joy they experienced in watching their children play sports as deeply important. When further probed, many agreed that these experiences were like leisure for them. The subjective feelings that surround leisure are meaning-making for people. Regardless, some type of foundation is necessary for these experiences to occur and places and spaces related to leisure have emerged as a relatively new way to associate meanings with leisure.

Places and Spaces

Although the three typical perspectives of time, activity, and state of mind previously discussed are central to leisure, these ideas focus primarily on the individual and how he or she creates meaning. Leisure, however, is greatly impacted by

circumstances outside the individual. Some of the health professionals have recently referred to this idea as social ecology, which examines both the micro and macro aspects of behavior. The social situation, the demographic characteristics, the community as well as nature environment, government regulations, and policies affect leisure, and thus, how people experience and find meanings in leisure. One area that has received increased attention is the physical environment or the places and spaces that give leisure importance.

Space and place have been defined in many ways. According to Tuan, the concept of space has absolute and relative dimensions with concrete boundaries. Place is perceptually and socially produced by individuals. Thus, spaces become places when they mean something significant. Spaces exist where leisure occurs and these spaces often become special places when leisure is an aspect of them. A sense of place is often associated with an emotional and affective bond between an individual and a particular space and may vary in intensity from immediate sensory awareness to long-lasting deeply rooted attachment. A sense of place is often a quintessential concept in thinking about nostalgia, memory, and the images that are evoked. The physical place may be less important, however, than the meanings that people attach to places in their minds as they participate in leisure. Therefore, people can make interpretations of their psychological states regarding leisure based on physical realities. Thus, as Foucault noted, space cannot be disassociated from the practice of the people who use the space. A sense of placelessness often exists in today's society and a sense of place experienced through leisure can provide meaning whether it refers to a neighborhood Starbucks or a special mountain lake.

Places combined with a sense of time to enjoy, opportunity to participate, and an open state of mind contribute to many people's sense of leisure meaning. As noted, however, the leisure meanings attached to macro places usually are associated with the individual micro perceptions. The influence of the social situation or cultural context may or may not be evident.

Cultural Context

The traditional definitions of leisure as personally fulfilling can separate leisure from other aspects of human activity. Leisure, however, is in society and therefore connotes a greater social cultural context than suggested by some of the early individualized definitions of leisure.

A cultural context calls for an integrated view of leisure that occurs in time and space with various social connotations. Individual preferences are not independent of social and cultural influences. People often choose activities based on their previous social experiences as well as because of what others around them are doing. Leisure is never free from these social or moral norms. The symbolic meanings of leisure often come from socialization and opportunities as well as culture. Rojek indicated that leisure time and space are continually made and remade by the actions of people in their social worlds.

Some people are beginning to challenge the cultural issues that surround the typical Western concepts of leisure. Researchers such as Iwasaki and his colleagues described, for example, how problematic leisure is from a global, and

particularly linguistic, perspective. These researchers recommended that the term 'leisure' not be used particularly with people from non-Western cultures. They rationalized that leisure is differently defined by various cultures and that it is an ethnocentric term used mostly in North American and European thinking. They also believe the term evokes the dominance and intrusion of this Western thinking. Not using the term leisure, however, may be one way to resolve some misunderstandings, but not having a term may also make interpretations of the phenomenon of leisure difficult. The cultural context, however, cannot be ignored, since leisure has social and cultural dimensions that may be both explicit and implicit in the meanings that people attach to the notion of leisure. Definitions such as time or activity assume social implications, but for many people the essence of leisure lies in the relationships and identities that surround any meaningful undertaking.

Expanding Leisure Meanings

These five areas only touch the surface of other ways that leisure might be understood. Although an identified universal does not exist, leisure clearly has components of voluntary behavior and a sense of enjoyment. However, other scholars have also argued that leisure has enlarged in ways that focus primarily on economics. Globalization implies that the most obvious way to promote positive leisure experiences is to provide activities that can be experienced, bought, and consumed. Therefore the commodity of leisure and the way that it is consumed or experienced relates to the product 'sold'. If people are not satisfied with their leisure, then perhaps more and better opportunities are needed. The leisure industries that have evolved in industrialized countries over the past 50–75 years are based on the idea that people's demands for leisure create supplies of opportunities. However, the economic notion of leisure is also bound to time, the nature of activities, state of mind, place, and social context.

Meanings have also been proposed by scholars like Freysinger and Kelly who regard definitions of leisure to include perspectives about the quality of action (i.e., self-taking action in a defined environment, social construction, political, and as a dimension of life). They concluded that aspects of freedom run through most of this discussion of leisure as quality of action. Regardless, leisure is ever changing and cannot be approached with only the traditional concepts of freedom, individual choice, and self-determination.

The ideas of multiple identities, the reflexive self, the breakdown of clear divisions between work and leisure, and the ambiguous and contradictory aspects of postmodern existence resonate with leisure theorists such as Rojek as well as feminist leisure scholars like Wearing who have been critical of traditional definitions. These expanding ideas suggest the need to be wary of essentializing any explanation of any idea.

A tension remains, however, between recognition of expanded meanings and the idea of commonality of experience related to leisure. For some researchers, perhaps the concept of tension itself is an important and useful element that mediates leisure. Taking into account unique situations and subjectivities of individuals as well as the possibility of shared experiences among individuals socially and culturally continues to be a challenge worth addressing.

The numerous meanings of leisure are both strengths and weaknesses. For example, a 'definition' of leisure remains problematic not only for researchers but also for social understanding. On the other hand, an open-ended definition allows interpretations about the meanings of leisure socioculturally as well as in situ. A strength of most leisure perspectives focuses on positive benefits. On the other hand, leisure is not always ideologically good when it results in some individuals and communities receiving negative outcomes as evident in activities such as sex tourism, pornography, drug taking, smoking, gambling, and other risky behaviors. If leisure has the potential for good, it also has the potential for evil.

Another strength and weakness in examining leisure meanings is the juxtaposition of individualism and collectivism. The disciplinary application of social psychology in the United States has tempered the sole focus on the individual in leisure science research. On the other hand, an individual's control on his or her life is dependent on environmental factors and cultural contexts. Further, the changes occurring worldwide with the emphasis on the commodification of leisure and the market economy may tend to amalgamate collective ideologies and individualism.

Expanding Leisure Opportunities

Although no one can 'give' someone else leisure, opportunities for leisure can be facilitated in many ways. A variety of organizations exist that focus efforts on providing leisure opportunities. These organizations can be categorized into three primary sectors: public (i.e., governmental), not-for-profit private (nongovernmental organizations, NGOs), and commercial private (i.e., for profit) sectors. Each has a somewhat unique mission but all contribute together to providing leisure opportunities to facilitate leisure experiences.

Over the past 100 years, these sectors have paralleled one another somewhat in their evolution in addressing the importance of leisure and recreation for individuals, communities, and societies. Public leisure industries are governmentally supported and are theoretically available to all citizens of a community, region, or nation. The public funding of recreation is based on the idea that leisure and recreation are among the rights of citizens in societies. Not-for-profit NGOs are usually focused on a particular activity or group of individuals and are limited based on the mission of the organization. Private commercial organizations are aimed at satisfying, and often creating, a demand for leisure services and are focused on appealing to participants (i.e., customers) who will purchase a product. These organizations focus on the privileges that people have related to fulfilling their recreation interests. Private leisure industries are probably the fastest growing sector because of the commodification of leisure and the market-driven nature of the economy. All sectors share a common focus on providing leisure, sports, recreation, arts, or tourism opportunities and experiences. However, they differ in their philosophies, objectives, facilities, financing, and membership.

As indicated at the outset, leisure is often misunderstood and can be interpreted in many ways by individuals as well as groups. Nevertheless, a good deal of academic research has focused on understanding dimensions of leisure.

The well-known top English language journals are *Leisure Sciences*, *Leisure Studies*, and *Journal of Leisure Research*, which all focus on various multidisciplinary approaches such as sociology, psychology, economics, business, environmental, and related social science disciplines.

Further, professional education provides individuals and organizations the skills and opportunities to facilitate leisure, recreation, tourism, and play experiences in a structured and organized fashion. The first formal university programs in the United States that trained individuals to teach and lead recreation started in the 1930s. These professional programs grew relatively slowly until the 1960s when they exploded in North America and other parts of the world such as Europe, Australia, and New Zealand. Today Asian countries such as People's Republic of China, Taiwan, South Korea, and India all have academic units focused on the professional aspects of leisure research and facilitation.

The purpose of much of the formal education was and continues to be to prepare individuals to manage areas, facilities, and programs that will offer recreation opportunities for people in all types of communities. The focus may be on parks, outdoor areas, tourist attractions, health institutions, or community programs. As noted, the venues might be governmental, not-for-profit, or private/commercial entities.

Further, the term profession is not used loosely in the academic world of leisure studies. Areas related to leisure such as parks, sports, and tourism are continuing to evolve in meeting the criteria of a profession, which includes an alliance with a social concern (i.e., the belief that professionals have in the value of recreation and leisure opportunities for the quality of individual and community life), professional societies and associations (e.g., World Leisure, Leisure Studies Association, National Recreation and Park Association), a code of ethics, a specialized body of knowledge (i.e., research), professional education and training, and professional standards of accreditation, certification, and licensing.

The Potential of Leisure

Several years ago, the National Recreation and Park Association (i.e., the largest citizen and professional organization in the United States that advocates for the value of recreation) launched a campaign called 'Recreation, The Benefits are Endless.' This campaign aimed to show the importance of recreation by describing benefits associated with individuals, communities and their sociocultural context, the environment, and the economy. One of the buzz words to describe the value of leisure is that it leads to 'quality of life.'

Quality of life can be defined as the degree to which a person enjoys the important possibilities in his/her life, which has many dimensions related to leisure. The understanding of how leisure and recreation contribute to this quality of life, however, is not always evident in people's minds until the benefits that leisure and recreation offer are considered.

Among the common benefits of leisure to individuals include physiological or physical health, psychophysiological, and psychological or mental health. Driver and his colleagues have described many benefits of leisure. The physiological benefits of recreation are usually embodied in regular exercise

and physical activity that often occur in free time. Many of the benefits of physical activity have been documented scientifically regarding how regular physical activity reduces people's risk for heart attack, colon cancer, diabetes, and high blood pressure and may reduce the risk for stroke.

From psychophysiological as well as mental health perspectives, many of the physiological benefits result in reduced stress. Leisure can result in mental and physical relaxation as well as positive changes in mood. Other psychological benefits of leisure can relate to better mental health through enhanced self-competence, improved sense of self-worth, self-identity, and a better ability to relate to others as a result of being involved in leisure and recreation.

Recreation has been documented to contribute benefits beyond those focused on individuals. For example, an economic benefit as a result of recreation occurs in communities where tourism dollars are spent. The economic impact of travel and particularly emerging activities such as sport tourism can be huge. The value of leisure and recreation involvement may also result in healthier lives that can result in saving money due to lack of absenteeism on the job.

Environmental and community benefits from recreation and leisure also exist. Environmental protection has been an outgrowth of a commitment to saving outdoor recreation resources. Parks and recreation play a role in preserving green space and the biological diversity of areas. Further, examples of community benefits may result from recreation or leisure when people develop pride in their community and in an ethnic heritage as a result of being involved in a recreation opportunity such as an ethnic festival.

Leisure can result in numerous benefits and is a ubiquitous aspect of people's lives in all cultures. Leisure, however, is not inherently good and is not always beneficial depending on how it is embodied. Nevertheless, for leisure to be meaningful and empowering, a milieu of social, economic, cultural, and environmental contexts should exist that contribute to better understanding of issues such as physical and mental health, social capital, environmental degradation, and numerous other cultural manifestations important for social change agendas.

Leisure is both a means and an end. Leisure is a means for human development whether related to physical, social, or psychological outcomes. As an end, it is an enjoyable experience that is voluntarily undertaken. Leisure may be misunderstood sometimes, but continues to have numerous and evolving meanings that provide great potential to enhance the quality of life for individuals, communities, society, and the world.

Glossary

Abstraction (reflective) Abstraction is the extraction and learning of invariant patterns (types) and individually variable characteristics (tokens) from actual experience, within and across situations. Abstraction often occurs in levels, the upper levels abstracting from lower ones. This abstraction process is reflective in the sense that upper levels mirror (reflect patterns or characteristics of) lower levels.

Attention (mental) Attention is the brain capacity to enhance or boost the activation of some knowledge (information bearing) processes. Spontaneous attention is spontaneously driven by the input (perceptual processes); mental or effortful attention, also called focal or executive attention, is endogenously driven by the brain's own activatory processes. Mental attention is needed to boost task-relevant schemes and interrupt/suppress irrelevant schemes, particularly within misleading situations.

Constructivism, constructivist (or cognitive) learning It is the theoretical view that knowledge is not directly innate or directly acquired from experience, but is dynamically constructed via reflective abstraction. This constructivist or cognitive learning occurs spontaneously in facilitating situations but needs mental attention in misleading situations.

Facilitating/misleading situations A situation is facilitating when salient aspects (activated cues, habits, schemes) make it easy to attain the intended goals. A situation is misleading when salient situational aspects interfere with intended goals.

Functional structures (e.g., schemes) Internalized patterns of structured information, often reflectively abstracted from

the person's own (external or mental) actions. Schemes are internalized functional structures (via cognitive learning). Functional structures emerging from performance are not in the repertoire of the person until internalized into schemes.

Invariants (types) Invariants are probabilistic patterns found to be stable across situations. Pierce and others call them types (signs that often are symbols). They are complemented by variants/tokens – characteristics that change across situations or individuals.

Model (or mental model) A system of signs/symbols that stands for either complex entities in reality, or procedures (blueprints for action), or for both. Mental models are functional structures, often complex schemes.

Relations (of coexistence; complexity of) Relations are functional structural patterns that actually coordinate objects or aspects of experience. Their complexity depends on the number of objects that necessarily must be coordinated via reflective abstraction to internalize a given activity or state of affairs. Relations of coexistence are abstracted relations that express a set of objects or actions (i.e., schemes) that in a given situation are coactivated and work together to produce an intended result.

Representation (levels of) This is the classic term referring to reflective abstraction of experientially encountered invariants and stable variable aspects.

Resistances These are invariant or variable aspects/characteristics of situations that impose necessary constraints on the functional structure of actions or representations of a person, relative to some goals in a given type of situation. Resistances are often relative to each species within a given type of situation.

Logic is the discipline that studies whether and how knowledge and linguistic statements convey truth, and how to draw true inferences from statements or state descriptions. Truth is the capability of knowledge representations, and of statements, to express information (or fail to express, in the case of falsity) that is suitably accurate or appropriate for the object of knowledge.

We distinguish two sorts of logic. The first, such as found in mathematical logic, is constituted by a collection of generic systems that represent and analyze thought as synchronic (atemporal), formal (focussed on form, rather than content or local meaning), categorical, and systematic. These generic logical systems serve to formulate possible 'objective' relations found among meaning-bearing structures of inference in thought and language, characterizing them as true or false (for instance, suitably accurate/inaccurate vis-à-vis actual experience).

The second sense of logic is found in dialectical and other approaches to philosophical/epistemological logic and also

in Piaget's developmental psychology. This sort studies the temporal (diachronic) emergence and evolution of logical systems of the first type within the minds of humans who mature and develop – a nonsystematic sort of constructivist process analysis, which is often probabilistic and dynamic/dialectical. This constructivist logic serves to investigate how and why the organism might produce categorical logical systems of the first type: This is in fact, as Piaget pointed out, a psycho-logic or developmental epistemological analysis of the first type of logic.

As Piaget and Garcia indicate, the two sorts of logic should be distinguished because the first type, being systematic, categorical, and atemporal, cannot describe or explain the steps of change that lead to its emergence and to its developmental evolution within individuals. Such emergence and evolution must be formulated with a logic (psychologic) of the second type. In this article, we focus only on this second type of logical analysis, suggesting how growth of mental attention

(the major maturational component of working memory), along with other organismic generators (i.e., schemes and operators), constrains the emergence and evolution in humans of the first type of logic.

Classic theory of knowledge (epistemology) sees logic (the first type) as a discipline that studies how to ensure suitable accuracy of a representation (in the subject of knowledge) vis-à-vis the object of knowledge (expressed in actual experience). Such a formulation is not clear, however, because of the ambiguous reality status of actual objects. Objects can be represented only after acts of knowledge; so how could accuracy of knowledge be appraised by matching a person's representation with his/her experience of the object, if both are in fact subjective representations? The nature of representation, thus, needs clarification.

Pierce, the nineteenth century logician and founder of semiotics and pragmatism, formulated representation in ways that anticipated current views. Pierce thought that objects of knowledge are cognitively grasped, that is, represented to the person's own mind, by way of signs (semiotics is the logical study of signs). A sign is the product of a habit, that is, the durable mental coordination (or functional structure – see below) of four meaning-generating constituents: (1) the token sign itself, often manifested in the act of communication, such as the French word 'homme'; (2) the context or ground of meaning from which this sign stems – for example, awareness that this is a word belonging to the French language; (3) the referent or actual object for which the sign stands – that is, a two-legged rational animal, etc.; and (4) the semantic operative that integrates meaning of the three previous constituents, combining them into a single semantic-pragmatic entity that we call 'man.' As Johansen has indicated, Pierce often collapsed terms (2) and (4) into a single term called interpretant. This triadic relationship among sign (or symbol), its referent/object, and their interpretant (or interpreted meaning, i.e., semantic operative plus context) is often emphasized in semantic logic. What enables an internal-meaning sign to be interpretant of another external sign is the equivalence of representative functions that

relate each of the signs ('homme' and 'man' in this case) to the referent/object. However, as we shall see below, a formulation of this semiotic function in terms of the original four terms is much more revealing in cognitive development.

A symbol is a sign that is not fixed in meaning, but is instead semantically/functionally detached from its referent and its context, so that meaning can change with a change in context, etc. For instance, when a baby begins to use language, one of the first words he/she learns is 'mom,' which is used in relation to the mother (see [Figure 1](#)). At first, the sign in question is not a symbol but rather a signal (a sign that is not a symbol); so the uttered 'mom' sign has a fixed meaning irrespective of the context. For instance, if the baby learned to say 'mom' as the mother tried to feed her, the sign in question might have the fixed meaning of 'feed me'; if she learned to say 'mom' in the context of playing, this sign might have acquired the meaning of 'raise me in the air,' etc. At this point, the infant might be 8 or 9 months. When he/she grows older, after 12 months of age, the sign 'mom' will have changed into a symbol, carrying the meaning of 'feed me' in the context of feeding, and the meaning of 'raise me in the air' in the context of playing, etc. Notice that symbols and signals can replace each other as functional processes. For instance, under emotional stress (or with habitual practice), symbols can turn into signals: When an anxious, panicky person hears someone shout 'fire!' inside a movie theater he/she may not take it as a symbol, suggesting the possibility of an actual fire, but rather may take it as a signal and run in panic to the door as if he/she were getting burned.

Complex systems of signs may be combined into models. Models are symbolic systems of ideas (or external signs) that stand either for complex entities of reality (e.g., universities, airports, cities, transportation organizations – which constitute figurative or object models) or for complex blueprints for action (these are operative or action/transformation, or executive, models); or they might combine these two aspects into more complete mixed models (e.g., theoretical, perhaps causal, model accounts).

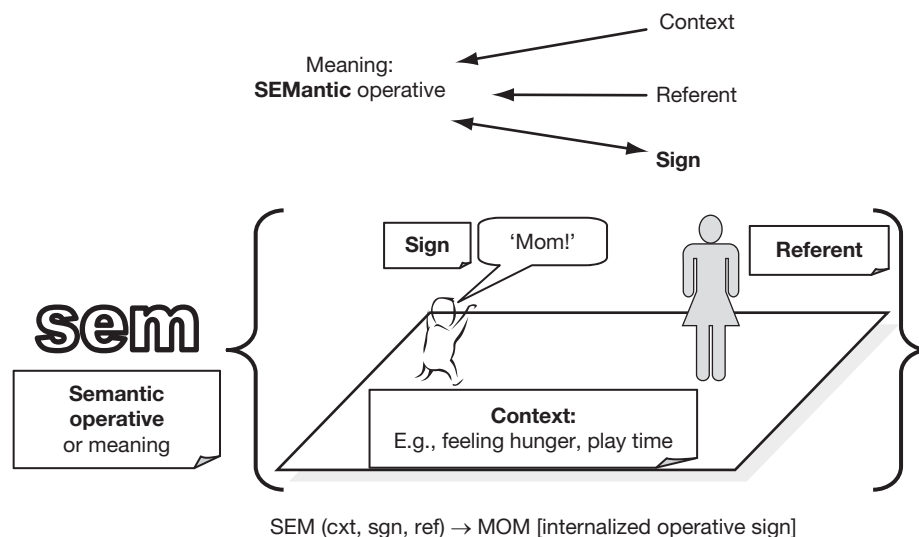

Figure 1 Schematic representation of constituents in a sign with illustrative example of baby calling his/her mother.

Logic relates the subject of knowledge (and epistemology) to the object of knowledge (and ontology) by studying the nature of truth, as well as languages and models used for representation. This observation, together with the fact that signs (semiotics) and truth are important aspects of logic, show logic's complexity. Relative to actual experience, which deals with particulars in the sense of entities that are grounded and concrete (i.e., offering resistances to action by imposing constraints), logic is mostly generic (representing kinds rather than concrete individuals) and often is organized in levels of representation, which become progressively more abstract. To provide insight on the psychology of levels of representation, we briefly discuss the problem of relations (descriptive and causal) between generic abstractions of knowledge and the particulars of actual experience; these relations were first expressed by Plato who unwittingly generated what we call 'Plato's problems.'

The Logic of High Cognition Versus Low Cognition

Plato's Problem

Plato was first to describe a dialectics between two modes of knowing/processing, whose dynamic interaction causes human experience and thought. For Plato, there were two worlds: the world of generic ideas (or being) and that of the senses. The world of ideas configured and categorized the world of the senses (or becoming) to make human knowledge possible. Humans partake of both worlds and use clear ideas to categorize and configure the confused world of becoming. Plato's way of formulating the problem of knowledge and its logic was oversimplified. There are not two distinct worlds, but rather many different levels or strata of knowledge, each serving as content to higher levels and giving form (informing!) knowledge of the lower levels.

Implicit in Plato's description, or in a description of nested levels, are problems that Plato did not solve and current cognitive science is facing. For instance, how to differentiate complementary but irreducible modes of cognitive processing: progressively more conceptual higher levels (i.e., generic, logico-mathematical, linguistic-logical, etc. – *high cognitive functions*) versus progressively more experiential low levels (concrete particulars, infra- or nonlogical, perceptual-motor and spatiotemporal processes, etc. – *low cognitive functions*)? How to differentiate between Plato's two modes (which translate into graded cognitive levels), while explaining both modes as emerging from common mechanisms? Indeed, interactions among innateness (maturation) and experience (learning, culturally mediated or direct) must be at the origin of both low and high cognition. How can these two sorts of knowledge processes be interfaced, maximizing adaptation to evolving realities, so as to embody in mental models the encountered changing resistances (reality constraints)? We attribute these problems to Plato because for him, the conceptual world of ideas was God given – it had causal sources distinct from those of experiential knowing. Some current neonativists, who think of conceptual knowledge as mainly expressing direct evolutionary acquisitions (logic and language largely explained by direct innate dispositions), might be seen as descendants of Plato.

Piaget's Reflective Abstraction

A better way to understand these two sorts of processing (low versus high cognition) is as a simplistic description of multiple nested functional levels resulting from cognitive learning – a process that Piaget called reflective abstraction. These cognitive levels occur as the brain constructively (i.e., level by level) represents to itself interrelations existing among packages of perceptual and/or mental experiences. This process occurs when experiences are sufficiently invariant (i.e., probabilistically replicable in approximate ways) from one situation to another, across space and/or time – whether experientially or during mental analysis. This cognitive learning is an abstraction because it ignores what is not probabilistically invariant, and then coordinates encountered invariants to create, in separate levels, progressively more complex objects and/or operative procedures. This learning is a reflective abstraction because packages of invariants at higher levels actually mirror/reflect general characteristics (patterns, configurations, or procedures) found at lower levels.

Reflective abstraction exists in many areas and content domains, but we illustrate it with a simple, intuitive example: the way a novelist might write a novel and a reader might come to appreciate its story, by integrating across chapters. The writer might begin with the gist of the story, a broadly formulated idea. Because the gist lacks concrete particular details and is restricted to general ideas, it qualifies as a high level of reflective abstraction. The writer would concretize and differentiate this idea by ordering in time general events and interactions that unfold in the story. He might divide the outlined story into chapters (chronological or not), creating lower levels of reflective abstraction. Progressively lower nested levels would emerge to differentiate events and happenings into more and more detailed concrete accounts, which progressively grow into different chapters. Finally, very concrete local details might be revised, at the lowest levels of reflective abstraction, to ensure emergence of local effects that express the concreteness of life experience. Whereas our writer proceeded predominantly top-down in the hierarchy of levels, often making bottom-up loops, the reader would proceed mostly bottom-up in the hierarchy, albeit with some reflective top-down loops. At the end, when the reader had constructed these levels of reflective abstraction in her own mind, she would have reached in intuitive completeness the gist with which the writer began, a gist level of abstraction that is on top of the hierarchy.

The novel might have, as life often does, circumstances that induce protagonists to err. These are misleading situations that often result from habits (automatized representations or actions) and may lead to error – that is, to represent or do something that contradicts intended goals or leads to misrepresentation. Salient but goal-misleading perceptual aspects may cause misleading situations. There are also facilitating situations caused by goal-relevant habits or perceptual salencies that induce persons to do what they must to attain their goal. These habitual and/or salient processes causing either misleading or facilitating situations typically exist at lower levels of reflective abstraction, and their activation dynamically hinders or facilitates goals formulated at higher levels of abstraction.

Piaget, who followed Kant in calling such processes schemes, emphasized these dynamic interactions among different levels

of reflective abstraction within a person's memory store or repertoire of schemes. Contemporary researchers on logical reasoning (e.g., J.S. Evans, P. Barrouillet, or D. Kahneman) have reached similar conclusions using different terminologies. They have contrasted two sorts of interacting processes (dividing the variation of levels into two categories, lower and upper, as Plato did): The heuristic processes (or reasoning system I) and the logical-analysis processes (or system II). These current authors think that misleading, or facilitating, situations occur when heuristic processes (which are more concrete, i.e., situated at lower levels and more habit-driven) hinder, or facilitate, implementation of more complex logical analyses that higher levels are attempting. To overcome misleading situations (problem-solving situations are often of this sort), higher level logical analyses that mobilize mental attention (working memory) and inhibit misleading lower-level heuristic processes may be needed.

Other Compatible Ways of Conceiving the Origin of Logic

Besides reflective abstraction, there are three other compatible ways of conceiving conceptual knowledge and logic: logic-as-structure-from-language, logic-as-structure-from-action, and logic-as-constructivist-invariant. Note that structure, a logico-mathematical notion, is defined by French epistemologists as a system of relations holding among constituent elements such that the system in question remains invariant (basically unchanged) as constituent elements are interchanged with other elements of similar kind. For instance, the relational system that identifies a face can be recognized, not only in animals but in designs using geometrical figures as eyes, nose, mouth, etc. A face is a visuospatial structure. There are also dynamic-system structures often found in executive procedures in business, in procedures of different games and sports, in language games we practice when communicating, and in logical operations we use in thought processes.

Within logic-as-structure-from-language one sees logic as a by-product of language and linguistic communication. This popular view, often called a rule-based or mental-logic approach to thinking, sees logic as main constituent of suitably accurate and/or valid reasoning, enabled by innate language characteristics refined and integrated using input from communication and cultural transmission. Language coexists with high cognition in high levels of abstraction, and many researchers think that high cognition emerges because of the power of synthesis afforded by language.

Piaget was perhaps the first research psychologist to have understood logic (and reasoning development) in terms of logic-as-structure-from-action (i.e., as internalized action). For him and many others, logic emerges by way of cognitive learning, as action-serving systems of representation and mental logical operations. These systems have functional structures that relate to actual experience (the truth function), such as relations of coexistence (see below) and/or ordinal relations among elements. They emerge as invariants in goal-directed activity addressed to the environment (i.e., praxis) – perhaps during problem-solving or analytical goal-directed thinking.

Consider now the third way: logic-as-constructivist-invariant approach, which in fact coordinates or integrates the other approaches. A current version of the levels approach given in the previous section, involves graded levels of reflective abstraction; this version helps to solve Plato's problems via cognitive learning. A liberalized version of the first approach (language and its structure as causal factors in logic and logical operations) is found in constructivist approaches. However, constructivism has also the second approach: mental activities of logic are seen as forms of *internalized action* (as current neuroscience has shown), that is, as dynamic interactions between internalized objects of experience (figurative processes) and operative processes – internalized procedures.

A Psychological Construct: The Organismic-Scheme Unit

Within a constructivist perspective, analysis of psychologic (logic embodied in functional structures of organisms, i.e., organismic logic) requires explicit formulation of psychological units – processes serving to relate high-level (abstract) functional categories to low-level concrete processes of life situations. Kant was the first to ask how to interface these abstract high-level concepts (logical structures) with concrete low-level processes representing particulars of experience. His answer was an interface of mediating processing units that he called schemes (or schemas). Within developmental constructivism, we define a scheme (Sch.) as a dynamic coordination of three components: (Sch.1) a functional component that embodies the scheme gist and expectancies of an outcome, that is, anticipation of consequences of the scheme application (representations, procedures, or operative effects); (Sch.2) a releasing component that has conditions that, when satisfied (matched) by features/aspects of a situation, induce the scheme to apply; and (Sch.3) an effecting component with effects (representations, operative procedures, etc.) that actually occur in the situation when the scheme applies. Notice that from a constructivist viewpoint representations, as much as operative actions, are effects; suitable conditions of the releasing component serve as the intermediaries between the input and the output (which is the effect). As Piaget often claimed, the coded stimulus (representation) is already a response. This empirical rationalist view is in sharp contrast with the radical empiricism of many scientists and philosophers, for whom figurative structures, such as objects, are already available in the external world; and the act of (figurative) knowing consists in making a copy of them as representations.

Consider our earlier example of the signal/symbol of mother, which 8-to-9-month-olds learn to use to control mother's activity by uttering the word 'mom.' As a signal, the scheme of mom might have the following definition in the infant (we use English language to describe the infant's feelings, which are not linguistic but experiential, i.e., low level): (Sch.1) gist: uttering 'mom' will get *Mother* to feed me (or play with me, or whatever concrete activity is at the origin of the scheme); (Sch.2) conditions: feeling hunger or wishing more of the particular food, seeing or hearing *Mother*; (Sch.3) effects: uttering 'mom,' looking at mother with the expectancy from

Sch.1 that she is going to feed baby in the usual way. The scheme embodies the signal 'mom' that baby can use as an *operant*, that is, a baby's operative action that will induce *Mother* to feed baby in the expected way when he/she wants. This is a low-level psychological structure acquired using simple associative learning. Notice that *Mother* is the baby's scheme representation of a protector-companion, which in part might be innate and species specific.

At 12 months or so, the baby begins quickly to produce symbols, that is, signs in which the meaning and/or the referent can change with the context because all constituents of the symbol, the sign (sgn), context (cxt), referent (ref), and meaning (sem – for semantic operative) are separate, distinct schemes that become coordinated as the symbol is formed (see Figure 1). In the case of the *Mother* symbol, sgn would be the utterance 'mom'; cxt would be the sort of situation, for example, the feeding context, the playing context, etc.; ref would always be *Mother*; and sem would be the actions of *Mother* that implement the operative intervention stipulated by cxt. Notice that this symbol coordinates the four schemes forming a spatiotemporal relation of coexistence among sgn, cxt, and ref thanks to sem. Such a complex, mobile coordination cannot be achieved with associative learning. It requires focused mental attention (i.e., working memory) and intentional, effortful activity: This is a high-level psychological reasoning that marks the origin of language acquisition.

This symbolic function serves to coordinate chosen schemes that functionally complement each other, which are reflectively abstracted into more complex, higher level schemes – eventually leading to the emergence of a mind. Logical operations are mobile and functionally complex symbolic processes that run mentally (internalized); they allow for reversible mental acts that exhibit adaptive variability. Preschoolers, and much more so school children and adults, produce this reversible and anticipatory symbolic processing, but other high primates (e.g., chimpanzees, orangutans) also can do it. However, mental processes of nonhuman primates lack mobility, reversibility, and combinativity relative to preschoolers, possibly because mental-attentional capacity of apes only compares to that of 26-to-35-month-old humans.

Consider, for example, chimpanzees' use of multiple tools (hammer-stone, anvil-stone, wedge-stone to stabilize the anvil) for cracking nuts, discovered by Matsuzawa and Yamakoshi. The logic of action in this behavior includes two nested functional components. First is an operative scheme (PLACE) for positioning the nut (*nut-food) on the anvil-stone (*anvil) during nut cracking (here figurative schemes are marked with a *). Second is another operative (CRACK) that uses the hammer-stone (*hammer) as tool and the nut as target (*nut-target). Although the schemes *nut-food and *nut-target both refer to the same actual object, in our method of task analysis they are distinct schemes because they belong to different contexts of use, that is, distinct functional activities or practical skills. To crack a nut, chimpanzees must coordinate at least these schemes:

CRACK(*hammer, PLACE(*anvil, *nut-food), *nut-target)
[1]

In English, this formula might be translated as follows: first the chimpanzee places the nut-food on top of, and supported

by, the anvil; then, always maintaining the nut in place, he cracks the nut by using the hammer-stone.

Because the situation is misleading (e.g., prior habit schemes should lead chimpanzees to take the nut to their mouth or ignore the stones), performance requires chimpanzees to boost all schemes with endogenous (i.e., mental) attention. Specifically, six distinct schemes must be simultaneously boosted in activation using mental attention. This is about the most complex symbolic coordination of schemes that great apes are capable of (six or seven perceptual-motor schemes), which places them on par with the mental-attentional capacity of 2- or 3-year-old children. This well-known example of problem-solving performance shows chimpanzees' symbolic anticipatory processing as well as their limitation. Processing is essentially perceptual-motor, cued by facilitating situations, and somewhat lacks mobility: Once habits are formed, great apes have a hard time in overcoming them within misleading situations. Although it is a logic-of-action operative coordination, this performance is indexing a relatively low level of reflective abstraction.

Consider now high-level mental processing in humans. We often encounter problems in which at least two variables interact in terms of certain relations of coexistence (i.e., definite states of the variables in which they either exist in the situation and appear together or do not, having some other relation of coexistence). The problem (perhaps a panel with buttons p , q , r , s , etc., some of which must be pressed to obtain or predict reward) might on a given trial be such that a desirable outcome, for example, a reward, occurs if variable p is present (or is acted upon) and variable q also is present (acted upon). However, when p but not- q , or q but not- p , or neither is present (acted upon), the desirable outcome is not obtained (note that not- p or not- q are, respectively, any buttons different from p or q). This particular pattern (or relation of coexistence) related to a suitably accurate (true) outcome is known in logic as a conjunction. What sort of mental process is needed to ensure that no error is produced when participants guess the outcome (e.g., when some buttons are pressed in the task just described)? A rational task analysis suggests that they must discover, and keep in mind, that only one possible truth state brings the good outcome: $p \& q$, that is, p is true (e.g., should be pressed) and q is true. Logicians may symbolize the same state of affairs by writing pq .

Sometimes the problem is more complicated. For instance, truth might occur (i.e., good outcome when buttons are pressed) in three different truth states: with pq , with $-p-q$ (i.e., not- p and not- q), and with $-pq$ (i.e., not- p and q); but not (false, or bad outcome when buttons pressed) when $p-q$ (i.e., p and not- q). Logicians call this state of affairs a conditional or implication relation, which they might represent as $p \rightarrow q$, meaning that the relation is such that true outcomes occur for $pq \vee$ (i.e., or) $-p-q \vee -pq$. (In psychology, the symbol ' \vee ' means 'or', the symbol '&' means 'and', and the symbol ' \rightarrow ' means 'if... then,' but only when the two terms p and q share meaning – i.e., are related by a semantic implication.)

A Venn diagram (i.e., a diagram in which circles represent all the individuals or objects that share, or fall under, stipulated predicates or propositional statements) can provide a clear figurative model for all possible relations of coexistence – all possible truth values – that relate p and q ; this is equivalent to

what has been called a truth table. In the four Venn diagrams of Figure 2, we symbolize with a dot areas of the diagram that are true for the state of affairs or atomic propositions being contrasted (i.e., p or q), and leave blank areas that are false for them. For instance, if in the upper-left Venn diagram, p stands for the predicate *father* and q for the predicate *man*, then the three dots found in this diagram show that pq (indicated by the upper dot area) is true for the two predicates; both $\neg pq$ (right-middle dot area) and $\neg p\text{-}q$ (lower dot area) are also true. Indeed, if a person is a father, he is also a man, but one can be a man without being a father or be neither a father nor a man. However, it is not possible to be a father without being a man, which renders $p\text{-}q$ (the left-middle dot area) false. These four cases exhaust all possibilities, making the diagram a pictorial representation of a complete truth table.

Under this diagram, we have written in symbolic notation the corresponding conditional (\rightarrow) operator, that is, $p \rightarrow q$ (often called implication, i.e., the propositional-connective *if... then*, in the language domain). This conditional operator translates into a description of truth states expressed by the formula $(pq \vee \neg pq \vee \neg p\text{-}q)$, where each truth state corresponds to one dot area in the diagram. The lower right diagram in Figure 2 corresponds to an inclusive disjunction operator ($pq \vee p\text{-}q \vee \neg pq$), interpretable in language as the connective *and/or*; which can be logically symbolized by $p \vee q$ (example: p is a *doctor* and q is a *man*; expressible in language by the sentence ‘The person is a doctor and/or a man’). The lower left diagram corresponds to a conjunction operator (pq), which in language corresponds to *and*, logically symbolized by $p \& q$ (example: p is *French* and q is *General* – ‘the person is a French General’). The upper right diagram expresses a biconditional operator ($pq \vee \neg p\text{-}q$), symbolized by $p \equiv q$ (example: p is a *medical doctor*, q has *completed studies in a Faculty of Medicine* – ‘The person is a medical doctor if and only if he/she has completed studies in a Faculty of Medicine’).

Figure 2 Venn diagrams (i.e., truth tables) of four logical operations: Implication, disjunction, conjunction, and biconditional.

In describing relations of coexistence between two (or more) variables, many logicians talk about (truth-) state descriptions if they mention only the truth states (i.e., the cases, areas with a dot in the Venn diagrams) that bring about truth; and they talk about truth tables when all possible cases (true and false) are given. In the current psychological literature, following Johnson-Laird’s theory of mental models, researchers on logical connectives may call a model each truth state (i.e., one dot area in a Venn diagram or one truth-table case). This usage contravenes use of this term in logic and much of science. We shall call model only the whole truth-table representation (all true or false cases) or the whole state description – which is just a truth table with false states left implicit. If we state all possible cases and identify true ($\$$) or false (\wedge) as values, the result is a logical truth table. We shall represent truth tables with the following notation:

$$\text{Conjunction [and]} : \wedge(\neg p\text{-}q \vee \neg pq \vee p\text{-}q), \$ (pq) \quad [2]$$

$$\text{Conditional or implication [if... then]} : \wedge(\neg p\text{-}q), \$ (pq \vee \neg p\text{-}q \vee \neg pq) \quad [3]$$

Notice again that these four cases (i.e., pq , $p\text{-}q$, $\neg pq$, $\neg p\text{-}q$) are all the possible relations of coexistence between two variables, and each variable can be either true ($\$$) or false (\wedge). Consequently, there are 16 possible different relations of coexistence, and each corresponds to a different logical connective that has its own linguistic form. Here are two other common connectives:

$$\text{Disjunction [and/or]} : \wedge(\neg p\text{-}q), \$ (pq \vee \neg p\text{-}q \vee p\text{-}q) \quad [4]$$

$$\text{Biconditional or equivalence [if and only if]} : \wedge(\neg pq \vee p\text{-}q), \$ (pq \vee \neg p\text{-}q) \quad [5]$$

In the case of conjunction ($p \& q$) problems, only the true state is spontaneously salient because its two variables, being positive, are easily processed at low level of reflective abstraction. This is due to the perceptual presence of positive values and people’s habit of ignoring negative values, focusing only on positive ones (these organismic biases are called heuristic factors in the literature). For this reason, the truth state in a conjunction is easy to remember. In contrast, in conditional ($p \rightarrow q$) problems, with a state description that has negative values in the variables (i.e., $pq \vee \neg p\text{-}q \vee \neg pq$), two of the true states will be difficult to remember because of the negative values. Problems involving the other two connectives we have mentioned, disjunction and biconditional, should be and are easier than those with conditionals, but harder than conjunctions.

This finding is well supported in the literature (see, e.g., the work of P. Barrouillet and his collaborators) but not clearly explained. The usual explanation rests on greater difficulty to process single negative values. In conditionals, negative values are found both in the true (pq , $\neg p\text{-}q$, $\neg pq$) and the false ($p\text{-}q$) values; however, in disjunctions and biconditionals, the truth states that contain one negation (i.e., $\neg pq$, or $p\text{-}q$) have the same value (false in the biconditional, and true in the disjunction). Thus by categorizing (recoding) them as states with only one negative variable, it is possible to treat both states together assigning the value they share. In contrast, in the conditional these truth states must be treated separately.

Piaget was aware of these differential degrees of difficulty among connectives. It has been shown that, developmentally, conditionals in problems are first treated as if they were conjunctions (e.g., by 8- or 9-year-olds); later they are treated as biconditionals (12-year-olds); and finally, older adolescents (14-year-olds) treat conditionals as conditionals. The current literature explains this finding in terms of heuristic versus logical analytical processes and of high working-memory demand in analytical processes. A much clearer explanation can be made by adopting a neo-Piagetian developmental approach, as we now briefly summarize.

Development of Logical Operations: Developmental Stages

Unlike Piaget's theory, in which qualitative logical characteristics of tasks are thought to determine developmental difficulty (i.e., age at which they first can be handled by children), current researchers tend to interpret tasks' difficulty as due both to their mental-processing demand (in the sense of working memory, i.e., mental-attention demand of the task) and their executive demand. Executives are neural processes that plan the logical operations to be carried out and control relevant schemes to be activated, as well as irrelevant or task-misleading schemes to be inhibited. Unlike many cognitive scientists, we separate mental attention (working memory and attentional interruption) from executives because tasks that control for executives (e.g., by teaching them) and that vary the demand for mental-attentional activation and inhibition, exhibit the developmental levels or substages that Piaget formulated (see Further Readings, for examples). In contrast, when the task demand on mental attention is kept reasonably constant, but the executive demand is increased by making the tasks procedurally longer or more complicated (while keeping the same mental demand), discontinuous developmental stages do not appear and instead performance level increases linearly with age. This happens whenever learning is the main causal variable because learning increases cumulatively with life experience.

Piaget described four main stages or cognitive (logical-operation) levels found in normal development. Existence of these stages assumes that children have sufficient executive know-how and are presented with suitably misleading tasks that are novel for them. (1) First is the sensorimotor stage (from 0 to 30 months of age), which features nonsymbolic (signalic) coordinations of perceptual-motor activities. The power for constructing symbols develops, on average, at 12 months; at 18 months, coordination of symbols (symbols of symbols) begins. (2) The preoperational stage begins at 3–6 years of age, when more or less complex symbolic coordinations of activities occur; but only in the context of present (here and now) situations. (3) In the concrete operational stage (7–11 years), children show symbolic activities vis-à-vis future situations, not just present ones. (4) With the formal operational stage (11 years and older), abstract reasoning begins in novel (not practiced) situations with mental activities addressed to (formally) possible situations – in addition to present or future ones. A situation is formally (not just empirically) possible when it does not contradict any relevant known fact, and so might be true.

We omit the discussion of sensorimotor processes from this article. Jonas Langer discussed them in his article on Logic in the previous edition of this Encyclopedia; moreover, the reader may refer to the list of Further Readings. We emphasize again, however, that at about 12 months of age, the ability to coordinate four distinct schemes appears, using the newly expanded power of mental attention (working memory). This maturational growth of mental attention causes emergence of the symbolic function, which explains why babies learn language in accelerated ways after 12 months. Then, with further growth of mental attention, at about 26 months of age, children become able to coordinate six distinct schemes, thus reaching the working-memory capacity that most adult chimpanzees seem to have (as shown by the chimpanzees' use of multiple tools for cracking nuts summarized above).

Levels of Mental Operations According to Piaget and Neo-Piagetians

Logical operations increase in complexity with both the person's executive know-how (as a function of learning) and his/her mental attention or working-memory capacity. Current researchers differ on how to measure this capacity (see Further Reading), although all the methods seem to be related. Among them, the simplest current one, closest to Piaget's own logical method, is Zelazo's Cognitive Complexity and Control theory. It consists of examining the depth of hierarchical coordination (levels of reflective abstraction) needed to solve the task. Another method, proposed by Halford, is based on the Relational Complexity of logical operations involved. For Halford, complexity is a function of the number of variables that must be jointly coordinated to solve a task. He distinguishes unary, binary, ternary, and quaternary relations. A unary relation occurs when a conceptual category or a predicative scheme in perception is applied on a single logical argument (an object) to categorize it. For instance (we write logical operators or predicates with capitals and logical arguments in lower case), the expression $\text{DOG}(x)$ says that an uncategorized perceptual entity x is a dog; and $\text{DOG}(\text{Rover})$ says that Rover refers to a dog. The sentence, or empirical observation, that the small elephant is larger than the dog involves a binary relation because there are two arguments: $\text{LARGER-THAN}(\text{elephant: dog})$.

In contrast, a logical-problem question such as "if I have in my hand three roses and eight daisies, do I have in my hand more flowers or more daisies?" can be solved only by coordinating a ternary relation, as represented in Figure 3. Namely:

$\text{INCLUSION}^{L1} (*\text{flowers: } \{\text{*roses}\}_{L1, \text{sit}}, *\text{daisies} \leftarrow [\text{flowers non-roses}])$

Figure 3 Representation of the class inclusion conceptual hierarchy with the operator logic formula of our mental problem for solving inclusion problems.

INCLUSION (flowers: roses, daisies \leftarrow [flowers non-roses])
[6]

There are only three logical arguments (objects), because in this formula, the expression $\leftarrow[\dots]$ indicates that inside the brackets are predicates or characteristics belonging to the representation of daisies. This ternary relation expresses the coordination of two levels of reflective abstraction: the hierarchical relation between a superordinate class (flowers) and its subordinate classes (roses, daisies, etc.) as shown in Figure 3. As Piaget and Inhelder (originators of this inclusion-of-classes task) knew well, logical coordination of this semantic hierarchy solves the problem. The problem exists because young children see in the hand only roses and daisies, and linguistically tend to assume that the question ‘are there more flowers or more daisies?’ makes reference to only roses and daisies (i.e., ‘flowers’ is taken to refer only to roses). To solve this tricky question, the child must remember that daisies also are flowers but are not roses (i.e., he/she should recall the semantic hierarchy). The task is difficult because it is semantically misleading, although Piaget may not have intended it to be. Our research shows that misleading situations (as contrasted with facilitating situations, where no activated scheme is misleading) serve better for estimating mental-attentional demand (working-memory processing complexity) of tasks. Nonetheless, a distinction between misleading and facilitating tasks is still often missing in the literature.

Halford considers that unary relations are handled by 1-year-olds (i.e., when the symbolic function first appears); binary relations are handled on average (median age) by 1–2-year-olds. Ternary relations are handled, depending upon the task, at various ages, much later than binary relations; according to Halford and Andrews (see Further Reading), ternary-relation tasks are passed by 70% of 5-year-olds and 78% of 7–8-year-olds. They also report that quaternary-relation tasks are generally accessible to 11-year-olds (no passing rate is provided). Clearly, Halford’s relational complexity metric, and its developmental passing ages, cannot explain all the levels found in the well-studied substages described by Piaget (see Table 1), which do coincide with levels of reflective abstraction given by Robbie Case and others.

In contrast, our earlier-developed method, which includes significant aspects also available in Halford’s approach (but adds new important distinctions), makes measurement of complexity more precise. Our method explains the transition from one Piagetian substage to the next as due to an increase in attentional capacity, which is indexed to each complexity level. The third column of Table 1 gives the mental-attentional complexity level (i.e., capacity) children in each substage have been shown to have available, on average, when tested with misleading tasks. For instance, in low concrete operations, we expect a majority of 7- and 8-year-olds to be able to coordinate, using mental attention, three symbolic schemes plus e sensorimotor schemes (e is the mental capacity available at 26 months – a constant that does not need to be quantified when analyzing mental tasks); all to a total of $e + 3$.

Consider again the inclusion-of-classes task (see formula [6] and Figure 3). We represent the complexity of this task in formula [7]:

$$\text{INCLUSION}^{L1}(*\text{flowers} : \{*\text{roses}\}_{L1, \text{sit}}, * \text{daisies} \leftarrow [\text{flowers non-roses}]) \quad [7]$$

Table 1 Chronological age of Piagetian mental-processing substages and predicted mental-attentional capacity

<i>Normative chronological age</i>	<i>Piagetian substage</i>	<i>Expected mental-attentional capacity ($e + k$)</i>
3–4 years	Low preoperations	$e + 1$
5–6 years	High preoperations	$e + 2$
7–8 years	Low concrete operations	$e + 3$
9–10 years	High concrete operations	$e + 4$
11–12 years	Introduction to formal operations	$e + 5$
13–14 years	Low formal operations	$e + 6$
15 years to adulthood	High formal operations	$e + 7$

Note: k refers to the theory-estimated number of symbolic schemes that an individual can simultaneously boost in activation using her/his mental-attentional capacity.

Here the operative scheme is written in capitals. Figurative schemes are in lower case with an asterisk (*) preceding them, indicating that these are symbolic schemes/signs and not referents – real objects. We have added to formula [6] assumptions about perceptual salience and chunking (i.e., automatized logical-structural learning, or L-learning – L1 in formula [7]). The coordination operator for the inclusion of classes (i.e., INCLUSION) has chunked to it (this is symbolized by superscript/subscript L1) the figurative scheme (*) of roses – a perceptually salient aspect of the situation (symbolized by subscripted *sit*), so that when mental attention boosts with activation the inclusion operator (this boosting is symbolized in the formula by underlining INCLUSION, *flowers, and *daisies), the *roses get automatically boosted as well. Thus, as formula [7] shows, there are three symbolic schemes (all underlined) that need attentional boosting. The mental or working-memory demand of the task is therefore $e + 3$ on average, which predicts that a majority of 7- to 8-year-old children (low concrete operations substage) will solve this task. This is what Piaget, Halford, and many others have found, although degree of facilitation or misleadingness of a particular task version can make an important difference. Notice that the schemes we count as boosted with mental attention here (during stages of preoperations, concrete operations, and formal operations – Table 1) are symbolic. Signalic sensorimotor schemes usually are facilitating and boosted with sensorimotor attentional resources (the e component of $e + k$ of mental capacity, which functions as a constant after 3 years of age). In formula [1] and our earlier analysis of the symbolic function, the schemes were sensorimotor.

Let us now consider an example at the high concrete operations substage. We gave the logical formula (truth table) for a conjunction in formula [2], and we now add (see formula [8]) aspects needed to describe a mental model of children processing this sort of problem:

$$\text{CONJUNCTION}(\underline{(-p-q \vee -pq \vee p-q)}, \underline{\$(pq)}) \quad [8]$$

For simplicity, we omit the star (*) that would mark true/false states as being symbolic figurative schemes. The conjunction operation (symbolized with capitals) carries out coordination of all true/false states relevant as alternatives (\vee) to

evaluate a conjunction in a suitable task. This operative CONJUNCTION includes the knowledge that either true (\$) or false (^) evaluation will be present, but not both. We assume that false (^) states, that is, all states that contain $\neg p$ or $\neg q$, are spontaneously chunked together (L-structured via logical learning), because subjects have a strong tendency (due to automatisms or heuristics, i.e., low-level processing) to deemphasize or neglect, and treat together, negative states (e.g., $\neg p$, $\neg q$) and false values; but emphasize and attend to true values and affirmative states (i.e., p , q). As the four underlines show, there are four schemes (or chunks) to be boosted simultaneously to synthesize a valid response. Thus, as shown in Table 1 (line of $e + 4$), the task can be solved at about 9 or 10 years of age, as much data show.

The process analysis of other connectives given in formulas [3] and [5] should be selfexplanatory after discussing formula [8]:

$$\text{CONDITIONAL } (^{\neg}(p \rightarrow q), \underline{\$}(p \vee \neg p \vee \neg q)) \quad [9]$$

$$\text{BICONDITIONAL } (^{\neg}(p \leftrightarrow q), \underline{\$}(p \vee \neg p \vee q)) \quad [10]$$

As the underlines in the formulas show, formula [9] has a mental demand of $e + 6$ and formula [10] of $e + 5$. A look at Table 1 shows the expected age (and stage) of solution for these misleading problems (misleading due to the relative neglect of negative states). Predictions agree with empirical results. Notice that mental models of Barrouillet and of Halford, among others, are consistent with the ones given here, although they differ in that they do not examine in sufficient detail organismic/situational factors that make task items more or less misleading or facilitating – thus failing to be explicit enough about mental demand or differential processing complexity of the tasks in question.

Children who fail often neglect attending to false states and negative terms, which causes, when conditional problems are used, the emergence of a developmental sequence: First incomplete solutions appear based on the CONJUNCTION operative (for 9-year-olds); then incomplete solutions appear using BICONDITIONAL operative (for 11-year-olds); finally complete solutions appear using CONDITIONAL operative (for 13-year-olds). Such developmental sequence of faulty solutions prior to the correct solution in conditional problems illustrates well the concept of *accessibility* proposed by Kahneman. As our theory formulates it, any given strategy will be accessible to subjects only when one of two conditions are met: (1) the task is facilitating, and low-level (system I) processing suffices to solve it; (2) the task is misleading, and high-level (system II) processing is required, but the task's mental-attentional demand is well within the subject's mental capacity as given in Table 1. An important corollary is that when a task-adequate strategy is not accessible (often with misleading tasks, and when attentional capacity is lacking), degraded strategies will be used (as illustrated here with the strategy series conjunction-biconditional-conditional) to optimize proximity to a correct solution.

Logical Reasoning in Adolescence and Adulthood

In terms of mental-attentional (working memory) resources, the main difference between adolescents or adults and children is that the former can coordinate as many as six or seven

distinct symbolic schemes simultaneously, allowing them to solve tasks with very high mental demand. This estimate, however, comes from our method. Other methods, such as Halford's, find no capacity difference between late adolescents, adults, and 11-year-olds (all coordinate quaternary relations). Another factor high in adolescents/adults relative to children is their executive know-how. Halford might appeal to this factor (i.e., less executive know-how) to explain the inferior performance of 11- or 12-year-olds relative to adolescents and adults, in Piaget's formal operational tasks (particularly with regard to truth-preserving semantic transformations that later in this article we call meta-operations/meta-operators). Halford could give the same reason to explain children's lower performance in task items with a very high mental-attention demand (see Pascual-Leone and Johnson's recent work).

In terms of logical structures, the most striking difference between children and older participants is the latter's capacity for logical operations of the highest order, *meta-operations* (i.e., operations on operations), or symbolic operations of second order, as Piaget called them. A good illustration of this power of meta-operations is in the high-level coordinations that interrelate all 16 logical-connective operations between two variables (p and q) in late adolescents and adults, manifested in high-level strategies of logical reasoning for transforming logical expressions across connectives.

We will use the example of conjunctions and disjunctions (see Figure 4); however, all 16 logical connectives are similarly interrelated. The top part of Figure 4 shows two Venn diagrams, that is, two sets of intersecting circles that respectively signify possible truth values (the mental model) of logical connectives AND (e.g., 'Peter and Jill love the theater') and OR (e.g., 'Peter or Jill loves the theater'). If p stands for 'Peter loves the theater' and q stand for 'Jill loves the theater' then the Venn circles indicate sets of individuals for whom these sentences are true. The X sign imposed on the circles demarcates all four possible truth states (p , $\neg p$, q , $\neg q$); its dots highlight truth states that are actually correct for the

Figure 4 INRC system of logical connectives illustrated with transformations that relate conjunction ($p \& q$) formulas with disjunction ($p \vee q$) formulas. Meta-operations: I (identity), N (negation), R (reciprocal), and C (correlative). Double headed arrows indicate reversibility of these transformations.

particular connective (this homogeneous logical notation was proposed in the 1940s by McCullock and Pitts). On the left side, we represented the AND truth table, and on the right side OR.

The square frame in the center of [Figure 4](#) is a classic logical diagram adapted by Piaget. It shows the coordinated meta-operations of Piaget's INRC model: I is an Identity operation that leaves a truth state unchanged. For instance, application of I on the conjunction in the top left corner of the frame, that is, $I(p \& q)$ yields $p \& q$. N is a negation (inverse meta-operation) that negates the logical formula truth value: $N(p \& q) = \neg(p \& q)$, as shown in the top right corner of the frame. R is a reciprocal meta-operation that negates both terms (atomic sentences p, q): $R(p \& q) = \neg p \& \neg q$ (right bottom corner). Finally, C is a correlative meta-operation that adds or subtracts (whichever is possible) to the truth table of a formula the truth states that have an incomplete negation (i.e., $\neg p, q, p, \neg q$): $C(p \& q) = p \vee q = (p \vee \neg p \vee q \vee \neg q)$ (bottom left corner).

[Figure 4](#) shows that these four meta-operations interrelate (or intertransform) logical-connective formulas. In our example, conjunction (top left corner), disjunction (bottom left), incompatibility (top right), and joint denial (bottom right). Meta-operations can be used to interrelate all 16 connectives, which is important because these interrelations have closure and other properties of mathematical groups. Indeed, any number of applications of these four meta-operations to a two-term propositional-connective formula always is equal to the application of one of the four meta-operations, thus ensuring closure (i.e., the four meta-operations suffice to describe all possible transformations of coexistence of atomic sentences p, q). As readers can verify in [Figure 4](#): $CNx = Rx = NCx$; $RNx = Cx = NRx$; $RCx = Nx = CRx$; $NNx = RRx = Ix$; $RCNx = Ix$; etc. In reading these formulas, x might be interpreted as $p \& q$, or as any other of the 16 propositional connectives. Meta-operators always apply to x one by one and from right to left.

Piaget believed that when people have structures (enduring high-level schemes) for these concretized INRC models, they can easily understand correspondences among logical connectives and their interrelated truth values. For instance, they can understand that saying that 'Peter and Jill do not love the theater' ($\neg(p \& q)$, i.e., Nx) carries the same meaning (same truth value) than 'No Peter and/or no Jill loves the theater' ($\neg p \vee \neg q$, i.e., RCx). The INRC model just presented is Piaget's. In what follows we shall show how the emergence in brain processes of such a model can be explained by the ability to keep in mind (boost with mental-attentional activation), and coordinate, two distinct but interrelated and complementary systems of meaning, which when coordinated yield the semantic relations allowed by the INRC system. One of these two systems integrates truth claims (assertions and negations) that bear on the *semantic totality* (total relational state of affairs) or superordinate sentence (this is the I/N system). The other system integrates truth claims that correspond only to the subordinate relational states or atomic sentences – that is, the *structural constituents* of the semantic totality (this is the R/C system). Our analysis also will show that coordination of at least six distinct semantically complementary schemes may be needed for this R/C system's dynamic synthesis to take place.

System I/N, hereafter called OP1, is constituted by the interaction between I and N. I is an identity operator, which when applying on a propositional-connective formula x (for instance, $p \& q$) leaves it unchanged. Notice that ordinarily in predicate or propositional logic, identity is seen as a relation; however, in constructivist operator logic, to describe how meaning is transformed when one or another legal transformation is carried out, identity appears as an operator that leaves its object (logical argument) unchanged. N is a propositional (semantic totality) negation operator, which applying on any of these formulas x obtains its inverse (for instance, $\neg(p \& q)$ is the negation of the total proposition) and when applied again onto its effect cancels this effect ($NNx = Ix$).

System R/C, here called OP2, is constituted by the coordination of R and C. These two operators, defined relative to Ix , can transform Ix by acting on its constituents (atomic sentences) rather than on the semantic totality (total sentence) as N does. R is a reciprocal, which applying on Ix brings negation to its semantic constituents (i.e., $\neg p \& \neg q$); C, the correlative, adds or subtracts (whichever is possible) to the truth table of Ix the truth states that have an incomplete constituent negation (i.e., $\neg p, q, p, \neg q$). For instance, since $(p \& q) = pq$, $C(p \& q) = (pq \vee p \neg q \vee \neg p q \vee \neg p \neg q)$. Furthermore, C is the totality negation of R, and their joint application produces Nx (i.e., $RCx = CRx = Nx$). As [Figure 4](#) helps to clarify, the two operative systems OP1 and OP2 are functionally intertwined, because *all* operations are defined from the same given position $I(x)$, which for our example of [Figure 4](#) is in terms of $I(p \& q)$. They thus need to be coordinated, and this is done by the meta-system OP3. This functional structure appears in [formula \[11\]](#):

$$\text{OP}_3(\text{OP}_2^{L1}(\underline{Rx}, \underline{Cx}), \{\text{OP}_1\}_{L1}(\underline{Ix}, \underline{Nx})) \quad [11]$$

As in other formulas, the underlined symbolic schemes require boosting with mental attention. Notice that OP1 does not need to be boosted; it is chunked with OP2 ($L1$ superscripted/subscripted) because both have the similar function of coordinating two complementary meta-operators (either I,N or R,C). Formula [11] mental model predicts that one must simultaneously hold in mind six or seven symbolic schemes (or five, in the unlikely event that all operators, OP, are chunked), in order to abstract INRC systems. According to [Table 1](#), this achievement might not happen earlier than 13 or 14 years of age – as has often been found empirically.

These systems of meta-operations also occur outside linguistic logic, in experiential, spatiotemporal, and mechanical domains. [Figures 5](#) and [6](#) illustrate the example of a two-arm balance scale, with a central fulcrum and weights ($W1, W2$, etc.). Weights are placed on each arm at various distances ($D1, D2$, etc.). Participants must predict whether given configurations of weights, at various distances from the fulcrum, preserve or not the equilibrium, which can be altered by adding (MORE) or removing (LESS) weight or distance. Our mental model, underneath the balance scale in [Figure 5](#), shows a relational complexity similar to that of the INRC system of logical connectives, with a mental-attentional demand of six or seven. [Figure 6](#) unfolds this functional structure to show that there are two coordinated INRC systems, one for the left-hand arm of the balance ($W1, D1$) and another for the right-hand arm ($W2, D2$).

Figure 5 Illustration of Piaget's balance scale task. The coordination of weights (W) and distances (D) can be represented by one INRC system for each arm of the scale (see Figure 6). Formula shows the operative and figurative schemes that need to be coordinated for success in the task (six, with practice – L1). Task should be accessible at formal or late formal substages.

Figure 6 Coordination of two INRC systems in Piaget's balance scale task.

Final Summary

Logical operations serve to investigate truth with the help of systems of signs. We have analyzed signs and shown how two developmentally important sorts, signals versus symbols, can be defined in terms of schemes – psychological units of processing in the organism. Piaget pioneered the psychological study of logical operations. He emphasized that schemes are naturally organized into levels of reflective abstraction, which he often called substages. We have provided an overview of these levels of psychological abstraction and have analyzed in detail some logical-problem tasks, to illustrate how in task-misleading situations developmental growth of mental attention (a maturational component of working memory) may enable progressively higher levels of abstraction. Basic neo-Piagetian methods for assessing logical complexity converge with current logical research.

Our neo-Piagetian mental models of meta-operations, found only in adolescents and adults, explain known limits of children's logical operations. They might also explain, but this is beyond the scope of this article, the encompassing imagination and creativity in some adolescents.

Glossary

Affection and liking A sentiment of fond attachment.

Commitment A pledge or promise to another.

Companionate love The affection and tenderness men and women feel for those with whom their lives are deeply entwined.

Culture The shared attitudes, values, goals, and practices of a given religious, social, racial, or ethnic group, which are transmitted from one generation to another.

Equity theory Equity theory posits that in personal relationships, two concerns stand out: firstly, how rewarding are people's societal, family, and work relationships? Secondly, how fair and equitable are those relationships? According to equity theory, people feel most comfortable

when they are getting exactly what they deserve from their relationships – no more and certainly no less.

Intimacy A process in which a couple who feel close and who trust one another reveal personal information and feelings to one another. As a consequence, they come to feel cared for, known, and validated.

Passionate love A state of intense longing for union with another. Reciprocated love (union with the other) is associated with fulfillment and ecstasy. Unrequited love (separation) is associated with emptiness, anxiety, or despair.

Reinforcement theory Reinforcement theory posits that human behavior is shaped by the rewards and punishments people receive for performing various actions.

Defining and Measuring Love

Love is a basic emotion, which comes in a variety of forms. Most social scientists distinguish between two major kinds of love – passionate love and companionate love. Passionate love is a 'hot,' intense emotion. It is sometimes also labeled obsessive love, puppy love, a crush, lovesickness, infatuation, or being-in-love. Scholars have defined it as:

A state of intense longing for union with another. Reciprocated love (union with the other) is associated with fulfillment and ecstasy. Unrequited love (separation) is associated with emptiness, anxiety, or despair.

The Passionate Love Scale was developed to assess the cognitive, emotional, and behavioral components of such love.

Companionate love is a 'cooler,' far less intense emotion. It is sometimes also called true love or conjugal love. It combines feelings of deep attachment, commitment, and intimacy. Scholars have defined it as:

The affection and tenderness people feel for those with whom their lives are deeply entwined.

Psychologists have used a variety of scales to measure companionate love. The Companionate Love Scale was developed to measure how much companionate love, commitment, and intimacy couples possess.

Scientists have proposed other, more detailed typologies of love. Some scholars suggest that people may possess six different styles of loving. The Love Attitudes Scale was designed to measure these love styles: *Eros* (passionate, intense, disclosing love), *mania* (obsessive, dependent, insecure love), *storge* (friendship-based, steady, secure love), *pragma* (practical, logical love), *agape* (altruistic, giving, spiritual love), and *ludis* (game-playing, cool, playful love). Another scholar proposed

a triangular model of love. He argued that the various kinds of love differ in how much of three different components – passion, intimacy, and the decision/commitment to stay together – they possess. Passionate love (which he labeled infatuation) involves intense passionate arousal but little intimacy or commitment. Companionate love, on the other hand, involves less passion but far more intimacy and commitment. The most complete form of love is consummate love, which combines passion, intimacy, and commitment.

Passionate Love

Passionate love is as old as humankind. Buried among the Sumerians' clay tablets (in around 3500 BCE) is inscribed history's first known love poem – a poem dedicated to King Shu-Sin by one of his chosen brides. She wrote: "Bridegroom, let me caress you/My precious caress is more savory than honey." The Sumerian love fable, telling of Inanna and Dumuzi, was spun by tribal storytellers in 2000 BCE. The world literature abounds in stories of lovers caught up in a sea of passion and violence: Daphnis and Chloe (a Greek myth), Shiva and Sati (Indian), Hinemoa and Tutanekai (Maori), Emperor Ai and Dong Xian (Chinese), and the VhaVhenda lover who was turned into a crocodile (African). Passion and desire possess a very long lineage.

In recent years, scholars from a variety of disciplines have begun to speculate about the nature of love. Cultural theorists and historians point out that cultural and social considerations have a profound impact on how people view love, how susceptible they are to falling in love, who inspires love, and how passionate affairs work out. Neuroscientists, neurobiologists, and evolutionary psychologists point out that in spite of all its variations, passionate love and sexual desire are cultural universals – existing in all times and in all places.

Cultural and Historical Approaches

Researchers contend that cultural values may have a subtle influence on the meanings people associate with the construct 'romantic love.' In a series of prototype studies (which get at the meaning of various concepts), researchers found that Americans and Italians tend to equate love with happiness and to assume that both passionate and companionate love will be intensely positive experiences. Students in Beijing, China, however, possess a darker view of love. In the Chinese language, there are few 'happy-love' words; love is associated with sadness. Not surprisingly, then, Chinese men and women tended to associate passionate love with such ideographs as infatuation, unrequited love, nostalgia, and sorrow love.

Historians, too, remind us that love has been viewed very differently in different historical eras. At times it has been viewed as a bane, at other times as a boon. For 1500 years – from the earliest days of the Roman Catholic Church to the 16th Century Protestant Reformation and Catholic Counter-Reformation – the Church proclaimed passionate love and sex (even marital sex) for any purpose other than procreation to be a mortal sin, punishable by eternal damnation. In those early days, love was not expected to end well. Romeo and Juliet, Ophelia and Hamlet, and Abelard and Eloise did not make love, get married, have two children, and live happily ever after. Juliet stabbed herself. Romeo swallowed poison. Ophelia went mad and died. Hamlet was felled by a poisoned sword point. Peter Abelard (a real person) was castrated and his beloved Eloise retired to a nunnery. In Japan, love suicides have been an institution since the end of the seventeenth century.

Today, of course, in the West, passionate love is highly prized. People generally assume it is the basis of a happy life; it is associated with mental and physical well-being. For most, it is the *sine qua non* of marriage. We see then that through time, visions of love can markedly change.

Anthropological, Neuroscience, and Evolutionary Approaches

In spite of the fact that cultural differences may exist in the way people view love, most scholars agree that a desire for love may well be built into the architecture of the mind. Some theorists argue that emotional 'packages' are inherited, adaptive patterns of emotional experience, physiological reaction, and behavior. At every phylogenetic level, organisms face the problems of survival and reproduction. If they are to survive and reproduce, they must find food, avoid being killed, mate, and reproduce. Many theorists believe that passionate and companionate love are built on the ancient circuitry evolved to insure that animals mate, reproduce, and care for their young. Recently anthropologists, neuroscientists, and primatologists have begun to learn more about the universal nature of love.

Anthropologists were among the first to document that passion and lust are universal feelings. Drawing on a sampling of tribal societies from the *Standard Cross-Cultural Sample*, they found that in almost all of these far-flung societies, young lovers talked about passionate love, recounted tales of love, sang love songs, and spoke of the longings and anguish of infatuation. When passionate affections clashed with parents' or elders' wishes, young couples often eloped.

Social anthropologists have explored folk conceptions of love in such diverse cultures as the People's Republic of China,

Indonesia, Turkey, Nigeria, Trinidad, Morocco, the Fulbe of North Cameroun, the Mangrove (an aboriginal Australian community), the Mangaia in the Cook Islands, Palau in Micronesia, and the Taita of Kenya. In all these field studies, people's conceptions of passionate love appear to be surprisingly similar.

The joys of love

Two neuroscientists attempted to identify the brain regions associated with passionate love and sexual desire. They selected men and women who claimed to be 'truly, deeply, and madly in love' and who received high scores on the Passionate Love Scale. Participants were then placed in an fMRI (functional magnetic imagery) scanner. This high-tech scanner constructs an image of the brain in which changes in blood flow (induced by brain activity) are represented as color-coded pixels. The authors gave each participant a color photograph of their beloved to gaze at, alternating the beloved's picture with pictures of a trio of casual friends. They then digitally compared the scans taken while the participants viewed their beloved's picture with those taken while they viewed a friend's picture, creating images that represented the brain regions that became more (or less) active in both conditions. These images, the researchers argued, revealed the brain regions involved when a person experiences passionate love and/or sexual desire.

They discovered that passion sparked increased activity in the brain areas associated with euphoria and reward, and decreased activity in the areas associated with sadness, anxiety, and fear. Activity seemed to be restricted to foci in the *medial insula* and the *anterior cingulate cortex* and, subcortically, in the *caudate nucleus* and the *putamen*, all bilaterally. Most of the regions that were activated during the experience of romantic love were those that are active when people are under the influence of euphoria-inducing drugs such as opiates or cocaine. Apparently, both passionate love and those drugs activate a 'blissed-out' circuit in the brain. The *anterior cingulate cortex* has also been shown to be active when people view sexually arousing material. This makes sense since passionate love and sexual desire are generally assumed to be tightly linked constructs.

Among the regions where activity decreased during the experience of love were zones previously implicated in the areas of the brain controlling critical thought (i.e., the sort of mental activity involved when people are asked to make social judgments or to 'mentalize' – that is, to assess other people's intentions and emotions). Such brain areas are also activated when people experience painful emotions such as sadness, anger and fear. The authors argue that once we fall in love with someone, we feel less need to assess critically their character and personality. (In that sense, love may indeed be 'blind.') Deactivations were also observed in the posterior cingulate gyrus and in the amygdala and were right-lateralized in the prefrontal, parietal, and middle temporal cortices. Once again, the authors found passionate love and sexual arousal to be tightly linked.

The dark side of love: Anger, sadness, and misery

Joyous passionate love is only one-half of the equation, of course. Love is often unrequited. What kind of brain activity occurs when passionate lovers are rejected?

Researchers studied men and women who had just been jilted by their beloveds. First, they hung a flyer on the SUNY at

Stony Brook bulletin board. 'Have you just been rejected in love. But can't let go?' Rejected sweethearts were quick to respond. In initial interviews, researchers found that heartbroken men and women were caught up in a swirl of conflicting emotions – they were still wildly in love, yet felt abandoned, depressed, angry, and in despair.

But what was going on in their brains? To find out, the researchers followed the same protocol they had utilized in testing happily-in-love men and women – that is, they asked participants to alternately view a photograph of their one-time beloved and a photograph of a familiar, but emotionally neutral individual. In short, the authors found that jilted lovers' brains 'lit up' in the areas associated with anxiety, pain, and attempts at controlling anger as well as addiction, risk taking, and obsessive/compulsive behaviors. Jilted lovers did, indeed, appear to experience a storm of passion – passionate love, sexual desire, plus anguish, rejection, rage, emptiness, and despair.

Currently, a number of other neuroscientists are investigating the brain activity associated with the joy of passionate love (when reciprocated) or the feelings of emptiness, anxiety, and despair associated with unrequited love.

Companionate Love and Intimacy

If romantic relationships deepen, they may gradually evolve into a more serious, longer-lasting form of love – companionate love. In this section, we will focus on what scientists have learned about three of the components of such love – affection and liking, intimacy, and commitment.

Affection and Liking

In the eleventh century, St. Anselm of Canterbury argued that the will possesses two competing inclinations: an affection for what is to a person's own advantage *and* an affection for justice. The first inclination is stronger, but the second matters, too. Social psychologists, too, have highlighted the importance of self-interest as well as fairness and equity in people's lives.

Reinforcement theory

Many psychologists use reinforcement theory principles to explain why people love and like others. According to reinforcement theory, men and women come to care for those who provide them with important rewards and to dislike those who punish them. They may come to feel the same way about people who are merely *associated* with pleasure or pain.

One group of researchers, for example, contrasted the behavior of happily married couples with those who were distressed. Happy couples generally had positive exchanges. They smiled, nodded, and made eye contact. They spoke to each other in soft, tender, happy voices. They leaned forward to catch one another's words. Distressed couples had corrosive patterns of interacting. They tried to bludgeon one another into agreements by complaints and punishment. They sneered, cried, and frowned at one another. Their voices were tense, cold, impatient, whining. They made rude gestures, pointed, jabbed, and threw up their hands in disgust; or they simply ignored one another. As soon as one partner resorted to these tactics, the other began to respond in the same way, leading to an escalation of reciprocal aversiveness.

Unfortunately, as couples settle into a routine, kind words are often replaced by harsh evaluations, thoughtful courtesies by neglect. For some reason, married couples frequently treat one another worse than they treat strangers.

Equity theory

Equity theorists point out that couples care both about how rewarding their relationships are and how fair they seem to be. According to the theory, people feel most comfortable when they are getting exactly what they deserve from their relationships – no more and certainly no less.

A few theorists have argued that couples have very different ideas as to the nature of appropriate behavior in *communal* relationships (such as love relationships, family relationships, or close friendships) as opposed to *exchange* relationships (such as encounters with strangers or business associates). In communal relationships, they argued, couples feel responsible for one another's well-being. They wish to show their love and affection, and to help those they love. They expect nothing in return. In exchange relationships, on the other hand, acquaintances do not feel particularly responsible for one another. They care very much about 'what's in it for me?'

Most theorists, however, take the equity perspective. One group of researchers, for example, assumed that couples must be careful to ensure that their partners feel loved, rewarded, and fairly treated. Otherwise, love relationships will suffer and possibly dissolve. These authors devised a simple scale for measuring how fair and equitable men and women believe their relationships are. They simply asked them:

Considering what you put into your dating relationship or marriage, compared to what you get out of it . . . and what your partner puts in compared to what (s)he gets out of it, how does your dating relationship or marriage 'stack up?'

- + 3: I am getting a much better deal than my partner.
- + 2: I am getting a somewhat better deal.
- + 1: I am getting a slightly better deal.
- 0: We are both getting an equally good, or bad, deal.
- 1: My partner is getting a slightly better deal.
- 2: My partner is getting a somewhat better deal.
- 3: My partner is getting a much better deal than I am.

On the basis of their answers, persons were classified as overbenefited (receiving more than they deserve), equitably treated, or underbenefited (receiving less than they deserve).

There is considerable evidence that in love relationships, equity matters. Equity considerations have been found to be important in determining who gets into relationships in the first place, how those relationships go, and how likely they are to endure. Specifically, researchers find the following:

- The more socially desirable people are (the more attractive, personable, famous, rich, or considerate they are), the more socially desirable they will expect a mate to be.
- Dating couples are more likely to fall in love if they perceive their relationships to be equitable.
- Couples are likely to end up with someone fairly close to themselves in social desirability. They are also likely to be matched on the basis of self-esteem, looks, intelligence, education, and mental and physical health (or disability).
- Couples who perceive their relationships to be equitable are more likely to get sexually involved.

- Equitable relationships are satisfying and comfortable relationships; inequity is associated with distress, guilt, anger, and anxiety.
- Those in equitable relationships are more committed to their relationships than are those in inequitable relationships.
- Those in equitable relationships are less likely to risk extra-marital affairs than are their peers.
- Equitable relationships are more stable than are inequitable relationships.

Researchers may disagree as to how *important* equity is in determining whether or not couples remain together, separate, or divorce. Most agree, however, that it plays at least some part in such decisions.

Intimacy

The word intimacy is derived from *intimus*, the Latin term for 'inner' or 'inmost.' When scientists reviewed the way most theorists have used this term, they found that almost all of them assumed that intimate relationships involve affection and warmth, self-disclosure, closeness, and interdependence. Most people mean much the same thing by intimacy. Some scientists asked college men and women to tell them about times when they felt especially intimate with (or distant from) someone they cared about. For most people, intimate relations were associated with feelings of affection and warmth, with happiness and contentment, with talking about personal things, and with sharing pleasurable activities. What sorts of things put an impenetrable wall between couples? For most, distant relationships were associated with anger, resentment, and sadness as well as criticism, insensitivity, and inattention. Men and women seemed to mean something slightly different by 'intimacy.' Women tended to focus primarily on love and affection and the expression of warm feelings when recounting 'intimate moments.' They rarely mentioned sex. For men, a key feature of intimacy was sex and physical closeness.

Clinical psychologists developed the *Personal Assessment of Intimacy in Relationships (PAIR)* to measure intimacy. They identified five types of intimacy: emotional, social, intellectual, sexual, and recreational intimacy.

The components of intimacy

The threads of intimacy – affection, trust, emotional expressiveness, communication, and sex – are so entwined that it is almost impossible to tease them apart.

Love and affection

Men and women generally feel more love and affection for their intimates than for anyone else; such mutual affection is probably the first condition of intimacy.

Trust

People seldom risk exposing their dreams or fears unless they know it is safe to do so.

Self-disclosure

When men and women are able to reveal their inner feelings and experiences to others, relationships bloom. Caring and

trust may be the soil in which self-disclosure thrives, but self-disclosure, in turn, nourishes love, liking, caring, trust, and understanding.

One group of researchers reviewed a series of studies on the 'social penetration process.' They made two major discoveries: firstly, intimacy takes time. As couples began to get better acquainted, they began to disclose more. Secondly, acquaintances tend to match one another in how intimate their disclosures are. In some relationships, both participants are willing to reveal a great deal about themselves. In others, both confine themselves to small talk.

Intimates confide two very different kinds of information – facts and feelings – to one another. On a first encounter, acquaintances usually reveal only the bare facts of their lives; they talk little about their feelings. New acquaintances are careful not to reveal too much too soon and not to reveal much more than their partners do. Daters tend to warm up fairly quickly, however. After 6 weeks or so, people are already confiding in one another at about as high a level as they ever will. It is in long-term love relationships that intimates can be *most* relaxed and trusting. Once couples know each other well, the recital of mere facts counts for little; it is the communication of feelings that is critical to dating and marital satisfaction. In long-term relationships, moment-to-moment reciprocity becomes unimportant. Things can wait. When relationships are about to end, however, the pattern of self-disclosure changes. Now, words can be used to wound. In terminal relationships, couples often begin to spew out the ugly accusations that they have kept hidden. They begin to spill out years of hatred, anger, and exaggerated grievances. Couples may begin to talk through the night, trying to figure out what went wrong and if there is any chance to set things right.

Nonverbal communication

Intimates feel comfortable in close physical proximity. They sneak little looks at their mates to convey shared understandings, gaze at one another, touch, stand close, and even lean on one another. Of course, people can reveal how alienated and distant they feel from one another via the flip side of these same techniques. If one feels that a potential date one has just met is moving too fast and one is starting to feel cornered, one can reduce intimacy in several ways – by averting one's gaze, shrinking back, shifting body orientation, or simply by changing the subject and steering clear of intimate topics. We all know how enemies behave when they want to sever all contact. They glare, clench their jaws, sigh in disgust, or walk on ahead.

The development of intimacy

Developmental theorists have observed that young people must learn how to be intimate. One scholar pointed out that infants, children, adolescents, and adults face a continuing series of developmental tasks. If loved and nurtured, infants develop a basic trust in the universe. They develop the ability to hope. In early, middle, and late childhood, children learn to be autonomous, to take initiative, and to be industrious. They develop a will of their own, a sense of purpose, and a belief in their own competence. The next two stages are those in which we are primarily interested. In adolescence, teenagers must develop some sense of their own identity.

Only when adolescents have formed a relatively stable, independent identity are they able to master their next 'crisis' – to learn how to become intimate with someone, and to learn how to love. Mature relationships, then, according to scholars, involve an ability to balance intimacy and independence. People differ markedly in how much intimacy they desire. Attaining the 'right degree' of intimacy often requires a delicate balancing act.

Why people seek intimacy

It seems a bit odd to ask *why* people wish for intimacy. When scientists ask men and women what they most desire in life, they generally mention a close intimate relationship. People can feel sad and lonely for two very different reasons. Some lonely people are experiencing *emotional loneliness*; they hunger for one special intimate. Others are experiencing *social loneliness*; they merely lack friends and casual acquaintances. Of the two, it is emotional loneliness that is the more painful. Contentment is better predicted by the existence of intimacy (i.e., lack of loneliness) than that of popularity, the frequency of contact with friends, or the amount of time spent with acquaintances. Theorists contend that intimacy has three major beneficial effects.

(a) Its intrinsic appeal

One scholar found that if people were happily in love, over 90% of them were also 'very happy in general.' If they were generally unhappy, most thought that love was the one thing that they needed to be happy. So people long for intimacy for itself.

(b) Its links to psychological well-being

A number of studies document that intimacy and psychological health seem to go hand in hand. Intimacy has been shown to be associated not just with happiness, but with contentment and a sense of well-being, as well. Intimate marriages provide social support.

(c) Its links to mental and physical well-being

A number of medical researchers have confirmed that intimacy and mental and physical well-being are connected. Intimate relationships apparently buffer the impact of stress. Intimacy problems are closely linked to many mental health disorders. If persons have a chance to disclose emotionally upsetting material to someone who seems to care, they exhibit improved mental and physical health in follow-up physical examinations. Most of our knowledge about the ties between intimate relationships and physical health comes from studies of the impact of a husband or wife's death on the survivor's mental and physical health. Investigators find that bereavement increases the likelihood of a host of mental and physical problems. Bereavement increases vulnerability to mental illness; produces a variety of physical symptoms (these include migraines, headaches, facial pain, rashes, indigestion, peptic ulcers, weight gain or loss, heart palpitations, chest pain, asthma, infections, and fatigue); aggravates existing illnesses; causes physical illness; predisposes a person to engage in risky behaviors – such as smoking, drinking, and drug use; and increases the likelihood of death. Of course, a 'close' relationship filled with hatred and strife can be worse than no relationship at all for couples' mental and physical health.

Why people avoid intimacy

Given all the advantages of intimate relationships, why would people ever be reluctant to become intimate with others? Men and women admit that they are hesitant to get too deeply involved with others for a variety of reasons: Some people feared that if they get too close to someone they will end up 'stuck' with them; having to take care of someone worse off than themselves. Some people fear that if they begin to confide in others, they will end up feeling worse – aware of how sad, frightened, or angry they really are. Some fear that if they reveal too much about themselves, others will criticize them, be disappointed in them, or get angry at them. Some worried that if a relationship were to end, vindictive dates or mates would confide the innermost details of their lives to subsequent dates, mates, or business associates. Close relationship researchers developed the *Perceptions of Risk in Intimacy* scale to measure people's fear of intimacy.

Are there gender differences in intimacy?

Researchers have observed that there is a gap between men's and women's ideas of what constitutes intimacy. One researcher interviewed 130 married couples at the University of Texas. He found that for the wives, intimacy meant talking things over. The husbands, by and large, were more interested in action. They thought that if they did things (took out the garbage, for instance) and if they engaged in some joint activities, that should be enough. The researcher found that during courtship, men were willing to spend a great deal of time in intimate conversation. But after marriage, as time went on, they reduced the time for close marital conversation while devoting increasingly greater time to work or hanging around with their own friends. The researcher observed:

Men put on a big show of interest when they are courting, but after the marriage their actual level of interest in the partner often does not seem as great as you would think, judging from the courtship. The intimacy of courtship is instrumental for the men, a way to capture the woman's interest. But that sort of intimacy is not natural for many men. Women complain about men's 'emotional stinginess.'

The researcher suggested a compromise: couples should try to engage in the sort of intimate conversation which springs spontaneously from shared interests. This requires, of course, that couples share some interests – that they read books, or watch films, or plan trips to Europe together and so forth.

Another researcher pointed out that men are taught to take pride in being independent while women take pride in being close and nurturing. Researchers contend that as men mature, they find it easy to achieve an independent identity; they experience more difficulty in learning to be intimate with those they love. Women have an easy time learning to be close to others; they have more trouble learning how to be independent. There is considerable evidence that men are less comfortable with intimacy than women.

Researchers find that in casual encounters, women disclose far more to others than do men. In our culture, women have traditionally been encouraged to show feelings. Men have been taught to hide their emotions and to avoid displays of weakness. In a study of college students, social psychologists found that women's friendships were more deeply intimate than were

men's. Women placed great emphasis on talking and emotional sharing in their relationships. Men tended to emphasize shared activities; they generally limited their conversations to sports, money, and sex.

In their deeply intimate relationships, however, men and women differ little, if at all, in how much they are willing to reveal to one another. Researchers, for example, asked dating couples how much they had revealed to their steady dates. Did they talk about their current relationships, previous affairs, their feelings about their parents and friends, their self-concepts and life views, their attitudes and interests, their day-to-day activities? Overall, men and women did not differ in *how much* they were willing to confide to their partners. They did differ, however, in *the kinds of things* they shared. Men found it easy to talk about politics; women found it easy to talk about people. Men found it easy to talk about their strengths; women found it easy to talk about their own fears and weaknesses. Perhaps this is because this was the kind of thing that interested them; perhaps this is because this was the kind of thing they felt most comfortable talking about. Interestingly enough, traditional men and women were most likely to limit themselves to stereotyped patterns of communication. More modern men and women were more relaxed about talking about all sorts of intimate matters – politics, friends, their strengths, and their weaknesses.

Women receive more disclosures than do men. This is not surprising in view of the fact that the amount of information people reveal to others has an enormous impact on the amount of information they receive in return. In any case, both men and women seem to feel most comfortable confiding in women. Tradition dictates that women should be the 'intimacy experts.'

Some authors have observed that currently, neither men nor women may be getting exactly the amount of intimacy they would like. Women tend to desire more intimacy than they are getting; men may prefer more privacy and distance. Couples tend to negotiate a pattern of self-disclosure that is bearable to both. Unfortunately, this may ensure that neither of them gets what they really want. Of course, as men and women's roles become more alike, these differences in intimacy might be expected to decline.

A prescription for intimacy

Most humans appear to flourish in a warm intimate relationship. Yet, intimacy is risky. What then is the solution? What advice do social psychologists give as to how to secure the benefits of deep commitment without being engulfed by its dangers? A variety of therapists and researchers have developed programs to teach young people intimacy skills. Generally, they focus on teaching men and women four types of skills: (1) encouraging people to accept themselves as they are; (2) encouraging people to recognize their intimates for what they are; (3) encouraging people to express themselves; and (4) teaching people to deal with their intimate's reactions.

Commitment

Perspectives on commitment

It is not always easy for people to guess how committed they and their partners are to one another. Researchers argue that:

Decision/commitment refers, in the short term, to the decision that one loves a certain other, and in the long term, to one's commitment to maintain that love.

Marriage and family researchers sometimes use the *Broderick Commitment Scale* to assess dating couples' and husbands and wives' commitment to their relationships.

Researchers have begun to elaborate on how the commitment process works. Researchers proposed that a close relationship's cohesiveness (stability) can be defined as 'the total field of forces which act on the pair to keep them in the marriage.' According to one researcher, there are three kinds of forces that influence cohesiveness: (1) Attractiveness of the relationship. Is the relationship more (or less) rewarding than the couple expected? The more rewarding and the less costly the relationship, the more stable it will be. (2) Alternative attractions. Is this relationship more attractive than other relationships or than living alone? The more attractive the alternatives, the more likely the marriage is to dissolve. (3) Barriers against leaving the relationship. These are the 'psychological restraining forces' that keep people in marriages. They include religious, legal, economic, and social barriers as well as responsibilities to children. Another researcher proposed a similar model to explain who likely will persevere in a relationship as opposed to those most likely to separate or divorce. She argued that the more satisfied couples are, the more eager they will be to preserve their relationships; the more they have invested in their relationships (in time, money, and effort) and the more limited their alternatives, the more reluctant they will be to sacrifice everything by leaving.

Recently, scientists attempted to test the relative importance of the factors that attract people to relationships (love and reward) versus the factors that prevent them from leaving (feelings of commitment and a knowledge that they have invested a great deal in the relationship) in keeping couples together in times of stress. They found that although love and rewards are important, even more important are the commitments couples feel they have made to the relationship and the practical investments they have made in it.

The Endurance of Love

Most people assume that the passage of time will have a very different impact on passionate versus companionate love. Passionate love is said to decline fairly quickly, while companionate love is thought to remain fairly stable (or actually increase) over time. This hypothesis was tested in a number of studies, which interviewed dating, newlywed, and long-married couples. Respondents ranged in age from 18 to 82. They were asked how passionately and companionately they loved their partners.

What impact did time have on love? As predicted, time *did* have a corrosive effect on love – but to researchers' surprise it appeared to have an equally detrimental effect on *both* passionate *and* companionate love.

The conclusion one draws depends on whether one is an optimist or a pessimist. On the positive side: contrary to portrayals in the mass media, in *absolute terms*, older persons, married for a quarter of a century or more, still felt a great

deal of passionate love *and* companionate love for their mates. On the negative side, however, pessimists might point to the fact that with the passage of time, people felt less and less love, passionate or companionate, for their partners.

Marital Dysfunction

S C South, Purdue University, West Lafayette, IN, USA

© 2012 Elsevier Inc. All rights reserved.

Glossary

Analog behavioral observation (ABO) A method of data collection in which an assessor designs, manipulates, or in some way constrains a situation such that verbal and nonverbal behaviors are elicited and observed.

Behavior genetics A scientific field that uses both quantitative genetics and molecular genetics to understand both the genetic and environmental contributions to individual variation in human behavior.

Diagnostic and statistical manual of mental disorders A manual published by the American Psychiatric Association

that provides criteria for the classification of mental disorders.

Diathesis-stress model A model for the etiology of mental illness, it suggests that an underlying predisposition (diathesis) is triggered by encountering a stressor.

Heritability The proportion of total variance in a behavior or trait that varies among individuals in the population that can be attributed to genetic influences.

Psychopathology The scientific study of mental illness, including causes, processes, and manifestations.

Introduction

Difficulties in marriage, variously referred to as problems, conflict, distress, dysfunction, and other terms, are ubiquitous; the nature and intensity of these difficulties vary within and between marriages. Marital dysfunction ultimately leads to divorce in more than 40% first marriages, and the likelihood of dissolution increases with each subsequent divorce. Even when distress does not lead to divorce, it is related to emotional and behavioral difficulties in both partners as well as in their children. Marital distress is also a risk factor for sexual infidelity and intimate partner violence. Therefore, researchers have spent a great deal of time trying to understand, prevent, and treat marital dysfunction. This article begins with a discussion of the myriad ways in which marital dysfunction has been defined, and the methods by which it is assessed in research and clinical practice. Next, findings on the impact of marital distress are reviewed. This is followed by a description of the risk factors most consistently associated with marital dysfunction and, finally, a review of the current research on prevention and treatment of marital distress is provided.

Defining and Assessing Marital Dysfunction

In the research literature, the terms marital satisfaction, adjustment, distress, dysfunction, and even conflict are often used interchangeably. The Diagnostic and Statistical Manual of Mental Disorders (DSM-IV-TR) defines partner relational problems as “a pattern of interaction between spouses or partners characterized by negative communication (e.g., criticisms), distorted communication (e.g., unrealistic expectations), or non-communication (e.g., withdrawal) that is associated with clinically significant impairment” (p. 737). There are two noteworthy things about this definition. First, it focuses on communication, or the lack thereof, between partners. Second, it is silent as to what defines clinically significant impairment and how it should be assessed. In fact, the numerous self-report, interview, and observational methods for assessing marital dysfunction vary in the

scope and nature of what they measure, and there is no current ‘gold standard’ definition. Many researchers and clinicians rely on unidimensional, global measures that provide an overall score on satisfaction or adjustment. Others suggest that marital satisfaction is a multidimensional construct. For instance, factor analyses of the Marital Satisfaction Inventory-Revised (MSI-R) indicate two related but distinct factors subsumed under the general construct of ‘satisfaction’: *disaffection* is a measure of emotional distance and lack of positive affect, while *disharmony* indexes the amount of overt conflict in the relationship. A related issue is whether distressed couples differ both qualitatively and quantitatively from nondistressed couples. Some argue that relationship discord is an identifiable taxon that can be reliably and validly assessed.

Another difficulty with conceptualizing marital dysfunction is the overlap between ‘relationship distress’ as measured by, for instance, a self-report inventory, and the emotional, behavioral, and cognitive complaints reported by individuals in distressed relationships. Distressed couples report emotional problems, in particular reciprocity of negative relationship affect and lack of intimacy. These couples also display more communication problems, sexual difficulties, and physical aggression. Low-satisfaction couples also display a variety of negative cognitive biases, including assumptions, attributions, beliefs, and expectancies about their partner and the relationship as a whole. Thus, the true test of either a marital researcher or a clinician working with distressed couples is to tease apart the determinants of marital distress from the resulting effects. Often, cause and effect go hand in hand; for instance, whatever original deficits in communication skills and problem-solving might have triggered greater amounts of distress might have solidified into a pattern of negative reciprocity and withdrawal/demand patterns characteristic of unhappy couples.

Snyder and colleagues outline an evidence-based approach to assessment of couple distress, in which self-report, interview, and analog behavioral observation (ABO) can be used individually or in combination, to measure individual- and couple-level characteristics across multiple domains (relationship behaviors, cognitions, affect, etc.). Assessment of relationship distress often

begins with a clinical interview, to gain information on relationship history, the nature of the current conflicts, and the origins of these conflicts. Interviews can be a rich source of information about behaviors, feelings, and thoughts at the dyad and individual level. In fact, the multitudes of goals and domains covered in such interviews may limit the psychometric evaluation of clinical interviews. In comparison, behavioral observations are narrower in scope and have been subjected to a great deal of empirical rigor. There are now dozens of coding schemes developed for ABO, covering six major classes of behavior: affect, communication, everyday behaviors, power, problem-solving, and support/intimacy. Limitations of ABO include questionable generalizability to other cultures and the daunting investment necessary to be trained to reliability on one of the many coding systems available.

By and large, assessment of couple distress relies on self-report measures. Most questionnaires and inventories ask respondents to report on their subjective evaluation of the relationship as a whole, or various components that are thought to underlie relationship satisfaction (e.g., finances, amount of time spent together, intimacy/sexual relations). Some are relatively homogenous or 'pure' measures of marital satisfaction. For instance, the Quality of Marriage Index contains six items assessing global satisfaction, and the MSI-R contains one scale that measures overall relationship distress and ten other scales that measure satisfaction in various areas of the relationship. These global measures can be supplemented with other self-report measures that assess specific aspects of relationship functioning: the Personal Assessment of Intimacy in Relationships (PAIR) assesses several aspects of intimacy in the relationship; the Areas of Change Questionnaire (ACQ) measures a respondent's desire for change in their spouse along 34 different behaviors; the Frequency and Acceptability of Partner Behavior Inventory (FAPBI) asks individuals to rate how frequently their partner does each of 20 behaviors and how acceptable those behaviors are at that frequency; and the Communication Patterns Questionnaire (CPQ) assesses the communication behaviors couples use when they have a disagreement.

The bulk of the literature relies on either the Dyadic Adjustment Scale (DAS), the most widely used measure of relationship adjustment, or the Marital Adjustment Test (MAT). The MAT is a 15-item measure that includes an overall assessment of the relationship as well as extent of agreement between spouses on key areas of the relationship. The DAS is a 32-item expanded and updated version of the MAT. Factor analyses of the DAS demonstrate that a higher order factor of Adjustment is composed of four lower order factors of Satisfaction, Consensus, Cohesion, and Affectional Expression; this factor structure is invariant across gender, demonstrating that it measures the same concept in men and women. Both the DAS and MAT were designed to distinguish distressed from nondistressed couples; however, recent research indicates that both measures contain a high degree of error measurement and noise. Funk and Rogge recently conducted IRT analyses on a large pool of items from the most widely used relationship satisfaction measures, including the DAS, MAT, and QMI. They found that existing measures, particularly the DAS and MAT, assess relationship satisfaction well enough to reveal meaningful relationships with associated variables (e.g., communication, personality), but lack enough precision to make

meaningful distinctions between groups. The authors developed a new measure, the Couples Satisfaction Index (CSI), composed of items from existing measures. Data from the initial development study look promising, but still need to be validated in future studies, particularly in couple samples.

Ultimately, whatever combination of self-report, interview, and observational methods are used to assess marital dysfunction will be guided by the setting (e.g., research vs. treatment), the goals of the assessor and the couple, and the feasibility and availability of each method. Regardless of how marital dysfunction is defined, any competent assessment will cover the major domains that are impacted as a result of marital discord as well as the factors that may have led to and continue to contribute to current levels of distress. These factors are reviewed below.

Impact of Marital Distress

Psychological Distress

A substantial body of research now supports the association between marital distress and psychopathology. Large-scale epidemiological surveys show a clear and substantial link between psychiatric disorders and marital distress, particularly for mood and anxiety disorders. Low levels of marital satisfaction have been linked with alcohol use disorders, drug use disorders, and personality disorders. Marital discord is also associated with subclinical levels of psychopathology and overall psychological distress.

As one of the most significant social forces in a person's life, marriage will undoubtedly play an important contextual role in the etiology and maintenance of psychopathology. Following from the diathesis-stress model of psychopathology, there is theoretical and empirical evidence to suggest that conflict laden or unsatisfying marriages may act as an environmental stressor leading to the development of mental illness in vulnerable individuals. However, others have suggested that marital distress is subsequent to, and a consequence of psychopathology. It is likely that both models are equally valid, although the direction of causality may differ by type of pathology.

One method by which researchers may attempt to disentangle the causal directions between distress and psychopathology is through the use of genetically informative designs. Traditionally a method for estimating the genetic and environmental influences on phenotypes, behavior genetics may be useful in understanding the interplay between social and interpersonal processes like marital relationship patterns and psychiatric dysfunction. Marital satisfaction, like many putative 'environmental' variables, is moderately heritable; for instance, variation in marital satisfaction as assessed in the Midlife in the United States (MIDUS) sample was due largely to nonshared environmental influences ($e^2 = 0.76$) with moderate genetic influences ($h^2 = 0.25$). Research has also shown genetic overlap between marital quality and general indices of well-being and depressive symptoms, suggesting that the same genetic influences are impacting both the quality of the marriage and mental health. A recent study found evidence of gene X environment interaction between internalizing psychopathology and marital satisfaction, such that there were greater genetic influences on an internalizing factor at low levels of marital

quality. Future research will need to examine whether similar processes are operating for different types of psychopathology.

Physical Health

Much of the research on marriage and physical functioning has focused on whether and how marital status (i.e., being married vs. single, divorced, or widowed), as opposed to satisfaction, is related to many aspects of physical health. Married individuals are, on average, healthier than single, divorced or separated, and widowed individuals, after controlling for income and age. Marriage has been linked to reduced risk of morbidity and mortality, although this benefit may be reduced in women as compared to men. More recently, research has examined whether quality of the marital relationship may impact both objective and subjective measures of physical health. Low levels of marital satisfaction are linked to various physical health outcomes, including chronic health problems, physical disability, and poor perceptions of health. A study using data from older married adults in the MIDUS study found that marital disagreement was negatively related to number of physical symptoms, while negative spousal behaviors were related to physical symptoms, chronic health problems, disability and poor perceptions of health. Of note, none of these associations were moderated by gender.

Research suggests that marital discord may affect mortality and morbidity through its effect on physiological functioning. Marital conflict, often assessed through observed spousal discussions, has been linked to cardiovascular stress measures, endocrine changes, and immune system downregulation. For instance, wound healing was slower and cytokine production higher following a marital conflict interaction task compared to a social support interaction task, particularly in couples with higher levels of hostility. Heightened levels of cytokines have been linked with a variety of negative health outcomes, thus one possible pathway between marital conflict and poor mental and physical health outcomes may be through stress-related immunological changes. Other work has shown links between marital conflict and changes in cardiovascular and endocrine functioning. Women in particular seem to show greater physiological reactivity (in the negative direction) than men during these laboratory tasks.

Child Adjustment

There is a longstanding and robust association between interparental distress and conflict and psychological and behavioral problems in children. The effects of marital conflict on children's adjustment problems persist even after controlling for important family and parenting contextual variables (e.g., parental depression). Of note, behavior genetic research has shown that genetic influences mediate the association between marital conflict and conduct problems in children; in other words, children who are exposed to marital conflict inherit a genetic liability to antisocial behavior, and may perpetuate the cycle by in turn experiencing marital conflict and passing on genes that influence both marital conflict and psychopathology. However, many questions remain as to how, why, and under what particular circumstances marital conflict and distress is most detrimental to children's development. For instance, researchers

still need to better understand how children perceive and interpret marital conflict to make the distinction between constructive and destructive interparental communication. One potential mediating pathway between marital conflict and children's adjustment is the quality of parenting. Dimensions of parenting mediate the pathway between marital conflict and internalizing and externalizing behavior in children, possibly due to spillover processes from conflict to parenting, or because parents in highly distressed marriages have less energy to devote to parenting.

Determinants of Marital Distress

Based on a review of longitudinal predictors of marital distress and divorce, Karney and Bradbury proposed a vulnerability-stress-adaptation (VSA) model of marital satisfaction. According to the VSA model, the determinants of marital satisfaction and stability can be grouped into three, interconnected domains: (1) enduring vulnerabilities, or the individual differences that define each member of the couple, (2) adaptive processes, or the ways in which couples interact and communicate with each other, and (3) stressful events that the couple face together. This model is based in large part on the tenets of the behavioral theory of marriage; for instance, a reciprocal relationship between marital satisfaction and behavioral interactions between spouses is assumed. Further, the enduring vulnerabilities of each spouse, including personality traits, are hypothesized to affect both the stressful events that couples encounter and the types of behavioral exchanges that occur between spouses. In essence, a couple's satisfaction, and therefore stability, depends on how they adapt within the marriage, which is a reflection of both enduring vulnerabilities and stressful life events. Findings from each domain are reviewed below.

Enduring Vulnerabilities: Background and Individual Differences

Research on the intrapersonal determinants of marital distress goes back decades, to the pioneering work of Terman and colleagues, who examined how personality traits were associated with marital satisfaction. Certainly, each of the members comes into the marriage with a unique background, including ethnicity, culture, attitudes, values, education, and personality. Surprisingly, since Terman's early work, there has been little research on how individual difference factors may affect the level of marital distress. Possibly reflecting the inconsistent findings from research on marital interactions and communication, a greater focus has recently been placed on how background factors may play into the level and change in marital satisfaction among couples. One line of research in this area has focused on how family-of-origin variables may impact later marital satisfaction. Children of divorce are more likely to have distressed or unstable marriages, and this relationship is largely mediated by quality of parenting. Parent-child attachment and parents' own marital quality and stability have been linked to their adult children's relationship quality and stability. Hostility observed in interactions with family members prospectively predicts later marital conflict observed in adulthood.

Much of the work on enduring vulnerabilities has focused on personality traits of both spouses in relation to marital

distress. The reemergence of interest in personality variables as predictors of marital distress follows from several advancements in the personality field: (a) the expansion of knowledge regarding personality traits, including heritability, biological substrates, and relationship to social and psychological variables; (b) the creation of personality measures with sound psychometric properties and construct validity; and (c) statistical advances that allow examination of the joint influence and interdependence of couples on each other. Most researchers have utilized traits from the Big Five/Five Factor Model of personality (i.e., extraversion, agreeableness, conscientiousness, neuroticism, and openness). The strongest and most consistent results with regard to marital satisfaction have been found for neuroticism, or negative affect, the trait-like tendency 'to report distress, discomfort, and dissatisfaction over time and regardless of the situation.' Individuals with high levels of neuroticism report high levels of marital dissatisfaction, and high levels of neuroticism in one spouse predicts marital dissatisfaction in the other.

Research regarding extraversion is inconsistent; some studies report no relationship with marital satisfaction, others find that higher levels of marital instability and dissatisfaction are related to higher levels of extraversion. A recent meta-analysis concluded that higher levels of extraversion were related to *satisfaction* and *instability*. One study found that the strongest predictor of marital satisfaction for both sexes was agreeableness in their spouse. Further, higher self-reported extraversion, openness, and conscientiousness in husbands and wives was related to higher levels of satisfaction in their spouse. Notably, discrepancy between personality trait ratings of their actual spouse and an idealized mate did not explain any unique variance in marital satisfaction above and beyond personality of their actual spouse. Husbands who are low in agreeableness and high in neuroticism act in ways that are especially likely to upset their wives, including alcohol abuse, emotional constriction, self-centeredness, unfaithfulness, and abuse. Distressed husbands describe their wives as condescending, possessive, jealous, self-centered, and unfaithful.

In addition to the effect of self and partner personality on one's own level of marital distress, research has examined whether spousal similarity for personality affects marital satisfaction. One study found that personality similarity on the Big Five and measures of adult attachment were related to marital satisfaction in a newlywed sample. However, a different study found that greater personality similarity in middle and later-life couples who were married at least for 15 years was related to declines in marital satisfaction over a 12-year period. The authors explained the discrepancy in findings as reflecting the differences in life goals and tasks between younger couples and couples later in life.

Adaptive Processes: Communication and Behavior Patterns

Even with early promising work on personality traits associated with marital distress, marital research moved from a personality-based perspective to an examination of entrenched and dysfunctional interaction patterns. This line of research explicitly rejected the idea that studying individual spouses, particularly using spousal self-report, was informative in understanding the marital dysfunction of couples. Beginning with the classic work

of Harold Raush and colleagues, who asserted that "Studying what people say about themselves is no substitute for studying how they behave . . . We need to look at what people do with one another," researchers broadened the scope of inquiry beyond individual difference variables to a focus on communication and interaction between couples. The *interpersonal* approach proposes that it is the dynamic between the partners, how they interact with and learn from their experiences with each other, which contributes to the course, stability, and satisfaction of the marriage. The basic hypothesis was that communication problems and conflict that arises during problem discussions would predict marital distress and ultimately dissolution. Process research was also spurred by an effort on the part of psychologists to help married couples deal with distress, and as a result, many of the observational methods and the resulting coding schemes used to interpret behaviors focused on conflict discussion tasks.

Research across different coding systems, studies, and countries has revealed certain facts about behavior observed during marital conflict discussions. Couples who are more negative during interactions are more likely to experience worse marital outcomes over time. Distressed couples are generally more hostile, as indicated by both verbal and nonverbal exchanges (e.g., criticism, excuses, denial of responsibility, and complaints about their partner's personality). They also display more negative, and fewer positive, nonverbal and verbal behaviors than satisfied spouses, are more likely to reciprocate negative behavior, and display escalating chains of negative behavior. Distressed couples and couples with a greater likelihood of separation tend to have specific deficits related to communication and problem-solving; for instance, their interactions are marked by criticism, contempt, defensiveness, and withdrawal, and they tend to show the demand-withdrawal pattern, in which one person (usually the wife) attempts to engage while the other partner reacts by withdrawing.

However, despite decades of research with an increasingly sophisticated toolbox of methodologies and data analytic strategies, findings from research on couple processes are often confusing, contradictory, and generally lacking in consistency, particularly from a longitudinal standpoint. For instance, one study found that negative interaction behaviors (i.e., disagreement and criticism) were related to positive changes in relationship satisfaction over time. This is not an isolated finding; others have also found that negative behaviors are beneficial, and positive behaviors detrimental for relationships over time. In attempting to explain this conundrum, researchers found that the use of directive communication strategies (both positive and negative) to attempt to bring about change in a partner was related to lower concurrent perceptions of success but greater change in the partner *over time*. The authors concluded that direct strategies, whether positive or negative, are a clear signal to the target that something is wrong; while it is the relative amount of positive versus negative valence in the discussion, and the target's response to the demands of his or her partner, that will determine whether the positive and negative aspects of communication '(cancel) each other out.'

There are also methodological limitations to the process research that has been done, which may, in part, explain the lack of consistent support for a link between marital interaction and distress. Studies of this sort tend to be based on small

samples of predominantly white, middle-class couples in various stages of marriage, and have only limited longitudinal follow-up. This may inhibit the ability to determine whether interaction processes have main or moderating effects over the course of different stages of marriage. Two promising trends mark the more recent state of communication and behavior research. First, researchers are acknowledging the need to understand how contextual influences impact couple interactions. This has resulted in more studies that attempt to incorporate an examination of interaction patterns along with the other two main components of the VSA model, namely enduring vulnerabilities (e.g., personality, family history) and stressors (e.g., economic hardship, parenting, biological processes). Second, process research has now moved beyond a concentration on overt conflict and hostility toward a recognition that positive dimensions of interaction, including spousal support and positive affect may be just as important to the success of the marital relationship. For instance, Johnson and colleagues recently showed that high levels of positive affect buffered the impact of negative behavior on marital satisfaction.

Stress and Context

The final domain of variables that must be considered in relation to marital distress and stability are the environmental contexts and stressors. Young age at marriage and cohabitation before marriage are both associated with lower satisfaction and greater marital instability, although a recent meta-analysis suggested that cohabitation might not be as strongly associated with negative outcomes in other countries, particularly countries (e.g., Scandinavian countries) in which most individuals cohabit at some point in their lives. Researchers have tended to focus on major stressors and critical life events (e.g., chronic illness, economic hardship), but have recently turned toward understanding the stress involved in more minor everyday hassles, problems, or situations. Marital researchers typically focus on *dyadic* stress, defined as stressors that affect both members of the couple, either because the stressor concerns both parties (e.g., parenting), or the stressor originally affects only one partner, but eventually spills over into the dyadic relationship. The VSA model posits direct associations between the (dysfunctional) personality traits of each partner, the poor communication and interaction processes between partners, and the stressful events one or both partners encounter. An alternative model, the stress-divorce model, argues more specifically that relatively minor but chronic daily stressors arising from external sources are the most damaging forms of stress for couples' satisfaction levels. There is probably more in common between these two models than would differentiate them; both suggest that stressors like work problems spill over into couple functioning by decreasing positive time spent together, increasing negative communication patterns, and triggering emotional and behavioral difficulties in partners who may already be at risk based on dysfunctional personality traits. Even though the bulk of dyadic stress research in couples has focused on major, external stressors, the results are relatively inconsistent, possibly hampered by a reliance on self-report in cross-sectional studies. Data from studies on minor stressors are more consistent in demonstrating a significant, negative relationship with marital satisfaction and stability.

The stress associated with the transition to parenthood has been extensively studied in its effects on marital quality. Parents report lower marital satisfaction than nonparents, and there is a significant, negative relationship between number of children and marital satisfaction. Research shows that the birth of the first child leads to sudden decreases in marital satisfaction above and beyond the normal decreases in marital satisfaction for nonparents, and that this decrease continues for several years after the birth of the child, although planning for pregnancy and quality of the marriage before birth of the child moderate the level of decline. Even though research is consistent that the addition of a child leads to declines in marital quality, comparatively less is known about how parenting, particularly disagreements and conflict over parenting, is associated with marital distress, and how the presence of children in the marriage negatively impacts marital quality.

Summary

The VSA model nicely conceptualizes the many factors that have an impact on marital functioning, and ultimately marital stability. Many of these factors have been well-studied in isolation, but the challenge as the field moves forward is to examine the model as a whole. This will require intensive, multimethod assessment of couples, particularly over time. For some time now, researchers have been sounding the call for the need to move beyond cross-sectional research to focus on longitudinal studies of married couples. Longitudinal studies are the best method for examining within- and between-couple change in marital quality, and recent work has elucidated the appropriate statistical tools (e.g., longitudinal growth curve models for dyadic data) to examine this type of data. It is certainly possible that not only are there mean-level changes in marital quality for couples at different points in the life cycle, but that the factors affecting marital satisfaction differ at different ages. Older adult couples, for instance, have certain challenges (e.g., chronic illness, retirement) that do not affect young adult couples. There is a limited amount of research on marital functioning in older adults per se, including late-in-life marriages. This is an area ripe for future research.

Treatment of Marital Dysfunction

Marital and Family Therapy

Decades of research with clinical samples and randomized clinical trials have consistently supported the use of couples therapy in the treatment of marital distress. A recent meta-analysis found a mean posttreatment effect size of 0.84 for any type of marital treatment compared to control groups; thus, on average, couples who receive treatment are better off at the end than 80% of couples who do not receive treatment. There are many different forms of marital therapy, and research has demonstrated approximately equal effectiveness across several different types of treatment. Unfortunately, gains at follow-up tend to decline from immediately following treatment, and some couples will show no benefit from therapy. In fact, across type of treatment, between 30 and 70% of couples completing marital therapy will fail to show long-term improvement.

The most well-researched forms of therapy are variants of behavioral marital therapy. Traditional behavioral couple

therapy (TBCT) is based on social learning and behavioral principles, and focuses on increasing positive behaviors between spouses, decreasing negative behaviors, and improving communication and problem-solving skills between couples. Short-term follow-ups indicate that gains made from TBCT treatment tend to persist over the 6–12-month period following termination. There is less evidence for continued gains over 2 years after therapy.

Although frequency of behaviors are certainly important, several theoretical and empirical lines of research suggest that assessing and intervening with one's reactions to a partner's behavior is also important. Following from these findings, Jacobson and Christensen developed integrative behavioral couple therapy (IBCT), which focuses on emotional acceptance within the romantic relationship. IBCT differs from both behavioral and cognitive behavioral couple therapy in the formulation of a couples' problem and the goal of treatment. Unlike behavioral interventions, which focus on increasing positive behaviors and reducing negative behaviors, and cognitive interventions, which focus on changing maladaptive cognitions that lead to behavior, IBCT promotes emotional acceptance – helping distressed couples accept previously unacceptable facets of their partners. Thus, IBCT parallels the incorporation of acceptance into many types of psychotherapy for individuals. In the largest clinical trial of marital therapy to date, Christensen and colleagues compared the effectiveness of TBCT and IBCT over the 5-year period posttermination; both showed statistically and clinically significant improvement by the end of therapy and at 2-year follow-up. Notably, couples in both treatment groups evidenced substantial improvement from pretreatment marital satisfaction scores over the 5-year period posttreatment.

There are still many limitations to couples therapy and current research into the effectiveness of the various types of interventions. First, most of the behaviorally oriented forms of couples therapy followed directly from interpersonal process research, and its limitations. Positive aspects of emotions, behaviors, and social support have only recently been investigated, and future research will need to understand how to incorporate these aspects into couples therapy. Second, couples therapy still fails to fully account for how (1) individual differences in each member of the couple and (2) the individual and dyadic stressors facing the couple, impact the positive and negative dimensions of couple interactions. Third, much of the research on determinants of marital distress and couples therapy have been conducted with middle- or upper-middle-class white couples; it is largely unknown how couples therapy will translate to couples of different racial or ethnic backgrounds, couples from lower SES levels, homosexual couples, or cohabitating couples.

Marital Enrichment Programs

While empirical research on the effectiveness of couples therapy continues, a parallel effort is growing in which a burgeoning field of marital and relationship education (MRE) programs attempt to address problems before they begin. There is a great deal of heterogeneity in the couples who attend MRE programs; some programs specifically target couples at certain distinct transitions, including engaged couples or those

expecting a child. The one constant is that MRE programs are designed for couples whose problems have not escalated to the point of needing a therapist. MRE programs may often be led by marital therapists, but they are not included under the rubric of marital interventions. Many of these programs are designed for couples to complete prior to marriage, although they have also been used for couples who feel that they need a 'tune up.' MRE programs generally consist of two broad, inter-related components: (1) a focus on improving communication and problem-solving skills along the lines of behavioral interventions and (2) instruction on key components of marital quality, including attributions and beliefs about marriage.

In general, research suggests that these marital education and enrichment programs produce significant, although modest, gains in communication skills and relationship quality. A recent meta-analysis of MRE programs included 117 studies, with a majority of the studies focusing on general enrichment for married couples. Results indicated significant, moderate effect sizes for two outcome indices, relationship quality and communication skills. There was no evidence of gender differences in these effect sizes. A significant dose–response relationship moderated the effect of MRE programs, with moderate-dosage programs (9–20 h) producing better results than lower-dosage (1–8 h) programs. The limitations of couples therapy research generally extends to research on MRE programs, that is, a reliance on white, middle-class, heterosexual married couples, and a lack of long-term (over 12 months) follow-up.

Summary

The field of marital satisfaction research stands at an interesting crossroads, having accomplished much, but poised to expand even farther if certain challenges and limitations are dealt with. The quality of research into the determinants, consequences, and treatment of marital distress has improved dramatically in only the last few decades. The tools available to assess and study marital dysfunction are more technologically advanced than ever, ranging from behavioral coding, to physiological measurement, to even behavioral and molecular genetic techniques. These improvements run in tandem, not coincidentally, with improvements in both prevention and intervention methods for marital distress. Particularly in the wake of the Healthy Marriage Initiative, the federal government is poised to have a major impact on research into the factors that promote well-functioning marriages.

As research moves forward, the challenges will be fourfold. First, in this time of changing demography of family life in the United States, researchers will have to determine how research on marital distress *per se* translates to other forms of romantic relationships, including cohabitating and homosexual couples. Second, more work needs to be done on the conceptualization and definition of marital distress; more sophisticated statistical analyses, including latent class analysis and taximetrics may be particularly useful here. Third, researchers need to continue taking into account contextual effects when examining theoretical and empirical models of marital satisfaction. The VSA model has now been widely accepted in the literature, but few studies attempt to measure and model variables

from all three latent domains (i.e., enduring vulnerabilities, stress, and adaptive processes). Finally, marital research needs to greatly expand its focus on diversity, from using samples of varying ethnic, racial, SES, and age categories, to modifying (if necessary) prevention and intervention efforts and finding ways to deliver them to underrepresented populations.

Mate Selection

K A Valentine and N P Li, Singapore Management University, Singapore

© 2012 Elsevier Inc. All rights reserved.

Glossary

Long-term mating Long-term romantic relationships (e.g., cohabitation, marriage).

Mate value One's value in the mating market, based on one's reproductive value as perceived by potential mates.

Minimum parental investment The amount of expenditure toward offspring that an organism or individual is physiologically required to make.

Ovulation In the human menstrual cycle, ovulation is when a mature ovum (egg) is released from an ovary and is therefore available to be fertilized.

Sexual dimorphism Differences in phenotype (physical appearance, behavior) between males and females within a species.

Short-term mating Engaging in sexual intercourse without commitment (e.g., one-night stands, casual sex).

Sociosexuality The extent to which an individual is open to and interested in short-term mating and the extent to which an individual is open to and interested in long-term mating.

Waist-to-hip ratio (WHR) The ratio of the circumference of the waist to that of the hips; an indicator of health and fertility in women, with a ratio of 0.7 (or lower) being ideal.

Introduction

The topic of mate selection is one that is intrinsically fascinating. Why do we choose who we choose? What makes them attractive to us? Certain features (e.g., breasts, hips, long hair, lips) are found alluring in women, while others (e.g., strong jaws, chiseled cheekbones, biceps) are found attractive in men. Men and women also seem to approach mating from different perspectives – generally, men are more interested than women in having short-term relations, while women are more interested than men in having long-term relations. A man seems to prioritize attractiveness in his partner, while a woman seems to prefer a partner who has a job that supports at least himself if not her as well (this is less of a concern to men). In what other ways do men and women differ in their mate preferences? In what ways are they similar? Why do these preferences exist? How did they come about? This article addresses these important questions. It (1) introduces social and evolutionary perspectives on mate selection (2) examines how individuals select mates for long- and short-term relationships, (3) presents empirical research on the effects of the ovulatory cycle on mate selection, (4) explores same-sex preferences, and (5) reviews studies on actual mate choices.

Perspectives

There are two prominent perspectives on why humans choose the mates they do. These perspectives are not mutually exclusive, but do have different foci. Some social psychologists focus on social role theory to explain mate preferences, while evolutionary psychologists focus on evolutionary adaptations. This article focuses on the evolutionary perspective, as most of the developments in mate selection have stemmed from predictions generated by this perspective. However, it briefly introduces both viewpoints here.

Social role theory argues that mate preferences are based on cultural expectations. That is, in each culture, there are generally held expectations for ideal male and female mates. Such

expectations, or social roles, are shaped by the values of a society, which in turn are shaped by various constraints. For instance, from a sociocultural perspective, women in most societies have less power socially and economically than men do. To gain better access to economic resources and upward mobility, women need to select marriage partners who have social status and income potential. Thus, these traits are an important part of the male social role. In contrast, men are not excluded from economic participation. Rather, they are free to pursue what society deems pleasurable, such as a person's physical attributes. As such, physical appearance is a large part of the female social role.

Why do those traditional sex roles exist in the first place? Evolutionary psychologists argue that it is because they were adaptive in our ancestral environment. From this perspective, human brains consist of problem-solving devices (i.e., adaptive mechanisms) that have been shaped over millions of years of natural and sexual selection. That is, psychologies that somehow aided ancestral humans in reproducing more successfully are likely to have been passed down over evolutionary history to the present day. Because men and women have different reproductive capacities and constraints, the sexes may have evolved different psychologies relating to mating and reproduction. In the following paragraphs, this theory is explored in greater detail.

Relationship Selection

What type of relationship to pursue may depend on an individual's sociosexual orientation, or willingness to have sex without commitment. Although both sexes seem to value long-term, committed relationships, men are significantly more inclined than women to engage in short-term (casual sexual) mating. Evolutionary theorists attribute this key sex difference to differential parental investment.

Evolutionary biologist Robert Trivers drew upon Darwin's writings on sexual selection as well as more recent research to formulate parental investment theory, from which many

hypotheses and fruitful studies have been designed. Trivers defines parental investment as “any investment by the parent in an individual offspring that increases the offspring’s chance of surviving (and hence reproductive success) at the cost of the parent’s ability to invest in other offspring.” In a species, the sex that makes the larger minimum parental investment typically evolves to be the choosier sex, whereas members of the less-investing sex compete among themselves for access to the more valuable sex. For humans and other mammals, females are physiologically required to make a much larger parental investment. In fact, because female sex cells (eggs) require more energy to produce and maintain than male sex cells (spermatozoa), when an egg is fertilized, females have already made more of an investment than males have. Mammalian females also incur the costs of a long period of internal gestation, birth, and subsequent lactation and nursing. In contrast, a male’s minimum parental investment may potentially end with the release of seminal fluid. This differential minimum required parental investment makes females more selective than males because females have more to lose from mating with a low-quality partner.

Another way to view this dynamic is to consider that men and women differ in terms of how partner number affects reproductive success. For men, each new sexual partner represents a potential increase in offspring. Women, however, are physiologically constrained by pregnancy and lactation and thus do not reproductively benefit from having numerous sexual partners. From the perspective of genes, upon which evolutionary processes operate, a gene or set of genes that promoted sexual promiscuity may have successfully propagated through males but not through females. It is important to note that genes, in order to propagate, do not require organisms, including humans, to be consciously aware of their operation. Just as a person does not need to be aware that eating contributes to the reproductive success of genes involved with hunger mechanisms, the individual does not need to be aware that he or she is propagating genes when choosing mates.

Several studies have shown that women are more cautious about engaging in short-term sexual relations. For instance, evolutionary social psychologists Norman Li and Douglas Kenrick recently performed an experiment to investigate the kinds of mates people would design if given varying ‘budgets’ of characteristics. When participants were asked whether they would enter into a long-term relationship if they encountered the ideal long-term mate they had designed, men and women were found to be similarly selective; however, women were significantly more selective when it came to short-term relationships. Women were more reticent than men to say they would engage in a short-term relationship even when they had a high budget to design an ideal partner.

In a classic field experiment, social psychologists Russell Clark and Elaine Hatfield found that when a female stranger asked a male university student whether he wanted to go to bed with her that night, 75% said yes. However, when a male stranger asked a female the same question, 100% said no. Evolutionary psychologists David Buss and David Schmitt asked people how many partners they would ideally like to have in a lifetime. For men, the mean was 18, whereas for women, it was 4.5. Men are also more likely than women to desire sex sooner after meeting a potential partner. In the same study, women and men were equally likely to have sex with

a potential partner after knowing them for 5 years; however, at every shorter interval of acquaintance (2 years, 1 year, 6 months, 3 months, etc.), men were significantly more likely to say that they would consent to sexual intercourse. This sex difference was replicated by Schmitt in a study of 52 cultures. Men also significantly lower their standards when it comes to short-term mating, while women do not. Additionally, men prefer women with sexual experience when engaging in short-term mating, but not long-term mating. The lowering of standards and the preferences for sexually experienced short-term partners make sense in terms of promoting sexual activity with a larger number of women and support an evolved preference for short-term mating in men. However, these findings could all represent how women prefer to be *seen* rather than their actual desires.

A recent meta-analytic review by Peterson and Hyde examined reports of 30 sexual behaviors and attitudes in 834 papers and 7 large national data sets between 1993 and 2007. Overall, men reported slightly more sexual experience and sexual permissiveness, but these effect sizes were small for everything other than pornography use and masturbation (for which there were medium effect sizes). However, even this difference might be explained by the fact that women underreport masturbation and pornography consumption, while men do not. While men were more supportive of casual sex and women were more supportive of sex with commitment, this latter point was the reverse of what Oliver and Hyde found in their meta-analysis of a similar nature that was conducted 20 years ago. This may reflect changes in social standards: it is now acceptable for a woman to engage in sex within a committed relationship, whereas 20 years ago, premarital sex was impermissible for a woman. The differences between males and females in sexual behavior and attitudes may not be as large as is often portrayed.

Which type of relationship is more prominent depends on the sex ratio. The more men versus women, the more a society leans toward long-term mating – less promiscuity and early marriage. The more women versus men, the more a society leans toward short-term mating – more promiscuity and late marriage. Thus, men’s preferred mating strategy is more likely when women are in greater supply, whereas women’s preferred strategy is more likely when men are in greater supply.

Long-Term Mate Preferences

When selecting for a long-term mate, men and women both make significant investments of time and resources, so there should be some similarities in their long-term mate preferences. Indeed, several studies have shown that long-term mate selection seems to be somewhat assortative. For example, Watson and colleagues recently investigated assortative mating in newlywed couples. They found that both sexes select for a mate with the same political inclinations, the same religion, and someone of a similar age. Moderate similarities have been found with respect to intelligence: people seem to prefer someone with a similar vocabulary, education level, and general IQ. It makes sense that people prefer mates who are similar to themselves, as similarity minimizes conflict in relationships while maximizing cohesion.

Although men and women are both selective and share similarities in what they seek in long-term relationship partners, there are also some key differences. Women care more than men about their partner's social status and ability to acquire resources, while men care more than women about their partner's physical attractiveness. Buss has shown that these differences tend to be found not only in the United States and other Western countries, but also across 37 different cultures worldwide. Buss and Kenrick have also shown that while couples tend to be similar in age, women are attracted to men who are their own age or older and men are attracted to women at peak fertility – that is, women in their 20s.

Physical attractiveness and resources are not only sex-differentiated, but they are regarded as necessities by men and women, respectively. That is, Li and colleagues found that when mating budgets are low, men tend to prioritize physical attractiveness above other traits in their long-term partners. In contrast, women tend to prioritize resource-related traits in their long-term partners. Once these traits are obtained in roughly average levels, both sexes tend to value other traits. In other words, both sexes ideally want a well-rounded mate who has it all. However, men seem geared toward ensuring that their long-term mates are not physically unattractive and women seem geared toward ensuring that their long-term mates are not destitute.

Multiple studies have suggested that aspects of females that are found to be physically attractive – breasts, buttocks, skin, hair, teeth, movement patterns, etc. – are related to youth, sexual maturity, and health, which impact a woman's ability to bear children. Less intuitive features that are found widely attractive, such as body and facial symmetry, are also cues to genotypic and phenotypic quality. In both men and women, low fluctuating asymmetry indicates better mental, cognitive, and physical health. Buss hypothesizes that the most compelling reason for men to pursue a long-term mating strategy is to monopolize a female's lifetime reproductive resources. If this is the case, then it makes sense to be particularly attracted to signals of fecundity and health, and also explains the common finding that men prefer younger women.

One particularly important measure of fecundity has been investigated by psychologist Devendra Singh: the waist-to-hip ratio (WHR). While preferences for body mass levels and weight vary across cultures depending on factors such as food scarcity, in most cultures, women with a lower WHR (generally in the 0.6–0.8 range) are found to be the most attractive. This has been found to be true in White-American, African-American, Hispanic, Indonesian, and British males, as well as in art and statues from around the world over the centuries, and more traditional hunter-gatherer societies such as the Aché. Investigating populations who live in conditions more similar to the ancestral environment showed that it is not necessarily the absolute WHR that matters, but rather that a lower WHR in comparison to the normal female range to which a man is exposed is found to be especially attractive. Direct relationships between WHR and fertility have been found, and it has been hypothesized that low WHR helps distinguish which females are of a fertile age and are not pregnant (pregnancy increases WHR). Furthermore, Hughes and Gallup recently found that females with low WHR had intercourse for the first time at an earlier age, reported having had more sexual partners, more

extra-pair copulations, and more instances of sexual relations with men already in a relationship. This provides further evidence of the attractiveness of a low WHR, but it also indicates a related issue: sexual infidelity.

As men tend to invest significant amounts of time and resources into long-term relationships, they may have evolved to ensure that their investment is not misdirected, by being sexually jealous and more interested in women who will be faithful to them. That is, men who invest in long-term relationships without regard to a partner's sexual fidelity likely do not leave any descendants. Buss and colleagues found that 60% of men would be more upset by sexual infidelity as opposed to emotional infidelity. Additionally, men find promiscuity acceptable in a short-term mate, but unacceptable in a long-term mate and, as mentioned earlier, find sexual inexperience to be an attractive quality in a potential long-term partner. These preferences support the idea that when a man selects a long-term mate, he may have an underlying need to ensure future paternity.

Women, on the other hand, have different concerns when it comes to selecting a long-term mate. A woman is always certain of her maternity because she is incubating and giving birth to the child herself. Instead, her concerns focus on a partner's investment, resources, and status. Through a long-term relationship with a man of high status who has a stable income, a woman can acquire direct resources for her children, as well as the indirect reproductive advantages that social and economic benefits can confer. Several studies have found that measures such as socioeconomic status (SES), social dominance, ambitiousness, or social status are valued and prioritized when women are selecting long-term mates.

Short-Term Mate Preferences

Men have similar criteria for selecting a short-term mate as for selecting a long-term mate. That is, for all of the reasons mentioned previously, physical attractiveness is especially valued in a short-term partner. Although women generally prefer long-term mating, some women do engage in short-term mating. Why would women engage in short-term mating when considering the potential costs? Beyond the sexual pleasure involved, the adaptive benefits for women have been hypothesized to include instantaneous resource acquisition (e.g., prostitution or 'gold digging'), better genetic quality, or being able to evaluate a mate for a long-term mating context. Li and Kenrick found that when women are selecting a short-term mate, they (like men) prioritize physical attractiveness. However, as opposed to looking for a fertile mate, women may be selecting good genes in a short-term mateship. That is, although a casual sexual partner may not contribute much in the way of income or resources, his genetic quality – which can be directly passed on to offspring – is relevant if pregnancy occurs. According to psychologist Steven Gangestad and biologist Randy Thornhill, a healthy set of genes and immune system provide resistance to pathogens that can adversely affect developmental stability. In addition to having negative health consequences, individuals who are not able to fend off pathogens during development tend to possess a greater degree of bilateral asymmetry (i.e., left-side development deviates from being

symmetrical to right-side development). Because testosterone suppresses the immune system, only men who have strong immunity are able to maintain high levels of testosterone and remain healthy. Thus, testosterone-related physical features, when present with symmetry, are honest indicators that a man's genes are resistant to pathogens. Consistent with this theory, women seem to prefer short-term mates who are symmetrical, muscular, tall, broad-shouldered, and have masculine facial features. Thus, whereas men seem to be seeking women who are capable of reproducing, women seem to be seeking good genes for their potential children.

Women, according to psychologists Steven Gangestad and Jeffrey Simpson, may have evolved to utilize short-term mating as part of a mixed mating strategy. That is, women want men who are strong and healthy, but they also want men who will invest and help raise children. However, this cannot always be found in the same individual, and such men, being high in demand, tend not to be loyal mates. So, although a committed relationship with a resourceful man who is also physically attractive is ideally preferred, most women have to choose between resourceful men for long-term relationships and physically attractive men for short-term relationships. As such, most women opt for the former. If the opportunity presents itself, some of these women may have sexual affairs with physically attractive men, thereby obtaining resources and investment from one man but genetic quality from another. Indeed, women's sexual affair partners tend to be more physically attractive and symmetrical than their regular partners.

Ovulatory Effects

Individuals vary in whether they utilize a short-term or long-term mating strategy. However, there is also important intra-individual variation. This section focuses on the way the ovulatory cycle affects women's own choices as well as men's attraction to women at different points in their cycle. It is one thing to say that men and women have unique preferences in the opposite sex in certain contexts, but quite another to think that a woman could be attracted to a certain type of man one day and a different type of man two weeks later. However, this has been found to be the case. Similarly, one generally thinks of a woman's physical attractiveness as being relatively stable; however, evidence shows that a woman actually varies in how attractive she is perceived to be based on the phase of her menstrual cycle. These processes are not conscious, but are rather driven by hormones and reactions to the hormones of others.

Women's Preferences When Ovulating

Ovulation is the most fertile phase of a woman's menstrual cycle. At this time, indicators of genetic quality become more important to women selecting mates. For example, Ian Penton-Voak and colleagues found that during phases of high conception risk, women preferred more masculine faces for short-term relationships. Consistent with the good genes theory mentioned previously, more masculine features might indicate genes that can resist disease, which would be beneficial for offspring. In contrast, when assessing attractiveness for long-term relationships, women choose men with more

feminine faces irrespective of the menstrual cycle, presumably because such men would be more likely to invest and less likely to have extramarital affairs. Additionally, when women are ovulating, they prefer the scent of men who are more symmetrical. Furthermore, they prefer the scent of men who scored high on a dominance scale when fertile or when currently in a relationship. Recently, Gangestad and colleagues found that women are more attracted to traits such as physical attractiveness, muscularity, and being confrontational when most fertile and when evaluating men as short-term mates. Anthony Little and colleagues found that women prefer facial symmetry in men during the most fertile phase of their menstrual cycle and also when they are in the midst of a long-term relationship. They also found an increase in preference for both symmetry and sexually dimorphic facial characteristics in women who consider themselves to be physically attractive. David Puts similarly found that lower frequency male voices were preferred by women for a short-term relationship over a long-term relationship, and were most preferred when women were ovulating. Additionally, preference for a deeper male voice was correlated with high self-reported mating success. Whereas women of low attractiveness or mating success might have a hard time keeping a high-quality mate, a woman of high attractiveness or mating success might be able to keep one or, even if he deserts her, find another man to help her raise her children.

Men's Preferences for Ovulating Women

Women are more receptive to short-term pairings during ovulation; they also judge themselves as more attractive and are judged as being more attractive by men during this time. Why might this be? In many mammalian species, females experience estrus. In these species, females only engage in sexual relations and can only be fertilized during this time. Females often display obvious signs of estrus, such as genital swellings or spontaneously elevating the hindquarters. Human females, like the other great apes, experience menstrual cycles rather than estrus cycles. This means that if no eggs are fertilized, the endometrial tissue is shed through menstruation rather than being reabsorbed. For many years it was thought that ovulation was entirely concealed in humans. As human females are sexually receptive throughout the menstrual cycle and do not show that they are ovulating (and might not even be aware of their own ovulatory patterns), it was thought that men would not be able to detect female fertility. It was also hypothesized that this might have evolved to extend investment from males and sexual interest throughout the entire cycle, encouraging monogamy. However, this mechanism would also enable females to cuckold males more easily because it would be more difficult for males to keep track of their partner's fertile window. In this way, it would have allowed women to mate with, and become impregnated by extra-pair men. However, more recently it has been shown that ovulation might not be as concealed as previously thought.

Recent laboratory studies have demonstrated that during the fertile phase of their cycles, women are more attractive to men. Women experience a decreased WHR, increased body symmetry, greater facial attractiveness, greater likelihood of wearing revealing clothing, more attractive scent, and even higher levels of creativity and fluency on high-fertility days.

Additionally, Kristina Durante and Norman Li found that higher estradiol levels (which fluctuate throughout the menstrual cycle and are higher during ovulation) were associated with higher ratings of self- and other-perceived attractiveness and the likelihood of mating. Furthermore, during ovulation women dress more provocatively, are perceived as trying to look more attractive, are guarded more closely by mates, and receive more attention and expressions of love from mates.

Recently, an innovative study by psychologists Geoffrey Miller and colleagues assessed the effects of the ovulatory cycle on tip earnings in lap dancers. Eighteen dancers recorded their menstrual cycles and reported on 296 cumulative work shifts over a period of 60 days. Participants who were not using any hormonal contraceptives earned US\$335 for each 5-h shift during ovulation, US\$260 during the luteal phase, and US\$185 during menstruation. Conversely, those using hormonal contraceptives earned only US\$193 per shift and experienced no ovulatory peak. This means that on average, normally cycling lap dancers make US\$80 more than those who use hormonal contraceptives each shift. This suggests that men, though almost certainly not consciously, are able to detect female ovulation in some way. However, the fact that women still make money during nonfertile phases suggests that this detection is imperfect. If infertile women were entirely unattractive, then they would make no money. This could be the result of an evolutionary arms race between men and women – women developing mechanisms to conceal ovulation in order to cuckold men and men developing mechanisms to detect ovulation in order to mate with fertile women.

Same-Sex Mate Preferences

Evolutionary psychologists rarely address same-sex attraction, mate selection, and relationships because the evolutionary function of homosexuality and bisexuality is still unclear. However, Alfred Kinsey found that ~10% of the male population have engaged in exclusively homosexual interactions for a period of 3 or more years. Estimates of female homosexuality are usually much lower; however, this may be because female sexuality is more fluid. Michael Bailey studied arousal patterns in men and women by measuring physiological arousal while watching different kinds of pornography. He found that men tended to be aroused either by watching lesbian and heterosexual sex or by watching homosexual male sex, but not both. Females, on the other hand, were equally aroused by homosexual male and female sex as well as heterosexual sex. Sell, Wells, and Wypij used a survey to measure the prevalence of homosexual attraction and behavior in the United States, United Kingdom, and France. They found that for men, the percentages of attraction and behavior tended to be similar, while for women, the percentage of females attracted to other females was higher than the percentage of those who had engaged in sexual behavior with other females. The important differentiation between attraction and behavior is discussed in a heterosexual context in the following paragraphs.

Several studies have suggested that there might be an innate component to homosexuality. This could be due to a gene that makes an individual more likely to become homosexual, and it could also be due to prenatal androgen signaling. If

homosexuality is heritable, why would that be? What benefits could it bestow for an individual's genes? One possibility is kin selection, whereby an individual is more likely to help his or her kin because they share a large proportion of genes. This means that benefits shared with kin indirectly benefit one's own genes and costs to kin are indirectly costly to one's own genes. The higher the proportion of genes shared, the more likely it is that an individual will help. Stated differently, genes can spread by inducing organisms to help their relatives, because relatives are likely to have copies of those helping genes. This has been demonstrated in species from ground squirrels to humans. So, if a homosexual individual helps to ensure the survival of his or her brothers' and sisters' children, that individual is also ensuring the survival of his or her own genes. This theory is consistent with the finding that having older brothers increases the likelihood of a male being homosexual. Anthony Bogaert found that each additional older brother increased the likelihood that the subsequent son would be homosexual by an average of 38%. However, evidence supporting this hypothesis is still inconclusive, and several alternative theories have been postulated.

Regardless of why homosexuals and bisexuals exist, it is clear that they do exist and they do show certain attraction patterns. While conclusions drawn from these studies are more tentative because they lack the replication of heterosexual studies, certain trends are still present. Bailey and colleagues performed a study comparing homosexual and heterosexual male and female participants, and found that sex had a considerably larger impact on their results than did sexual orientation. Men – both heterosexual and homosexual – were more interested in uncommitted sex and prioritized physical attractiveness more than women. However, there were some proclivities that were a bit more complicated. Men were much more interested in visual sexual stimuli than women generally, but lesbians were more interested than heterosexual women in pornography (though not as much as heterosexual men). Men were more likely to express that partner's status is unimportant, but lesbians were just as likely as heterosexual men to say the same. Men were more likely to be sexually jealous, while women were more likely to be emotionally jealous, but homosexual men were more similar to women than men in this case. Men were more likely than women to prefer a younger partner, but heterosexual males displayed a stronger preference than homosexual males (however, homosexual males were still more likely than females to prefer a younger partner). Finally, men had higher sociosexuality scores than women, but homosexual men had even higher sociosexuality scores than heterosexual men. However, this difference reflects differences in opportunity rather than motivation to engage in casual sex (the difference depended on the behavioral items on the Sociosexual Orientation Inventory). These collective findings suggest that generally, males and females vary more intersexually than intrasexually on these items and also that sexual orientation adds complex dispositions that should be further explored.

Actual Mate Choices

In a meta-analysis of gender differences in mate selection preferences, Alan Feingold rightly highlights that in mate selection research, experimenters rarely distinguish between attraction,

self-professed mate preferences, and actual dating/mating choices. What people say they want could be entirely different from what they are actually attracted to, which could still be different from who they actually end up with. There are three main paradigms which have sought to explore mate selection in the real world because of this problem: (1) Personal advertisements, (2) Marriage data, and (3) Speed-dating studies. Personal ads reveal, in a naturalistic manner, what potential partners want. Speed-dating studies tell us what aspects are important in a brief encounter that could lead to a date. Marriage data tell us who really ends up with whom.

Personal Ads

Personal ads are mate preferences revealed in competitive mating markets. Various studies have shown that advertisements are consistent with surveyed mate preferences. Women who promote themselves as being physically attractive make more demands for affluent mates. Additionally, women become less demanding as they get older, while men become more demanding. Younger women get more responses than older women and older men get more responses than younger men. This supports the idea that both men and women are able to pursue their preferred mating strategy when they perceive their own mate value as being high. More recently, a study of internet personal ads across the life span found that predictions from evolutionary psychology still hold true in this modern context: from 20 to over 75, men sought physical attractiveness and offered more status-related information; women sought more status than men did and were more selective. As men age, they look for progressively younger women; women look for men older than themselves until 75 and older, at which point they start to look for younger men. These measures seem to confirm past findings of sex differences in what men and women are looking for in a mate and the age of the preferred partner.

Actual Marriages

Collecting data using married individuals gives researchers a different perspective on mate selection – what kind of mates are actually selected for long-term relationships? Do higher-status men attain more attractive females? Is the male usually older than the female in a marriage? Several marriage studies have found that men with successful careers do indeed have more attractive wives. Indeed, a woman's physical attractiveness, as indicated by her high school yearbook photo, is a significant predictor (more so than her intelligence) of the social status of the man she marries.

Marital satisfaction studies have also supported evolutionary predictions. Glenn Weisfield and colleagues found that a woman is more satisfied with her marriage if her husband made most of the decisions (i.e., dominance is attractive), but excessive dominance reduced satisfaction (potentially getting to the point of making a wife scared of her husband). A man is more satisfied if his wife is more attractive than him. The notion that dominant men gain more attractive wives was also supported. Overall, marriage data support evolutionary hypotheses of mate selection and validate hypothesized sex differences.

Speed Dating

One of the ever-present difficulties of psychological research is attempting to maintain ecological validity while retaining experimental control, and this balance can be particularly hard to achieve in attraction and mate selection paradigms. Preferences that people state on questionnaires about what traits they are looking for in a partner can differ from who they actually choose. Speed dating helps bridge the gap between stated preferences and choices on who one actually wants to see again. Social psychologists Paul Eastwick and Eli Finkel performed an experiment to test whether stated preferences would prove true in an actual face-to-face dating situation by using a speed-dating paradigm. On a pre-speed-date questionnaire, men (more than women) reported that physical attractiveness would be an important characteristic when selecting for an ideal partner and for a speed date. Women (more than men) thought they would find earning potential to be an important characteristic when selecting for an ideal partner and for a speed date.

However, post-speed-date questionnaires that asked participants why they selected the specific people they did showed that, while physical attractiveness, good earning potential, and personable characteristics were all related to romantic interest, there was no evidence for sex differences in selecting for these characteristics. There was also no evidence suggesting that the lack of sex differences had anything to do with participants' long versus short-term mating preferences. Additionally, what participants thought they wanted and what they actually chose were largely independent (e.g., a participant might have said they thought physical attractiveness was very important, but then said in the postdating questionnaire that they selected their partner based on personality).

The lack of congruence between stated mate preferences and actual mating choices raises issues that deserve further study. For instance, are there really no sex differences in the importance of earning potential in mate choice, or can this be attributed to where the speed-dating study was conducted – a university campus, where most of the students are of a certain economic level as well as having a certain level of intelligence. Additionally, since most of the female participants were around 20 years old, a certain level of fertility could also be assumed. Thus, male and female participants may have less need to discriminate on the basis of earning potential and physical attractiveness, respectively. Instead, both can focus more on how well they get along with their potential mates.

Conclusion

Mate selection is a complex process that is influenced by biology as well as culture and the environment. Individuals look for long- or short-term mates, or both, depending on hormones, phase of life, and self-perception. In general, women seem to prefer long-term relationships, but still engage in short-term mating. Although most men end up in long-term relationships, most men seem to prefer short-term mating. These types of decisions are also influenced by sex ratios of available mates versus intrasexual competitors. A strategy becomes more desirable as a function of the number of

available mates responding to that strategy and the lack of many intrasexual competitors employing that tactic. Recent speed-dating studies have shown fewer differences between men and women than previous studies found with other methods (e.g. self-report). Whether this finding can be replicated in populations with more diversity in levels of attractiveness and SES, however, has yet to be seen.

Men and women seem to be more similar when it comes to what they are looking for in a short-term partner, but differ in what they desire in a long-term partner. Good looks are a requirement for short-term mating, and other factors are less important. However, when looking for a long-term mate, women prioritize status and resources, while men continue to prioritize physical attractiveness. However, only a certain level of these is necessary. Whereas a man with an average, stable job is much more highly valued than a destitute man, a man who earns a lot more is only slightly higher in desirability to most women. Conversely, women who are moderately physically attractive are strongly preferred over women who are clearly unattractive. However, further gains in attractiveness are associated with smaller increases in overall desirability. Beyond differences in what they initially prioritize, men and women tend to ideally prefer the same kind of long-term partner – a well-rounded individual who is attractive, smart, industrious, funny, creative, and kind.

Embracing an evolutionary viewpoint does not mean ignoring cultural and social factors. Evolutionary explanations tend to focus more on the ultimate origins of preferences and behaviors, and evolved adaptations are complex processes that can have different implications depending on environmental and cultural factors. Studying mate selection across cultures and across other contexts would allow a more intricate understanding of how adaptive mate selection processes shape and are shaped by environmental factors. Indeed, scientific research across cultures is becoming more common as the world grows smaller; this is an encouraging trend.

Media Influence on Behavior

B J Bushman, The Ohio State University, Columbus, OH, USA; VU University, Amsterdam, The Netherlands

J L Whitaker, The Ohio State University, Columbus, OH, USA

© 2012 Elsevier Inc. All rights reserved.

Glossary

Agenda setting The ability of news media to decide what it is newsworthy and how important the news story is.

Aggression Any behavior that is intended to harm another person who does not want to be harmed.

Aggressor effect The phenomenon wherein exposure to violent media can cause the viewer to also behave more aggressively.

Conditioning The pairing of stimuli with rewards and punishments.

Conscious-numbing effect The phenomenon wherein individuals who have been repeatedly exposed to violence in the media are no longer bothered by acts of violence in the real world.

Desensitization The process where constant exposure to a stimulus diminishes reactions to that stimulus.

Fear-of-victimization effect The phenomenon wherein increased exposure to violent media can cause individuals to believe they will become violence victims.

Framing The ability of the media to portray a topic in a positive or negative manner.

Habituation Overexposure to a stimulus such that it no longer elicits a novel reaction.

Identification Feeling a personal connection to some stimulus (usually a person) portrayed in the media.

Media The collective name for all forms of nonpersonal communication between individuals and/or groups.

Mimicry The immediate copying of an action after a single exposure.

Observational learning The act of learning and displaying more long-term behaviors after constant exposure.

Priming The activation of a concept in the neural network when exposed to an associated concept.

Script The cognitive map outlining what to expect and how to behave in particular situations.

Communication – the exchange of information between individuals and/or groups – has played an important role in the development of humanity. People have always employed various methods to convey ideas and meanings to one another. In the course of time gestures, sounds, and spoken language evolved into pictures and written words. The advent of printing technology allowed for the dissemination of books, newspapers, and other literature to new audiences. Electronic and digital advancements facilitated communication among great masses of individuals through the use of the radio, film, television, and Internet.

In modern society, the term media can be defined as the main means of mass communication. Generally, this includes both print media and electronic media. Numerous modes of communication are accessible to most individuals, and it is easier and simpler than ever to inform, persuade, and entertain people around the world.

The goal of the media is to impart information, and in so doing influence the behaviors of its audience. Such changes in behavior as a result of media influence have become a new area of academic study. Though communication is as old as humanity, the effects of the media have been seriously considered only in the last century. The field of media influence research examines the changes and effects the media brings about in everyday life.

What Is Media Influence?

Everyday we are bombarded with media messages, some as short as a commercial, others as long as a novel. Many

messages simply convey factual information, such as the date of a presidential address; others entice us to purchase a specific product or service; and still others attempt to entertain us or influence our opinion on some particular matter. Often, the media presents multiple messages, some obvious and some more difficult to extract. Messages, both noticeable and opaque, can even be unraveled in media meant as innocuous entertainment. For example, the children's television program *Power Rangers* may overtly communicate the importance of teamwork while at the same time implicitly endorsing the use of violence as a means to solve problems.

It is not unreasonable to believe that exposure to the media can affect a person's conduct. Concern over the possible influence the media may have on an individual's actions has prompted academic inquiry into how people and the media interact.

In the fields of psychology, sociology, and communications, media influence (also known as media effects) refers to the ways in which the mass media can affect the thoughts, feelings, and actions of its audience. Of particular interest are the ways in which media consumption can have an effect on subsequent behavior in both the short run and the long run. Researchers are also interested in the ways the media affects young children, and how such exposure can help shape their lives as adults. Numerous ways in which the media can influence behavior have been uncovered. For the most part, media effects research focuses on the influence of violence in media on later aggressive behavior. Further lines of research examine the media's influence on other behaviors, such as prosocial actions and learning, as well as how the media shapes attitudes (which in turn affect behaviors).

Media Influence Processes

How can exposure to the media affect a person's behavior? The media can influence a consumer's behavior both in the short term and the long term.

Short-Term Effects

Short-term effects occur immediately after exposure to some type of media. These effects primarily occur through the processes of priming and mimicry.

Priming

People hold ideas about how the world works. They have a complex network of links and associations between objects, concepts, and behaviors in their minds. Exposure to a stimulus can activate one idea in a person's mind, which can then trigger the activation of another idea. This process is called priming.

Priming is subtle; it usually occurs without conscious awareness. The content of the media can prime certain ideas, thoughts, feelings, and behavioral tendencies in memory. This makes it more likely that individuals will consciously experience those thoughts. This in turn increases the possibility that people will act on what they are thinking and feeling. For example, after watching a commercial about buying a house, the consumer may have different ideas about houses, after being primed. In addition to the idea of buying a house being activated in the mind, a different idea that might be associated with buying houses may be activated, such as the act of constructing houses for the homeless. The activation of this later idea may prompt the viewer to donate time to building homes for charity.

Mimicry

Mimicry is the act of copying the behavior of others. When a particular behavior is shown in the media, some people are likely to mimic it in other situations. This is especially prevalent with children. For example, a famous experiment by Albert Bandura showed that children who watched a model act violently against a doll in a TV program later mimicked the model's violent actions.

The propensity to mimic actions displayed through the media increases if observers identify with the character and want to become like the character. For instance, if a TV program shows a young African-American girl brushing her teeth, viewers are more likely to imitate that action if they are also young, female African-Americans. Not only physical qualities, but the attitudes and values of a character can also prompt identification. For example, young boys who want to be brave and smart like a cartoon superhero may identify with the character and mimic the character's actions.

Long-Term Effects

Long-term effects occur after prolonged exposure to the media. These effects take place over time and may require multiple experiences with the media content to develop. A prominent long-term effect is the altering of behavioral scripts (and subsequent behavior) through observational learning.

Observational learning

Mimicry and observational learning are similar but have an important difference. Whereas mimicry refers to the short-term copying of an action following its presentation (usually needing only one exposure), observational learning refers to the process of being exposed to the media repeatedly over a period of time, absorbing its message(s), and displaying the learned behavior. This new learned behavior may persist over time, rather than just occur once. In this manner, observational learning can be thought of as a more powerful extension of mimicry.

With observational learning, the observers modify scripts (ideas about what to expect in certain situations and how to interact with the world) according to what they have been exposed to in the media. These altered scripts can subsequently influence how they perceive situations and the types of behavior acceptable in certain situations. For example, repeatedly watching a television program wherein the main character says 'Bless You' after someone sneezes can lead viewers to alter their script about sneezing to include saying 'Bless You'. Later, when they see someone sneeze, they will have learned through the media to say 'Bless You.' Observational learning through the media plays an especially important role for children, as they learn to model their behaviors after media figures.

Effects of Violence in Media

A major line of research involves investigating the effects of exposure (especially, prolonged exposure) to violence in media. Violence in the media is fairly commonplace in the United States. For example, 60% of television programs contain violent content, as do 90% of video games. The Internet is rife with violent websites and games, many songs contain violent lyrics, and even newspapers tend to feature violent events that occur over the world. The media can portray various types of violent content, from descriptions of real-life fist-fights in news reports and videos of riots posted on the Internet, to the fictional murder of a person in a television crime drama or shooting enemies in a video game.

First, we need to define what we mean by the terms 'aggression' and 'violence' because researchers use these terms differently than lay people do. Lay people may describe a salesperson who tries really hard to sell you something as 'aggressive.' Most researchers define aggression as any behavior intended to harm another person who does not want to be harmed. Thus, researchers would not call a salesperson aggressive because the salesperson does not want to harm potential customers. This definition includes three important features. First, aggression is a behavior – you can see it. Aggression is not an emotion, such as anger. Aggression is not a thought, such as mentally rehearsing a murder. Second, aggression is intentional (not accidental) behavior. For example, a dentist might intentionally give a patient a shot of Novocain (and the shot hurts!), but the goal is to help rather than to harm the patient. Third, the victim wants to avoid the harm. Thus, again, the dental patient is excluded, because he or she is not seeking to avoid the harm (in fact, the patient probably booked the appointment weeks in advance and paid to have it done!). Sadomasochistic sex is also not included because again the

victim actively seeks to be harmed. Likewise, suicide would be excluded because the individual does not want to avoid the harm. Behaviors that are intended to harm others are still acts of aggression even if they do not actually harm them. For example, if a person shoots a gun at you but misses, that person still acted aggressively.

Laypeople and researchers also differ in their use of the term violence. A meteorologist might call a storm 'violent' if it has intense winds, rain, thunder, and lightening. When researchers use the term, *violence* refers to aggression that has as its goal extreme physical harm, such as injury or death. For example, one child pushing another off a tricycle is an act of aggression, but it is not an act of violence. One person intentionally hitting, kicking, shooting, or stabbing another person is an act of violence. The United States Federal Bureau of Investigation (FBI) classifies four crimes as 'violent': homicide, aggravated assault, forcible rape, and robbery. Researchers would also classify other physically aggressive acts as violent even if they do not meet the FBI definition of a violent crime, such as slapping someone really hard across the face. But a husband who calls his wife every name in the book would not be committing an act of violence by this definition. All violent acts are aggressive acts, but not all aggressive acts are violent (only the ones that cause extreme physical harm are).

Thus, violence in media depicts acts of extreme physical aggression. Constant exposure to violent media can lead to changes in how the viewer perceives and responds to the world. Two of these processes are the fear-of-victimization effect and the conscience-numbing effect. Together, these processes contribute to a third process, the aggressor effect.

Fear-of-Victimization Effect

Heavy television viewers (usually defined as individuals who watch at least 4 h of TV each day) develop the perception that the world is a hostile place and that others cannot be trusted. One consequence of this perception of the world is the fear that one will become a victim of violent crime. We call this the fear-of-victimization effect. It has been found in both adults and children as young as 7 years old.

What can explain the fear-of-victimization effect? When predicting the amount of violence they will experience, people tend to use information readily available to them. If they have been exposed to a great deal of violent content through the media, they may more easily think of instances of violence compared to people who are not exposed to much violence in media. Because heavy TV viewers can produce violent examples so easily, they may overestimate the amount of violence they will encounter in their everyday lives.

Conscience-Numbing Effect

As a person is constantly exposed to a stimulus, that stimulus may lose its novelty and become quite common. It is no longer as interesting and does not draw as much attention from the person. Eventually, the person may fail to react to the stimulus at all. This process is known as habituation.

Constant exposure to violence in the media can cause a kind of habituation. The more violence in media a person is exposed to, the less likely he or she is to become upset by it;

the violence becomes commonplace, normal, and expected. In effect, the viewer has become numb to violence. This conscience-numbing can have an enduring effect, lasting long after the experience of violence in media is over.

Research shows how people can become numbed by violence in media. The more violence in media a person is exposed to, the less physiologically aroused he or she becomes to subsequent exposures to violence. The diminished physical reactions indicate that the person is less bothered by the violence. One study by Bushman, Anderson, and Carnagey showed that constant exposure to violence in video games led to the players becoming desensitized to violence in the real world.

People who are exposed to a great amount of violence in media may also become less sympathetic to victims of violence – both to victims portrayed in the media as well as to the victims encountered in their daily lives. For example, in one study people who played violent video games gave less severe punishments to violent criminals than those who played nonviolent games, suggesting that they found the violent crimes to be less reprehensible. Along with decreased sympathy, exposure to violence in media may make people feel less empathy for violence victims. This reduced empathy renders people less willing to help real-life victims of violence.

Aggressor Effect

Perhaps most important, short- and long-term exposure to violence in media increases aggression. Over 300 studies have been conducted on this topic, and the findings are clear. Exposure to violence in media influences people to act more aggressively, both immediately after exposure as well as hours, days, months, years, and even decades later.

The tendency to act more aggressively is increased after short-term exposure. For example, immediately after watching violent media content, people are more willing to give painful electric shocks to others; children are also more likely to attack others.

Long-term exposure can alter belief structures, which in turn can affect behavior. Children, who are still developing their own beliefs about the world, are especially prone to changing their ideas and behaviors due to constant media exposure. Children who are exposed to high amounts of violence in media can come to believe that acting violently is socially acceptable. This belief can influence them to act more aggressively later in life. In one longitudinal study by Huesmann and colleagues, for example, it was found that men who watched violence in media as children were more likely to assault their wives and be arrested for crime 15 years later. Likewise, women who watched a lot of violence in media as children were more likely to throw things at their husbands 15 years later.

New forms of media such as video games may have an even greater effect on behavior than more traditional, passive forms of media such as TV and films. Violent games also explicitly reward players for violent acts. Constant reward for violent actions can condition players to believe that violence is good, and this can carry over to other real-life situations. The Internet also presents the opportunity for people to create and distribute their own content. If people receive positive feedback for posting violent content, they may continue to post violent content, which may negatively affect those who see it.

Other Media Effects

While much attention has been devoted to examining the influence of violence in media, other lines of research study the effects of nonviolent, more prosocial media; media influence on attitudes; and media effects on health.

Prosocial Effects

All media are not violent. Many kinds of media try to present positive messages that promote prosocial behaviors. Educational programs for children, such as *Sesame Street*, help children learn about the world. Many children's programs also attempt to instill positive values such as sharing. The media can also bring public attention to a topic (see section 'Public opinion') that otherwise might have gone unnoticed; for example, the newspaper accounts of the Nixon Watergate Scandal inspired political reform.

Newer forms of media such as the Internet have provided fresh avenues for creativity and self-expression. User-created content sites such as YouTube have presented people the opportunity to share their own personal media with the world. Media watchers can more readily become media producers, engaging with their audience on a more personal level. Online social networks (e.g., facebook) can provide additional methods of social support and social connections.

Effects on Attitudes

Body image and self-esteem

The inclusion of beautiful models and actors to endorse or sell a product is a tactic frequently employed by advertisers in the mass media. Magazines, commercials, television shows, and movies use beautiful models to appeal to the audience. Unrealistic expectations about body image can be fostered by exposure to the media. As people are exposed to these advertisements, distorted beliefs about beauty standards can develop. This effect is especially common among adolescent girls (and increasingly among adolescent boys).

When media watchers fail to achieve the high-impossible media standard of beauty, self-esteem can plummet. This lowered self-esteem can bring about negative effects in other domains, such as poorer interpersonal relationships and decreased ability to perform at work. In some severe cases, the media images of beauty can prompt adolescent women and men to fall prey to eating and/or exercise disorders.

Public opinion

The media plays an important role in educating the public about the world around them. Through the processes of agenda setting and framing, the media can shape public opinion.

News media, such as television programs and print and electronic articles, are pivotal in bringing matters to public attention. The media wield powerful control over what is deemed newsworthy. The news media must choose what is important enough to feature, as well as how much time or space to devote to the topic. This ability to decide what news is important and how important it is, is called agenda setting.

In addition to choosing newsworthy topics, the media can also portray the topic in a positive or negative manner, which is

called framing. Combining agenda setting and framing, the media can effectively determine what is worth knowing and how a topic should be perceived. Public opinion can thus be shaped – and following that, public action. For example, many believe that the media placed much emphasis on President Bush's plans to invade Iraq, and that this decision was portrayed in a positive light. This may have caused many people to be more supportive of the war in Iraq than they would have otherwise been.

Health

Exposure to the media – especially for extended periods of time – can influence the health of the consumers, both physically and mentally.

The information and entertainment provided by the media can be very alluring. Exposure to the media can be preferable to engaging in other activities; for example, a child might choose to play a video game inside rather than play hide-and-seek with neighbors outside. Prolonged media exposure can lead to physical inactivity and obesity.

Prolonged media exposure can also detract from time spent on other activities. This can be detrimental if the media interferes with work, home, or social responsibilities. Like gambling, some forms of media can be addictive, such as playing video games. Internet and video game addiction are relatively new research areas receiving significant attention.

On the positive side, the media (especially the Internet) can be a wonderful source of information about health issues. Many people first turn to the media when they want to learn about an illness.

Regulating Media Influence

The media can be a powerful influence on shaping the thoughts and actions of those who consume it. Most of the time, the influence of the media is subtle, and the messages it presents may not be easily recognized.

Awareness is the key to understanding media effects. If a person is knowledgeable about the ways in which media can influence him or her, then he or she may be more likely to carefully scrutinize media messages. Educating the public about media effects can help them become savvy media watchers.

Parents also have a responsibility to talk to their children about media content. Parents can put TV sets and video game consoles in a public location rather than in bedrooms. Parents can use ratings and reviews to select appropriate media for their children. Parents can also restrict the amount of time children spend on media. The good news is that parental mediation works. The bad news is that not many parents do it. Parents often use the media as babysitters. Unfortunately, the media can be shoddy babysitters.

Conclusion

The mass media provides many opportunities to improve or worsen the lives of those who are exposed to it. The field of media effects research has uncovered numerous ways in which the media can subtly guide thought and behavior.

It is important to understand the ways in which the media can wield its influence, so that the negative effects of the media can be mitigated and the positive effects encouraged. Knowledge about media is the key to regulating the effect the media can have on one's own behavior.

Meditation: The Science and the Art

D Shannahoff-Khalsa, University of California San Diego, La Jolla, CA, USA

© 2012 Elsevier Inc. All rights reserved.

Glossary

Chakras An energy center of consciousness associated with the seven nerve centers (nerve plexuses) of the body and one with the psychoelectromagnetic field of the body, called the aura.

Kundalini Comes from the word 'kundal,' meaning coiled energy and the creative potential of an individual.

Meditation The art and science of how to manipulate the thought waves to achieve a state of thoughtlessness, wherein

the individual experiences both existence and nonexistence simultaneously, and where the field of consciousness then becomes a novel sensory experience, wherein new levels of awareness and new skills in the mental realm are developed.

Pranayama The yogic system of meditative breathing exercises.

Yoga An ancient science and art where the finite experiences the infinity consciously within oneself.

Introduction

According to the Oxford English Dictionary, the word meditation can have at least two meanings that are relevant here: (1) "The action or practice of profound spiritual or religious reflection or contemplation; *spec.* a variety of private devotional exercise consisting of the continuous application of the mind to the contemplation of a particular religious text, truth, mystery, or object." Or (2) "In Buddhism, Yoga, and other systems of religious or spiritual discipline: a practice of the mind (and body) aimed at achieving the eradication of rational or worldly mental activity." The latter definition is closer to the subject and intention for this article. A note on the historical origin, a brief overview of the scientific evidence supporting the efficacy of meditation, and a description of some techniques and how they can be applied are covered. Also, the yogic concept of consciousness along with the 'eradication of rational or worldly mental activity' as noted in the second definition is briefly discussed. The major focus of this article is on the techniques discovered in the original system of yoga referred to here as 'Kundalini Yoga as taught by Yogi Bhajan,' which was an integrated science before various individuals, groups, or lineages proceeded to selectively fractionate the system, or were later left with only the remnants of the original ancient teachings as a result of natural catastrophes and nomadic invasions. Descriptions of some of the other popular meditation techniques that are now taught are also included.

The exact time of the historical origins of the discovery of yogic meditation techniques remains controversial. However, the evolution of this ancient science was believed to have its origins long before the advent of the formal religions. This suggests that the initial experiential efforts and much of the experimental study that led to the development of these meditation techniques may go back to at least 7000 B.C.E. The people who participated in this ancient process of discovery, called the 'rishis' (people of power), are thought to have lived in the region of the Indus river valley. This ancient society is now called the Indus-Sarasvati civilization, which is believed to be the first civilization in the Indian subcontinent.

The Science of Meditation

The Western experimental scientific literature on meditation started in the 1960s. In 2005, the National Institutes of Health and National Center for Complementary and Alternative Medicine funded a systematic review of the scientific literature that was published in 2007. This is the most comprehensive systematic review to date and it was published as *Meditation Practices for Health: State of the Research*. This review was conducted by the University of Alberta Evidence-based Practice Center. Comprehensive searches were conducted in 17 electronic databases up to September 2005. Other sources of potentially relevant studies included hand searches, reference tracking, contacting experts, and gray literature searches. The studies had to be in English, be comparative, focus on any type of meditation practice, include more than 10 adults, and provide quantitative data on health-related outcomes. Studies on the different meditation techniques were then included for analysis in one of five broad categories, which were defined as mantra meditation, mindfulness meditation, yoga, Tai Chi, and Qi Gong. Evidence on the state of the research was provided from 813 predominantly poor-quality studies. Physiological and neuropsychological effects of meditation practices were also evaluated in 312 poor-quality studies. Meta-analyses of results from 55 studies indicated that some meditation practices produced significant changes in healthy participants. The authors conclude "Many uncertainties surround the practice of meditation. Scientific research on meditation practices does not appear to have a common theoretical perspective and is characterized by poor methodological quality. Firm conclusions on the effects of meditation practices in healthcare cannot be drawn based on the available evidence. Future research on meditation practices must be more rigorous in the design and execution of studies and in the analysis and reporting of results." However, this summation statement does not imply that high-quality and well-controlled studies demonstrating important health benefits for ill populations or unique findings in the healthy have not been published. The aforementioned conclusion is a generality. It provides a statement that is a 'mean' of the published studies. The problem with this review is analogous to an attempt to make a

description of all the organisms in the sea. There are so many different 'species' that it is difficult to conclude much more than that there are simply millions of different species in the sea. In meditation research, no two studies have been the same, that is, attempts to replicate previous findings per se have been almost nonexistent. There are variations in the techniques studied, age ranges, skill levels, healthy versus disordered populations, the parameters measured including variations of the scale(s) used, types of control group if any, length of the studies, testing conditions, etc. Also, this type of analysis does not focus on, or extract, the more unique and important findings of single studies.

However, several unique meditation studies that have shown important results are described here. Lazar and colleagues studied the brain's physical structure using magnetic resonance imaging (MRI) to assess cortical thickness. They looked at 20 subjects who had long-term experience with 'Insight meditation,' which involves a focus of attention on internal experiences. They found that brain regions, including the prefrontal cortex and right anterior insula, and other areas associated with attention, interoception, and sensory processing were thicker in the meditation practitioners compared to controls. They also found that differences in prefrontal cortical thickness were more pronounced in older practitioners, suggesting that meditation might offset age-related cortical thinning. Shannahoff-Khalsa and colleagues compared a unique multipart disorder-specific Kundalini Yoga meditation protocol for treating obsessive compulsive disorder patients against the classic mindfulness meditation technique and the relaxation response for a matched patient group. This was a randomized controlled trial, and after 3 months, the control group showed no efficacy on any of the six psychological measures used to assess psychological symptom severity; however, the Kundalini Yoga group showed a significant improvement on all six scales. The groups were then combined using the efficacious protocol, and after a 1-year trial, the patients showed a 71% improvement on the Yale-Brown Obsessive Compulsive Scale, the current 'gold standard' for psychological assessment of obsessive compulsive symptoms. To date, this clinical trial remains the most effective treatment result for all treatment modalities for this disorder. Tang and colleagues studied a traditional Chinese medicine meditation technique called integrative body-mind training (IBMT). They report that 11 h of IBMT increases fractional anisotropy, an index indicating the integrity and efficiency of white matter in the corona radiata, an important white matter tract connecting the anterior cingulate cortex to other structures. They conclude that IBMT could provide a means for improving self-regulation and perhaps reducing or preventing various mental disorders. Finally, Brefczynski-Lewis and colleagues studied 'concentration meditation' in which sustained attention is focused on an object such as a small visual stimulus or the breath. Using functional MRI, with age-matched participants, they found activation of a network of brain regions typically involved in sustained attention that showed an inverted u-shaped curve in which expert meditators had more activation than novices. They conclude that the hours of practice suggest a possible plasticity in these brain mechanisms.

Given the potential for new advances in healthy development, prevention, and for treating illnesses, only trivial

funding has been allocated to the field. In addition, this article is limited in length and cannot give adequate attention to the more noteworthy findings in the fields of both the basic sciences and clinical sciences. However, there are substantial new scientific insights in the understanding of the dynamics of mind-body relations, functions of the brain and peripheral nervous system, the natural endogenous mechanisms that have evolved in humans for the purpose of self-regulation. All these insights were based on the ancient teachings of the rishis. The variety of highly structured techniques described in the following sections suggests that the ancients had developed what may best be called a 'technology of the mind,' and indeed may provide us with very sophisticated insights for understanding the nature of human consciousness and the pathways for mental development.

Description of Kundalini Yoga Meditation Techniques

The following techniques in this section are all from the original and ancient system of 'Kundalini Yoga as taught by Yogi Bhajan.' From 1969 to 2004, Yogi Bhajan taught openly what had been kept secret for the last 3000 years; previously, it had been transmitted by a few masters to selected disciples. During these 35 years, he taught ~5000 different meditation techniques. Selected techniques are provided for their highly structured nature, complexity, and often disorder-specific or other benefits. Prior to being hidden in secrecy, these and many other techniques were practiced by both yogis and householders.

In the system of Kundalini Yoga as taught by Yogi Bhajan, there is a mantra that is chanted prior to practice, which is called 'tuning in.' This procedure helps to induce a protected meditative state of mind and helps to keep the system balanced and safe. This mantra is unique and only specific for this system.

Technique to Induce a Meditative State: 'Tuning in'

Description of the technique: Sit with a straight spine and with the feet flat on the floor if sitting in a chair. Put the hands together at the center of the chest in the 'prayer pose' – the palms are pressed together with 10–15 lbs of pressure between the hands (a mild to medium pressure, nothing intense). The area where the sides of the thumbs touch rests on the sternum with the thumbs pointing up (along the sternum), and the fingers are together and point up and out at a 60° angle to the ground. The eyes are closed and focused at the 'third eye' (imagine a sun rising on the horizon or the equivalent of the point between the eyebrows at the origin of the nose). A mantra is chanted out loud in a 1-1/2 breath cycle. Inhale first through the nose and chant 'Ong Namo' with equal emphasis on the Ong and the Namo. Then immediately follow with a half-breath inhalation through the mouth and chant 'Guru Dev Namo' with approximately equal emphasis on each word. (The 'O' in Ong and Namo is a long 'o' sound; Dev sounds like Dave, with a long 'a' sound.) The practitioner should focus on the experience of the vibrations these sounds create on the upper palate and throughout the cranium while letting the mind be carried by the sounds into a new and pleasant mental space. This should be repeated a minimum of three times.

The first meditation technique is included here because two clinical trials using it have shown significant efficacy in the treatment of obsessive-compulsive disorder (OCD) patients. This technique has also been studied using whole-head 148-channel magnetoencephalography brain imaging.

Meditation Technique for Treating OCD

Description of the technique: Sit with a straight spine in a comfortable position, either with the legs crossed while sitting on the floor or in a straight back chair with both feet flat on the ground. Close the eyes. Use the right thumb tip to block the end of the right nostril, the other fingers pointing up straight. Allow the arm to relax (the elbow should not be sticking up or out to the side creating unnecessary tension). A small cork or secure plug can also be used to plug the right nostril. Inhale very slowly and deeply through the left nostril, hold the breath in for a long time, exhale out slowly and completely through the same nostril only (left nostril), and hold the breath out for a long time. Every effort should be made to keep the four phases of the breath cycle of equal duration. The mental focus should be on the sound of the breath. Continue this pattern with a maximum time of 31 min for each sitting. Initially, begin with a comfortable rate and time, but where the effort presents a fair challenge for each phase of the breath. This technique should be perfected and has its greatest clinical benefits when the complete breath cycle is one minute in duration, each section of the cycle lasting exactly 15 s. This rate of respiration for the full 31 min can be achieved by most individuals within 5–6 months with daily discipline. The ancient yogis claimed that 90 days of 31 min per day using the perfected rate of one breath/min with the four 15 s per phase would completely eliminate all obsessive-compulsive disorders. The balance of equal times for the four phases is akey with this technique.

Gyan Mudra Kriya

This meditation was taught for when you do not know what to do, and it is claimed to be excellent for treating anxiety disorders and inducing a clear and stable state of mind. The claim is that “it is very simple, but very powerful if done correctly, that it coordinates both brain hemispheres, gives powerful insight, solves many complications, and coordinates the mystery of the spiritual phenomena into the mastery of the three bodies (physical, mental, and spiritual).”

Description of the technique: Sit straight, rest the back of one hand in the palm of the other with the thumbs crossing each other in one palm. If the right hand rests in the palm of the left hand, the left thumb rests in the right palm and the right thumb then crosses over the back of the left thumb. Either this hand orientation is acceptable or the reverse with the left hand resting in the palm of the right hand and then the right thumb is in the left palm covered by the left thumb. The hands are placed at the heart center level about two to three inches in front of the chest, but the hands do not touch the chest and the elbows are resting down against the ribs. The eyes are open but focused on the tip of the nose (the tip/end point that you cannot see). The breathing pattern has four parts that repeat

in sequence: first, inhale and exhale slowly through the nose only, and then with the second breath, inhale through the mouth with the lips puckered as if to kiss or make a whistle; after the inhalation, relax the lips and exhale through the mouth slowly; for the third breath pattern, inhale through the nose and exhale through the mouth (the lips are not puckered) the fourth breath pattern is inhaling through the puckered lips and exhaling through the nose. Continue this four-part cycle for 11–31 min.

Terhula Kriya – An Advanced Technique for Attaining Healing Powers and for Overcoming Phobias

This technique was taught for ‘achieving self-mastery and learning to heal others from a distance’ and it is one of the most advanced techniques in the system of Kundalini Yoga. Yogi Bhajan commented: “Terhula Kriya can make you a perfect master.” While it presents a challenge for learning, its benefits go far beyond the amelioration of phobias.

Description of the technique: Sit in an easy pose. Bring your elbows next to the ribs, forearms extended in front of you, with the hands in front of the heart center area, right over left, palms up. The hands are $\sim 10^\circ$ higher than the elbows. There is no bend in the wrists, the fingertips to the elbows form a straight line. The thumbs are extended out to the side of the hands, the fingertips and palms do not exactly line up, they are slightly offset. The eyes are closed looking at the backs of your eyelids. For the inhale, pull back on the navel and inhale through the nostrils and hold. Mentally repeat the mantra Har Har Wha Hay Guru as long as you are able to retain the breath. While you are doing this, visualize your hands surrounded by white light. For the exhale, exhale through the nostrils, and as you exhale, visualize lightning shooting out from your finger tips. When you have fully exhaled, pull mulband (pull in on the rectum, sex organs, and navel) and hold for as long as you can, again mentally repeating the mantra Har Har Wha Hay Guru. The maximum time is 62 min. Other comments by Yogi Bhajan include “It has been suggested that this meditation be done in a cool room or at night when the temperature is cooler, because it stimulates the Kundalini directly and generates a great deal of heat in the body. The word Terhula relates to the thunderbolt of Shiva, the ultimate deliverer. Terhula can heal everything. It is a self-healing process. This meditation is for the gunas. It brings the three nervous systems together. It also gives you the ability to heal at a distance, through your touch or through your projection. Many psychological disorders or imbalances in the personality can be cured through practice of this meditation. It is very helpful in getting rid of phobias and especially father phobia.”

Gan Puttee Kriya – A Meditation for Healing the Past, the Present, and the Future

Description of the technique: Sit with a straight spine, either on the floor or in a chair. The back of your hands are resting on your knees with the palms facing upward. The eyes are nine-tenths closed (one-tenth open, but looking straight ahead into the darkness, not into the light below). Chant from your heart in a natural, relaxed manner, or chant in a steady relaxed

monotone. Chant out loud the sound Sa (the *a* sounds like 'ah') and bring your thumb tips and index finger tips together quickly simultaneously; then chant Ta and touch the thumb tips to the middle finger tips; then chant Na and touch the thumb tips to the ring finger tips; next chant Ma and touch the thumb tips to the little finger tips; then chant Ra and touch your thumb tips and index finger tips; next chant Ma and touch the thumb tips to the middle finger tips; then chant Da and touch the thumb tips to the ring finger tips; now chant Sa and touch the thumb tips to the little finger tips; then chant Sa and touch your thumb tips and index finger tips; next chant Say (sounds like the word 'say' with a long 'a') and touch the thumb tips to the middle finger tips; then chant So and touch the thumb tips to the ring finger tips; now chant Hung and touch the thumb tips to the little finger tips. Chant at the rate of one sound per second. The thumb tip and finger tips touch with a very light 2–3 lbs of pressure with each connection. This helps to consolidate the circuit created by each thumb–finger link. Start with 11 min and slowly work up to 31 min of practice. To finish, remain in the sitting posture and inhale and hold the breath for 20–30 s while you shake and move every part of your body. Exhale and repeat this two more times to circulate the energy and to break the pattern of tapping, which affects the brain. Immediately proceed with focusing the eyes on the tip of the nose (the end point that you cannot see) and breathe slowly and deeply for 1 min. The sounds used in this meditation are each unique and they have a powerful effect on both the conscious and subconscious mind. The sound Sa gives the mind the ability to expand to the infinite, Ta gives the mind the ability to experience the totality of life, Na gives the mind the ability to conquer death, Ma gives the mind the ability to resurrect, Ra gives the mind the ability to expand in radiance, this sound purifies and energizes, Da gives the mind the ability to establish security on the earth plane, it provides a ground for action, Say gives the totality of experience, So is the personal sense of identity, and Hung is the infinite as a vibrating and real force. Together, So Hung means 'I am Thou.' The unique qualities of this 12-syllable mantra help cleanse and restructure the subconscious mind and heal the conscious mind to ultimately experience the super-conscious mind.

Medical Meditation for Habituation – A Technique for Curing Addictions

Description of the technique: Sit either in a chair or on the floor. Straighten the spine and make sure the first six lower vertebrae are locked forward. This means the lower back is pushed forward as if you are 'at attention.' Make fists of both hands and extend the thumbs straight. Place the thumbs on the temples and find the niche where the thumbs just fit. This is the lower anterior portion of the frontal bone above the temporal–sphenoidal suture. This place is usually sensitive to the touch, so do not apply pressure per se, simply touching is adequate. Lock the back molars together and keep the lips closed. Vibrate the jaw muscles by alternating the pressure on the molars. A muscle will move in rhythm under the thumbs. Feel it massage the thumbs. Keep the eyes closed and look at the brow point – the 'third eye' – the point where the top of the

nose meets the forehead. Silently vibrate the five primal sounds 'Sa Ta Na Ma' at the brow point (the fifth sound here is the sound 'ah' that is basic to the other four sounds. The effects of each syllable of the mantra have been described earlier in the technique called Gan Puttee Kriya. This mantra is claimed to put one's consciousness through the cycle of infinity, life, death, and rebirth. Continue for 5–7 min and slowly build the practice to a maximum of 31 min.

'Shabd Kriya' – A Meditation for Treating Insomnia, Regulating Sleep Stages, Promoting the Growth of Personality, and Mastering the Mental Realm

Description of the technique: Sit with a straight spine with both feet flat on the floor. Place the hands in the lap, palms up with the right hand over the left hand. The thumb pads, last joint, are touching together and point forward. Focus the eyes on the tip of the nose with the eyelids half closed. The tip of the nose is the point you cannot actually see, but if you use a finger tip to touch the end of the nose; this is where the eyes are focused. This is not an 'eyes-crossed' posture but may seem like it initially. The sides of the nose will look blurry during the focus, but a real cross-eyed posture makes the sides of the nose appear to balloon up, which is not the correct eye posture. Inhale through the nose only in four equal parts, mentally vibrating the mantra Sa Ta Na Ma (one syllable per part of the 4-part inhale). Hold the breath and mentally vibrate the 4-syllable mantra a total of four times for a total of 16 'beats', and then exhale through the nose in two equal parts mentally vibrating the mantra Whahay Guru, one word per part or beat. This equals a 22-part or 22-beat cycle. Continue for at least 15 min and work up to 62 min. When finished, relax completely and go to sleep. One of the caveats with this meditation technique is that it may disrupt sleep for several weeks when it is first practiced, prior to having its healing benefits.

The Jupiter Finger Chakra Meditation – A Meditation for Abused and Battered Children for Developing a Balanced Psyche

This meditation was originally taught by Yogi Bhanjan as a meditation for children, but it can also be practiced by adolescents and adults. It was claimed that anyone with past trauma resulting from abuse and victimization will benefit from this practice. Even someone without past trauma supposedly can improve the balance of their personality by its use. This meditation helps to balance the chakras and meridians in the body. It is an excellent meditation technique for children. It will evoke many feelings that have stuck with the individual since childhood. It will help adults get rid of the 'childhood syndrome,' a condition where they cling to something that is already finished. This syndrome can easily ruin and limit anyone's life.

Description of the technique: Sit with a straight spine either on the floor or in a chair. Place the left hand on the chest at the heart center with the fingers and thumb pointing toward the right. Use the index (Jupiter) finger of the right hand (keep the other fingers closed in a relaxed fist with the thumb over the other fingers) to touch in sequence the following

points – (1) the middle of the lower lip, (2) the tip (end) of the nose, (3) the outer skin area or edge/corner of the eye socket (the region of the skull bone near the outside of the eye), and (4) a point about three-fourths of an inch above the indent of the nose which is just below the forehead (a point that would be the midpoint between the eyebrows). Chant the following mantra (Sa Ta Na Ma) out loud in sequence with the touching of the respective points. Chant Sa as one touches the lower lip, Ta as one touches the tip of the nose, Na as one touches the outer edge of the eye socket, and Ma as one touches the forehead point. But since there are two eyes and thus two outer edges of the eye socket, the patient alternates sides each time they go up in the sequence. Start by touching the right side first. Each round of touching the points and chanting the mantra through takes about 4–5 s. Keep the eyes closed when doing this meditation. The maximum time is 33 min and it can be practiced for the full time the first time. Younger people may have to start with 11 min or even less. When ending the technique, inhale deeply and hold the breath, then while holding the breath, feel the ‘inner child’ by self-hypnosis, exhale, inhale, and hypnotize one’s self, picture oneself as a child in one’s own heart, where the left hand has been resting, concentrate, exhale, inhale, and repeat the picture of one’s self, bless that child, be that child, and let the breath go.

The Ultimate Pranayam – Sodarshan Chakra Kriya

The developmental stages of self-realization and awareness experienced through the practice of this technique were in part described by the ancients: “I am powerless, my power has been broken, my unstable mind has been stabilized, and my unadorned soul has been adorned. I drink in the Ambrosial Nectar. Within my mind, I utter the Name of the Primal Lord, the source of all virtue. My vision, that You and I are separate, has melted away. I worship the One who is worthy of being worshipped. I trust the One who is worthy of being trusted. Like water into water, I merge into the Lord. I meditate and contemplate the Luminous, Triumphant Lord. I am lovingly absorbed in the Nirvana of God.”

Yogi Bhajan comments: “If you can do this meditation for 62 min to start with, and develop it to the point that you can do it 2 1/2 h per day, it will give you ‘Nao niddhi, athara siddhi’ or the nine precious virtues and 18 occult powers. And in those 27 total virtues of the world lies the entire universe. When practiced 2 1/2 h every day, it makes a perfect superman out of you. It purifies, it takes care of the human life, and brings together all 27 facets of life and makes a human perfect, saintly, successful, and qualified. This meditation also gives one the Pranic power. This kriya never fails. It can give one all the inner happiness and bring one to a state of ecstasy in life. It will keep all the chakras open so you will not fall into any ditch. It is better to live a life of courage than to live many many years like a coward. Courage is in inner vitality, and if all your chakras are open, you will not be handicapped in vitality. You will get a grip on your life. No matter how bad circumstances are, your intuition will guide your way to happiness, and your vitality shall support you.”

This pranayama technique, as a single technique, is the ultimate in Kundalini Yoga meditation techniques. Its multiple facets make it a completely balanced technique. When

practiced alone, there are no other requirements for other techniques to achieve full human development. For example, the rate of respiration can eventually be reduced to less than one breath per minute during practice. This technique changes one’s perception of the self and the world. The practitioner develops a consciousness that becomes the living experience of the timelessness of life, transcending time and space. The negative patterns of the subconscious mind are eliminated. This technique helps to overcome the stumbling blocks of the inner world. It helps to cut through inner darkness, and it eliminates both neurotic and psychotic mental patterns. According to Yogi Bhajan: “You are cleaning your subconscious. You can clean it as fast or as slowly as you want. You have to decide how much time you want to devote to getting rid of the fear, anger, insecurity, etc., . . . the negative thoughts in your subconscious that block your success and prosperity.”

Description of the technique: Sit with a straight spine on the floor in a cross-legged position, or on a firm chair with both feet flat on the ground. The lower spine (lumbar region) is pressed forward slightly. This spinal posture signals the nervous system to remain alert by setting a ‘ready mode.’ The eyes are open and focused at the tip of the nose – the end that you cannot see. With eyes focused at the tip, the sides of the nose appear to blur. Some individuals are less able to achieve this eye focus, and practice over time can help to overcome this deficit. This eye position is called ‘Ajna Band,’ which means mind lock. Focusing the eyes in this way pressurizes the optic nerve and helps to stabilize thought processes. It is a common element with meditation techniques that are used to tranquilize the mind. Initially, the eye muscles may become sore due to a lack of use. The breathing pattern has three phases:

1. Use the right thumb tip to block off the right nostril (close the nostril by covering the end, not by pushing in the side); keep the four fingers of the right hand pointed up straight; and inhale slowly and completely fill the lungs.
2. While holding the breath, begin pumping the navel point in and out for a total of 48 pumps while mentally vibrating the sound Wha Hay Guru 16 times per 48 pumps, with one pump per Wha, one pump per Hay, and one pump per Guru, or 16×3 sounds = 48 pumps.
3. Then, slowly exhale through the right nostril by first closing off the left nostril with the end of the index finger. This three-phase cycle is repeated. (Note that the reverse pattern of inhaling through the right nostril, holding, and exhaling through the left nostril is not performed.) Yogi Bhajan recommended a counting scheme to maintain the exact numbers of pumps and ‘Wha Hay Gurus.’ “For counting 1–16 (Wha Hay Guru’s), one (with three pumps), two (with three pumps), three (with three pumps) is counted with the little finger moving slightly three times, four (with three pumps), five (with three pumps), and six (with three pumps) moves the ring finger three times, seven (with three pumps), eight (with three pumps), nine (with three pumps) moves the middle finger three times, ten (with three pumps), eleven (with three pumps), and twelve (with three pumps) moves the index finger three times, thirteen (with three pumps), fourteen (with three pumps), fifteen (with three pumps) moves the thumb slightly for three beats, and sixteen (with three pumps) brings the index finger over to close the left

nostril just before exhaling through the right nostril." When ending this meditation, after the last exhale, inhale and hold the breath for 5–10 s and mentally circulate the energy produced; then exhale. Then stretch and shake the entire body for 1 min to complete the exercise. The bija mantra *Wha Hay* Guru induces a state of great wonder, bliss, and ecstasy, an experience of the totality of the universe, the universal nature of consciousness, and the oneness and unity of creation. Eleven minutes is the first peak of accomplishment, followed by 31 min, 62 min, and 2 h and 31 min.

Descriptions of Other Popular Meditation Techniques

This section includes five popular meditation techniques called the Mindfulness Meditation, Sahaja Yoga Meditation, Transcendental Meditation®, Ujjayi meditation as taught by Swami Sivananda, and Zen Meditation. Other similar meditation techniques are also widely taught, including the Vipassana technique, the Relaxation Response by Herbert Benson, the four Art of Living meditations as taught by Sri Sri Ravi Shankar, and techniques by Swami Muktananda of the Siddha Yoga lineage, Swami Satchidananda of the Integral Yoga Society, Swami Rama of the Himalayan Research Society, and Swami Ramdev of the Divya Yog Mandir Trust. Most of these techniques are common to the Hatha Yoga meditation tradition.

Mindfulness Meditation Technique

The standard description for this meditation is the following: One can practice Mindfulness Meditation by sitting in an appropriate upright position, cross-legged, and by focusing on the breath or anything else, such as mental and physical processes which help the practitioners to become aware of their present thought patterns and inner state. The practice of Mindfulness Meditation focuses one's attention on one's thoughts, actions, and present moments nonjudgmentally. It does not encourage evaluating or thinking about past actions, nor does it take one's thoughts into the uncertain future. Mindfulness Meditation helps and trains the mind from getting distracted by outside disturbances and enables one to focus one's thoughts and relax the mind.

Description of the technique:

1. Find a quiet and comfortable place. Sit in a chair or on the floor with your head, neck, and back straight but not stiff.
2. Try to put aside all thoughts of the past and the future and stay in the present.
3. Become aware of your breathing, focusing on the sensation of air moving in and out of your body as you breathe. Feel your belly rise and fall, the air enter your nostrils and leave your mouth. Pay attention to the way each breath changes and is different.
4. Watch every thought come and go, whether it be a worry, fear, anxiety, or hope. When thoughts come up in your mind, do not ignore or suppress them but simply note them, remain calm, and use your breathing as an anchor.
5. If you find yourself getting carried away in your thoughts, observe where your mind went off to, without judging, and simply return to your breathing. Remember not to be hard on yourself if this happens.

6. As the time comes to a close, sit for a minute or two, becoming aware of where you are. Get up gradually.

Sahaja Yoga Meditation as Taught by Shri Mataji Nirmala Devi

Shri Mataji Nirmala Devi says on her Web site: "You can receive your Self Realization (connection with your Self) while sitting in front of your computer. The only condition is your sincere desire to have it."

Description of the technique (extracted from her Web site): "During the experience you will keep your left hand with the palm upwards on your lap and place the right palm on various parts of the body on your left side only with a specific sequence (see below), while keeping your eyes closed for the entire duration. This way you will be free of distractions and able to keep your attention inside. The sequence for placing your right hand during the guided meditation is the following (on left side only), first hold it with the palm against the chest at the heart center level, then on the chest below the nipple line, then just above the waist line, then against the side of the neck; for the next three positions, the right hand is held in the middle of the forehead, the back of the head, and then the top of the head. Now, after the end of the meditation, see if you are feeling relaxed and if your thoughts have slowed down or gradually disappeared. This is the first stage of meditation – thoughtless awareness – where you are fully alert but without any thoughts, in a state of pure and peaceful consciousness. Now see if you can feel a sensation of a gentle cool breeze in your palms and above your head. It might be warm in the beginning which is a sign that your Kundalini energy is purifying your chakras, but it will eventually cool down. You can verify it by placing your left palm 6–12 in. above your head, then trying with the right palm. If you are unable to feel it, you have probably not forgiven everyone. Say again from your heart, 'Mother, I forgive everyone,' a few times and check again if you feel the cool breeze above your head. This is the beginning of a fantastic journey into your own spiritual existence. It is a door opened to a new dimension of your awareness, which you can open and explore. If sustained through regular meditation, you will be able to feel your subtle centers (chakras) as well as the chakras of others on your fingertips, and correct them using your spiritual energy (Kundalini)."

Transcendental Meditation® Technique

Transcendental Meditation®, also called the "TM" technique, was formulated by Maharishi Mahesh Yogi. Some claims about the TM technique are the following: "The ordinary thinking process is said to be transcended (or gone beyond) as the awareness gradually settles down and is eventually freed of all mental content, remaining silently awake within itself, and producing a psychophysiological state of restful alertness." These periods are referred to as "pure consciousness or transcendental consciousness." Steps in TM® Meditation: Step 1, Sit comfortably; Step 2, Close your eyes; Step 3, Engage in effortless mental repetition of a special sound for approximately 20 min, twice daily. Note: The special sound in Step 3 is a Sanskrit mantra(s) that is claimed to be exclusive to the TM® tradition. These mantras are taught when a person pays

for the teachings and the recipient is instructed not to share his or her mantra with others.

Ujjayi Pranayam Meditation

The ujjayi meditation technique, as described here, along with its claimed attributes is one of at least seven different meditation techniques taught by Swami Sivananda. This technique is a standard practice in many Hatha Yoga traditions.

Description of the technique: Sit in your usual asana. Close the mouth. Inhale slowly through both the nostrils in a smooth uniform manner. Retain the breath as long as you can; do it comfortably and then exhale slowly through the left nostril by closing the right nostril with your right thumb. Expand the chest when you inhale. During inhalation, a peculiar sound is produced owing to the partial closing of the glottis. The sound produced during inhalation should be of a mild and uniform pitch. It should be continuous also. This Kumbhaka may be practiced even when walking or standing. Instead of exhaling through the left nostril, you can exhale slowly through both nostrils. Swami Sivananda comments on this technique. "This removes the heat in the head. The practitioner becomes very beautiful. The gastric fire is increased. It removes phlegm in the throat. Asthma, consumption and all sorts of pulmonary diseases are cured. All that arise from deficient inhalation of oxygen and diseases of the heart are cured. All works are accomplished by Ujjayi Pranayam. The practitioner is never attacked by diseases of phlegm, nerves, enlargement of the spleen, dyspepsia, dysentery, consumption, cough or fever. Perform Ujjayi to destroy decay and death."

Zen Meditation Technique

Zen Buddhist meditation originated in India and was introduced to Japan from China in 1191 AD. Sit on the forward third of a chair or a cushion on the floor. Arrange your legs in a position you can maintain comfortably. In the half-lotus position, place your right leg on your left thigh. In the full lotus position, put your feet on opposite thighs. You may also sit simply with your legs tucked in close to your body, but be sure that your weight is distributed on three points: both of your knees on the ground and your buttocks on the round cushion. On a chair, keep your knees apart about the width of your shoulders, feet firmly planted on the floor. Take a deep breath, exhale fully, and take another deep breath, exhaling fully. With proper physical posture, your breathing will flow naturally into your lower abdomen. Breathe naturally, without judgment or trying to breathe a certain way. Keep your attention on your breath while practicing this Zen meditation. When your attention wanders, bring it back to the breath again and again – as many times as necessary! Remain as still as possible, following your breath and returning to it whenever thoughts arise. Be fully, vitally present with yourself. Simply do your very best. At the end of your sitting period, gently swing your body from right to left in increasing arcs. Stretch out your legs and be sure they have feeling before standing. Practice easy Zen meditation every day for at least 10–15 min (or longer) and you will discover for yourself the treasure-house of the timeless life of zazen – your very life itself.

The Art of the Practice and the Application of the Techniques

Today, a majority of people practice meditation techniques for the purpose of achieving a calmer state of mind, reducing stress, and finding inner peace. Some practice to gain the experience of a greater or transcendental awareness. Many also seek a more natural approach to the treatment of psychiatric disorders and psychological issues, and for improving social relationships. However, in addition to self-healing, the ancients devised the science of meditation primarily for the purpose of exploring the unknown realms of the psyche and for mastering the realms of consciousness. They understood the possibility of devising a neurodevelopmental approach to awakening the dormant regions of the brain and developing unique mental powers, or what yogis called the siddhis.

The ancients apparently achieved a great understanding for the nature of consciousness. They discovered the chakras, the subtle energy centers that supposedly relate to the eight different levels of consciousness. This is a very foreign area for the western scientist who has at least two primary questions about the nature of consciousness: (1) Can consciousness transcend time and space? and (2) Is consciousness only an epiphenomenon of the brain? The ancients devised a practical and systematic view of consciousness that has eight discrete levels. Yogis viewed the chakras as repositories or centers for psychic or mental energy. They claimed that an individual's consciousness is then determined and affected by the amount of energy and the distribution of activity in the eight centers, and that this is related to the individual's behavior, personality structure, and level of awareness. Ultimately, meditation techniques are supposedly a means of healing the mind and also attaining higher levels of consciousness.

In addition to the more subtle nature of the chakras, each chakra also supposedly has a physiological correlate in the body. The first chakra is related to the area of the rectum (sacro-coccygeal plexus); the second chakra to the sex organs (sacral plexus); the third chakra to the navel point region (solar plexus); the fourth chakra to the heart center (cardiac plexus); the fifth chakra to the thyroid and parathyroid or throat center (laryngeal plexus); the sixth chakra, called the 'third eye,' to the activity of the pituitary gland; the seventh chakra, called the 'crown center,' to the pineal gland and cerebral cortex; and the eighth chakra is the aura or the psychoelectromagnetic field that surrounds the body.

The intensity of activity in any one chakra supposedly affects one's world perspective, understanding of cause and effect, and source of motivation and desire. An individual who lives mainly in the consciousness of the first chakra is concerned primarily with survival. His or her action and values are based solely on the need to survive. Fears and paranoia coincide with this center, as do instincts, concerns about elimination, destructive sexual activities, and habitual and addictive activities. Blocks and imbalances in this center can lead to a rigid and stubborn mentality and a range of diseases. Second chakra consciousness reflects a mentality directed mainly toward reproduction and sexual activities. Overactivity here leads to sexual neuroses, whether it is in the form of abnormal sexual indulgence or a 'puritanical' and abstinent mentality.

A balanced second chakra helps establish a creative and expressive mentality. The third chakra is the center of power, territory, and ego: the 'Me' mentality prevails to the exclusion of the well-being of others. This center is the source of physical well-being. When it is weak, deficiencies lead to a wide range of illnesses and a weak character, drive, and will power. The first three levels are claimed to be equivalent to the nature of the beast and all three of these levels also prevail throughout the animal kingdom. Much of society's ills are the result of an imbalance in the first three chakras. Yogis view development in going from the third level of consciousness to the fourth as the biggest step in human development. The fourth chakra, the heart center, embraces the human element of compassion, the attitude to nurture and give without consideration of the cost to one's self. This center is considered to be the first level of 'higher consciousness,' where the human can experience a true expansion in awareness. Love is born through activity in this center. When the heart chakra is not awakened, greed, selfishness, and ego dominate. The fifth chakra is the center for creative communication through expression. When this center is active, the individual can speak and live a blunt truth, and when it is blocked, that person will feel stifled and unable to be direct and truthful with others. A characteristic of 'higher consciousness' that supposedly manifests with this center is that of clairaudient awareness. The sixth chakra allows for both sides of the coin to be seen and here the dual nature of life is understood in the sums of the polarities rather than simply as 'right versus wrong.' This center is said to be responsible for intuition and clairvoyant abilities. Supernatural abilities are also said to be governed by this center. The seventh chakra is the center for saintly intelligence, and thoughtless awareness where actions are based on concern for the highest good for all. This center is called the 'thousand-petalled lotus,' and it is said to be the seat of universal consciousness where there is a clear realization of how all things are connected. The eighth chakra is the aura, and how it functions is representative of the relationship of all the other chakras. This chakra is said to act both as a shield against illness and calamity and as a source of attraction for events in one's life. Awareness in this center takes one's consciousness beyond the realm of time and space, into the realm where the past, the present, and the future merge. It is said that if an individual lives in the consciousness of this center too long, the world will pass them by.

The fully awakened yogi supposedly has the ability to consciously activate any and all chakras in any given combination for achieving the most effective outcome under any given situation. Supposedly normal individuals have one chakra that predominates to establish their primary personality, and over time, this center may change as a personality matures. This growth process is supposedly one of the benefits of some meditation techniques.

The Development of a Personal Practice

Some systems offer a single meditation with a supposed benefit or range of benefits, and some systems offer a few techniques that vary significantly in their overall effects and benefits. The original parent science of the yoga, called Kundalini Yoga, the Yoga of Awareness, as taught by Yogi Bhajan, has thousands

of different meditation techniques. Some are much easier than others to practice, and the approach for the beginner, novice, or intermediate practitioner should be based on what he or she hopes to achieve and how much time and effort he or she wants to commit. The best advice here is to experiment with a variety of techniques and to seek the direct guidance from a well-trained and talented teacher, regardless of the system that is chosen.

The Clinical Application of Techniques for Patient Populations

All the techniques described earlier are claimed to be of benefit for mental health purposes. However, the evidence presents a challenge because of the relatively poor overall quality of the published clinical trials. Some of the best- and well-designed randomized controlled trials that showed substantial efficacy still require replication by others. However, there is reason to be optimistic as yogis had discovered techniques that are supposedly 'disorder-specific.' These disorders include OCD, depression, generalized anxiety disorder, phobias, bipolar disorders, addictions and impulse control disorders, sleep disorders, ADHD and comorbid disorders, PTSD, schizophrenia, the variants of the personality disorders, the pervasive developmental disorders, and cancer. None of these disorders are new and yogis had recognized these disorders even in ancient times. Individuals who are interested in attempting to treat any of these disorders with meditation techniques should seek the assistance of those who are highly trained both with the specific techniques and the specific disorders. In time, clinical trials will likely test the efficacy of these techniques in well-designed studies and no doubt compare meditation techniques from different systems in 'head-to-head' trials.

Summary

The discovery of meditation techniques goes back to the time before the advent of the formal religions. Today, there are at least 5000 different meditation techniques that are known, discovered by the ancient yogis. However, only about six techniques are commonly practiced in the West. While hundreds of different scientific studies have been conducted, the majority have used the Transcendental Meditation® technique, the Mindfulness Meditation technique, the Relaxation Response, the Zen Meditation technique, and a variety of Hatha yoga meditation techniques. A recent systematic review of the scientific literature finds that there are many uncertainties about the practice of meditation, the scientific research does not have a common theoretical perspective, the work is characterized by poor methodological quality, and that firm conclusions cannot be drawn about the health effects based on the available evidence. However, since this research is only in its infancy and very little funding has been appropriated for this work, it is not surprising that little can be said about the positive virtues of the work. Nonetheless, there are a number of well-designed trials that show unique and important results. In addition, since there are so many different, highly structured, and complex techniques, along with the deep yogic

insights into the nature of consciousness, there are good reasons to be optimistic about the true richness of this topic for future study. A definition of meditation is offered – the art and science of how to manipulate the thought waves to achieve a state of thoughtlessness, wherein the individual experiences both existence and nonexistence simultaneously, and where the field of consciousness then becomes a novel sensory experience, wherein new levels of awareness and new skills in the mental realm are developed.

Memory

G A Radvansky and A K Tamplin, University of Notre Dame, Notre Dame, IN, USA

© 2012 Elsevier Inc. All rights reserved.

Glossary

Category An organized set of conceptual entities (objects, events, concepts, etc.) that are treated as similar to one another in some respect.

Episodic memory Memory for knowledge localized in time and place.

Explicit memory Memory that involves a deliberate and conscious act of remembering (e.g., recognition and recall).

False memories Belief in having a memory, when in fact, it did not occur or is altered from what was first encoded.

Implicit memory Memory that operates through unconscious mechanisms.

Long-term memory A large-capacity portion of memory where information is stored for long periods of time, possibly lasting a lifetime.

Memory The mental systems, representations, and processes involved in the retention of information.

Procedural memory Memory for performance activities, including stimulus–response associations (e.g., knowledge of how to ride a bike or drive a car).

Schema General world knowledge of well-defined common human experiences used to organize new information and reconstruct information that may have been forgotten.

Semantic memory Memory for encyclopedic general world knowledge which does not refer to a specific event in the individual's life.

Short-term memory A limited capacity portion of memory where information lasts for only a short period of time, sometimes referred to as working memory.

Spreading activation The idea that the activation or availability of one conceptual entity spreads to other related conceptual entities through a complex of associative pathways.

Introduction

Several characteristics of memory are of interest in how people encode, store, and retrieve information. The issues of concern include (1) the specification of different types of memories, (2) whether memories are permanent, and (3) how aspects of memory impact people's daily lives.

Ways of Understanding Memory

Memory holds information as widely varied as knowledge of people's faces, how to drive a manual transmission, phone numbers, the names of the countries of Europe, and the smells of good home cooking. A complete account of memory must specify how memories are created, their organization and influence on one another, and how they are retrieved. Because memory cannot be directly observed, theoretical accounts make use of metaphors. Models of memory used metaphors based on technological innovations, starting with a filing cabinet or bin system. Later, with the expansion of the telephone, memory was referred to as though it were a switch board. With the advent of the digital computer, models of memory adopted a computer metaphor, along with the processes involved in encoding, storing, retrieving, and operating on information. Late in the twentieth century, there was an effort to consider how information might be represented neurally, with people using a brain metaphor. More recently, there has been a focus on how memory is used for living. This is a more functional approach that assesses the influences of embodied or grounded cognition. In essence, these approaches look at how people interact with the environment and consider how

memory evolved and has been adapted to meet those environmental demands.

Types of Memory

Memory exhibits different characteristics under different conditions. For instance, a person might have trouble recalling the names of people met at a party a few weeks ago, but might remember how to ride a bicycle throughout his life. A person can often repeat back what was just said immediately afterward, but not a week later. Experiences such as these have led to the suggestion that there are different types of memory, and these types have different characteristics.

Short- and Long-Term Memory

Many conceptualizations distinguish between long-term and short-term memory. Traditionally, long-term memory contains a lasting record of information, whereas short-term memory exists for only a short period of time (<30 s) unless actively maintained or transferred to long-term memory. Moreover, only a limited amount of information can be actively processed in short-term memory, typically described as an average of 3, 4, or 7 units of information, depending on the particular theory. So, while long-term memory contains information that has accumulated over a lifetime, short-term memory's limited capacity allows only a small set of information chunks. More details on how memory and brain structures are related are discussed elsewhere in this encyclopedia. In contrast, some theories suggest that short-term memory is only a portion of

long-term memory that is currently active rather than a separate memory itself. In these views, the limit on short-term memory capacity depends on the amount of long-term memory information that can be called into consciousness at any one time.

A more elaborate idea over short-term memory that has emerged is that of a *working memory*. This includes not only a short-term store aspect, but also the active processing of information. Working memory itself may be divided into subcomponents, such as a phonological loop for linguistic information, a visual-spatial sketchpad for visual-spatial information, an episodic buffer for integrating information from various modalities and long-term memory, and an overarching central executive that controls information processing. These subsystems may be semiautonomous. So, while one subsystem is actively processing information, another might be available for other tasks. For example, it is easier to read a paragraph (a phonological loop task) if one is simultaneously trying to remember the location of a dot on a screen (using the visual-spatial sketchpad) than if one is trying to remember a set of words (another phonological loop task).

In general, information remains in short-term/working memory until something comes along to force it out. Because capacity is limited, new information is likely to push out the old, leaving only the most recently encountered information available. This process is called interference. This leads to what is called the recency effect in which the recently acquired information is more available than earlier information. For example, if a person is given a list of names and then recalls them, the names at the end of the list will have a better chance of being remembered because they have not impinged upon by further information.

Single versus dual processes

One concern about memory is whether retrieval involves a single process, or two separate processes. At the crux of this issue is the subjective awareness of what it is like to remember in different ways. In some cases, a person is consciously aware of having experienced something and is able to remember a number of details about an event, such as how it was learned, where people were, who told them, the sound of a person's voice, and so on. These vivid memories are called recollections. For example, if you can remember a lot of details about some event, such as a car accident you were in. Comparatively, in other cases a person may not remember many if any, details. The person simply knows that he or she knows something. For example, if you know what a platypus is, but have no memory of learning it, this would correspond to one of these types of memories.

According to a single process view, various parts of the brain act in concert in the service of a single unified search. The primary difference between recollections and known memories is how much information is recovered. The attraction here is that this has the advantage of being theoretically parsimonious. In contrast, for a dual process view there are two processes that operate in parallel to help retrieval. The first is a fast-acting heuristic-like familiarity process that assesses how strong a memory is. The stronger it is, the more likely a person will say it is known. This is a largely unconscious process. The second process is a slower, more deliberative search which

actively seeks various details in memory to consciously retrieve. These two types of memory processes may involve different neurological structures, and can be doubly dissociated. This suggests that memory uses different methods to retrieve different memories.

Organization of Long-Term Memory

Information in memory is often organized on the basis of both its content and the context in which it was presented. However, not all types of information are represented in the same way. Theories of long-term memory postulate different systems and subsystems, each of which is dedicated to different types of information, and each exhibits properties that are not found in the others. Endel Tulving's monohierarchy of memory provides a useful framework for conceptualizing how different types of information are organized and remembered. Other types of organizations will be considered at the point in which they conform to the different levels of this hierarchy.

Tulving's Monohierarchy

Tulving's monohierarchy is a three-level organization, with one system at each level, and the higher systems being dependent on the lower ones. These systems are procedural, semantic, and episodic.

Procedural memory

Procedural memory, at the most basic level of the monohierarchy, contains memories for how to perform activities, including stimulus-response associations. Examples of procedural memories are knowledge of how to ride a bike or drive a car, how to play the drums, how to solve a puzzle, and how to walk. The procedures contained here can be activated without conscious awareness. Thus, the procedural knowledge that governs driving a car is applied with minimal attention to the specific sequence of steps needed to do this. As this observation implies, information in procedural memory is often difficult to articulate, but lasts for quite a long time. In addition, procedural knowledge is relatively resistant to deliberate changes to add, modify, or rearrange various components.

Semantic memory

Semantic memory, the second level of Tulving's monohierarchy, contains general knowledge that does not refer to a specific event in the individual's life. As such it is an encyclopedic knowledge. The contents of semantic memory are retained for a long time. Semantic memory differs from procedural memory in that people can often articulate the information that is stored. Semantic memory is typically conceptualized as being highly integrated in which related concepts are functionally stored together. This organizational structure of semantic memory can be seen in its use. For example, it exhibits effects of relatedness. Information is identified faster if it is preceded by information that has similar content.

Some theories conceptualize semantic memory as an associative network of concepts. Each concept represents a separate entity that is associatively linked to other entities by pathways. Concepts that are more similar to one another are more closely

associated in the network. So, when information from one concept is used, other concepts that are associated with it are also brought to mind. There are also theories of semantic memory that suggest that it is composed of sets of features that define the nature of things, how they function, and how we relate to them. These feature-based views do not assume a structure to semantic memory, but assume that apparent structure is derived from how information is used. Two types of mental representations in semantic memory, schemas and categories, are worth noting. Further explanation on this is dealt elsewhere in this encyclopedia.

Schemas are semantic memory structures that help people organize new information they encounter. In addition they may help a person reconstruct bits and pieces of memories that have been forgotten. For example, if you remember going to a new restaurant, you may not actually remember reading the menu, but your schema for restaurant dining can fill this information in. Each schema is a structured representation of all the information that a person has, referring to a well-defined domain of common human experience, such as washing a car, applying to a school, or reading a newspaper. Schemas help people figure out things that they may have temporarily or permanently forgotten, or even missed entirely. Anyone who has begun watching a television show or movie from the middle of the story has had the experience of being able to figure out what has gone on previously without having actually seen it. People essentially fill in the gaps with what they know about similar situations. This reconstructive process can sometimes lead people astray. In James Bartlett's famous work on schemas, students in England were given a Native American folktale to read. This folktale possessed a structure quite different from the stories of English culture. Bartlett found that as time passed, the students forgot more of the details and structure of the original story. The forgotten portions were replaced with ideas that were Westernized transformations of the story. The students had filled in the gaps in their memory with schematic knowledge of what they knew about folktales and the topics covered in the folktale.
