At first glance, social loafing and social facilitation may appear contradictory. After all, social loafing suggests that the presence of other people often reduces our motivation and performance, whereas social facilitation suggests that the presence of others can enhance our performance (unless the task is complex or we are unfamiliar with it). However, this apparent discrepancy is readily resolved by recognizing that the two phenomena consider unique aspects of social motivation by systematically manipulating different task environments that produce distinctive types of other people who are present in the situation. Specifically, the social loafing paradigm compares performance on collective tasks with performance on coactive tasks. Equal numbers of people are physically present in both conditions. The only difference is whether individual inputs are combined into a group total. Social loafing research thus speaks to the issue of how working on a collective task where inputs are combined into a group total affects one's motivation level. As highlighted by the evaluation perspective, when inputs are being combined, one has the opportunity to hide in the crowd and rely on the efforts of others. Additionally, as highlighted by the dispensability and expectancy-value perspectives, individuals may feel lost in the crowd and unable to make a distinctive or valuable contribution to the group.

In contrast, the social facilitation paradigm compares performance on individual tasks where participants work alone to performance on either coactive tasks or on individual tasks that are performed in the presence of either observers or an audience. Therefore, the number of people present across the alone and coaction conditions is systematically varied, and individual inputs are never combined into a group score. Thus, social facilitation research focuses on the effects that the mere presence of others has on individual performance rather than on the motivational effects of working with others on a collective task.

Although research on social loafing and social facilitation has developed into separate literature streams that focus on different aspects of social motivation, they nevertheless have some commonalities and compatibilities. Social facilitation explanations based on differences in the mere presence of others cannot account for social loafing, because the number of people present across conditions (and therefore, the levels of drive, arousal, or distraction) is held constant. However, several of the theories developed to explain one of these phenomena appear to be readily applicable to the other phenomenon as well, provided that the nature of the other people present is accounted for appropriately. Specifically, as previously mentioned, evaluation explanations provide viable accounts of both social loafing and social facilitation effects from a common

evaluation potential basis. Namely, this perspective suggests that individuals engage in social loafing because they are less easily evaluated on collective tasks than on individual tasks, and suggests that social facilitation occurs because individuals experience more concern for evaluation when coactors or observers are present than when they are working alone. The logic of social impact theory can also provide a means for integrating social loafing and social facilitation by positing that coactors and observers serve as additional sources of social impact when people work individually, but that coworkers provide a means for diffusing the impact of an outside source of social impact across multiple group members when people work collectively. The arousal reduction viewpoint expands on that social impact logic to state that the presence of others can actually reduce arousal when those others are coworkers rather than coactors or observers. From this latter perspective, social loafing is inversely related to social facilitation such that arousal reduction should reduce performance on simple collective tasks, but should enhance it on complex or unfamiliar collective tasks.

Relationships with Other Phenomena

Social loafing and social facilitation address the basic, fundamental issue of how the presence of other people influences the motivation and performance of individuals. Two additional phenomena address other aspects of the influence that the presence of others can have on individual behavior. Specifically, research on social dilemmas examines how conflicts between individual and group interests affect individuals' use of shared resources and contributions to pooled resources. Research on social inhibition examines situations in which the presence of other people can inhibit behaviors that individuals would otherwise engage in.

Social Dilemmas

Social dilemmas are situations in which behaviors that are beneficial to individuals are detrimental to the group as a whole when many individuals choose to engage in those behaviors. Thus, when many individuals are sharing a common resource (such as water, electricity, or space on a public freeway), it is to each individual's short-term benefit to use the resource freely, but when most people behave this way, the resource rapidly depletes or becomes ineffective over time. Similarly, when many individuals are responsible for contributing to a public good (such as a social service organization or a public television station), individuals may be tempted to withhold their contributions to the detriment of the larger group. Social dilemmas have significant conceptual overlap with social loafing, even though the two areas use distinctive research paradigms and are often viewed as separate phenomena. Namely, social loafing can be thought of as a type of social dilemma in which individuals may withhold their contributions from the group for their own convenience or efficiency by working less hard on collective tasks. However, if most members reduce their efforts in this manner, the performance of the group will suffer. Similarly, a social dilemma can be viewed as a situation in which individuals reduce their efforts to manage

pooled resources or to contribute to public goods because they can rely on the efforts and contributions of others. Thus, both phenomena are concerned with how considerations involving other people influence individuals' efforts and contributions on collective tasks or in collective situations. Significant methodological differences between the two paradigms, such as the direct combining of inputs in a small group setting in most social loafing studies and the absence of coactive comparison conditions in most social dilemma studies, require caution in extrapolating findings across the two areas. Nevertheless, the two areas can provide each another with some promising insights and linkages.

Social Inhibition

The presence of others people does not just influence motivation and task performance, it can also influence other types of behaviors. A number of studies of social inhibition have identified situations in which the presence of others inhibits people from behaving as they would when alone. For example, individuals riding in elevators were found to be less likely to take a free hamburger coupon or a free condom when others were riding with them. Similarly, individuals working on a computer task were slower to seek help with a malfunction when other people were present than when they were working alone. This phenomenon does appear to have some conceptual linkages with both social loafing and social facilitation.

In the case of social loafing, the paradigms are clearly quite unique in that social loafing is concerned with effort on collective tasks, whereas social inhibition studies a range of behaviors in situations where individuals do not combine their efforts with those of others. However, from a social impact perspective, both processes might be understood in terms of sources and targets of impact. In the case of social loafing, the other people are present as coworkers and therefore reduce the shared impact of a source of outside influence on the individual. In contrast, in the case of social inhibition, the others present serve as additional sources of social impact on a single individual, increasing the pressure to refrain from behaviors that could bring unwanted reactions or negative evaluations from others. Therefore, although the types of behaviors studied and outcomes produced clearly differ across these paradigms, some similar social influence processes may be operative.

Social inhibition also has some conceptual ties with social facilitation. Once again, the two paradigms clearly differ in that social facilitation focuses on motivation and performance on simple versus complex tasks, whereas social inhibition focuses on a range of behaviors that are relatively distinct from task performance. Yet, both compare behavior in alone settings to behavior in the presence of others, and some common processes may be shared across these phenomena in certain situations. For example, the presence of others could activate evaluation concerns in both situations. In the case of social facilitation, those evaluation concerns might enhance a drive to perform well (enhancing performance on simple tasks and debilitating it on complex tasks), whereas in the case of social inhibition, those evaluation concerns might lead individuals to refrain from behaviors that might lead to unfavorable evaluation or scrutiny from others.

Glossary

Buffering hypothesis Theory that social support is only beneficial to people who are under stress.

Invisible support Social support that is provided to a person without his/her awareness.

Social network The people with whom one has some form of regular social contact.

Social support Resources from the social environment that can be beneficial to psychological and physical health.

Support functions The quality of social relations a person has, as indicated by the material, emotional, and informational resources those social relations provide.

Support structures Quantitative indicators of the form, or nature, of a social network, such as its size or the frequency of contact with different members.

Types of Social Support

Social networks have different dimensions that may influence the availability of social support or the effectiveness of social support in maintaining individuals' health and well-being. Two dimensions of primary importance are the *structural and functional* characteristics of social networks. Structural characteristics are quantitative indicators of a social network. Structural measures of support assess the degree to which individuals are socially integrated in their family and community. Structural aspects of a social network include its size, the amount of contact a person has with social network members, or how many people in a network know one another. Functional characteristics are quantitative indicators of the resources provided by members of one's social network. In other words, functional aspects of social networks are the things that people do for one another, such as providing emotional and material aid.

Social support depends on both the availability of a social network and the provision of particular resources through that network. Obviously, with a network size of zero, one cannot receive any social support. Indeed, differences in social support availability might explain the different health prospects for socially isolated versus socially integrated people: as a group, social isolates have more health problems than people who are integrated in a social network. Aside from such extreme situations, social network functions usually are more critical to an individual's health than structural factors, such as size or type of relations between social network members.

Social networks appear to be supportive, or helpful, in four primary ways: (a) they provide emotional comfort and enhance self-esteem; (b) they provide financial or other material aid; (c) they provide information or advice; and (d) they provide assistance or instrumental help. People often benefit from social support if it is tailored to a particular problem. For example, a person who needs help in making a mortgage payment will probably get more benefit from a friend with money to loan than from one with advice to give. However, emotional support, or confirmation that one is loved and esteemed by others, appears to be beneficial to many individuals and under a number of diverse situations. People who cannot get financial support from friends can benefit psychologically by confiding in friends about their financial problems and worries. It is often

comforting to have someone to talk to about one's problems, even if that person cannot solve the problems.

Finally, it should be noted that social support is not always directly provided by the social network. Sometimes people benefit from having supportive social relations without having any direct exchange of support. The mere perception that support is available is often enough to boost a person's morale or to reduce the negative impact of a stressful situation. Support also can protect individuals' mental and physical health when they are unaware that support has been provided. 'Invisible support,' or support that occurs without the recipients' knowledge, may protect people by preventing exposure to stressors. For instance, one could protect loved ones, or provide invisible support, by keeping bad news from them. Thus, the supportive functions of social networks are not always tangible to the recipient, but are nevertheless effective in maintaining the well-being of that person.

Relation of Social Support to Physical and Mental Health

Social support has been linked to lower levels of mortality, morbidity, and psychological symptomatology. Over a century ago, sociologist Emile Durkheim observed that more socially isolated people had a higher risk of committing suicide than people who were more socially integrated. This was one of the earliest clues that interpersonal relationships might have a role in promoting and maintaining physical and mental health. Since Durkheim's study, many more studies have shown that people who are less socially integrated have more physical and psychological health problems, as well as higher rates of mortality. Many of these studies have tracked how social integration affects health over time. Moreover, some studies have shown that the differential mortality rates cannot be explained by differences in major health risk factors, such as blood pressure, cigarette smoking, or cholesterol levels in isolated versus integrated people. Thus, it appears that social integration can alter health outcomes and that the observed associations are not simply due to health altering the level of social integration.

It is possible that more socially integrated people have lower mortality risk than isolated people because there are health

benefits associated with being socially integrated. There is some evidence that people who have more social ties have low rates of psychiatric disorders, accidents, pregnancy complications, and tuberculosis. People who are more socially integrated also appear to be at lower risk for heart disease and death from heart disease than their isolated counterparts. For example, women who are less socially integrated appear to be at greater risk for ischemic heart disease; men who are less socially integrated are likely to live longer after surviving a heart attack; and Japanese-American men who are socially integrated appear to be less susceptible to coronary heart disease.

The associations between social integration and health outcomes, which range from psychiatric disorders to mortality, suggest that there are health benefits derived from having social ties. Whether the health benefits of social integration are due to the supportive functions provided by social networks is not entirely clear. It may be that some other factor that is associated with social integration or social isolation is responsible for the different health outcomes of integrated versus isolated individuals. For example, isolated people may be economically disadvantaged relative to more integrated people. If isolated people are also indigent, their health problems may be explained by a lack of affordable or adequate health care. To determine whether social support actually has a role in maintaining or promoting health, it is important to look directly at the relation between the quality of social support that people receive and their health status. Knowing that a person has regular contact with their social network, or that he/she has a social network, only indicates that a person can potentially receive social support. Many people who have frequent contact with their social networks may perceive their network as unsupportive or, worse yet, view their social ties as a source of stress.

There is emerging evidence that the quality of social support people receive from others can influence physical health. However, scientific investigations of the relation between social support and health do not always present consistent or clear results. For example, one researcher has found that people who believe that they have adequate social support are at lower risk of mortality than people who believe they have inadequate social support. In contrast, other researchers have found that people who are satisfied with their marriage and social interactions with others do not have a lower risk of mortality than their counterparts who are dissatisfied with their social relations. There are several reasons why studies present an inconsistent picture of the effects of social support on health. A primary reason is that social support is conceptualized and measured differently across studies. Different types of social support may be needed in different situations, but the right measure is not always used. The remaining discussion will present additional evidence on the relation between support and health, but with particular attention given to the type of support and the mechanisms through which support is expected to influence health outcomes.

Explaining the Positive Effects of Social Support

Social Support as Protection from Stressors

A central theory on the role of social support in health is that support functions by protecting, or 'buffering,' people from the

inimical effects of life stressors. According to the stress-buffering theory, social support will have positive effects on the mental and physical health of people under high levels of stress, but have no effect on people with less or no stress. The rationale behind this theory is that social support somehow helps people to cope with the stress of life, thereby reducing the health toll of stress. People who have social support available to them in the absence of stress would not be expected to gain any immediate health benefits from that support.

The buffering theory has been tested mainly with psychological rather than physical health outcomes. One of the reasons that so little is known about the role of social support in physical disease outcomes is that many of the major diseases, such as cancer and heart disease, develop over many years and are difficult to track. Thus, researchers are seldom able to identify and assess the social support networks of people before they develop a particular disease. Mental illnesses, on the other hand, have a relatively short onset and progression. Therefore, it is easier to test how social support influences mental illnesses than physical illnesses.

The stress-buffering effects of social support have been tested using both structural and functional measures of social support. Studies using structural measures, such as marital status and number of close friends, have consistently shown buffering effects on psychological health. People who are married or have a close friendship tend to experience less depression under stress than do people who lack significant social ties. People who have frequent contact with close friends during personal crises, such as health problems, divorce, and unemployment, also are happier and more satisfied with life than people who have relatively little contact with close friends. Although having close interpersonal relationships appears to protect people from the adverse psychological effects of stressors, having casual social connections do not seem to buffer stress. Casual social ties may develop through church membership, interaction with neighbors, or participation in clubs and organizations. People who have greater access to such ties tend to have less psychological distress and greater morale than people with relatively little access to such ties, but this is true regardless of the amount of stress in their lives. Thus, it appears that close social ties may be beneficial to mental health because they provide supports that help people to cope with stress, whereas more casual social ties may be beneficial to psychological well-being because they serve other functions, such as providing companionship. Increasingly, individuals are turning to computer-mediated social networks for social support through bulletin boards, listserves, and social networking sites. The Internet is obviously an effective tool for linking individuals to a vast amount of information and even emotional support and companionship, particularly through weakly connected social ties. However, it is not yet clear whether computer-mediated social support is an effective stress buffer.

There is only limited evidence that social support protects people from stress-related physical illnesses. For example, a study of male factory workers showed that workers with high levels of job-related stress had fewer health complaints if they perceived their spouse and supervisor to be supportive rather than unsupportive. A Swedish study has shown that a greater level of social involvement with coworkers appears to reduce the negative effects of work stress on coronary heart disease

prevalence in men and women. Finally, an Israeli study has shown that highly anxious men who perceive their wives to be supportive have a lower incidence of angina pectoris than men who do not perceive their wives to be supportive. Again, it appears that close, or significant, social ties are most beneficial. There is no strong evidence that casual social ties, or simply the number of social ties one has, can reduce the negative effects of stress on health complaints.

Social Support and Health Behaviors

Social support networks may influence health by regulating individuals' health-related behaviors. For example, in contrast to relatively isolated people, people who are more socially integrated tend to smoke less, drink less alcohol, avoid between meal snacks, eat breakfast, maintain a healthy weight, get adequate sleep, and engage in regular physical activity. Among the elderly, degree of social integration and contact, as well as perceived amount of social support available, is associated with better self-care. Among people trying to quit smoking, those who feel that they have others with whom they can discuss their problems are able to abstain from smoking for a longer period than those who do not feel that they have such confidant relations.

Social networks also may promote health by encouraging individuals to seek needed medical attention or to comply with medical treatments. For instance, the degree to which pregnant women consult with friends about health care issues has been shown to influence the degree to which they seek prenatal care. More generally, people who have relatively frequent interactions with friends tend to obtain preventive health care and seek help quickly when they are ill. Finally, in contrast to people who believe they have relatively little support from their spouse, friends, and health care providers, those who believe that they have high levels of support are more motivated to adhere to their medical regimen and are more acutely aware of the negative consequences of noncompliance. In turn, the heightened adherence motivation and awareness of the costs of noncompliance are associated with greater compliance. One way that support may protect people from stress is by increasing their medical adherence. For example, in a study of patients with hypertension, those facing many life stressors were more likely to miss appointments with their physician than those who had little stress. However, stressed patients who believed they had much support from significant others were less likely to miss appointments than stressed patients who felt they had little support.

Social Support and Physiological Functioning

If social support reduces stress-related health problems, it is possible that it does so by influencing physiological responses to stressors. A number of bodily changes tend to occur in people confronted by stressors. For instance, stress tends to activate the sympathetic nervous system, which causes increases in heart rate, blood pressure, and generalized arousal. The physiological responses to stressors are part of the body's coping mechanism. By increasing blood flow away from the organs and to the muscles, individuals are prepared to 'fight' or 'flee' in response to a stressor. Increased arousal also allows

people to be more vigilant or attentive to their environment or threatening stimuli.

The most common biological markers of stress are increased heart rate and blood pressure, and elevated levels of hormones known as cortisol and catecholamines. Catecholamines are basically responsible for increasing bodily arousal, whereas cortisol is primarily useful in reducing swelling in tissue that might be damaged during fight or flight. Although increased arousal and production of catecholamines and cortisol are adaptive responses to stressors, they also can have harmful effects on health. For example, extreme levels of stress-induced arousal might lead to heart attacks, and chronically high levels of stress-induced hormone production might contribute to heart disease. If social support can dampen the body's reaction to stressors, it might prevent stress-related illnesses and disease processes. Several laboratory studies have shown that people who are challenged by acute stressors, such as giving a speech or being socially harassed, experience smaller blood pressure and heart rate increases if they are in the presence of a supportive person than if they are alone or in the presence of a nonsupportive person. However, there is no evidence to date that social support in naturalistic settings, where people can experience very severe and repeated stressors, acts to reduce stress responding in the same way that it does in laboratory settings, with relatively mild stressors.

Social support also might be beneficial to health by enhancing immune system functioning. The immune system protects people from harmful viruses and pathogens, which are noxious or toxic materials that enter the body. The most familiar defense mechanism of the immune system is the production of white blood cells that can circulate throughout the body to fight infections. When people are under stress, the immune system becomes compromised, producing fewer and less effective immune cells than normal. Findings from several studies suggest that social support may enhance immune functioning. For example, lonely people have poorer immune functioning than nonlonely people. In addition, higher social support appears to be related to enhanced immune functioning among the elderly and spouses of cancer patients.

Conclusions

People who are socially integrated appear to be at lower risk for a variety of psychological and physical health problems, as well as mortality, than people who are relatively isolated. The psychological and health benefits of social integration are partly attributable to the supportive functions provided by social networks. People who receive social support from members of their social network, particularly if it is from significant others such as spouses and family members, tend to have fewer psychological problems than people who do not receive support. To date, there is more evidence linking social support to psychological well-being than to physical health. However, several studies suggest that social support does play a role in physical health.

Several theoretical models have been posited to explain how social support can influence physical and psychological health. Social support appears to be particularly beneficial to individuals under stress.

Therefore, support may operate by helping people to cope with stressors, which can be detrimental to physical and psychological health. Support also might function by promoting healthy behaviors, discouraging risk-taking and other unhealthy behaviors, and encouraging people to seek needed medical care or to adhere to medical regimens. Finally, social support appears to reduce stress-related arousal, dampen the production of catecholamines and cortisol, and to enhance immune functioning. These latter physiological effects of social support may prove to have health benefits.

Glossary

Competitors Individuals who tend to approach interdependence situations with the goal of getting more than others.

Cooperators Individuals who tend to approach interdependence situations with the goal of maximizing joint gain for themselves and others.

Decomposed game An instrument used to assess social values on the basis of preference for abstract distributions of resources to the self and others.

Individualists Individuals who tend to approach interdependence situations with the goal of getting as much as possible for themselves, with little concern for the outcomes provided for others.

Interdependence Situations where individuals' outcomes are a joint function of their own choices and the choices of others; often interdependence structures produce unexpected complications for participants.

Might over morality hypothesis The proposal that cooperators think about cooperation and competition in

terms of morality, whereas competitors think about them in terms of strength.

Prisoners' dilemma An interdependence structure between two individuals, characterized by a situation where the rational pursuit of one's own interests can produce suboptimal outcomes for both participants.

Social dilemma An interdependence structure similar to a prisoners' dilemma but extended to more than two individuals.

Social values Stable preferences for particular patterns of outcome distributions afforded to the self and others.

Tit-for-tat A strategy for playing a multitrial prisoners' dilemma game, characterized by choosing the option that the other player picked on the previous trial.

Triangle hypothesis The proposition that cooperators anticipate the possibility of either cooperation or competition from others, whereas competitors uniformly expect competition.

Defining Social Values

Social values refer to a stable personality trait of preferring certain patterns of outcome distributions between self and others. Social values have been used to explain behavior in a variety of negotiation and decision-making situations where people need to coordinate their actions. Social value orientations, which reflect a trade-off between self-interest and collective interest, can be divided into two broad categories. People with proself orientations focus on the benefits they can acquire for themselves, whereas those with prosocial orientations focus on balancing their own benefits with others' benefits.

The most common proself orientations are individualism and competition. An individualist tries to maximize his or her own gain with little or no regard for the welfare of others. Competitors focus on maximizing their own gain relative to others. To see the difference between these two orientations, consider [Table 1](#). A person has to choose among different monetary payoffs, labeled A through G. The choice determines his or her payoff, as well as what the other receives. Choice C provides the greatest gain to the self (60) and would be what an individualist prefers. In contrast, a competitor would prefer Choice B, even though it provides a lower dollar payoff than Choice C, because it provides a relative advantage of \$25 rather than the \$20 provided by Choice C.

The most common prosocial orientation is cooperation, illustrated by Choice A in [Table 1](#). A cooperator focuses on joint gain and would therefore prefer maximizing joint benefit between the self and another. The cooperator prefers \$55 to \$60

because Choice A also provides \$50 to the other person for a joint total of \$105, in comparison to the smaller joint totals for the other choices. Another prosocial orientation is egalitarianism, a preference for equality between the self and another. Choice D in [Table 1](#) represents an egalitarian preference because it minimizes the difference between the self and another person. Egalitarians would prefer Choice D over Choice A because of the value they place on equality of outcomes, whereas cooperators would prefer Choice A over Choice D because of the value they place on joint gain. Recent research has suggested that people traditionally labeled 'cooperators' may be more motivated to maximize equality than joint gain.

A number of other possible social value orientations do not appear with great frequency in the population. An altruist would prefer Choice E, which provides the other with the greatest payoff, even at a cost to the self. An aggressor would prefer Choice F, which provides the other with the lowest possible payoff, even though it costs the self as well and only provides a \$15 relative advantage compared to the \$25 relative advantage provided by Choice B. Finally, masochists would intentionally reduce their own outcomes and would, therefore, find Choice G the most appealing.

Problems Measuring Social Value Orientations

Because it is impossible to read someone's mind, it is necessary to infer a person's social value orientation on the basis of

Table 1 Different social value orientations

	<i>A</i>	<i>B</i>	<i>C</i>	<i>D</i>	<i>E</i>	<i>F</i>	<i>G</i>
You get	55	30	60	50	40	15	0
Other gets	50	5	40	50	55	0	15

observed behavior, that is, the choices they make to divide resources among themselves and others. There are two problems with making inferences about social value orientation on the basis of observed behavior.

One problem is that the same choice may reflect more than one social value orientation, depending on the others available. For example, compare Choice A and Choice D in [Table 1](#). A person who chooses A over D may be trying to gain a relative advantage (55 provides 5 extra points to the self relative to the other's 50 points). But Choice A also maximizes joint gain (a combined value of 110 rather than 100). It is impossible to be certain what social value orientation is being satisfied when a choice confounds two or more possible motives.

Another problem concerns the distinction between goal-oriented and strategic behavior. Goal-oriented behavior is performed to advance some agenda or cause. The motive to do better than others can be only satisfied by making competitive choices. Because a strategic choice is motivated by the desire to make the other person behave in a certain manner, it may actually contradict an actor's social value orientation. For example, a competitive person may make a series of cooperative choices in order to lull the opponent into a false sense of security for later exploitation. Altruistic cooperators are motivated to provide resources to others. They are more concerned with others' outcomes than their own. In contrast, reciprocal cooperators will cooperate strategically to get others to cooperate with them. A cooperator may make competitive choices to send a stern message to an opponent.

Decomposed Games

Decomposed games, the most widely used method to assess social value orientation, were developed to avoid measurement problems inherent in using behavior as the basis for inferring social value orientation. A decomposed game presents an individual with a set of (usually) three choices. Each choice provides an outcome for the self and a hypothetical other. The individual is asked to indicate the most preferred choice. People are presented with a series of decomposed games that vary the point payoffs in a systematic way. A person is assigned a social value orientation on the basis of making a majority of choices consistent with a particular orientation.

In [Table 2](#), Choice A maximizes joint gain, Choice B maximizes relative gain, and Choice C maximizes individual gain. These preferences reflect cooperative, competitive, and individualistic social value orientations, respectively. In practice, most research on social values has used a triple-dominance measure of social values that is designed to distinguish cooperators, individualists, and competitors; however, in theory, it would be possible to design decomposed game to assess any possible social value orientation.

Table 2 An example of a decomposed game

	<i>Choice</i>		
	<i>A</i>	<i>B</i>	<i>C</i>
You get	55	30	60
Other gets	55	0	40

Table 3 An example of a decomposed game that can distinguish between joint gain maximization and equality maximization

	<i>Choice</i>		
	<i>A</i>	<i>B</i>	<i>C</i>
You get	50	70	60
Other gets	50	60	40

It is important to note that Choice A maximizes equality in addition to maximizing joint gain. To eliminate this confound, people could also be presented with another decomposed game, such as the one presented in [Table 3](#). In this example, column B maximizes joint gain, but column A maximizes equality. If a person chose A in the first game and A in the second, he or she would demonstrate a consistent tendency to minimize the difference between the self and another. Such a person would be classified as an egalitarian. However, if a person chose A and then B, it would suggest a tendency to maximize joint gain. This person would be classified as a cooperator.

Typically, someone is classified by the decomposed game measure if a majority of choices are consistent with a particular social value orientation. There is evidence that about 57% of a sample can be categorized as cooperators, about 27% as individualists, and about 15% as competitors. In some cases, about 10% cannot be classified because they do not display a majority preference for a particular social value orientation. Researchers often combine individualists and competitors into a group called proselves and call cooperators prosocials.

The decomposed game measure has several advantages. By judiciously manipulating point values across a series of decomposed games, it is possible to narrow down a person's preferences to a single social value orientation. Because the decomposed game format does not require that people actually make choices with another player, strategic and self-presentational aspects of interacting with another person are removed. The decomposed game measure is also easy to administer and score, using either a paper-and-pencil format or computer.

The decomposed game assessment has several weaknesses. One important limitation is that the measure reduces a continuous variable to a few discrete categories. As a result, someone who indicates 10 out of 10 cooperative choices is classified the same as someone who gives 6 out 10, even though it is possible that a consistent cooperator is different from an intermittent one. Overall, the categorical classification produces a loss of measurement precision. Generally, researchers do not encourage people to give up a more sensitive measure in favor of a less sensitive one.

The majority rule fails to take into account the choices made in the minority cases. For example, someone who gives six competitive and four individualist choices would be scored the same as someone giving six competitive and four cooperative choices. The former individual seems to more clearly possess a prosocial orientation.

However, it should be noted that researchers have found that the categorical classification of social values performed about the same as a more complicated assessment that kept track of the total number of points awarded to the self and others. Thus, an argument on the basis of parsimony would suggest retaining the categorical level of analysis.

Another problem with the majority decision rule concerns how to conceptualize unclassified individuals (those who do not make a majority of choices consistent with a specific social value orientation). Often, data from unclassified individuals are discarded prior to data analysis. This loss of information is regrettable. It would be interesting to gain a better understanding of the motivations of people who shift from one social value orientation to another in the short span of time required to complete the measure. For example, it is possible that unclassified people are expressing one of the less common social value orientations, which most triple-dominance decomposed game measures are not designed to find.

Another area that has not been adequately developed concerns the relationship between social values and other psychological constructs. There is little research on whether different measures of social values produce similar findings. In addition, few researchers have examined how social value orientation relates to psychological constructs such as independent-interdependent self-construal, cultural values of collectivism, or personality traits such as introversion or narcissism.

Although the decomposed game is the most popular method of assessing social value orientations, other methods have been developed, in part to overcome some of the limitations of the decomposed game. Like the traditional triple-dominance decomposed game measure, because preferences are evaluated in the absence of actual social interaction, strategic influences for these new measures are also eliminated.

The ring measure requires people to choose between two pairs of own-other outcomes. The outcomes are derived from a two-dimensional axis of own and others' outcomes measured at a fixed radius from the origin. One advantage of the ring measure is that it includes negative payoff values, that is, asks subjects to choose between losses as well as gains. For example, a person might have to choose between +14.50 for the self and -3.90 for the other or +13.00 for the self and -7.50 for the other. With this measure, it is possible to conceptualize social value orientation as a vector connecting the origin to the point, representing the total amount of points allocated to the self and to the other.

Another technique uses multiple regression analysis to predict the desirability ratings of 49 self-other distributions from subjects' actual preferences for their own gain, others' gain, and relative gain. An advantage of the procedure is the judgment process, which is quite different from the act of making choices in a real situation of social interdependence. A disadvantage of the technique is that it requires sophisticated statistical methods such as multiple regression and conjoint analysis.

Interdependence and Social Values

Social interdependence exists when the outcomes that two (or more) people receive are determined by both (or all) of their choices. More specifically, in the two-person case, the outcomes that A receives depend on both A's behavior and B's behavior. Similarly, the outcomes that B receives depend on both B's behavior and A's behavior. Interdependence often creates a conflict between trying to do as well as one can for the self by competing against others and trying to benefit the group by cooperating with others. Social values describe how individuals differ in the way they approach interdependence problems.

The idea of interdependence characterizes many social relationships ranging from the way a married couple has to decide how to spend Friday night together to the way that rival nations decide how to coexist peacefully despite the threat of nuclear weapons. In the case of a married couple, the spouse who gets to decide what they do every Friday night is more satisfied than the one who does not. In the case of two rival nations, it is better to do the attacking than be attacked. But, in the long run, the relentless pursuit of self-interest can lead to a failed group outcome: A marriage goes sour or two countries go to war.

Much of the research on social interdependence has been carried out using the tool of matrix games, such as the one presented in Table 4. This matrix is for a two-person game. The actor's choices appear on the left side, and the other's choices appear along the top row. Each person has a choice between a cooperative act and a competitive act. A matrix like this is often called a mixed-motive game because of the temptation to make a competitive rather than a cooperative choice. Point values are assigned to each choice for each person. In this example, the cooperative choices are X and A. The competitive choices are Y and B. If the actor chooses to compete and the other chooses to cooperate, they end up in the lower left hand cell, with the actor receiving 4 points and the other receiving 1. If they make the mutually cooperative X, A choice, they end up with 3 points each.

The Logic of the Prisoners' Dilemma

The name given to a matrix with this pattern of point values is 'a prisoners' dilemma game' because it was originally presented as two prisoners deciding whether to cooperate with or compete against each other to avoid a potentially long prison sentence. There have been literally thousands of studies conducted using the prisoners' dilemma game in anthropology, biology, economics, political science, psychology, and sociology. This seemingly simple problem is very important because the

Table 4 A two-person, two-choice interdependence game

	Other's choices	
	Choice A	Choice B
Actor's choices		
Choice X	3,3	1,4
Choice Y	4,1	2,2

instability of the solution calls into question how to define rationality. Often, especially in economics, rationality is defined as maximizing own gain. This is the case made for the invisible hand of Adam Smith as a fundamental principle of economics: the greatest good comes from people pursuing their own self-interest.

In the case of the prisoners' dilemma, the competing choice is more logical than the cooperative choice because it affords more points. The competitive choice will yield either 4 or 2 points, depending on whether the opponent chooses to cooperate or defect, respectively. The cooperative choice will yield either 3 or 1 point, depending on whether the opponent cooperates or defects. Thus, the competitive choice is more logical because 4 is greater than 3 and 2 is greater than 1. This analysis points toward competition as the logical choice. Because the matrix is symmetric, the other player goes through the same analysis. But the consequence of a rational analysis is the suboptimal 2,2 outcome.

The dilemma that these two people face is that having made the jointly cooperative choice, each will regret not making the competitive choice. If they had, they would have ended up with 4 rather than 3 points, and the other would have ended up with 1 rather than 3. However, if they had both made the competitive choice, they would have regretted their decisions and preferred to have made cooperative choices (so as to have 3 rather than 2 points each). The problem with this game is that the relationship of point values among the cells prevents it from having a stable solution.

In the case of the married couple planning their Friday night, the defecting choice would be to buy nonrefundable tickets to a play. The cooperative choice would be wait to decide what to do until both the husband and wife could meet and discuss a plan that was mutually beneficial. In the case of two rival nations, the defecting choice is attack the other country before it attacks. The cooperative choice is to delay attacking. In both the marital and rival countries examples, the problem with making the cooperative choice is that the cooperator becomes open to exploitation by the other. If the wife does not buy tickets to her favorite play, but the husband comes home with tickets to his, then she has little choice but to attend his choice. If one country resists the urge to bomb the other, it may leave itself open to attack. The worst outcome occurs when both parties pursue their own best interests. The married couple has paid for two sets of tickets to two different plays but can use only one set. Each country has destroyed the other.

The payoff structure is what gives the prisoners' dilemma matrix an unstable solution. Consider, for example, what would happen if the payoffs in the upper left corner were changed to 6,6. Then, cooperation would be the logical choice because it would lead to the greatest gain. Competing would at best provide 4 points, which is less than 6. Although the prisoners' dilemma is the most extensively studied matrix game, other games have been identified and have received empirical attention. For example, the case of nuclear attack has often been described as a chicken game because the consequence of mutually defecting choices is so extremely negative. The name chicken is derived from a dangerous game where two people drive their cars toward each other at high speed. The first one to swerve loses and is the chicken. If neither swerves,

they both die. In this kind of high-stakes game, a likely outcome is mutual death. This is a much worse choice than the mutually competitive cell in [Table 4](#) where the payoff for being exploited is not too much worse than the payoff for joint exploitation.

To produce cooperation in a mixed-motive game, players need a cooperative mindset. They have to be willing to adopt the goal of cooperation. But being willing to cooperate is not enough to guarantee cooperation. People must also expect that other players will cooperate, so they do not worry about being exploited.

The development of cooperative or competitive behavior in an ongoing mixed-motive game may operate like a self-fulfilling prophecy. If people initially expect competition, they come out with guns blazing and preemptively compete as a defensive, self-protective measure. As a result, they may cause a person who would have cooperated to compete, also as a self-protective measure. In contrast, if people initially expect cooperation from others and they act cooperatively in response, they may create a beneficial cycle of mutual cooperation.

The inherent problem with acting cooperatively is the danger of being exploited in a multitrial mixed-motive game. A cooperative cycle might be terminated because one of the actors decides to take advantage of the other's cooperation. The more cooperative the opponent, the better the chance of being able to take advantage of him or her on the next trial. Research has shown that one of the best strategies to maintain a cooperative cycle is to use a tit-for-tat strategy. The tit-for-tat strategy starts out cooperatively, but if the opponent makes a competitive choice, then the tit-for-tat also does so in the next trial. However, the tit-for-tat strategy is also forgiving. That is, if an opponent returns to a cooperative choice, a tit-for-tat will also return to cooperating, unless it is once again provoked.

The logic of the prisoners' dilemma can be extended to more than two people. Multiperson games are called social dilemmas, but the conflict between collective and individual gain is the same. Social dilemmas occur frequently in the real world. Plunging real estate markets in 2009 had the characteristics of a social dilemma. Once housing prices started to fall, people faced the choice between holding out and selling right away. By getting out of the market quickly, they minimized their own personal loss. But as more houses flooded the market, prices dropped even further, and everyone ended up worse off. Because of the additional players, social dilemmas can be almost impossible to solve.

Research Findings on Social Value Orientations

The concept of social values emerged out of research on social interdependence. A personality trait can be considered an internal disposition that influences how a person thinks, feels, or behaves across a variety of situations. A particular social value orientation can be thought of as a tendency to respond in a similar manner across a range of interdependence patterns and interaction partners. We would expect a cooperator to cooperate in different situations and with different people. Competitors would tend to make self-interested choices across a variety of contexts.

One reason why proselves and prosocials play the prisoners' dilemma game differently can be understood in terms of a matrix transformation. The given matrix is the actual matrix presented to players and can be considered an objective presentation of available point values. The effective matrix represents the socially constructed meaning applied to the given matrix. The socially constructed meaning can be considered different weightings of the value of outcomes for the self + value of outcomes for the other + value of equality.

Consider the A,X cell of Table 4. A joint gain transformation views the 3,3 outcomes as a joint gain of $(3+3=)$ 6 points. In contrast, a relative gain transformation views them as a relative gain of $(3-3=)$ 0 points. If prosocials tend to create a joint gain effective matrix that sees outcomes for the self, and others, and for equality as all important, it makes sense that they would prefer the 3,3 option. If proselves assign a high degree of importance to their own outcomes and little or no importance to the outcomes of others or for the goal of equality, it would make sense that they would opt for the 4,1 cell. Competitors would actually negatively weight equality and outcomes for the other, thus making the 4,1 cell even more attractive.

One difficulty with studying behavior in interdependent structures is the way that past behavior and outcomes may influence future choices. Consider, for example, a cooperator who is playing a series of repeated trials of the game in Table 3 against a competitor. In the beginning, the cooperator makes Choice X, but the competitor makes Choice B. The end result is 1 point for the cooperator and 4 points for the competitor. Strictly speaking, the cooperator should see this outcome as relatively positive. After all, the joint gain is 5 points, which is only 1 point away from the maximum benefit. Prior research has shown that in this environment, the cooperator is likely to begin making competitive choices. Even prosocials will shy away from being exploited by others.

Prosocials and proselves differ in the extent to which they expect cooperation from others. Proselfs enter into social situations expecting others to compete. Given this expectation, it makes sense that they would immediately adopt a competitive stance to avoid being exploited. In contrast, prosocials are more open to the idea of either competition or cooperation from others. As a result, they may adopt an initially cooperative stance but shift to competitive choices if others behave competitively. The idea that people with different social value orientations hold different expectations for cooperation from others is known as the triangle hypothesis.

Prosocials and proselves respond differently to opponents' emotions in social interaction. Surprisingly, research indicates that proselves are more sensitive than prosocials to an opponent's disappointment during a negotiation. When faced with an opponent who expressed disappointment, proselves reduced their level of demand more than prosocials. One way to make sense of this finding is that proselves will engage in strategic cooperation to ensure their own future outcomes, so they must pay careful attention to information about others' opinions of them. Individualists' willingness to make sacrifices in close relationships is closely tied to their level of commitment to the relationship. One explanation for this finding is that, because individualists are focused on their own gain, they will only give up something they feel is worth their sacrifice.

A long-term, committed relationship may create the assumption of an eventual payback and return to equity.

Proself and prosocial individuals think differently about the meaning of cooperation and competition. The might over morality hypothesis suggests that prosocial individuals think about the competition-cooperation dimension in terms of morality and view cooperation as morally good and competition as morally bad. In contrast, proself individuals tend to think about competition as strength and cooperation as weakness. Prosocials tend to see cooperation as an intelligent behavior and competition as an unintelligent behavior, whereas proselves view them in the opposite manner. Proselfs tend to expect cooperative behavior from unintelligent people, whereas prosocials expect cooperation from more intelligent others.

There is also speculation that people with prosocial orientations take on a different time perspective when dealing with a social dilemma. They are more likely to take into account a longer time perspective on the future fate of a shared resource. Perhaps as a result of this longer time perspective, they are better able to appreciate the way that social dilemmas can trap people into engaging in behaviors with long-term negative consequences.

Most of the research on social values has focused on how social value orientation influences preferences to distribute resources to self and others. The focus of distributive justice research is on what would be considered a fair allocation. Prosocials tend to see fair allocations as those that benefit the group. In contrast, proselves define fairness in terms of personal gain. When evaluating another person who had produced equal inputs as themselves, prosocials saw equal outcomes as fairer than either overbenefit or underbenefit. In contrast, proselves saw favorable outcomes to the self as fairer than unfavorable outcomes to the self.

The focus of procedural justice is on whether the process used to distribute resources is considered fair. Often, people will be satisfied with unfavorable outcomes if they feel that the procedure used to arrive at a certain outcome distribution is fair. Proselfs show more concern with procedural fairness than prosocials. In comparison to prosocials, proselves have been shown to prefer having a voice in outcome allocations and will report being more satisfied when they do so.

A final issue about the influence of social value orientation is whether findings obtained using mixed-motive games will generalize to more realistic aspects of human interaction. There is evidence that social value orientation, as assessed with the decomposed game measure, can predict other, qualitatively different behaviors, such as volunteering for charity work or taking steps to protect the environment by using mass transportation. Proselfs are also more likely than prosocials to take advantage of another person when setting a selling price in a negotiation. Prosocials are better than proselves at inferring others' mental states.

When Social Value Orientations Do Not Make a Difference

People do not always behave in accord with their social value orientation. Often, personality variables, such as social values,

have their greatest influence when situational cues are weak or ambiguous. With strong situational constraints, people tend to conform to environmental cues. For example, given a choice between a million dollars for the self and a million dollars for another versus \$20 for the self and \$1 for another, a competitor should – technically – choose the latter choice, which affords a \$19 advantage to the self rather than the zero advantage of each receiving a million dollars. In practice, it is probably safe to assume that everyone, regardless of social value orientation, would prefer the million dollar outcome. In other words, the external pressure to obtain a certain reward overwhelms the influence of an internally based social value orientation.

Social norms might influence behavior in interdependence settings. The norm of social responsibility is the tendency to help those who are in need of help. Although people, especially competitors, might be tempted to exploit someone who seemed weak or vulnerable, it is also possible that people would act more charitably toward someone in need or who acted in a supplicating fashion. The norm of reciprocity refers to behaving toward a person in a manner similar to how the person behaved. This is how a tit-for-tat strategy works. Reciprocity would mean making cooperative choices toward an opponent who acted cooperatively and making competitive choices toward an opponent who acted competitively. One application of the norm of reciprocity involves keeping promises to cooperate. One interesting research program found that people were willing to keep promises when they played a prisoners' dilemma with a computer program, even when they knew they were playing against a computer. Equality is another influential decision rule because it seems to appeal to a sense of fairness. There is research that shows both prosocials and proselves will adopt an equality allocation rule when dealing with a social dilemma. However, if group members see that they are failing to manage the task properly, then social value orientation will exert a greater influence on choice, with prosocials restricting their consumption to a greater degree than proselves.

Much of the research on social values has been conducted in the United States or other Western cultures. As a rule, these Western cultures tend to have more individualistic rather than collective orientations. Cultural norms toward collectivism could increase levels of cooperative behavior. However, in a recent research conducted in Taiwan, ROC has found evidence for the presence of both prosocial and prosocial value orientations, thus suggesting that social value orientations may exist among very different cultures.

Increasing incentives for cooperating or competing will reduce the influence of social value orientation. Expecting to interact with the person in the future would increase the social costs of competing and, therefore, encourage cooperation. Sharing a collective identity can also increase the tendency to cooperate, especially among proselves. Interpersonal dynamics would probably affect cooperation rates. People might be less likely to exploit a likeable or attractive opponent. It is interesting to speculate on the role of sexual attraction on behavior in a mixed-motive game. We would expect more competitive behavior when people are deindividuated, that is, given a situation where their identities are anonymous. In this instance, there would be fewer social costs associated with competing.

One limitation of using matrix games such as the prisoners' dilemma to understand social behavior is that the game, while useful, is only a limited model of human social behavior. People are required by the experimental instructions to make one of two possible choices. One feature missing from game simulations is that people often walk away from aversive real world situations with a mixed-motive structure. Research has shown that everyone, regardless of social value orientation, will avoid interacting with a competitive opponent. Cooperators and individualists appreciate tit-for-tat partners, but competitors avoid them. Thus, social value orientation may influence not only the way a person acts in an interdependent situation but also the types of situations people get into in the first place.

Origins of Social Value Orientations

Certain matrix transformations may require a greater level of cognitive development than others. For example, an individualistic orientation only requires that a person look at his or her own outcomes. In contrast, competitive and cooperative orientations require that people compare their own outcomes to others' outcomes using a mathematical transformation (either subtraction or addition). There is evidence that social value orientations develop across the life span. Very young children (<4) tend to satisfy individualistic motives. Between the ages of 4 and 5, competitive orientations emerge. Finally, between 6 and 7 years, cooperative social values begin to manifest themselves.

Socialization is another basis for the development of social value orientations across the life span. Children learn that competition may be necessary to acquire scarce resources, particularly attractive toys, parental attention, and candy. At school, children learn that they can gain the attention of their teachers by performing at a higher level than their peers. At the same time, it is likely that as children grow older, they are exposed to the cultural value placed on cooperation through lessons from teachers, parents, and religious authorities.

One important influence on a person's development is family. Paradoxically, prosocial orientations are associated with coming from a larger family and with having more siblings, despite the greater competition for resources that would occur in a large family. Rather than leading to greater conflict among siblings, the competition for resources might lead children to develop a joint gain orientation as a more skillful way to negotiate their share of resources. In addition, parents may delegate child care duties among their children, and, as a result, children may develop the habit of thinking about the welfare of others from a relatively early age.

Another factor that may contribute to the development of prosocial social value orientations is sufficient wealth and comfort so that sharing becomes feasible. In an impoverished environment, it might be more difficult for people to develop the insight that greater overall benefit might be derived from cooperation rather than the pursuit of self-interest.

Social values may develop in part as a result of biological predispositions. If there is a genetic component to social values, then the correlation of social value orientations between identical twins would be higher than it would be for

siblings. Of course, it would be necessary to rule out similarities due to similar home environments rather than a biological predisposition. The fact that related constructs, such as altruism and empathy, show a genetic relatedness component of about 50% hints that a similar finding might be obtained for social values. However, such work has not been conducted to date. Even if such a relationship were obtained, it would also be necessary to determine what aspect of biology was producing similarity in the development of social values.

Both the triangle hypothesis and the might over morality hypothesis implicitly favor an etiology based on socialization. People learn to expect cooperation, competition, or both from prior interactions with others, observation, and exposure to mass media. As these expectations develop, they become tinged with a connotative meaning of morality or strength. Thus, it seems likely that biological dispositions will be moderated by learning that occurs in the home, at school, and elsewhere.

Conclusions

Much of the early research on social values focused on explaining the behavior of individuals playing mixed-motive games such as the prisoners' dilemma. In this research, the general finding was that people with different social values transformed the payoff outcomes in a given matrix into a new set of outcomes that reflected the actor's underlying values. In general, transformations seemed to focus on an actor's own gain, relative gain, or joint gain. An individual difference approach was successful in explaining some of the variation in how people played matrix games.

Much of the initial work on social values conducted in the 1960s and 1970s focused on the behavior of college students playing mixed-motive games in the United States. Starting in the 1990s, the external validity of the social values concept was greatly expanded. Many cross-cultural studies have demonstrated that social value orientations describe people's choice behavior in a wide range of countries, including the Netherlands, Sweden, and Taiwan. Another important contribution of recent research on social values has been to expand the

ecological validity of social values as an explanatory construct. This research has tried to gain a better understanding of how social value orientation influences the way people respond to real-world situations of social interdependence. Rather than focusing on behavior in an artificial game, researchers have examined how social values influence a variety of prosocial behaviors. An important and growing trend among social values researchers is to better understand individuals' subjective experience of cooperation and competition. This work has focused on the symbolic meaning that cooperation and competition have for individuals who choose to behave one way or the other.

Glossary

Differential susceptibility The idea that certain genes are not just 'vulnerability genes,' but rather that they seem to make children more sensitive to environmental influences, whether they are positive or negative.

Emotion regulation The internal and external processes involved in monitoring, evaluating, and modifying emotional reactions (especially their intensive and temporal features) to accomplish one's goals.

Functional view of emotions The idea that emotions are related to changing or maintaining relations between the organism and the environment in ways relevant to one's goals.

Gene polymorphism The variations in genetic characteristics that are associated with different physical or behavioral tendencies.

Limbic-hypothalamic-pituitary-adrenocortical (LHPA) axis A network of nervous system and endocrine system

processes that constitute the body's primary stress system, and which contributes to the immediate surge of energy, attentional focus, and emotion following threat as well as the long-term arousal that is also associated with stress.

Molecular genetics Molecular genetics is the study of the structure and function of genes at a molecular level.

Social referencing Looking to the emotional expression of another person for cues about how to evaluate an ambiguous person, object, or situation.

Socioemotional development An aspect of developmental science concerned with the convergence of social and emotional growth.

Structural view of emotions The idea that emotions are discrete, coherent constellations of physiological, subjective, and expressive activity that are organized neurobiologically, and are thus structured consistently across culture and history.

Socioemotional development can be defined by the convergence of social and emotional growth. This is a broad field of developmental study because of how significantly, throughout life, emotional reactions influence social behavior, and how social experiences affect emotional growth.

The field of socioemotional development addresses many issues. These include: how emotion is expressed in social contexts, the social elicitors of emotional responses, the social and cultural construction of emotion understanding, the social consequences of emotional reactions, the sociocultural influences on emotion and emotion regulation, and the effects of emotion on social behavior. It also includes the study of empathy and its development, understanding and enactment of emotional display rules, the social dimensions of temperamental individuality and its genetic determinants, the development of guilt, shame, and other self-conscious emotions, the effects of developing neurobiology on the growth of emotion and emotion regulation, changes in the social environment that alter emotional demands, and many other topics.

Socioemotional development is central throughout life. In infancy, for example, socioemotional development is reflected in the emotional attachments of infants to their caregivers and their emotional reactions to unfamiliar people. In adulthood, socioemotional development is reflected in how older adults become more selective in their social interactions to create and maintain an emotionally satisfying life.

The field of socioemotional development has important practical implications. It is concerned, for example, with understanding the impact of social relationships on risk for affective pathology (such as depression or anxiety) and social

influences on the prevention and treatment of emotional disorders. Socioemotional development is also relevant to the origins of school readiness, social competence, and coping with stress. The field of socioemotional development integrates themes of cognitive development, neuroscience, developmental biology, molecular genetics, culture, developmental psychopathology, and many other fields. It is a broad, complex, and integrative field of study.

In this entry, we do not strive to discuss each of these facets of socioemotional development. Instead, we begin with a discussion of current views of emotional development and its relevance to social functioning. This is because the field of socioemotional development is enlivened by a new theoretical understanding of the nature of emotion, its development, and the influence of emotion on social behavior and growth. In the sections that follow, we focus on selected topics in socioemotional development that highlight emerging directions for this field. First, we discuss the interaction of genes and environment in socioemotional development and its implications for the traditional 'nature versus nurture' debate. This discussion profiles the increasing importance of genetic approaches to understanding socioemotional development. Second, we discuss how socioemotional development is based on the developing brain and biological systems in the body as they respond to environmental events. This discussion profiles how emotion is a complex neurobiological process in which social influences can have immediate and long-term effects. Finally, we discuss emotion regulation and its development. This discussion profiles the complex foundations on which emotions are managed, and their implications for socioemotional development.

Current Perspectives on Emotional Development

The field of socioemotional development is enriched by new perspectives on the influence of emotion on social behavior and development. Traditionally, children have always been viewed as emotional in nature, with emotions accounting for children's exuberance, carefreeness, irrationality, disorganization, or at times their disturbing behavior. This is one reason why emotional self-control is traditionally viewed as a mark of growing maturity. Similarly, personality theories in psychology have also emphasized emotion as creating stress, disorganization, or impulsivity, with therapy sometimes required to restrain emotional influences and channel them in productive directions. These views of emotion are consistent with our everyday experience, of course, but they neglect the constructive role of emotions in behavior and development. Although emotions always retain their capacity to disorganize or undermine effective functioning, the idea that emotions contribute constructively to social understanding, self-awareness, social competence, morality, and many other aspects of effective functioning is central to the field of socioemotional development.

One source of this new awareness of the influence of emotion is evolutionary psychology. Emotion is deeply rooted in the evolution of our species. Emotion has neurobiological foundations in subcortical structures that have a long biological heritage. Basic emotional reactions are universally evident in human behavior across cultures, and the universal recognition of facial expressions of basic emotions further suggests that emotion is an innate feature of human functioning. Adding to this view, emotional arousal is associated with many biologically adaptive motivational tendencies: the impulse to flee potentially threatening events (fear), the capacity for self-defense (anger), quickly gathering information concerning unexpected events (surprise), attentive information intake (interest), expelling noxious events (disgust), and so forth. Emotional expressions are also potent social signals that convey one's arousal and action tendencies, contribute to social bonding, and alter the behavior of others (such as when an attacker withdraws after perceiving the victim's anger).

Understanding emotions in this way helps explain why we are so sensitive to the emotional expressions of others, and how emotions function in development. Consider, for example, the powerful emotions that contribute to infant-parent attachment: the mutual joy that occurs in parent-infant play, the baby's wariness or fear of unfamiliar people who are not caregivers, the distress that occurs in the parent's absence that is readily relieved when the caregiver returns, and the parent's pleasure in the baby's recognition of him or her. Attachment theorists believe that these emotions and associated behaviors are not just learned reactions to a familiar caregiver, but have evolved to promote the baby's proximity to familiar caregivers as a means of ensuring the baby's survival. They argue that in the natural settings of human evolution, where predation, natural dangers, desertion, and other risks posed formidable challenges to individual and species survival, such emotions and behaviors helped to ensure that infants remained close to caregivers who would be protective, nurturant, and instructive. They have functioned, in other words, to ensure that infants survived to maturity and contributed to the survival of the human species. Viewed in this light, emotions are central to

the adaptive, psychologically constructive behaviors that have long been part of our species.

Emotion in Psychological Development

The conclusion from evolutionary psychology that emotions are adaptive and psychologically constructive is consistent with what we observe in child development, as attachment research illustrates. Even though casual observation of young children contributes to the view that emotions lead to irrational exuberance or defiant tantrums, upon closer examination, developmental researchers have learned that emotions are central to the development of social understanding, self-awareness, morality, and other aspects of behavioral competence.

Consider the emergence of social understanding in infancy. Even though infants and toddlers are commonly viewed as 'egocentric' – that is, incapable of understanding how another's perspective, feelings, or thoughts differ from the child's own – researchers have discovered that very young children have an early, nonegocentric awareness that what other people see, feel, and think is different from the child. A simple and easily-observed example is social referencing, which consists of looking to the emotional expression of another person for cues about how to evaluate an ambiguous person, object, or situation. Adults engage in social referencing all the time (recall the last time you were in a group and heard a comment that could either be interpreted as funny or sarcastic), and so do infants. When 1-year-olds encounter a friendly but unfamiliar adult, for example, they typically look to their mother's face for cues about how to respond. If mother looks positive or reassuring, infants are more likely to respond sociably; if the mother looks fearful, infants will withdraw and may become distressed. Babies are thus aware that even if they do not know how to respond, mother does, and by 'reading' her emotional reaction while she is looking at the ambiguous event (e.g., a friendly stranger), they can gain information from her emotional reaction about whether this event is positive or negative. (Incidentally, if mother is *not* looking at the ambiguous event, 1-year-olds will work hard to attract her attention to that event). Social referencing is an early example, therefore, of acquiring understanding through the emotions of another.

Infants are capable of social referencing because early in the first year, they learn to appropriately 'read' the facial and vocal emotional expressions of others. They respond distinctively and appropriately to expressions of anger, sadness, fear, and happiness that they detect in another's face or voice. Emotion is thus an early entrée into another's internal experience (in this case, feelings), and infants use others' emotions to learn more about people. In one experiment, 18-month-olds watched as a friendly experimenter ate broccoli (while showing expressions of delight and pleasure) and goldfish crackers (showing disgust and unhappiness). Even though the toddlers themselves preferred the goldfish crackers, when they were asked by the experimenter to give her more of the food that she liked, they nonegocentrically handed her more broccoli. The emotions of others provide young children with tools for social understanding. As they grow up, they appraise the emotions of others even more insightfully as they develop greater social competence and an appreciation of how people are similar and different.

Emotions are also crucial to how young children understand themselves. Although developmental scientists used to believe that young children perceive themselves primarily in terms of their physical characteristics and what they can do (e.g., 'I'm big!' 'I run fast!'), careful research has revealed that preschoolers also have psychological self-awareness. The earliest words they use to describe their own internal states describe their feelings, needs, and desires. By the ages of 4 and 5, preschoolers are aware of some of their personality characteristics, which they describe primarily in terms of emotional characteristics, such as their timidity (or boldness), agreeableness, negative mood, and positive or negative self-image. These self-descriptions are influenced by how young children are perceived by their mothers and the quality of the parent-child relationship (one study reported that preschoolers with low self-concept had mothers with high parenting stress and depressive symptomatology) but they are also based on children's experience of themselves. One reason why emotional characteristics are so prominent in young children's self-awareness, in other words, is because the emotions associated with being shy, negative, or agreeable are experienced every day in recurrent social situations.

Emotions also have a positive, constructive influence on the growth of moral awareness. Traditional moral development theories have emphasized emotions such as fear of punishment, anxiety over the loss of parental love, anticipated rewards for compliance, and feelings of guilt and shame. These emotions are undoubtedly important, but young children's sensitivity to the feelings of others is another important influence on the early development of moral awareness. Emotional sensitivity is central to children's earliest judgments of good or bad behavior ('that made her sad') and of people ('he was mean'), and the human consequences of behavior are crucial to young children's judgment of the seriousness of wrongdoing. Because young children understand others' feelings from such an early age, emotion is a bridge between moral standards and the human consequences of good and bad behavior. Several studies have shown that children were more advanced in moral development if their mothers talked to them about people's feelings and the human consequences of misbehavior, in contrast with when mothers instead discussed rules and the consequences of breaking them. Emotions are a foundation for the development of moral understanding based on the consequences of actions for people.

Emotions are also important to the growth of social competence, especially as children develop significant networks of peer relationships. The ingredients of successful peer relationships, including the capacity to be a self-confident, outgoing play partner, manage conflict constructively, be appropriately assertive in expressing preferences and opinions, and maintain positive expectations for friendship are each based on skills in emotion understanding and emotion self-regulation. By contrast, children who develop significant problems with peers are characterized by aggressive conduct, deficient social problem-solving skills, and a hostile attribution bias that causes them to interpret benign social behaviors of others as having hostile intent. Some intervention programs designed to help children with poor social skills are focused on enhancing children's sensitivity to the emotions of others and enlisting that understanding into social problem-solving skills that include respect for the feelings and needs of other children.

One important reason that emotions can have psychologically constructive influences on social understanding, self-awareness, morality, and social competence is emotional development is embedded in children's relationships with their caregivers. Parent-child relationships are important to the organization of emotional development beginning in infancy, when parents help to manage infants' emotions, buffer stress, and contribute to the baby's emotional well-being. Later, parents help young children understand emotions through their responsiveness to the child's feelings and in conversations when they talk about the causes and consequences of others' feelings. Parents also coach children in emotion self-regulation. The importance of close relationships to emotional development is one reason that children in secure parent-child attachment relationships are higher in emotion understanding and social competence than are insecurely-attached children. Through parental responsiveness and parent-child conversation, emotion becomes connected to children's understanding of themselves and others, emerging values, and other relationships.

Emotion: Its Structure and Functions

Another feature of the study of socioemotional development is a new understanding of emotion itself. Traditionally, researchers have viewed emotional life as a set of distinct emotions that arouse and subside, much as we experience emotions in everyday life. According to this structural view of emotions, emotions are discrete, coherent constellations of physiological, subjective, and expressive activity that are organized neurobiologically, and are thus structured consistently across culture and history. In this view, humans possess a repertoire of basic emotions – including anger, fear, joy, sadness or distress, surprise, interest, and disgust in most theories – that are differentiated by unique patterns of physiological activation, subjective experience, action tendencies, and expression (in particular, facial expression). The emotion of anger, for example, includes a unique subjective experience, the physiological concomitants of that feeling (which accounts for the specific kind of energized arousal that accompanies angry feelings), a unique facial expression (e.g., lowered eyebrows, narrowed eyes, mouth grimace), and specific behavioral tendencies (which may include approach and attack).

Some basic emotions (such as distress) are apparent at birth. Others (such as anger and fear) develop early as the baby becomes capable of relevant conceptual appraisals of people and events. In later years, the repertoire of basic emotions is supplemented by a range of secondary emotions – such as embarrassment, guilt, and gratitude – that are not as strongly organized by biology and are thus more culturally variable. The circumstances eliciting secondary emotions can differ markedly in different societies (e.g., shame is a more significant moral socializer in Asian societies, than in the United States), and not all cultures have the same repertoire of secondary emotions. As earlier noted, basic emotions and the facial expressions signaling them are universally evident in humans. This has led researchers to use facial expressions as indicators of emotion, even in infants and young children. By carefully measuring facial expressions of children as they respond to different experimental events, in other words, researchers

guided by a structural view of emotions expect that they will learn about the underlying subjective emotion that the respondent is experiencing.

Although we typically think about our feelings in a manner consistent with the structural view, other emotion theorists have questioned whether emotional experience is organized in this manner. Cultural theorists point out that people in different societies refer to emotional experiences for which there is no English term, and which are thus not captured in most structuralist accounts of emotion. Some developmental researchers have noted that the facial expressions of young infants are often inconsistent with their circumstances (such as a baby who shows surprise while staring at a soft light), suggesting that facial expressions may not always be reliable indicators of underlying subjectivity. Furthermore, many students of emotion suggest that typical emotional experience consists not of the succession of discrete emotions, but rather subtly nuanced blends of a broad variety of emotional states that range in their intensity and timing. This, too, is consistent with everyday emotional experience.

For these reasons, another way of understanding emotion has emerged to complement the structural view. According to the functionalist view, emotions are defined not by biologically based constellations of expression, experience, and arousal, but rather by an organism's goals and their attainment. Emotions not only reflect success or failure in goal achievement, but are also related to changing or maintaining relations between the organism and the environment in ways relevant to these goals. The emotion of anger, for example, is associated with one's goals being blocked by another, and the action tendencies of anger are directed toward removing this obstacle in order to better achieve the goal. Functionalist approaches emphasize the motivational qualities of different emotions, the importance of emotional expressions as social signals (not necessarily direct reflections of underlying feelings), and the association between emotional arousal and how a person appraises the meaning of environmental events. Although functionalist approaches use the language of discrete emotions, they also refer to broader 'families' of emotions that are connected by common patterns of organism-environment transactions.

A functionalist view of emotion is thus more open to the influence of cultural meanings on emotional life and the view that emotional experience includes blends of feelings rather than discrete emotions. From a developmental perspective, a functionalist approach highlights the importance of the child's goals in specific situations, and these goals may be complex, rapidly changing, and very different from that of accompanying adults (e.g., a toddler seeking candy during a supermarket visit). Measuring emotion also requires attention to more than facial expressions and includes the variety of behavioral, vocal, gestural, postural, and other indicators of emotional experience.

Taken together, structuralist and functionalist views enliven the study of socioemotional development by underscoring the multifaceted influences on emotional experience, and how these change with development. Understanding emotion in these ways also aids researchers in understanding the role of emotion in parent-child attachment, social competence, moral awareness, or other topics in the field of socioemotional development.

The Intersection of Genes and Environment in Socioemotional Development

Socioemotional development is a complex and integrative field of study, uniting consideration of social influences, cognitive development, language ability, the growth of the self, culture, and many other developmental influences with emotional development. Traditionally, developmental study has tended to emphasize either nurture (such as parenting influences or neighborhood quality) or nature (such as genes or brain development). In recent years, however, research in the area of molecular genetics – which studies the structure and function of genes at a molecular level – has rejected the traditional 'nature versus nurture' debate by showing how the expression of specific genes in behavior depends critically on characteristics of the environment. 'Nature versus nurture' has become scientifically obsolete as researchers are discovering that nature and nurture are completely intertwined and that socioemotional development occurs at the intersection of biological processes and social contexts.

Each child enters the world with a unique genetic profile that significantly influences how the child responds socially and emotionally. Molecular genetics research has identified several common genetic polymorphisms (i.e., genetic variations) with specific socioemotional characteristics. These include the dopamine D4 7-repeat (DRD4 7-repeat) which is associated with novelty seeking and impulsivity, and the serotonin transporter promoter short allele (5-HTTLPR), which is associated with negative emotionality and cautious, inhibited behavior. Children with these polymorphisms are more likely to show the social and behavioral characteristics associated with them.

However, children with the same genetic polymorphisms often show *different* behavioral profiles, and research on gene-environment interaction illuminates why. While individual differences in genetic characteristics are set at conception, these differences interact with the environment as the child grows up. In particular, the quality of care is an important influence on how specific genes are expressed in behavior. For example, children who have the DRD4 7-repeat polymorphism and experience harsh, insensitive parenting are significantly more likely to show later behavioral problems compared with children with the DRD4 7-repeat who experience high quality parental care. Beyond the family, social support can also be important. One study, for example, indicated that children with the 5-HTTLPR polymorphism whose mothers reported low levels of social support were more likely to show inhibited behavior in middle childhood compared with children with the same polymorphism whose mothers experienced greater social support. These studies indicate that knowledge of genetic individuality is important in the context of the environment in which that individuality develops.

In light of these conclusions, it is not surprising that children with genetic proneness to negative or inhibited behavior who develop warm, secure parent-child relationships have better socioemotional outcomes than children in insecure relationships, and indeed this is true. One study showed that children with the 5-HTTLPR polymorphism with insecure parent-child attachments showed higher levels of distress and fear.

But children's genetic characteristics may also contribute to the security of the parent-child relationship. Children with the

DRD4 7-repeat or the 5-HTTLPR polymorphisms are more likely to develop insecure, especially disorganized, attachment relationships when their mothers are insensitive and unresponsive. In each case, the polymorphism may heighten children's susceptibility to negative parenting, making these children more vulnerable to developing insecure attachments. Although parental sensitivity is the key influence on the development of secure attachment, hereditary influences may cause some children to be more affected by variations in parental responsiveness than others. In this respect, genetic characteristics can moderate the effects of environmental influences (such as the quality of parental care) on socioemotional development.

Genes and Risk for Emotion-Related Psychopathology

An understanding of gene–environment interaction can help answer some of the perplexing questions of socioemotional development. Why do some children who are abused and neglected early in life appear to develop normally, whereas others become aggressive, depressed, or show other negative outcomes? More generally, why do two children who experience similar rearing environments turn out so differently? The answers to questions like these concern how genetic characteristics can buffer or enhance the effects of environmental influences.

One illustration comes from research on the monoamine oxidase A (MAOA) gene, which encodes the MAOA enzyme that plays a role in regulating aggression and antisocial behavior. Genetic characteristics leading to low MAOA enzyme production are associated with aggressive conduct. One researcher found that in a large sample of men, some of whom had been abused as children, the long-term effects of early maltreatment depended on whether genetic characteristics led to high or low MAOA activity. Men who had low MAOA activity and had been abused as children exhibited, as adults, higher rates of conduct disorder, violent behavior, and antisocial behavior than men with high MAOA activity, even though both groups had experienced child maltreatment. Men who had not been abused in childhood showed low levels of adult negative behavior regardless of their MAOA activity.

Thus, while maltreatment heightened the risk of later problem behavior, this risk was especially increased for men with a particular genetic characteristic. Another study found that when young adults experienced stressful events (such as problems with health, employment, or significant relationships), whether they later became depressed was predicted by whether they also had the 5-HTTLPR polymorphism. Those with 5-HTTLPR were more likely to later show depressive symptoms after encountering life stress compared to those without the 5-HTTLPR polymorphism, whereas individuals who had not experienced significant stress showed little depression. These findings are a good illustration of gene–environment interaction, and how genetic characteristics can moderate the effects of even severe environmental challenges.

Based on these findings, it is easy to conclude that children with the 5-HTTLPR or DRD4 7-repeat polymorphisms or with low MAOA activity have inherited genetic characteristics that increase their risk of socioemotional difficulty. For this reason, they are sometimes described as 'vulnerability genes.' However, some researchers suggest instead that these genes contribute to

the child's differential susceptibility to *both* negative *and* positive environmental influences. Some studies find, for example, that children with the DRD4 7-repeat polymorphism show greater negative behavior when they experience harsh parenting compared to children without this polymorphism, but also that they respond more positively to responsive parenting than children without the DRD4 7-repeat. Viewed in this light, certain genetic characteristics seem to make children more sensitive to environmental influences, whether they are positive or negative. Clearly, this view changes the portrayal of these genes from 'vulnerability' genes to 'sensitivity' genes, and this has implications for how to construct environments that enable children with different genetic tendencies to thrive socioemotionally.

The research on molecular genetics adds to the field of socioemotional development the recognition that genetic individuality is an important contribution to the growth of emotional and social characteristics. It shows that the environment influences how genes are expressed in behavior, and that the effects of the environment (such as parental warmth and responsiveness) depend, in part, on the child's genetic characteristics. This research puts to rest the traditional 'nature versus nurture' debate by showing that genes and environments interact continuously in development, and that an understanding of genetic influences requires an appreciation of the environments in which genes are expressed.

Socioemotional Development and the Developing Brain

The field of socioemotional development is also enriched by current research on brain development. Research in this area highlights, in particular, how children's social experiences can influence the complex neurobiological processes in the brain and body by which emotional responses are constituted and regulated.

Emotional responses are complex neurobiological phenomena. An emotional reaction typically begins in the reciprocal influences among multiple brain areas relevant to the appraisal and evaluation of environmental events. Some of these brain areas in the subcortex (such as the amygdala) are deeply rooted in our mammalian heritage, while others in the cortex are evolutionarily newer regions involved in complex judgments. As events are appraised, these brain systems lead to the activation of multiple processes in the sympathetic nervous system and endocrine system that create the physiological and subjective experience of emotion as the body responds to the instigating event. For example, the limbic–hypothalamic–pituitary–adrenocortical (LHPA) axis is a network of nervous system and endocrine system processes that constitute the body's primary stress system, and in coordination with other neurobiological systems, it contributes to the immediate surge of energy, attentional focus, and emotion following threat as well as the long-term arousal that is also associated with stress. At the same time that sympathetic nervous and endocrine systems are activating the body to respond, other systems are beginning to help the body self-regulate and recover. The parasympathetic nervous system, for example, restores nutrients and modulates the increase in heart rate and other physiological systems to restore the body. In addition, regions of

the prefrontal cortex, which contribute to the brain's initial activation of an emotional response, also contribute to the regulation of emotional reactions as they unfold.

There are two important characteristics of the neurobiology of emotion that are sometimes overlooked. The first is that these systems are in constant interaction, with mutual influences that contribute to the complexity of socioemotional responding. Although researchers have long understood how the prefrontal cortex regulates brain structures like the amygdala, for example, it is also true that activation of the amygdala affects cortical areas associated with thinking and judgment – which is reflected in the cognitive focus on threat and danger that accompanies stress responding. Because multiple higher and lower neurobiological systems associated with emotion are deeply interconnected, emotional responding derives from the complex interaction between them.

The second important point is that these brain and biological systems develop over time, and this helps explain certain features of socioemotional growth. As the parent of any newborn can attest, the LHPA system is functional at birth, but as it matures, emotional reactions become less intense and labile, more modulated, and more easily managed. These changes in emotionality also occur through the gradual maturation of other neurobiological systems associated with emotion regulation. Some of these systems, particularly in the prefrontal cortex, have a very extended maturational timetable, which helps to account for the slow growth of skills in emotion self-regulation throughout childhood and adolescence.

The development and functioning of brain areas associated with emotion is also affected by caregiving experience. This can happen in at least two ways. First, in the immediate situation, a parent's warmth and support can buffer stress for a child. One study showed that when physiological stress responses were measured in toddlers following a series of challenging events, the highest levels were shown by toddlers who were temperamentally inhibited and were in insecure relationships with their mothers. For inhibited toddlers in secure relationships, the mother's presence helped to buffer the physiological effects of challenging events, and toddlers who were temperamentally uninhibited were not bothered by the challenges at all. Caregiver sensitivity provides support that better enables children to manage emotional challenges. Second, in the long term, the responsiveness of caregivers and the quality of early experiences can alter the development of neurobiological systems governing stress reactivity and emotion. Children growing up in early adversity, for example, are more likely to become attentionally focused on signs of threat, biologically and emotionally more reactive to challenge, and less capable of adaptive self-regulation. It appears that recurrent experiences of adversity cause neurobiological systems associated with emotion and stress to recalibrate to adjust to the greater threats and difficulty the child regularly encounters. This results in over-reactions to perceptions of threat or danger.

This developmental process is observed most clearly in children who have been maltreated. Many studies indicate that abused children are hypersensitive to adult expressions of anger, perhaps because this enables them to anticipate and prepare for abusive conduct before it begins. Some researchers have identified areas of the brain that contribute to abused children's heightened attention to angry (but not happy or

fearful) adult expressions in the face and voice. Furthermore, maltreated children are more likely to develop heightened LHPA reactivity to stressful events that can cause them to respond with more intense emotion and behavior to threats and challenges. These changes in neurobiological stress systems can help to explain why maltreated children are more physically and verbally aggressive to peers, tend to interpret others' benign social behavior as having hostile intent, and are more likely to develop conduct disorders and other problems later in life.

Understanding socioemotional development in the context of the developing brain underscores that emotional responses to social events are neurobiologically complex, involving constant interaction between multiple neural and endocrine processes. These biological systems mature throughout childhood and adolescence, which helps to account for the progressively more modulated, socially sensitive, and self-regulated quality of emotional responding with growing maturity. These studies also highlight how the neurobiological systems governing emotion and stress reactivity are affected by social experience, particularly the quality of parental care. In situations when children experience significant early adversity, this increases the probability that brain systems governing stress and emotion will become hypersensitive to threat in ways that may pose long-term problems for social functioning.

Emotion Regulation

Emotion regulation consists of the internal and external processes involved in monitoring, evaluating, and modifying emotional reactions (especially their intensity and temporal features, such as speed of onset and recovery) to accomplish one's goals. Emotion regulation is an important topic in the field of socioemotional development because of its theoretical and practical implications. Theoretically, emotion regulatory processes incorporate individual goals, parental socialization processes, societal values, and cultural beliefs into the construction of emotional life, and contribute to how people are emotionally distinct but also share emotional qualities in different social groups. Practically, research on the development of emotion regulation is important to designing interventions that can help children and adults with problems associated with emotion dysregulation, including depression, anxiety, aggression, and relationship disturbances. More generally, research on this topic addresses the challenges of enlisting emotional reactions constructively into adaptive social functioning.

The definition of emotion regulation given above highlights that regulatory processes can be involved in managing positive as well as negative emotions (such as suppressing laughter when hearing a joke at a serious event), and can involve how other people regulate one's emotions as well as one's own self-regulatory efforts. Emotion regulation by others is, of course, especially important to infants and young children. This definition of emotion regulation also underscores that emotion is managed by altering its intensity and its temporal features (such as its escalation, decline, or lability). Individuals self-regulate in order to reduce the intensity of feelings of sadness, for example, or to retard the rapid escalation to anger when provoked, and it is the intensive and

temporal features of emotion that are often characteristic of emotion-related psychopathology like depression.

Emotion regulation is important for accomplishing one's goals. This is consistent with the functional view of emotion earlier described, and is important for understanding how and why individuals manage their emotions as they do. In developmental analysis, adults may misperceive children as emotionally dysregulated in situations where children are functioning quite well as emotional tacticians (e.g., a toddler fussing for candy, an adolescent becoming moody to elicit sympathy from friends). Multiple goals can guide emotion regulatory efforts, and different self-regulatory strategies can serve different goals in different situations. A child who is being threatened by a peer, for example, may manage emotions differently to accomplish the immediate goal of averting the bully (e.g., crying loudly to elicit help) or to deter future intimidation (e.g., controlling fear and enhancing anger to defend oneself). The efficacy of alternative emotion regulatory strategies in accomplishing goals depends, of course, on the presence of other people and the child's relationships with them, cultural values (e.g., Nepalese children, are socialized to avoid *any* expression of negative emotions), and many other factors.

In some circumstances of emotional adversity, the self-regulatory challenge faced by children is that there are no optimal strategies for coping with the emotional demands they face. Their emotion regulatory strategies are likely, therefore, to involve inherent trade-offs that purchase immediate coping at the cost of long-term difficulty, and which ultimately may increase rather than diminish their emotional problems. Some of the problems faced by abused children discussed earlier, for example, derive from their hypersensitivity to signs of adult anger that enables them to anticipate an abusive encounter to come, but also renders them more prone to socially inappropriate, aggressive conduct with others. Likewise, children with anxiety disorders devote considerable self-regulatory effort to avoiding encounters with anxiety-provoking stimuli, but in doing so they obtain immediate emotional relief at the cost of long-term dysfunctional behavior. Viewed in this light, emotion regulation for children in conditions of emotional adversity can be seen as a double-edged sword.

Developmental changes in emotion regulation provide significant contributions to social and emotional competence. Whereas a newborn infant may cry uncontrollably, the toddler can seek assistance from others, the preschooler can reflect on and talk about her feelings, the school-age child can redirect attention and use other deliberate strategies to reduce distress or anxiety, and the adolescent can evoke personal strategies (like listening to favorite music) that manage emotion. Many developmental advances in the skills of emotion regulation account for these changes. With increasing age, children become familiar with and adopt sociocultural expectations for emotional expressions, especially in public settings. They assume greater responsibility for managing their own positive and negative feelings. Their repertoire of self-initiated strategies for managing emotions grows, from an initial reliance on behavioral tactics that often rely on social support (e.g., seeking help; avoiding emotionally arousing events) to increasing use of mentalistic strategies of emotion self-regulation (e.g., attentional redirection; cognitive reappraisal). Over time, furthermore, children show increasing breadth, sophistication, and

flexibility in their use of different emotion regulation strategies, and are capable of adapting preferred strategies to the demands of the situation, substituting more effective strategies after others have proven ineffective, and even using multiple strategies when needed. Children also develop strategies that are more effective in managing certain emotions (such as fear) than others (such as anger). The development of emotion regulation is also based on developing an understanding of emotion, growing capacities to monitor one's feelings and appraise the effectiveness of self-regulatory efforts, and incorporate emotion self-regulation into a broader variety of circumstances (such as to enhance problem-solving effectiveness).

As noted earlier, the development of emotion regulation is also associated with brain development, and especially with the slow maturation of areas of the prefrontal cortex that assume a significant influence in emotion management. However, as earlier noted, many brain systems are mutually influential in emotion arousal and regulation, which means that cortical brain regions relevant to emotion self-regulation are also influenced by the activity of brain structures associated with emotion activation. For children and adults who suffer from emotion-related psychopathology that involves alterations in normal hormonal and neurobiological processes associated with emotion, the effectiveness of prefrontal and other cortical areas involved in emotion self-regulation is blunted because of the effects on these areas of lower emotion processes that have been affected by psychopathology.

The study of emotion regulation enlivens the field of socioemotional development because of the important issues it raises concerning how emotional experience is individually and socially constructed, and because of its important practical implications for understanding the origins and treatment of emotion-related psychopathology. As this short discussion has also illustrated, the study of emotion regulation is also uniquely integrative, involving neurobiology, cognitive development, social understanding, cultural values, individual goals, and a variety of other developmental influences.

Conclusion

The field of socioemotional development highlights new understanding of the constructive role of emotion in behavior and development, the continuous interaction of social influences with emotional development, and the importance of integrating the understanding of developing neurobiology, genetics, culture, cognitive growth, temperament, and many other developmental influences. Study of socioemotional development also has significant practical implications, including the importance of understanding emotion and self-regulation to social competence, the significance of emotion to morality, and understanding the origins and treatment of emotion-related psychopathology.

In the specific topics discussed in this article, new ideas concerning the interaction of genetics and environment in socioemotional development are profiled to underscore the obsolescence of the traditional 'nature versus nurture' debate. In addition, the importance of social influences on the developing neurobiology of emotional and stress reactions, and the multiple influences on the growth of emotion regulation,

were also discussed. Taken together, the field of socioemotional development continues to expand in important and provocative new directions.

SD Somatoform disorder.

SSD Somatic symptom disorder.

SzD Somatization disorder.

USD Undifferentiated somatoform disorder.

Introduction

Definition

The primary hallmarks of somatoform disorders (SDs), according to DSM-IV-TR, are “somatic symptoms presumed caused by general medical conditions, but are not fully explained by them, other mental disorders, malingering or substance intake. They must cause major clinical distress or decline in daily function.” The SDs according to DSM-IV-TR are multidimensional, primarily seen in primary care, have ~50% comorbidity with anxiety and depression, and are categorized in the following seven subtypes: somatization disorder (SzD); undifferentiated SD (USD); conversion disorder; somatoform pain disorder; hypochondriasis; body dysmorphic disorder (BDD); and SD not otherwise specified (NOS).

Subtypes

SzD is characterized by a history of lifetime multiple unexplained medical problems or physical complaints beginning prior to the age of 30. Patients report symptoms affecting multiple organ systems or physical functions, including pain in at least four unexplained localizations, at least two nonpain gastrointestinal conditions, at least one sexual problem, and pseudoneurological symptoms. Although medical explanations for the symptoms cannot be identified, individuals with SzD experience genuine physical discomfort and distress, and they will usually visit a number of medical specialists.

USD is similar to SzD, but has fewer symptoms or of shorter duration. Common symptoms by one or more medically unexplained physical symptoms (MUPSs) lasting for at least 6 months include for example, chronic fatigue, pain, loss of appetite, and gastrointestinal distress. This diagnosis is appropriate for patients who do not meet all the diagnostic criteria for SzD. Escobar and colleagues have proposed the label ‘abridged somatization’ to be applied to men experiencing four or more unexplained physical symptoms or to women experiencing six or more unexplained physical symptoms, while Kroenke and colleagues have suggested the term ‘multi-somatoform disorder’ to describe men or women currently experiencing at least three unexplained physical symptoms and reporting a 2-year history of somatization.

Conversion disorder is marked by unexplained sensory or motor symptoms that resemble those of a neurological illness

or injury. Common symptoms include paralysis, loss of sensation, double vision, seizures, inability to speak or swallow, and problems with coordination and balance. Doctors often detect conversion disorder when symptoms do not make sense anatomically. Conversion disorder is characterized by the presence of one or more pseudoneurological symptoms that are associated with psychological stressors or conflicts. The conversion disorder construct reflects that somatic symptoms are the result of psychogenic distress.

In somatoform pain disorder, the patients perceive that physical pain causes significant distress or disability, or leads an individual to seek medical attention. Pain is medically unexplained, or associated with a medical condition, but far more severe than expected from the condition itself. Like patients with SzD, people with somatoform pain disorder often have a history of consultations with numerous physicians.

Hypochondriasis is diagnosed when a person is excessively concerned by fears of having a physical disease or injury. Individuals with hypochondriasis usually do not complain of disabling or painful symptoms. Instead, they tend to overreact to minor physical symptoms or sensations, like rapid heartbeat, sweating, small sores, or fatigue. Many people with hypochondriasis develop fears in response to the illness or death of a friend or family member or after reading about a condition or seeing a feature on television. Hypochondriacal fears can be confined to a single disease or may involve a number of different physical concerns. Individuals with hypochondriasis seek frequent reassurance by consulting physicians or talking about their fears, which provide only temporary relief from their fears.

BDD is characterized by preoccupation with a defect in physical appearance. It is a somatic delusion that a part of one’s body has been injured or altered in some manner. Often, the perceived defect of concern is not apparent to other observers, or if there is a genuine defect, it is far less disfiguring than the patient imagines. Common preoccupations include concerns about the size or shape of the nose, chin or cheek, skin appearance, body or facial hair, hair loss, or ‘ugly’ hands or feet. Individuals with BDD may be extremely self-conscious, avoiding social situations because they fear others will notice their physical defects or even make fun of them. They may spend hours examining the imagined defect, for example, hair loss, or avoid mirrors altogether. Time-consuming efforts to hide the defect, such as application of cosmetics or adjustments of clothing or hair, are common. Many people with BDD undergo

procedures like plastic surgery or cosmetic dentistry, and plastic surgeons should be advised not to perform such procedures on this group of patients. Somatic delusions are more serious than other SDs, which can explain why BDD is suggested to be removed in the new DSM-V revision.

SD NOS, is diagnosed when somatoform symptoms are present but criteria for another SD are not met. DSM-IV-TR includes several examples of symptoms that could merit this diagnosis, including false pregnancy, and hypochondriacal fears or unexplained physical symptoms of recent onset or short duration.

Historical Overview

Briquet was the first scientist who conceptualized specific multiple somatic symptoms as one syndrome, which he named hysteria. Others have later applied the term Briquet to this syndrome. Freud later noticed patients who were appearing with the same phenotypes, but unlike Briquet, he distinguished between two different phenomena which both presented somatic symptoms, namely, *conversion hysteria* and *neurasthenia*. Freud defined conversion hysteria as psychic in origin, but neurasthenia as being somatic in origin. The so-called nerve-sick epoch suggested a detrimental effect on the nervous system by fast walking, fast driving, fast eating, fast drinking, fast bargains, fast business, fast 'everything.' The eyewitness descriptions from that time could be as follows: "The noise from the streets, the ceaseless thunder from the vehicles, the rush to-and-from of multitudes of people is more than people can bear. The ceaseless hurry and disruption of business life, the feverish pace, the clamor of the wagons, the endless variety, all the entertainments that exhaust body and soul and continue until late at night; it exhausts the nervous system." Briquet's hysteria concept was further developed by Purcell et al. in 1951 and operationalized by Perley and Guze in 1962. Hysteria, as defined by these authors, was characterized not only by the presence of multiple somatic complaints, but also by anxiety and depressive symptoms. Hysteria was the precursor to the SzD concept, which had an unclear nosological status until the DSM-III defined it in 1980. Anxiety and depressive symptoms were from then no longer a necessary diagnostic criterion for SzD. Lipowski has placed the behavioral dimension into the somatization and SD conceptualization of DSM, based on Pilowsky's abnormal illness behavior paradigm: It is the "tendency to experience and communicate somatic distress and symptoms unaccounted for by pathological findings, attribute them to physical illness and seek medical help for them." Later, several other classifications and terms have been introduced. A line of descent can be traced from the DaCosta syndrome through soldier's heart, shell shock, and battle fatigue to the Gulf War syndrome. Musculoskeletal pain in the workplace, which previously manifested as writer's cramp and telegraphist's wrist, was later termed repetition strain injury in Australia in the 1970s. There are similarities between railway spine, common in the early twentieth century, and the more recent chronic whiplash syndrome. Although the similar constellations of benign symptoms acquire different diagnostic labels, they can be attributed to different causes in different time periods, and thus seem to appear in epidemics or as 'contemporary diseases.'

DSM-IV Compared to ICD-10

SDs are also defined in the International Classification of Diseases (ICD) classification system. As in the DSM system, it relies on subjectively perceived and expressed symptoms. The DSM classification indicates that there are mental causes for SDs, but has also a plausible multilevel conceptualization as expressed by its five axes (*Axis I*: clinical disorders, including major mental disorders, and learning disorders; *Axis II*: personality disorders and mental retardation; *Axis III*: acute medical conditions and physical disorders; *Axis IV*: psychosocial and environmental factors contributing to the disorder; *Axis V*: Global Assessment of Functioning).

The ICD-10's interpretation of SDs is similar, but is not multileveled: "SD's are disorders characterized by distressing, subjective physical symptoms, but without biological changes that can satisfy the requirements of any recognized physical illness." In the ICD-10 system, which classifies both mental and somatic disorders, the SDs criteria differ from those in DSM-IV-TR in several important respects. In ICD-10, BDD is incorporated in the criteria for hypochondriasis. In addition, the ICD-10 includes a category called somatoform autonomic dysfunction (SAD). The criteria for SAD claim symptoms of autonomic arousal in the absence of any known disturbance of structure or function. The criteria for SzD demand at least 2 years of multiple and variable unexplained symptoms representing at least two organ systems. The ICD-10 criteria for pain disorder call for persistent, severe, and distressing pain, continuously for at least 6 months, that cannot be explained by a objective measures or a physical condition. DSM-IV-TR, by contrast, specifies an important role for psychological factors in somatoform pain disorder, but claims no duration requirement. A problem with the ICD-10 classification system is that it has only one category for the diagnosis (e.g., fatigue can be respiratory (R-diagnoses), neurological (G-diagnoses), or psychiatric (F-diagnoses)), but cannot claim more than one explaining factor. However, there is also a problem with the DSM system because it merely is a psychiatric classification system. However, its five axes broaden the perspectives of the causality (e.g., *Axis II* expresses personality features, *Axis III* expresses medical and physical disorders, and so on).

Common characteristics of SDs both in the DSM and ICD system are that the symptoms suggest a medical condition, but that no objective, medical state can be found by a physician. In other words, a person with an SD might experience significant pain without a known medical or biological cause, or they may constantly experience minor aches, pains, and fatigue without any clear reason for these symptoms to exist.

Other Conditions Approximating the SDs

Phenomenon, Symptom, Illness, and Disease

To conceptualize SDs, it is convenient to apply both subjective and objective measures of medical terminology, and to distinguish between phenomena (what we observe), symptoms (abnormal functions or feelings subjectively noticed by the patient), illness (subjective apprehension by a patient of an objectively defined disease), and disease/disorder (i.e., abnormal conditions affecting the body of an organism with known

pathogenesis). A question is whether it is plausible to apply descriptive or etiological diagnoses, as well as process or outcome evaluations. Traditionally, the golden standard for a diagnosis features an explanation in its name, that is, it is etiologic (sinusitis informs about a sinus infection, while fibromyalgia just describes 'pain in muscles'), and while somatization describes a process, somatoform describes an appearance or outcome and thus borrows nomenclature both from Greek ('soma') and Latin ('form').

Medically Unexplained Physical Symptoms

MUPSs or medically unexplained symptoms (MUSs) are defined as subjective patient symptoms for which the treating physician, other healthcare providers, and research scientists have found no medical cause. The term does not mean that a physical cause does not exist, but rather that causes for the given symptoms are uncertain, unknown, or disputed, that is, there is no scientific consensus. Subjective health complaints (SHCs) are also a term for these unexplained symptoms.

Indications of a major or substantial illness can be concluded by using the following parameters: the amount/number of the MUPSs, for example, how many pain localizations or gastrointestinal problems do the patients have; the length of the illness, that is, the illness duration of the symptoms, for example, pain lasting for more or <6 months; their impact on the quality of life; increased medical consumption; the number of symptom groups (e.g., pain, fatigue, bowel problems, sexual dysfunction); and psychological comorbidity. In some patients, the symptoms are attributable to a known somatic disorder; in others, they result from unrecognized factors which may involve physiologic or immunologic hyperactivity and perceptual hypersensitivity. Others may have symptoms that are caused by a psychiatric disorder, or stressful life circumstances. Our knowledge of the functional somatic syndromes (FSSs) is incomplete, and we do not fully understand the etiologic roles of biological, psychological, and socio-cultural factors. How can we understand the patients with subjective symptoms without objective findings?

These patients represent a large and troubled group. Many symptoms coexist and overlap in the patients, for example, fatigue, pain, insomnia, paresthesias, headache, depression and anxiety, sicca symptoms (dry mouth and eyes), gastrointestinal problems, urge incontinence, and Raynaud phenomena (very cold and white hands/feet). They are diffuse, nonspecific, and ambiguous, and they are very prevalent in healthy, nonpatient populations. The similarities seen have led some to propose that the somatic syndromes share a common pathophysiology. However, we do not know if there is one syndrome or discrete syndromes, or if they share common etiological factors. The boundaries between these conditions and their relation to more traditional and accepted diagnoses are still not clear.

Although we are not yet able to explain these conditions satisfactorily, it is recommended that research has a direct focus on the common features with an open-minded multidisciplinary approach. Syndromes characterized by chronic, medically unexplained fatigue, effort intolerance, cognitive dysfunction, widespread musculoskeletal pain, and tenderness are highly prevalent in medicine. They cause a great deal of problems and grave physical, mental, social, and vocational disability. MUSs

are given various labels mainly as a result of their most pronounced symptoms. Examples are central sensitization syndromes (CSSs), for example, chronic fatigue syndrome/myalgic encephalopathy (CFS/ME), fibromyalgia (FM), irritable bowel syndrome (IBS), painful bladder syndrome/interstitial cystitis (IC), temporomandibular joint disorder (TMJD), tension headache, vulvodynia, and multiple chemical sensitivity (MCS).

Factitious Disorder and Factitious Disorder by Proxy

In some cases, patients intentionally produce or pretend physical or psychological signs or symptoms, where the motivation for this behavior is to assume a sick role and external incentives for the behavior are absent. According to the DSM-IV-TR or ICD-10 classification systems, the official diagnoses of these cases are called factitious ('artificial') disorder (FD); F68.1 in the ICD-10; 300.16 or 300.19 in the DSM-IV-TR. The craving to obtain a behavior according to the patient's role, rather than to gain external rewards, distinguishes FD from malingering. However, both malingering and FD differ from the SDs in the DSM-IV-TR and ICD-10 classification systems, but not according to the up-to-date DSM-V draft per October 2010. The primary purpose of this behavior is to gain some form of internal gratification such as attention for themselves. A few FD subtypes are specified in the DSM-IV-TR: patients with primarily physical signs and symptoms (300.16), patients with primarily psychological signs and symptoms (300.19), or combined subtype (300.19). Some experts also use the term Munchausen's syndrome, which actually is not regarded as a discrete disorder, but more like a subtype of factitious disorder (FD) (also called 'Adult Munchausen' and 'adult factitious disorder').

Factitious disorder by proxy (FDP) (also called Munchausen's syndrome by proxy, MSBP or Munchausen's by proxy syndrome) is a label characterized by hidden and often misinterpreted child abuse. Proxy means substitute. FDP can be difficult to detect and confirm. Richard Asher introduced the term MSBP in 1951 to describe behavioral traits of caretakers who deliberately exaggerate and/or fabricate and/or induce physical and/or psychological-behavioral-mental health problems in others, mainly their own children. DSM-IV introduced the term factitious disorder by proxy (FDP) in 1994 to describe the mental illness of a perpetrator who fabricates illnesses on their victims. However, FDP is not regarded as an official category in the DSM-IV, but there is a description of it in Appendix B, in the section of disorders which need further study. The DSM-IV advises practitioners to use the diagnosis of FD NOS for individuals who satisfy the FDP criteria. In both diagnostic systems, ICD-10 and DSM-IV, the criteria for FD and FDP are nearly identical (see [Table 1](#)).

Somatic distress and MUSs have always been endemic to daily life, but the social and cultural characteristics of every era shape the expression, interpretation, and attribution of these symptoms. SHCs without or with minimal somatic findings (pain, fatigue) are common and frequent reasons for encounter with the general practitioner (GP) and for long-term sickness leave and disability. The complaints are often attributed to the stressors of modern life. However, studies have shown that common, MUSs are not specific for industrialized societies. For example, aborigine mangyans living under primitive conditions in the jungle and by the coast of the

Philippines have more musculoskeletal complaints, fatigue, mood changes, and gastrointestinal complaints than a respective Northern European population, but they ignore them to a greater extent.

New Definitions?

The classification of SD is a complicated task, and while this article is written, there is a debate going on about how these should be defined in the new classification system DSM-V, for example, to replace the term SDs by the new term somatic symptom disorders (SSDs) and for example, the subcategory SzD with the term complex somatic symptom disorder (CSSD) (see Table 1). Thus, we debate some of these taxonomic issues, especially from a clinical point of view, and eventually present our own related term complex symptom disorders (CSDs) which we have not proposed as a new diagnosis, but used as an adjuvant to the official diagnoses.

Is SD a Mental or Somatic Disorder?

Somatization has been defined in many ways, but despite their differences, the definitions have one element in common, namely, the presence of somatic symptoms that cannot be adequately explained by organic findings. Somatization and SDs are poorly understood, both in view of conceptuality, nosology, causality, pathogenesis, clinical phenotypes, and treatment. However, somatization has traditionally been categorized as (1) "a phenomenon secondary to psychological distress, that is, *presenting somatization*" or (2) as "a primary phenomenon caused by somatic distress characterized by MUSs, that is, *functional somatization*." The so-called *presenting*

somatization from psychological distress is considered to be a psychiatric disorder. This is why psychiatrists and psychologists have considered somatization as their sphere of influence. However, somatic symptoms are also the features of the so-called functional somatization due to somatic distress, that is, where specific suppositions about causality are excluded. It is interesting to note that it is exactly the relation between somatization, anxiety, and depression, which are the two discrete ways in which somatization has been conceptualized, namely, as a somatic manifestation of psychological distress on the one hand versus somatic distress or the experience of MUS on the other hand. Thus, earlier theoretical speculation and empirical investigations of SD have been difficult to evaluate and compare with later versions.

It is plausible to view SDs on a continuum from symptoms to disorders, and from subjective to objective measures. MUSs present no objective findings, or their symptoms are more apparent than could be expected from the objective findings.

Functional Somatic Syndromes

These health symptoms may cluster and can thus be conceptualized as somatic *syndromes*, which are named FSSs by some authors. The term functional somatic syndrome refers to several related and overlapping syndromes that are characterized more by symptoms, suffering, and disability than by disease-specific, demonstrable abnormalities of structure or function. These are, for example, chemical sensitivity, sick building syndrome, repetition stress injury, chronic whiplash, chronic Lyme's disease, side effects of silicone breast implants, candidiasis hypersensitivity (yeast infection), the Gulf War syndrome, food allergies, chronic carbon monoxide poisoning, chronic mononucleosis, symptoms resulting from exposure to video

and PC display terminals, carbonless copy paper or weak electromagnetic fields, CFS, total allergy syndrome, burnout, CFS/ME, fibromyalgia, psychogenic headaches, MCS, el-allergy, environmental illness, and dental amalgamism.

Although the FSS are not new, patients who have these syndromes today differ from their predecessors by being less relieved by negative findings on medical evaluation and less responsive to explanation, reassurance, and palliative treatment. Several factors may account for this shift. To explain the endemic of our time, we have three hypotheses. First, the authority and prestige of the physician have declined: the reassurance of one's personal physician and the opinions of medical and public health authorities are no longer as calming, reassuring, and palliative as they once were. Second, the current situation is powerfully shaped by the mass media, which often use tabloid and uncritical reporting to portray the FSSs. Preliminary data, tentative findings, and the personal accounts of individual sufferers are reported as conclusive medical evidence. Finally, the contemporary climate is marked by the prominent political, legal, economic, and regulatory ramifications of the FSSs. Individuals and organizations may have interests in the status of these syndromes, and the actions of these persons and groups thus reinforce sufferers' beliefs that their symptoms have a medical basis.

Epidemiology

According to various European and American studies, an SD has been diagnosed to ~16% of consecutive consulting patients in a general practice and up to 30% in the community. According to a Norwegian study, 7.8% of the population has SDs according to ICD-10; 9.8% for females and 5.7% for males. The prevalence of SzD in the general population and general practice has been estimated to 0.1–0.7%. USD appears significantly more prevalent than SzD as defined by DSM-IV-TR, counting from 4% to 13.8% of the community samples and up to 13.0 in general practices. Prevalence of conversion disorder ranges from 0.01% to 0.3% both in the community and in general practice, while somatoform pain disorder has a corresponding prevalence of 0.6–1.6 according to the DSM criteria, but probably much more when including disorders with no or mild impairment, as the estimated prevalence of chronic pain in the general population is about 30%. Furthermore, an Italian survey also found the following 1-year prevalence: 0.7% for BDD and 4.5% for hypochondriasis, in addition to the disorders mentioned before. In most SD categories, a female predominance exists. The female-to-male ratio has been estimated to 10:1 for SzD, from 2:1 to 5:1 for conversion disorders, from 1:1 to 9:1 for pain disorders (chronic low back pain and fibromyalgia, respectively), and 1:1 for hypochondriasis. These figures tell us that the epidemiology of these disorders is difficult.

MUSs/MUPs: 86–95% of the general population has at least one somatic symptom in a given 2–4-week period. The typical adult has a symptom every 4–6 days and 81% of healthy college students report having at least one somatic symptom in a 3-day period. A total of 33% of all physical symptoms are MUS. A total of 50% of people suffering with depression have MUS, which can cause two to three times higher risk for anxiety and depression, and younger females

have more bothersome symptoms than males. Pain and gastrointestinal problems are the most customary symptoms. Longitudinal studies are few with methodological difficulties and thus must be treated with caution. Nevertheless, the occurrence of MUS seems to come and go, but also stays steady for a subgroup of about 8%. Negative predictors are female sex, age, and psychological distress. Approximately two-thirds of the patients have kept their DSM-III SzD, conversion disorder, or hypochondriasis after 4–5 years. More specifically, 48% of the entire SD group (DSM-IV) still have their diagnoses after three and a half years, with 28% continuing to have SzD/Briquets syndrome (DSM-IV) after 1 year. Approximately 60% of MUSs are forgotten after 12 months measured by Composite International Interview (CIDI).

Treatment

SzD and USD

In a recent review, Kroenke revealed the efficiency of treatment for SDs. He found that cognitive behavioral therapy (CBT) was effective for SzD, USD, and MU(P)S in five of the seven trials. Most positive outcomes were for somatic symptoms (5), and then psychological (3) and functional outcomes (3). Antidepressants were effective in three of the four trials on somatic and psychological symptoms, but not on function. A psychiatric consultation letter to the primary care physician about strategies for managing the somatoform patient to improve physical functioning and reduce costs was effective in three of four trials, but on function only. A multicomponent nurse-administered intervention, using a type of CBT and antidepressants as indicated, was beneficial in one trial on psychological symptoms, whereas one of the two trials using non-CBT psychotherapy was positive on function and psychological symptoms. One trial found aerobic exercise ineffective, and emotional disclosure through writing was ineffective in a single trial. Other studies have revealed that short-term psychodynamic psychotherapies induce modest effects on physical and psychiatric symptoms and social adjustment. *Hypochondriasis*: according to Kroenke's review, CBT was effective in four of four trials, and one using educational intervention methods. All trials benefited in psychological symptoms, that is, hypochondriacal cognitions and behaviors, while somatic symptoms and function only benefited in one of the four trials. BDD: CBT did well in two of two trials, while fluoxetine (an SSRI) was effective in one single trial. All the three trials showed benefits in terms of obsessive-compulsive BDD beliefs and behaviors, while function improved in one CBT trial and the SSRI trial, while none improved somatic symptoms. *Conversion disorder*: the results were inconclusive for the *conversion disorders*.

The review reveals that two types of interventions, antidepressant medication and CBT, are supported by level I (systematic reviews) evidence as benefiting patients with MUSs, but there were no studies comparing the efficacy between pharmacological and psychological treatments. There were poorer evidence for other pharmacological and psychological interventions, for example, collaborative care model, consultation letter, bioenergetics exercise, St. John's wort extract, and levosulpiride. We recommend reading Kroenke's review in *Psychosomatic Medicine* (2007) for further details.

A review conducted by Lesley Allen in 2010 showed that CBT work satisfactory for SzD, hypochondriasis, and BDD. All in all, CBT seems to be effective across a spectrum of SDs, including SzD, USD, hypochondriasis, and BDD. Antidepressants seem beneficial in some trials, but it is not clear whether it is a general effect mediated through reduced depression and anxiety or a specific effect on somatic symptoms. All treatment reviews have recommended further high-quality studies and also commented on the low number of studies in primary care. There is still too little data about how the treatment works on health care use, and there are still too few good studies on the treatment of conversion disorder or of pain disorder to make any conclusions.

Challenges and Controversies

The SDs represent a difficult taxonomic/nosological challenge. They are primarily seen in primary care settings, have significant comorbidity with anxiety and depression, and are often dimensional in nature. Their classification is a complicated task that offers no easy solutions. In primary care, most symptoms are not related to somatic or an explainable organic disease, but rather have unexplainable causes. A 3-year incidence of ten common symptoms in primary care of chest pain, fatigue, dizziness, headache, edema, back pain, dyspnea, insomnia, abdominal pain, and numbness showed that <10% had organic causes. Approximately 50% of the symptoms in primary care appear to be medically unexplained; in follow-up studies, ~10–15% are organic after 1 year, while ~4% appear mainly organic after 6 years. Secondary care specialists have their own ‘symptom disorder phenotypes’; for example, in orthopedics (low back pain), gynecology/obstetrics (pelvic pain and premenstrual syndrome), otolaryngology (tinnitus and vocal-cord dysfunction/dysphonia), neurology (unspecific dizziness, headache), cardiology (tachycardia and atypical chest pain), pulmonology (hyperventilation, chest pain), rheumatology (fibromyalgia), dentistry (TMJD), internal medicine (CFS), gastroenterology (IBS, nonulcus dyspepsia), urology (IC), endocrinology (hypoglycemia, hypothyreosis, labile hypertension), rehabilitation (closed head injury), and occupational medicine MCS. Some authors assume a psychobiological neuronal sensitization, which maintain somatoform symptoms by major symptom attention and vigilance, and risk individuals are those with low self-efficacy and a high level of helplessness and hopelessness.

Patients with these syndromes very often have explicit disease attributions for their symptoms, and they resist information that contradicts these attributions. They may have a strong sense of assertiveness and embattled advocacy with respect to their etiologic suppositions, and they may devalue and dismiss medical authority and epidemiologic evidence that conflicts with their beliefs. Moreover, dysfunctional beliefs concerning unexplained medical symptoms are powerfully shaped by the mass media, which often use hyperbole and uncritical reporting to portray the FSSs.

Complex Symptom Disorders

The contemporary climate is marked by the prominent political, legal, economic, and regulatory ramifications of the FSSs. Individuals and organizations may have interests in the status

of these syndromes, and the actions of these persons and groups thus reinforce sufferers’ beliefs that their symptoms have a medical basis. In many patients, it is unclear if the appearance of somatic symptoms is caused by mental or somatic factors. Actually, it is a Cartesian dualistic paradigm to distinguish causality in this manner. Expanding on the biopsychosocial perspective might highlight the problems of assuming a Cartesian attitude. Probably, many somatic symptoms appear as a result of both dimensions.

As the authors of this article have experienced that many patients classified as having SDs, for example, chronic pain and chronic fatigue patients, neither satisfy a somatic nor a psychological diagnosis, we have chosen to use the neutral term CSDs as a supplement to the DSM and ICD diagnoses. This includes states with significant somatic symptoms when biopsychosocial factors are particularly closely interwoven, and where no single recognized mental or somatic diagnosis or factor can fully explain the symptoms. Examples can be generalized muscular pain and CFS when one cannot identify a single triggering cause. Those syndromes can be conceptualized as CSD, that is, complex symptoms of both mental and somatic factors with unknown contribution to the causality. The CSD term was first introduced clinically by our group in the 1990s, in order to describe patients with ‘psychosomatic illness,’ when psychopathological and somatic conditions were disproved. The conceptualization has since been used as a term when one cannot conclude what is the triggering cause or dominant maintenance factors, and when it is plausible that somatic symptoms and psychological and social factors mutually influence each other. The CSD term is neutral, and the patients seem to accept it as less stigmatizing than functional disorders, psychosomatic illness, or SD.

An experienced GP rarely needs to refer patients with CSD in early phases to specialist services. At that stage, he probably would rule out both physical and mental illness and convince and motivate patients to pick up their pace of normal function and to empower them to be healthy. If such an understanding has not been conceptualized, however, the management of the early phases can be complicated by extensive somatic investigations, unnecessary surgery, and addictive drugs. The term CSD should only include patients with significant functional impairment and multiple symptom appearances often complicated by iatrogenic factors. When these patients are referred to specialist health services, we are talking about a patient group that preferably requires close coordination between various medical specialists, psychologists, and physiotherapists in order to exclude well-defined disease and to understand and treat the disorder. While a CSD in the early stages usually can be prevented in primary care, it usually requires substantial resources in the specialist care. In specialist care treatment, the clinician will aim to convince the patient that the pursuit of an undetected disease is detrimental and that invasive and drug treatment must be terminated, and that thoughts and behaviors ought to change. Based on our criteria, it is misleading to speak of a ‘CSD’ when you have (1) a defined chronic physical illness with psychiatric symptoms, (2) a defined psychiatric illness combined with somatic symptoms, or (3) a combination of several well-defined diseases. The related concept MUSs or MUPs is a useful term to use in general practice, but would probably be harder to use by an outpatient clinic in specialist

health services. Another difference in relation to CSD is that MUS/MUPS previously have been conceptualized as dominantly 'somatic in origin,' and also include less severe problems which can easily be solved by a GP.

Conclusion

The question we need to ask is whether diagnosing the somatic symptoms as SDs helps or impedes us to understand and treat these patients. DSM-V suggests renaming SD into SSD and also changing the categorization of the subtypes, for example, SzD to CSSD (see [Table 1](#)). The author group of this article introduces the term CSDs as a supplement to certain complex or multifaceted disorders, where no known somatic or mental factors can explain the illness. A problem with the complex term is that it might be understood as *difficult* rather than primarily communicating that there are *many different levels* of analyses that need to be understood. Evidence-based investigation indicates that CBT is the best documented treatment for SDs.

Spatial Orientation

Glossary

Action, afference, and efference Actions are goal-oriented movements. They are coordinated with the actor's spatial orientation relative to one or more features of the surrounding environment. Actions involve efference, that is, sets of motor commands to the relevant muscle and limb systems together with expectations of the results of one's own actions. And actions involve afference, that is, feedback about the results of the action, from joint and muscle receptors, from vestibular receptors about the body's linear and angular accelerations, and from seeing or hearing or touching the environment.

Bayesian weighting of different forms of information Humans coordinate most actions with a single unified cognitive representation of their spatial orientation. Spatial orientation is specified by partially redundant types of information about the body and environment. There is not a singularly important type of information, so the various types are integrated with different weights to form a unified representation. Bayesian weighting schemes base the weights of the different types of information on the relative reliabilities of the different types of information.

Body axes The left-right or 'x-axis,' the front-back or 'z-axis,' and the head-toe or 'y-axis.' By convention the body axes are used to specify both object locations relative to an observer and degrees of freedom for actions used to change orientation. Facing direction can be controlled along each of the three body axes: rotating around the y-axis is called turning, rotating around the z-axis is called rolling, and around the x-axis is called tilting or changing pitch. Location can be translated along the same three axes, moving along the y-axis results in change in elevation relative to an object, along the x-axis in radial direction, and along the z-axis in distance.

Calibration of perception and action People can see, hear, and/or touch (sometimes smell or feel a temperature gradient) to know their location relative to the goal of their action. But knowing the goal's distance, direction, and angle does not, by itself, specify the actions needed. The system needs to know the calibration of the perceptions with their possible actions, that is people need to know how various

forms of actions map onto needed changes in self-to-object distance and direction.

Cognitive mapping Processes by which people come to know the straight line distances and directions relating objects and features of their surroundings that are experienced across circuitous walks which are mutually occluded from view during the walk.

Frames of reference Information used to define direction and distance. Egocentric frames of reference depend on using body information to specify facing direction and location; it can include left, right, up, down directions and it can include distances expressed in terms of the body's scale, for example stride lengths or eye-heights. Environmental frames of reference depend on using environmental information to specify facing direction and location. It can include large features visible from great distances like mountains or ridgelines, or small features visible in the local surroundings like buildings or road signs; and it can include gravity to specify tilt.

Spatial structure A network of distances and directions. The structure of a person's perspective from a given point of observation consists of the self-to-object distances and directions from that point. These change dynamically whenever the person moves. The dynamic changes in perspective can be computed from the rotations and translations occurring during locomotion. Spatial layout, the structure of the environment, consists of object-to-object distances and directions. It is intrinsic to the environment and is unchanging when the person moves. Knowledge of spatial layout is often referred to as a 'cognitive map.'

Spatial updating Processes to keep track of dynamic changes in spatial orientation that occur during locomotion. One major type of process relies on body-based information from locomotion, so that spatial orientation is updated by integrating information for locomotion with the initial orientation. Dead reckoning and path integration are examples of this. Another major type of process relies on environment-based information, so that spatial orientation is updated by noticing changes in orientation relative to large features of the surroundings that are continuously in view and using these to know position relative to small features that are occluded from view.

Spatial orientation refers to the alignment or position of the whole body or body part relative to some frame of reference. Research emphasis is on the whole body. Before the mid-twentieth century, emphasis was on understanding static cases of spatial orientation from a fixed position and body tilt relative to gravity. But spatial orientation is dynamic whenever an organism moves and emphasis has shifted to dynamic spatial orientation – that is, how people keep up to date

on their changing self-to-object distances, direction, and tilts when they move. Spatial orientation is essential for perceptual-motor coordination, since the force and direction of actions need to fit the distances and directions of the objects toward which the actions are directed. 'To orient' refers to producing motor actions that control spatial orientation. The four basic issues of spatial orientation are about (a) what information is used to guide actions, (b) space perception and how

the person-environment distances and directions are detected and represented, (c) perceptual-motor coordination and how the forces and directions of motor actions are calibrated relative to what is needed to get the job done, and (d) information integration in situations where multiple forms of information are available and are combined to form a single unitary representation. Much of the continuing research about spatial orientation relates to four practical problems: (a) falling and controlling balance; (b) becoming lost and way finding; (c) disorientation and nausea in conflicting cue situations, especially those involved in space travel; and (d) exploring information on the web and in electronic databases.

General Definitions and Issues

‘Spatial orientation’ and ‘orienting’ can be broadly defined as all states and actions that are actively ordered in space. Examples abound across the plant and animal species. For plants, consider tropisms accounting for plant growth to line up the roots, stems, and leaves with the direction of gravity and light, and consider the daily movements of sunflowers to face the moving sun. For insects, consider the foraging of honey bees and ants, flying or walking via sometimes long and circuitous paths in search of food sources and then returning to their hive or nest via much more direct routes. For long-distance migration without electronic aids, consider the one-way 2000 mile journey of Monarch butterflies weighing about 0.005 kg from Southern Canada to Northern South America, the 12 000 mile journey of the 0.9 kg Artic Tern from its Artic breeding grounds to the Antarctic and back, and the 6000 mile journey of the 30 000 kg gray whale from the Bering Sea to the Baja Peninsula and back.

Feats like these of nonhuman animal orientation are remarkable. They outstrip what most humans can imagine doing without electronic aids to maintain their spatial orientation and mechanical aids for locomotion. What does this mean? That is, how is it possible that the brain of a Monarch butterfly (weighing less than 0.0005 kg) outperforms the brain of a human being (weighing about 1.3 kg, about 2600 times more)? There are two parts to the explanation, natural selection and cognitive flexibility. As for natural selection, the idea is that some nonhuman animal species have evolved by mating in a location favorable to mating and navigating long distances to a location favorable for feeding. In some cases, their navigation is rigidly limited to the sun and/or stars as orientation guides, but in other cases their navigation can exploit a wider range of heavenly and earth-bound landmarks. But it is limited to a few well-defined strategies. Humans, on the other hand, can draw on a very wide range of strategies – the benefit of flexibility in spatial orientation comes at a cost of less specialization for each strategy.

Perception and Action: Spatial Orientation as Something that People Perceive or Figure Out and Know

People often know their spatial orientation. They can reflect on this knowledge and use it strategically, for example to think through alternative routes when they walk into a blocked

route. And they can use their knowledge with little reflection, for example their knowledge of their position relative to the walls of a racket-ball court while running to strike the ball. What ‘type’ of knowledge is knowledge of spatial orientation? By any definition it can be explicit and used self-consciously to plan future actions, and it can be implicit and used without self-conscious deliberation to plan and act. The explicit knowledge might often be referred to as semantic or conceptual knowledge, and it is easy to see that many features of spatial orientation are explicitly semantic, for example cardinal directions, landmark names, and names for metric distances. The implicit knowledge might often be referred to as motor knowledge or procedural knowledge, meaning that it was acted on or incorporated into decisions without conscious awareness. The access times for the explicit knowledge are likely slower than access times to the implicit knowledge.

People coordinate their knowledge of spatial orientation with a broad range of actions and across a broad range of situations. They need to do this in order to coordinate their actions with their spatial orientation and know how much force to exert and in what direction to exert it. The actions include tilting or leaning or stooping to control body posture, turning to face a conversational partner or turning to reach for a nonhuman object, walking to the grocery store or running to catch a Frisbee, manipulating the controls of an aircraft, and moving a mouse to search more deeply into a website. Consider each in turn.

In classic studies of spatial orientation, emphasis was on static visual object constancy. For static postures and situations, the classic issue is that people report seeing or hearing or feeling the same objects or situations when the proximal stimulus changed. By ‘proximal stimulus’ what is meant is the specific sensory receptors that would be stimulated when perceiving it – and these, in turn, depend on the body’s tilt and facing direction and distance from the relevant objects, no matter whether one is looking, listening, or touching. For example the visual or auditory or haptic stimulus for a given object is different when a person tilts (the retinal stimulus rotates in the picture plane, the auditory stimulus changes its relationship to the two ears, and the haptic stimulus changes in terms of the distance and orientation of the reaching hand)), or walks forward (the retinal stimulus expands geometrically, the auditory stimulus is louder, and the haptic stimulus involves smaller joint/muscle movements), or turns (the retinal stimulus undergoes a rotation, so that visible objects change in perspective and some objects go out of view while others come into view). The classic problem of ‘object constancy’ was that people perceived the same object or situation when looking, listening, or touching despite changes in their distance or direction from the object or situation. In other words, people perceived a constant stimulus object or situation across changes in the receptor level sensory input.

The same issues apply to dynamically changing postures and body locations. Beginning during the middle of the twentieth century, works by James J. Gibson and Gunnar Johansson emphasized that people are always moving and that events are always changing – consequently perceiving in most situations would depend on understanding how distal features of an object or event could remain constant while the proximal features signaled by sensory receptors would vary.

Their great insight was that constant properties of objects and events in the world are signaled by changing stimulus values at the receptors. For example, when moving toward a visible object, its retinal projection becomes larger and larger and yet people perceive the object's size to be constant; when moving toward a noisy object, its loudness at the ears becomes louder and louder and yet people perceive the object's perceived loudness to be constant; and when people touch an object and move toward it to lift it, the visual angles change in ways that are consistent with the object growing larger and larger, and yet people perceive its size to be constant.

Human and nonhuman animals alike tend to perceive constant distal events in the face of dynamically changing proximal stimulus values. On the one hand, for dynamic spatial orientation, the proximal stimulus values consist of self-to-object distances and directions and these change whenever a person moves. People need to coordinate their actions with the distances and directions. When they are moving, these distances and directions are constantly changing and they need to plan their actions before they launch their actions – in other words they need to anticipate their future spatial orientation and coordinate their actions with this predicted future. This prediction can be computationally complex. Research and theory on such predictive spatial orientation was initiated in books by James Gibson (1966) and by Nicoli Bernstein (1967) and developed by researchers and theorists like Emilio Bizzi, Claes von Hofsten, David N. Lee, Herbert L. Pick, Wolfgang Prinz, Michael T. Turvey, and William H. Warren.

History of Concepts and Research

The rise of modern philosophy in sixteenth and seventeenth century Europe emphasized the historical origins of knowledge and genetic epistemology, that is, the study of the ontogenesis of the capacities to perceive and to know. Early thinkers focused on stationary observers and static objects and worked to describe the visual cues that specified spatial orientation. Nativists like Descartes and Kant assumed that minds are organized to understand the spatial meaning of cues without the benefit of experiences. Empiricists like Hume and Berkeley, on the other hand, assumed that experiences associated with physical actions give meaning to visual cues. The early modern philosophers were touch/motor imperialists, in the sense that they assumed that information provided by touch and the motor system was the primary information and that people needed to learn how to interpret visual and auditory cues by way of their association with touch/motor cues, so that touch informed seeing and hearing. Twentieth century scientists, on the other hand, hypothesized that vision and hearing could be primary sources of information, so that seeing and hearing informed touch. In the twenty-first century, these issues have become central in the study of the multisensory basis of perception and of spatial orientation. The earlier thinkers argued about whether touch taught and dominated vision or whether vision taught and dominated touch. During the twenty-first century theorists agree that vision, hearing, touch, the other senses, and motor information contribute to perceiving and representing one's dynamically changing spatial orientation. They believe that all of these multiple sources of information

are unified together into a single representation, and that this unified representation generally serves to mediate action. A central argument is how the multiple sources of information are unified. The alternatives span a broad range. For example: Is a single source of information dominant and so the other sources are ignored? Are the multiple sources of information all equally represented? Or are the alternative sources all represented, and weighted differently in order to reflect their utility?

Principles and Research Strategies

The emphasis of this article is on two general principles and cognitive strategies that underlie spatial orientation. One is that spatial orientation is specified by multiple, partially redundant sources and types of information and that the most informative source and type depends on the situation and the person. For example, visual information is not useful in heavy snowfalls or when someone is blind, but it is quite useful in many other situations for persons who can see. Only a biologically reckless system would depend on visual information in the dark or other situations where vision provides little or no useful information. The potential utility of visual information not only depends on the situation, but it also depends on the visual status of the perceiving persons, and varies as a function of visual impairment and blindness.

Intersensory Integration

How is it that multiple modalities and types of information are combined and typically result in a unified representation of spatial orientation? Consider three possible models. One is a simple dominance model, through which the multiple types of information are evaluated, the most informative one is identified, and people perceive their spatial orientation based on the single, dominant cue. A simple dominance model seems wasteful in the sense that much of the potential information would be discarded. The second is an unweighted average model, through which all of the informative types of information are identified and added together in a simple average to create a unified representation. An unweighted average model seems wasteful, since it would give imprecise information as much weight in the unified representation as highly precise information. Finally, a weighted average model seems more optimal. A weighted average would include all forms of information in the final unified representation, but the different forms would be valued differently. Their values would be informed by past experience and depend on their relative degrees of reliability that were learned through the sometimes hard knocks of experience. Because the relative weightings of different forms of information depend on probabilities learned through past experience, these are broadly referred to as Bayesian weighting models. Some of the seminal writings are by Ernst, Banks & Bulhoff, by Huttenlocher and Hedges, and by Cheng, Shettleworth, Huttenlocher & Rieser.

Bayesian weighting models provide a powerful scientific advantage over simple dominance or equal-weighting models. The reasons are that they provide a method to estimate the relative degrees of reliability of different forms of information, and they suggest a simple algebraic combination of the

different forms of information, weighted by their respective degrees of reliability. They provide an optimal estimate of the weightings in terms of the relative degrees of reliability. Current challenges to the model are focused on two issues. One is that human perception occurs in complex situations involving many possible sources of information, and yet the estimates for the reliability of each cue are based on simpler stimulus situations, which generally involve only two possible stimulus cues. The other is that the evolution of human perceptual systems is not necessarily optimal, and instead follows fits and starts that are shaped by child development and by evolution.

The second general principle is that perceiving and updating spatial orientation depends on two types of cognitive strategy. Each can act alone or they can act in mutually supportive ways. One cognitive strategy is based on integrating information for locomotion to update one's initial egocentric representation of self-to-object relations. For example, if one looks at a room from one point of observation and then walks into another room so that the first room is occluded from view, one can use information from the walk to update the initial self-to-object relations. The second cognitive strategy is based on using the environment as a frame of reference. For example, if a hiker spots a notch in a ridge from a distance and then cannot see the notch but can still see the ridge, the hiker can navigate toward the notch by referring to the visible ridge and mental representation of the notch's position relative to the ridge.

A central component of successful control of spatial orientation is updating the information regarding the body in the physical space relative to the surrounding environment. This ability depends on the integration of multisensory feedback, mainly from the visual, auditory, vestibular, and motor systems. In addition, efference, that is, motor commands originating locomotion carry with them information about the expected consequences of locomotion in terms of expected changes in perspective. And this efferent information is thought to play a role in updating spatial orientation as well as afferent feedback.

How sources of afferent feedback from visual, auditory, vestibular, and proprioceptive modalities are integrated into a unified perceptual representation of spatial orientation is a topic of continuing investigation by brain scientists. Recent research is focused on the role played by multisensory integration areas of the cerebral cortex such as temporal-parietal junction, the central sulcus, the intraparietal sulcus, and the posterior premotor frontal network which seem especially active in updating spatial representations.

Methods and Approaches to the Scientific Study of Spatial Orientation

Human spatial orientation is studied from a wide array of approaches, focused on understanding the role of cognitive strategies, regions of brain activation, underlying computations, emotionality, child development, and culture-based variations. Cognitive scientists focus on cognitive strategies and the underlying computational models. They tend to measure how accurately people maintain their spatial orientation when walking with or without vision as a function of how much they can see or hear while walking, as a function of the complexity

of their walking path, and as a function of whether they are distracted by other tasks. Brain scientists focus on identifying which regions of the brain are activated when making different types of spatial orientation decisions, for example, whether they should turn left or right at a particular intersection when imaging standing at a particular intersection; a limitation of brain science methods for the study of spatial orientation is that typically the subjects of study need to be stationary while the brain recordings are made. Cognitive scientists and brain scientists alike create computational models, hypothesizing how different geometries and different network models might underlie the computational results.

Emotionality plays a role in spatial orientation. For example, wilderness experts are taught to calm down to think through their spatial orientation in crisis situations, firemen, and firewomen are known to lose their way in emergency situations, and first responders to large-scale crises often become disoriented, and lose their way, resulting in personal injury and failed support to others.

Children of different ages are studied to investigate the ontogenesis of the cognitive strategies and sensitivity to different types of information. On the one hand continuing findings indicate that during the first year of life infants can use motor information, local landmarks and the geometrical shape of the surrounding room in order to maintain their orientation relative to a hidden target. On the other hand, infants and young children become easily disoriented, in simpler situations and after simpler routes, than older children. Too little is understood about what changes with development.

There are well-known examples of culturally defined roles for which exceptional spatial orientation is central to the tasks of long range navigation. One example are the feats of expert long distance spatial orientation is of the navigators of the Puluwat Islanders. They traveled more than 1000 miles over open seas without losing their way. In order to accomplish this, they depended on 'childhood-long' apprenticeships in navigating, in order to learn how to use the stars, the sun, and underwater perturbations in wave patterns to help them keep track of where they were and to steer their course.

Historical Changes in Assistive Technologies for Human Spatial Orientation

Historical changes in spatial orientation describe changes in technologies. This is a historically old skill. Archeological evidence indicates that human ancestors roamed across the plains, among the mountains, and through the jungles. Clearly, they must have kept track of where they were relative to where they were headed. There are not records of how they did this, but logically their methods must have included strategies for estimating or sensing distance and direction. Later and in connection with sea travel records were kept about how such spatial orientation was accomplished. The problem remains the same, determining direction and distance traveled. Sometimes there are environmental cues and sometimes there are not. In the case of traveling along a coast environmental cues are available; the directions of points of interest are visually available, as is the progression or distance traveled. Staying oriented by such information is referred to in modern parlance as piloting. The environmental information is relatively close

at hand. When out of sight of land, environmental information that specifies direction can still be available, for example, information from the stars to guide celestial navigation. Even navigational systems of different cultures exploit stars for directional information. A beautiful example is that of traditional Micronesian navigators sailing their outrigger canoes on long journeys in the South Pacific. They take advantage of the fact that given stars always rise in the same direction on the horizon. As any particular star rises it is followed by another star in about the same direction, resulting in a series of stars appearing successively across the sky in an arc, all setting then in the same direction on the opposite side of the sky. The sky path of such a sequence of stars is called a linear constellation. The point is that such a linear constellation can always provide information about the direction of travel. Edwin Hutchins (1995) wrote about this.

Stars are not always visible, for example, in the daytime or when it is cloudy. Then determination of direction must be accomplished by different means. When out of sight, land distance must also be determined by different means than progression based on landmarks. The direction problem can be solved by use of a compass and the magnetic compass for such purpose came into use around the twelfth century. There are some disadvantages in the use of the magnetic compass for directional orientation, involving differences in the location of the magnetic north pole and geographic north pole. Thus, sailing due west according to your magnetic compass near the equator will be quite a different direction on a map than sailing due west by compass when you are in the arctic ocean. Many such disadvantages were overcome with the invention of the gyroscopic compass in 1907.

Distance traversed was not quite as easily solved when out of sight of landmarks. Of course, sailors have an intuitive sense of speed based on their experience with the strength of wind and how their ship progresses when landmarks are in sight. However, this is only approximate. A somewhat more definitive method came into practice by the sixteenth century. This was known as the chip log method. A chip of a log was tied to a rope and dropped over the stern of the ship. The rope was paid out as the ship moved on away from the log chip which was essentially stationary in the water. The time taken for a specific length of rope to be paid out provided a means for estimating the ship's speed. (The length of paid-out rope was indicated by knots tied in the rope and that was the origin of using the term knot for specifying nautical speeds.) Given that the ship's speed could be so measured, distance of travel was determined by multiplying how long one was sailing at that speed.

By keeping track of distances sailed in various directions, it was possible to estimate the distance and direction of one's homeport or other known locations even though they were out of sight. This process of integrating direction and distance of movement over time came to be called dead reckoning, a variation of the term 'deduced reckoning.' Keeping track of this information for extended periods of time became a problem in itself. One technique for a period of a few hours involved a device called a traverse board. It was a round board on which pegs could be inserted at various angles around the center indicating direction of travel, and distance from the center indicating distance traveled in that direction. Beyond this period of time the information needed to be transcribed into a logbook. It is interesting

to note that Columbus' logbook strongly suggests that he used dead reckoning to navigate in his voyages to America.

Of course another way of keeping track of the information of travel is by means of maps or navigational charts. One's estimated position can be represented on these graphic displays of the space of interest. Map making has a long history. One early and persistent problem was how to represent the spherical globe of the surface of the earth on a 2D surface. One solution is the Mercator projection developed in the sixteenth century. The Mercator projection has the disadvantage of distorting sizes and shapes of land masses and sea areas but for navigational purposes has the advantage that straight lines between two points on the chart would yield a constant angle or course which could be steered on the ocean to go from one location to the other. The general idea of representing spatial layouts by means of 2D maps became extremely common. It became so common that when psychologists and others began to think about how spatial information was mentally represented they coined the term 'cognitive map.'

Human Factors and Engineering Applications of Research on Spatial Orientation

Technologies to assist people in maintaining spatial orientation are rife throughout history and across cultures. They include education about way-finding that is ubiquitous across all cultures and eras. They include the specialized education of those selected and trained to be navigators in the Puluwat Islands. They include the development of maps and map projections, magnetic compasses, and electronic compasses. They include the creation of GPS systems, the debate about whether the user's position should be displayed egocentrically so that the person's heading was 'up' on the display or geocentrically so that north was 'up.' It is a telling indication of the flexibility of human spatial orientation that GPS displays provide humans with the option of being oriented egocentrically or geocentrically.

Computers provide a fast method of generating maps and updating the maps to take into account one's dynamically changing spatial orientation and changing environmental conditions. Such computer-based virtual environments are often displayed on desktop- or vehicle-based displays. For desktop computers, the changes in perspective are created when the person manipulates a computer keyboard or computer mouse.

A recent development is the study of the perception and representation of self-to-object distances and directions when exploring immersive virtual environments. These provide the observer with life-like spatial layouts and virtual objects placed at strategic points. A human observer can look at this environment through a helmet-like 'head-mounted display' unit, and can walk in this environment just as in a physical environment. Virtual environments are particularly applicable in situations where it may be difficult to explore actual, physical environments such as a battlefield, or behind-the-lines military operations. Studies have shown that humans treat virtual environments as functionally similar to physical environments. In studies that involve learning and remembering object locations following rotations and translations, humans' sensitivity to flow rates in virtual environments is comparable to sensitivity in real environments, albeit with longer decision latencies in virtual environments.

Virtual environments can be presented as desktop displays, in which people view a simulation of a place on a desktop computer and manipulate their view with a mouse or keyboard. They can also be immersive displays. In the case of immersive displays, human users either stand in a 'virtual cave' or wear a 'helmet mounted display'. In a virtual cave, the person is surrounded by three or four walls, with a floor and ceiling, all displaying a remote place. When the person moves, the visual (and auditory) information is updated, so that the person's changes in perspective are rendered in changes in the sights and sounds that would occur in the physical environment. In a helmet mounted display (an HMD) people wear binocular goggles that provide renderings of remote places, and when they locomote the images displayed on the HMD dynamically change in the ways they change when people locomote in the physical environment. The computer-based systems provide realistic displays, the visual displays are updated quickly enough to approximate the time constants of human vision, but the technologies limit the visual field of the display to about 90° of visual angle. Such displays are useful for training and for gaming. But they are not yet completely immersive: people are not tricked into perceiving themselves as 'being there' in the virtual environment and their performance in the virtual environment is often deficient.

Spatial orientation is especially problematic for some persons, more than for others. Biological factors seem to play a role, so that some of us can maintain our spatial orientation across complex 1–5 km routes in familiar or novel cities, in the woods, and in the desert without technological aids whereas other persons can lose their way walking or driving in their home neighborhoods. It seems likely that those who succeed at some occupations, such as wilderness explorers or taxi drivers, succeed in part because they have especially good spatial orientation. It seems clear that some persons, for example, persons who are born without vision, tend to report they are at a disadvantage for spatial orientation. This is intriguing, since people born without vision have life-times depending on non-visual information for spatial orientation, whereas persons who lost their vision after childhood tend to be more skillful and have fewer years of practice. This indicates that the experiences provided by watching and looking play a role in the

development of spatial orientation. And the research indicates that brain plasticity plays a role in the development of this skill. Continuing research is aimed at understanding what types of nonvisual experience might substitute for visual experience in the development of the underlying skills. And continuing research is aimed at understanding how technologies can be used to provide auditory and tactual information to substitute for visual information, to assist persons who are blind or have severe visual impairment.

Glossary

Allocentric reference frame A representation of the environment that reflects the absolute relationship between objects. For example, a street map shows the spatial relationship between streets regardless of the location of the viewer.

Binocular visual cue Perceptual information contributing to distance perception that uses input signals from both eyes. Examples of binocular cues include stereopsis and vergence angle (rotation of the eyes inward for close items, and apart as objects move away).

Egocentric reference frame A representation of the environment with regards to the viewer. For example, when you are face a building, it is in front of you, but if you turn around it is behind you.

Monocular visual cue Perceptual information contributing to distance perception that can be processed by information from a single eye. Examples of monocular cues include: occlusion, familiar size, linear perspective, shadow, atmospheric haze, and accommodation (change of lens shape to focus an image).

Peripersonal space The area immediately around the body that is within reaching distance of the hands.

Spatial imagery/spatial memory An internal 'mind's eye' representation of the spatial properties of an object or scene composed of multiple objects.

Stereopsis The perception of depth created by slightly different visual images (binocular disparity) impinging on each eye.

What Is Spatial Perception and What Is It For?

Spatial perception refers to the processing and interpretation of the spatial relationships present in the physical world. This broad term refers to a host of sensory and cognitive processing stages that ultimately enable us to interact with the world around us. In this article we will introduce some of the factors influencing spatial perception. Perceptual modalities including vision, hearing, and touch provide different types of spatial information. Visual information plays a dominant role in assessing spatial layout (e.g., Is that a ripe red apple on the tree?). Auditory information can indicate where and how quickly an out-of-sight item is moving (e.g., Is the train coming in on time?). These sensory signals are processed by the brain and used by the motor systems to plan future actions. We will include brief mention of some of the sensory illusions that create misleading spatial percepts. These illusions can shed light on how the brain processes spatial information and where there are limitations. These sensory components are processed for a reason: we use spatial information to plan actions. For instance, we are nearly always manipulating single objects (e.g., How wide do I have to open my fingers to pick that big round apple? How much pressure should I apply to pick up that egg without breaking or dropping it?); as well as navigating through the larger environment (e.g., Do I have time to cross the tracks before the train arrives? How far is the nearest Indian restaurant, and which way should I go to get there?). As humans are mobile beings, efficient action requires ascertaining the locations and properties of objects and surfaces.

How Do We Perceive Spatial Information?

Visual Cues

Monocular visual cues

In any 2D representations such as a photograph or drawing there is considerable spatial information. This can be verified by asking people to choose the item closest to them in a picture. People perform this task easily and consistently, choosing the item closest to the foreground. However, all of the items are at exactly the same distance in the flat plane of the picture. Cues that exist in these 2D representations are termed 'monocular' because a single eye can process them. When you close an eye, you are still able to look at a picture and decide which item is closest. Monocular cues are distinguished from binocular visual cues, which require inputs from both eyes. There are many examples of monocular visual cues including occlusion (interposition), motion parallax, texture, familiar size, relative size, linear perspective, shading, and atmospheric haze. *Occlusion* is visible when one object partially obscures a second object. This cue indicates the relative ordering of near-far objects. For example, the chair is in front of the window, because the chair can be seen in full but the window is partially blocked by the chair. *Motion parallax* also provides position information when the viewer is moving. Imagine you are walking down the street. You pass by closer objects such as fire hydrants more quickly than farther objects such as buildings. In addition, closer objects partially obscure more distant items. *Familiar size* serves as another estimate of distance. If a house appears to be only a speck in a large field, it is interpreted as very far away because we know that houses are relatively large.

Other information such as *texture* cues, like the grain in wood or the pattern on a carpet, become steadily less visible as distance increases. The distortion of a known texture provides information regarding the height of a stairway or the slope of a hillside. *Linear perspective* provides spatial information due to the fact that parallel lines appear to converge as distance increases. As such, the wider portion of a road is interpreted as closer than the narrower portions. *Lighting* and *shading* reveal information regarding the shape and dimensions of an object, in particular, whether something is concave or convex. A brightly lit spot on an item indicates that it is closer to the light, whereas darker spots suggest they are farther from the light. Additional shape information comes from shadows. A shadow beside an object suggests that it is resting on a surface, perhaps a glass resting on a counter. Whereas a shadow below an object suggests that it is suspended above, such as a light hanging above a table. *Atmospheric haze* describes the observation that farther items, such as distant mountains, appear more bluish than closer mountains. This cue provides a sense of distance over very large distances.

Finally, there is a physiological cue called accommodation that also contributes to spatial perception. Accommodation refers to the adjustment in curvature of the lens. Contraction and relaxation of the tiny muscles in the eye that hold the lens in place produce accommodation. These muscles automatically relax or contract to improve focus, but the lens can only change shape by a small amount, thus the contribution is modest and only effective when viewing items within approximately 6 ft.

Binocular visual cues

Human eyes are positioned several inches apart from each other. This distance means that the images on the retina of the left and right eyes are slightly different, a situation referred to as *binocular disparity*. The two eyes working together provide additional spatial cues. These types of cues are classified as binocular cues. The most prominent binocular cue is a stereopsis. Stereopsis refers to the compelling sense of depth that arises through the combination of differences between the images in each eye. If one closes one eye then the other, there is a subtle, but perceptible, shift between the images provided by each eye. This difference is more noticeable when you are looking at something nearby, for instance something in your hands versus something across the room. The difference between images is negligible for objects in the far distance. For a special group of objects at a particular distance there will be no shift at all. These objects are aligned on an imaginary arc of space called the *horopter*. When a small object is fixated and along the horopter the image will stimulate the same portion of the retina in each eye. There will be a single fused image of the fixated object, whereas objects in front of or behind the object will have two representations because they are stimulating different portions of the retina in each eye. It remains poorly understood how these different representations for each object are appropriately matched up in the brain. This problem is called the *correspondence problem*. Stereopsis serves as an effective cue for items within 100 ft. Surprisingly, in the general population there are a number of people who have difficulty seeing objects in depth. The incidence of this *stereoblindness* is thought to occur in about 2–4% of the

population, but up to 15% of the population have some degree of trouble seeing objects in stereo depth. Thus, the loss of stereo information does not eliminate visual spatial perception but it does reduce the quality of the spatial representation. There are also several cases in the literature suggesting that some people with impaired stereopsis can improve their perception with extensive training.

A second binocular cue comes from the fact that the eyes can move in the orbit, courtesy of the three pairs of muscles that hold them in place. In particular, the *vergence angle* refers to the angle of one eye with regard to the other. When the eyes move toward each other the angle is termed *convergent*. This situation arises when you look toward your nose and ‘cross’ your eyes. When you return your gaze forward to look toward the distance, your eyes will *diverge* or move in opposite directions. Over short distances up to about 25 ft vergence angle can serve as an effective cue to spatial distance (Figure 1).

Neural correlates of visual spatial information

The monocular and binocular distance cues described above are largely processed by the visual system. These issues have been investigated using a number of experimental techniques including functional neuroimaging (e.g., fMRI) and neurophysiological (e.g., recordings from neurons in nonhuman primates) approaches. There is clear evidence that portions of the brain including posterior areas in the superior occipital and inferior parietal lobes are essential for visual spatial processing. These structures are located in what is called the dorsal visual stream or the ‘where’ visual pathway. These findings are confirmed in neuropsychological patients with brain damage to these areas due to stroke, disease, or injury. Patients can have a variety of visuospatial deficits including the inability to attend to the full visual field. In some striking cases patients experience a condition called *hemispatial neglect*. These patients may ignore one side of space, usually the left side of the visual world. Patients may only eat the food on half of their plate, or they may not notice things happening in the ignored side of space. In some very rare patients, both the left and right hemispheres are damaged. This type of damage can lead to a condition called *simultanagnosia*. This peculiar condition prevents them from being able to see more than a single item at a time. For instance, such a patient may look at a computer keyboard and see the letter ‘H’ but no other keys. In these patients, spatial perception is tremendously disrupted. However, they may still be able to rely on familiar size cues, accommodation, and vergence angle to provide limited spatial information.

Auditory Cues

Although the visual system provides the dominant source of spatial information, at least in sighted individuals, other sensory modalities including the auditory system contribute spatial information. Auditory information provides key information indicating the spatial location of objects. There are three primary cues interpreted by the auditory system: *sound level*, *interaural differences*, and *reverberation*. If something is producing sound, the sound level will be louder as the listener gets closer. For familiar sounds, the overall intensity of the sound can be a strong cue to spatial distance. Another example

Figure 1 Examples of monocular visual cues. This 2D photograph provides 3D spatial information through a combination of monocular cues.

incorporates motion. If something is moving away from the listener, it will have a steadily decreasing sound level, likewise, something moving toward the listener will have a steadily increasing sound level. The second cue, interaural differences, accounts for the 'head shadow,' which produces a difference in sound intensity between the ear closest to the sound and the ear that is farther away. The head blocks some of the sound waves from the farther ear and muffles the sound. This information can help specify the spatial location of a sound source, particularly for lower sound frequencies. Thirdly, reverberation refers to sound waves from the sound source that reach the ears after first bouncing off from elements in the environment, such as walls and ceilings. For distant sound sources, the reverberation can improve distance estimations.

Perceptual Constancies

Our experience with objects in the world provides us with consistency when interpreting spatial information from all of these various visual cues and under different viewing conditions. One example of this ability is called *shape constancy*. This term refers to our ability to account for distortions in shape due to perspective. For instance, when we look at an open door, it does not look like a trapezoid. A second perceptual constancy is *size constancy*. Size constancy allows us to interpret objects as a single constant size regardless of how close we are to the item. For example, we do not perceive that a person grows taller as he approaches; instead we interpret the change as a reduction in distance.

Perceptual constancy, in particular size constancy, occurs so automatically that it is important to note that understanding the mechanism is not trivial. Our ability to appropriately make size judgments is an important precursor to interaction with any objects in our environment. Historically this ability was seen as a particular challenge since the retinal image varies with both actual size and viewing distance. In other words, a large object far away and a small object nearby could produce the

same sized retinal image. Size judgments required adding information to what was provided by the retinal image.

When we accurately perceive the size of an object the size is not coded as an abstract metric amount (e.g., 1 in. tall). Rather, humans perceive the size of objects relative to their bodies (e.g., bigger than me). This coding naturally scales objects to our hands and fingers, or whatever part of the body would interact with the object. Thus, an adult and a child would create different size codes reflecting their different interactions with the same object (e.g., grasping a ball requires one hand or two). This individually based coding may explain why the furniture in a childhood classroom seems so small when we return as adults. The size of a child's chair relative to an adult's body is much smaller than the size of the same child's chair relative to a child's body.

Perception of size is scaled to the effectors that interact with objects (e.g., hands and fingers) and to skill level. Another example comes from the automatic calculations related to locomotion, discussed more specifically below. Humans judge the width of openings relative to the width of their own bodies and also allowing extra room for the sway in the trunk that occurs when walking. For example, people will turn sideways in advance of entering a narrow passage, or a subway turnstile.

Perceptual Mysteries: Ames Room

One clever illusion that takes advantage of perceptual constancy is the *Ames room* illusion. In this illusion, a seemingly standard square room is shown, often with two people standing in the two far corners of the room. One person is shown with her head touching the ceiling and appearing to be a giant. The second person appears to be tiny, only half the size of the first person, with his head about half way up the wall of the room. The illusion relies on perceptual constancies to interpret the room as a standard square room. However, it is actually highly distorted such that it is trapezoidal in shape. The tiny person is actually standing at a much farther distance

from the viewer than the giant person. In addition, the ceiling is not flat, but slanted so that the height of the room enhances the distortion. These manipulations allow for two people of identical size to appear to be dramatically different in the trick room.

Perceptual Mysteries: Moon Illusion

A second, classic illusion related to size constancy is called the *moon illusion*. At one time or another most people have noticed that the rising moon looks much larger than a moon high in the sky. However, of course, the moon does not change size so something about our interpretation of the sensory information changes. Two classes of explanation have been offered for this illusion, a *taking-into-account theory* and a *direct size judgment theory*.

The taking into account theory is based on an account of size judgments that combines retinal image size with estimates of an object's distance. The actual sizes of distant objects can be calculated from these two quantities using simple geometry. Notably, if the distance estimate is in error then there will be a proportional error in the perceived size. So, according to this theory the distance-to-the-moon used to estimate actual size is smaller when the moon is overhead than when it is on the horizon. The greater distance on the horizon reflects the richer information for distance on the horizon (e.g., the moon is behind everything on the surface of the earth), while the moon overhead offers little distance information so the visual system uses a default value.

The challenge for this explanation is that when asked about the distance of the moon, people report that it appears closer when it is near the horizon. This is exactly opposite to the theory, which predicts that people would say it appears farther away. Fixes have been offered that distinguish between conscious experience of a perceptual value and a *registered distance*, a quantity used by the visual system in size calculation.

An alternative explanation is that we judge size by comparing adjacent objects. Thus when we compare the moon to nearby objects on the horizon, the nearest objects will likely be large (e.g., house, tree, or mountain), thereby enhancing the size estimate of the moon near the horizon. Whereas when the moon is overhead there is little to compare it to other than leaves of trees, perhaps. The final answer to this question is one of many areas of open inquiry in the field of spatial perception.

Development of Spatial Processing Skills

Over the course of development we gradually acquire the ability to process the spatial cues that were described above. Not surprisingly, the ability to process individual spatial cues develops at different rates. One classic illustration of the development of spatial processing is called the *visual cliff*. In this demonstration, babies' access to spatial distance information is evaluated. The demonstration apparatus consists of a clear glass table with an opaque band, such as a piece of wood, placed across the middle of the table. On one side of the band, there is a tablecloth pressed against the underside of the glass. On the other side of the glass, the tablecloth is laid against the floor so that the distance from the glass table to the floor is visible. Human babies will not crawl across this second

side of the table toward their mothers after the age of about 6 months old. Prior to this age, they will cross over the open side, suggesting that they are not yet able to incorporate spatial information that would show them they are suspended above the ground. This fear emerges after the crawling stage begins supporting the notion that locomotion provides the experience necessary to learn about spatial relationships underlying the visual cliff. Indeed, in adults this fear may prevent them from walking over clear glass floors in elevated viewing towers such as in the CN Tower in Toronto.

How Is Spatial Information Represented?

Space Around Us

In the paragraphs above, we described some of the perceptual information underlying spatial processing. Here, we note that all space is not considered the same. In humans and some other species, the closer space holding items within arm's reach is processed differently from more distanced space. The first area is called *peripersonal* space. Peripersonal space refers to the space immediately around the body. This space encompasses objects within our grasp. It also includes items in range to act on using a tool. For example, we are operating in peripersonal space when we write on a piece of paper with a pen, and also when we pile leaves with a rake. The second area is called *extrapersonal*, or *action*, space. Action space refers to the space just beyond peripersonal space. This is the space populated with objects that we *plan* to act on. For example, we cross the kitchen toward the cookie jar that we intend to investigate. Neuroimaging data reveal that items in peripersonal space increase activity in regions at the back of the brain such as the inferior parietal lobe including the supramarginal and post-central gyri. These areas are also implicated in the planning of motor actions. In contrast, items in extrapersonal space increase activity in more anterior brain areas including the ventral premotor area, middle frontal gyrus and superior temporal lobe. These areas are implicated in recognizing and interpreting the actions of others. The dissociation between peripersonal and extrapersonal space is also found in neuropsychological patients. Some patients with hemispatial neglect only ignore items within peripersonal space, while others may ignore items only in extrapersonal space.

Finally, there is a third space for very far distances up to the horizon, called *vista* space. Vista space refers to the objects and surfaces well beyond our immediate surroundings. On a scenic drive through the mountains, you allocate most of your attention to the far off distance to appreciate the view. In addition, the spatial configuration of vista space is perceived almost entirely by monocular visual cues.

Egocentric/Allocentric Reference Frames

Spatial perception supports motor planning and execution. With little digging it becomes clear that spatial representations are complex and multilayered. In the preceding section, we described how the factor of proximity is important in space perception. Here, we mention a second dimension of spatial processing: *reference frame*. The phrase reference frame indicates from where you are basing measurements. According to

an *egocentric* reference frame, spatial properties are interpreted with regards to the viewer. Since people are often moving, these representations require nearly continual updating. For example, the car is parked six blocks down the street. If I walk ten blocks down the street, the car is now going to be four blocks behind me. Egocentric reference frames can be parsed even more finely because our body parts are independently mobile. There is very active research investigating eye-centered, head-centered, and body-centered reference frames to help us understand how space is processed under various situations. Much of the time, these reference frames are in synchrony; such as when we are walking forward, or seated working in front of us. The eyes, body, and head are aligned; what is to the left of the eyes is to the left of the body and head. However, it is not clear which reference frame dominates spatial representations in more complicated cases. For example, imagine someone is seated at a desk (body facing forward), turning his head over his shoulder (head facing sideways) and looking toward the ceiling (eyes pointed upwards). In this case, all three egocentric reference frames would be providing different information about where the front of the classroom is located.

In contrast, an *allocentric* reference frame places objects in relationship to each other. Thus, allocentric reference frames do not need constant updating because they are independent of the viewer. For example, the car is parked on the corner of Broad and Main Streets or the park is to the South of the monument. An allocentric reference frame is what is used in a map.

Individuals differ significantly in their preference for the two types of reference frames – some prefer to give directions from a first person egocentric perspective while others from an allocentric overhead perspective. There is considerable evidence suggesting that egocentric and allocentric reference frames are processed by dissociable neural systems. This means that the ability to use one of these reference frames

can be selectively impaired leaving the second one intact. For example, brain damage to structures in the ventral occipital lobe and medial temporal lobe structures causes disproportionate deficits in allocentric spatial memory, leaving egocentric task performance intact. These findings show that medial temporal lobe structures perform computations essential for processing objects in an allocentric reference frame. In contrast, damage to the superior occipital and inferior parietal lobes causes impaired performance in patients when they are asked to conduct tasks using an egocentric reference frame (Figure 2).

Spatial Perception in the Service of Action

In the previous paragraphs, we have introduced factors related to the perception and interpretation of spatial relationships. As described above, there is a long list of perceptual abilities devoted to interpreting spatial relationships in the external world. We have provided a mere glimpse of the complexity and importance of spatial perception. Next, we address what this spatial information is used for, in essence why spatial perception is worth the effort. In short, the capacity to appreciate spatial information is essential because we are mobile. Perceiving the space around us allows us to plan and execute actions, interact with the things we need, avoid the obstacles in our path and even remember the route home. In the following paragraphs we touch on factors associated with moving through the environment.

Locomotion Requires Perception

Moving through the world, or locomotion, relies on spatial perception to avoid obstacles and steer a path toward a goal.

Figure 2 The divisions of space around us from closest to farthest: peripersonal, extrapersonal, or action and vista space. The dotted lines approximate the divisions between these areas of space. Demonstration of two reference frames: egocentric and allocentric. The egocentric reference frame takes into consideration the viewer, and considers the space between the viewer and the object. Here, the pitcher is in front of the viewer. The allocentric reference frame considers the relationship of one object to another, here the positions of the mug and pitcher are shown without regard to the position of the viewer.

We rely on the pattern of changes in the visual field as we move by. These changes in the visual signal accompanying locomotion are called *optic flow*.

Larger scale navigation includes moving to visible (e.g., to the doorway across the room) and invisible destinations (e.g., to the movie theater across town). When navigating, route selection is influenced by both environmental and individual factors. People will tend to use routes with the longest lines of sight at each intersection, meaning the path with the clearest view and the greatest extent of spatial information. People also avoid changes of direction whenever possible, a strategy that reduces the spatial complexity of the route traveled. Perceiving and acting on spaces beyond the sensory horizon (i.e., beyond the vista space) entails a constructive process of generating a mental model of a spatial layout. Such mental representations are necessary for a range of spatial tasks like perspective taking (e.g., the store is not visible from the Southern corner) and finding one's way. These points of consideration underscore the close relationship between spatial perception and the field of navigation research.

Locomotion Enables Perception

As much as perception is required for locomotion, the reverse is also true: locomotion enables and enriches perception. Indeed, the ecological school of visual perception argued that movement is essential to perceive the environment. Their rationale for advocating this perspective is the following. It is important to note that the 3D veridical structure of the external world cannot be fully reconstructed from the 2D representation provided by the two retinae to the visual system. This is a consequence of the fact that the retinal image is not in 3D.

Locomotion causes systematic changes in the retinal image that allow for a more robust reconstruction of the visual image.

Over changes in distance there is a greater accumulation of monocular and binocular cues providing spatial information. For example, there is increased motion parallax allowing occluded objects to come into view. These updated visual signals can have direct effects in terms of updating the motor plan for achieving a particular goal state. In many cases, there is even a direct coupling between the changes in the retinal image due to locomotion and a resulting motor action. For instance, when you run backward to catch a fly ball in baseball, you correct your position based on changes in the path of the ball and you do this continually until you catch (or miss) the ball. Other well-studied examples include steering during walking and posture control. In short, locomotion, and spatial perception enjoy close interactions that facilitate and improve each other in a reciprocal manner.

Stress and Blood Pressure Dysregulation*

W Gerin and M J Zawadzki, The Pennsylvania State University, Pennsylvania, PA, USA

© 2012 Elsevier Inc. All rights reserved.

Glossary

Ambulatory blood pressure monitoring (ABPM)

A technique by which blood pressure can be assessed as patients go about their usual activities. ABPM measures are an important predictor of heart, brain, kidney, and arterial damage, and of cardiovascular events.

Blood pressure The force of the blood flow on the inner arterial walls. Sustained higher blood pressure is a cause of heart, brain, kidney, and arterial damage.

Cardiovascular reactivity The magnitude of the acute change in blood pressure from a resting level to the stressor

level. Greater reactivity is hypothesized to contribute to the development of hypertension and coronary heart disease.

Hemodynamic patterning The underlying forces that regulate blood pressure change, with initiation from centrally mediated processes, including cardiac output (amount of blood pumped from the heart on each beat), and peripherally mediated forces, including total peripheral resistance.

Hypertension Morbid condition in which the resting blood pressure is greater than 140 mmHg (systolic) or 90 mmHg (diastolic).

Introduction

Hypertension, a major risk factor for coronary heart disease and all-cause mortality, affects ~29% of Americans. The cause of most of these cases is unknown; however, a great deal of epidemiological data show that psychosocial factors such as stress, emotional self-regulation, and social support are strongly linked to its development. Generally speaking, there are two main pathways by which such factors may contribute to high blood pressure (BP): (1) by affecting other health risk-related behaviors (e.g., increased nicotine/alcohol/drug use, poor eating habits, less exercise) and (2) by exerting direct effects on the biological mediators of the stress–clinical outcomes' relationships. This article focuses on the second pathway.

Human stress psychophysiology has matured a great deal in the past couple of decades. The measures have become more sophisticated and now focus on a wide array of biobehavioral markers of the bodily systems involved in the stress response, instead of the exclusive focus on BP that marked earlier experiments. These markers include (but are not limited to) heart rate variability (HRV), endothelial function, platelet aggregation, cortisol and other neurohormonal markers, markers of immune function, and fMRI. Moreover, the laboratory has spilled over into the natural environment, where measurements are taken using ambulatory monitoring of BP, HRV, salivary cortisol, and self-reports of relevant state and situational dimensions, including affect, thoughts, persons with whom one interacts, what time the subject went to sleep and woke up, and when the subject took her/his medication. This work has progressed even further with the recognition that the biological systems under study operate not only in parallel but synergistically as well, and this has had the effect of fostering greater interdisciplinary research in which more than one such system is investigated in the same research subject at the same time. This is clearly a necessary development for the field to continue advancing.

Origins of Stress-Psychophysiological Investigations

Cannon's 'Fight or Flight' Studies: An Early Influence on Acute Stress Research

Modern ideas regarding stress and its effects on the body date from the classic studies of the physiologist Walter Cannon. Cannon first described the 'fight or flight' response to threat, work that led to modern conceptualizations of the role of the environment in provoking perturbations in the biological systems of the body. Relevant to the present article, he concluded that we could learn about regulation and dysregulation by observing physiological processes at rest and under an emotional 'load' – that is, upon exposure to stress. Thus, his work anticipated the basic laboratory stress paradigm that is prevalent today.

In his studies, Cannon showed the effect of emotional arousal – fear, in particular – on coordinated autonomic and neurohormonal activity, the latter notably involving adrenaline (epinephrine). Cannon identified the function of this process as preparation of the organism for a 'fight or flight' response. This response involves a chain of biochemical reactions that follow threat perception and include activation of the sympathetic nervous system and stimulation of the adrenal medulla to secrete the catecholamines, epinephrines, and norepinephrines. This sympathetic adrenomedullary (SAM) activity triggers the peripheral physiological processes associated with the fight-or-flight response, including cardiovascular and respiratory changes that increase the supply of oxygen to the brain and muscles to mobilize the organism for action. The sudden activation of these responses at the first sign of danger provides the basis for the study of physiological reactivity in response to acute laboratory stressors. These processes can provide a means of survival for the organism in the short term; however, they may have undesirable physiological consequences when sufficiently prolonged, frequent, or intense, and when provoked by threats for which vigorous behavioral activity is not an optimal solution.

*Conflicts of interest: None.

Selye Describes the General Adaptation Syndrome

An important advance in the stress field occurred in the early 1950s when Hans Selye put forward a model in which the term 'stress' referred to the nonspecific elicitation of a physiological response by diverse noxious stimuli. Selye referred to that response as the general adaptation syndrome (GAS) and characterized it as triphasic. In the initial *alarm* phase, the mobilization of metabolic resources is initiated, which is marked by an increase in adrenal activity and other physiological changes. Following this stage is the *resistance* phase, where the body begins to suffer effects of heightened activity. This stage is marked by continued increased physiological arousal, including the production of corticosteroids by the adrenal cortex, though this arousal becomes more moderate over time. Secretion of corticosteroids serves protective functions through metabolic effects that include elevations in blood sugar levels and through downregulation of immune responses, including inflammation of body tissue. Eventually, the body cannot maintain its heightened level of arousal, and the *exhaustion* phase begins. In this stage, resistance is depleted and the body is unable to continue to function at high levels, and corticosteroid production becomes depleted. If the stress persists, Selye proposed that exhaustion could lead to illness and disease because the adrenal gland and immune system cannot function properly.

Selye's formulation provided a heuristic basis for the study of stress: a different model for each environment-biology transaction was not required. Rather, a range of factors operate via the same channels, producing the perturbations described by Cannon and triggering a hormonal response from the hypothalamic adrenocortical axis (HPA). In addition, Selye suggests that stress can lead to illness and disease as the body becomes exhausted. Taken together, the work of Cannon and Selye anticipated the modern study of stress effects on biological dysregulation.

Strategy of Psychophysiological Investigations into Stress-Outcomes Research

The methodology for most stress-psychophysiological studies is based on Cannon's assertion that we can learn about bodily processes by placing them under a load. In stress-reactivity studies, the load is represented by having to cope with or overcome a stressor of some sort and the experience of the often negative emotions this engenders. The methodology across studies is remarkably consistent. Although differences in procedures exist due to the nature of the manipulation and the particular measures used, studies usually comprise assessment of the target measure during or following a resting baseline and then during or immediately following exposure to a stressor. (Figure 1 shows a theoretical example.) The methodology provides a means for the investigation of psychosocial factors as they affect the acute physiological response under controlled laboratory conditions. This article focuses on BP, which was the main focus of these investigations until the past 20 years or so.

The acute BP response to stress has been labeled cardiovascular reactivity (CVR) and refers to the change in heart rate

Figure 1 Schematic overview of CVR-testing procedures.

(HR) and/or BP that is observed in the laboratory upon exposure to a stressor. The basis is that persons who exhibit greater CVR to stress are thought to be at greater risk for hypertension (HTN) and coronary heart disease (CHD) than those whose responses are lower. This has been referred to as the 'reactivity hypothesis.'

It is clear that behavioral and psychosocial factors such as anger, hostility, lack of social support, and exposure to stress are linked to HTN and CHD. The pathways by which these factors increase risk for disease, however, remain controversial. The reactivity hypothesis suggests that the acute BP or HR response to stress serves as a marker for HTN and CHD risk and possibly as a mechanism underlying the stress-HTN-CHD relationship.

BP and Hypertension

BP is the force of the blood flow on the inner arterial walls. An increase in one's BP is generally due to a combination of increased sympathetic outflow, mediated centrally via cardiac output and more predominant in earlier stages of HTN, and by increased peripheral resistance, which is more predominant in the later HTN stages. In most people, the BP starts out low, but in many individuals the level becomes elevated over the course of the life span. High BP is not only a significant risk factor for heart disease and all-cause mortality, it is also a cause of damage to the heart, kidney, brain, and arteries.

It is often thought that developing high BP is an inevitable consequence of age. This is not the case, however, and one particularly evocative naturalistic study of an order of Italian nuns suggests this is not so. Over 20 years of observation of the members of a secluded order who spent most of their time in silence and prayer, and of the lay women who took care of the secular aspects of life, the BPs of the lay women, but not the nuns, rose with age (similar work has also been conducted and described by Gordon in the United States). The groups had the same diet, lived in similar quarters, and none in either group smoked or took oral contraceptives. It seems that it was only when individuals were exposed to the stress of dealing with the exigencies of everyday life that BP increased.

The study of the Italian nuns suggests that to understand the causes of developing higher and higher BP over the years, we must consider the role of psychological and environmental factors that contribute to HTN. The study of CVR has dominated this research.

The First Study of Acute BP Response

Early in the twentieth century, two physicians, Edgar Hines Jr. and George Brown, developed a test that could be applied to their patients with normal BP, which would allow the prediction of future HTN. The test involved first the taking of a baseline BP, followed by exposure to a 'cold pressor,' in this case an ice-water bath in which the patient immersed his/her hands while the BP was measured. The hypothesis was, the greater the difference between the baseline and cold pressor BP measurements, the greater the likelihood the patient would later develop high BP. To test the hypothesis, they conducted a simple study in which they took BP measurements in both normotensive and hypertensive patients, first during a resting (baseline) period, and then following exposure to a cold stimulus – the patient immersed both hands in an ice bath for 2 min. They found that, indeed, the BP of the hypertensives climbed during the ice bath more than that of the normotensives, supporting their hypothesis.

The cold test has not, unfortunately, proved useful for diagnosis, but it did provoke investigation that has continued for 80 years, until the present day. Their simple study was to become a template for how stress psychophysiology was accomplished, that is, to take measurements during an initial resting period and then again during a challenge or stressor of some sort.

The focus on CVR has persisted since Hines and Brown's study. It remains the predominant approach to the understanding of biobehavioral investigations into sustained elevated BP.

Does BP Reactivity Predict Future HTN and Cardiovascular Disease (CVD)?

Cross-Sectional Studies

Over the past several decades, many studies have replicated Hines and Brown's results, using the cold pressor and, later, psychological and emotional stressors. The most common has been mental arithmetic. These studies suggest that CVR may serve as a marker, and possibly as a cause, of future high BP. However, caution must be exercised in interpreting these results as they are cross-sectional, and in most studies, age, which tends to be greater in hypertensives in these studies, was not controlled.

Prospective Studies

Several prospective studies have examined the effect of increased CVR on a variety of endpoints, including the development of HTN, subclinical endpoints including left ventricular mass (a measure of heart damage), carotid atherosclerosis/coronary calcification, and of clinical endpoints (including myocardial infarction and death). An exhaustive review of this literature is beyond the scope of this article; however, the literature might be summarized as showing sufficient positive effects on prospective mechanisms and clinical outcomes to warrant the continued investigation into the magnitude of the BP response to stress.

Predictors/Determinants of Cardiovascular Reactivity

Hemodynamic Patterning as a Determinant of BP Reactivity

Acute BP elevation is determined by various factors, and the specific impetus for the BP increase is associated with the development of HTN and CHD. At the simplest level, the change in BP is a product of the cardiac output (CO: amount of blood pumped by the heart during a single cycle) and total peripheral resistance (TPR: systemic resistance to blood flow through the arteries). Addressing the conditions under which one system or the other is likely to predominate provides useful information regarding the underlying physiological mechanisms by which mental stress affects HR and BP. A noninvasive technique to assess these processes, called impedance cardiography (IC), provides a means to assess myocardial contractile force, particularly the cardiac pre-ejection period (PEP; the amount of time it takes for the heart to contract strongly enough to pump blood out of the heart during each heartbeat).

Identifying the source of the acute BP increase in response to stress – CO or TPR – is useful because, it has been theorized, each maps onto a different set of psychological responses. Thus, an individual who is late for an appointment, is driving, and is in heavy traffic may up his/her efforts to drive faster and to weave in and out of traffic, trying hard to arrive on time. Such a situation is referred to as 'active coping' by Paul Obrist, a prominent psychophysiolgist. That is, one can overcome the challenge if one puts the effort into it. Active coping-type stressors, according to Obrist, lead to BP increases that are mediated primarily by a *cardiac* response pattern, mediated by the sympathetic nervous system (SNS). This response also comprises increased CO, myocardial contractile force, HR, and systolic BP.

However, consider the situation in which you are late, driving, and in traffic, but stuck in bumper-to-bumper traffic that is not going to move for an hour. Once again, a stressful situation, but now there is nothing one can do about it. One's BP will rise in these circumstances – what is referred to as 'passive coping' by many – but Obrist suggests that the rise will be due, in this instance, to a *vascular* response pattern, also mediated by the SNS, and includes increases in TPR and diastolic BP, as well as HR responses that are mediated by the peripheral nervous system (PNS).

Factors Affecting Cardiovascular Reactivity

Social support

Individuals who report higher amounts of social support are at reduced risk for developing CVD. Some researchers have suggested that the presence of a supportive person may buffer the effects of stress and, therefore, will be associated with reduced CVR. Indeed, several studies have found that the presence of a supportive individual produces lower BP responses than not being provided with support, although a few studies have failed to replicate these findings.

Hostility

Recent literature suggests that persons who score high on trait hostility tend to exhibit larger CV responses compared to low-hostile persons, but only in situations in which this aspect of

personality is relevant, such as when the subject is being harassed while working on a stressful task.

Race

It is known that African-Americans are more likely to develop HTN and CHD than whites, but the cause is not well understood. Some studies have examined black-white differences to stress and found mixed results, although a preponderance of these studies has shown that both black children and adults tend to exhibit greater CVR compared to white subjects. The evidence is sparse, however, due to the paucity of published studies.

Sex

Men are more likely to develop HTN and CVD than women during early adulthood and middle age. However, women tend to catch up after menopause. Comparisons have tended to show that men exhibit greater systolic BP reactivity to stress, while women tend to have slightly greater HR responses.

Menopause

Few studies of pre- versus postmenopausal women have been conducted. However, the data that do exist suggest that postmenopausal women tend to have greater HR and systolic BP reactivity than premenopausal women.

Menstrual cycle

The role of the menstrual cycle on CVR remains unclear. The results comparing women's CVR using a between-subjects design have found little effect of the luteal or follicular phase of menstruation on CVR, and within-subject studies have tended to show positive but small differences. An analysis of the results across studies suggests that the menstrual cycle probably does not largely influence CVR. However, it is noted that reproductive hormones may play a role in modulating the stress responses in women with abnormal menstrual cycles and that changes in hormonal levels may play a role in stress reactivity.

Effects of family history of HTN

Individuals with one or two parents with HTN are themselves at greater risk for this illness. One research strategy has been to see if persons with a positive family history tend to have greater CVR than individuals with no hypertensive parents, and the evidence, although sparse, supports this.

Twin studies

Overall, there tends to be a stronger relationship between stress reactivity in monozygotic than in dizygotic twins, suggesting that there is a genetic basis for the magnitude of the BP or HR response to stress. The NHLBI Twin Study examined 101 twin brothers who were veterans of World War II and the Korean conflict. The results of a comparison of the CVR in both brothers in each dyad indicated that a moderate proportion of the variance in CVR appears to be attributable to genetic factors.

Limitations of the Reactivity Hypothesis

Perhaps the major limitation to the usefulness of the reactivity hypothesis concerns the degree of interpretation – and sometimes overinterpretation – to which the results are

subjected. First, of course there are many factors that are implicated in the observed association between stress and HTN/CHD; the reactivity hypothesis is one small part, but tends not to be incorporated into a larger framework, and this is crucial for progress in this area. Another aspect of overinterpretation concerns the nature of the data – we cannot examine the long-term health effects on manipulated CVR, so we do not have evidence that allows statements concerning the causal role of CVR in CVD.

Summary

The examination of the determinants and role of CVR in the development of HTN and CHD has been useful for understanding the important role that stress may play in this process. There are limitations concerning the interpretability of the data, but true to Cannon's notion, the study of the biological parameters – in this instance, of BP and HR – while exposed to a 'load' (a stressor or challenge) has the means to provide a window into biological mediators of stress and illness.

New Developments in Stress-Psychophysiological Research

Over the past 20 years or so, it has become increasingly apparent that to understand the nature of the effects of stress on chronic illness, we must examine the multiple biological systems that mediate the transactions between the environment and the future dysregulation of those biological systems, with the resultant increase in probability of developing HTN or heart disease. For example, it is now clear that the regulation of inflammation is subject to environmental stress and plays a central role in CVD and many other chronic illnesses. Thus, it must be considered in any model attempting to specify and understand the stress – illness connection.

A New Approach: Cognitive Underpinnings of Sustained Biological Dysregulation

Most of the research described in this article concerns acute dysregulations of the BP and other biological systems that are affected by stress and implicated in the development of HTN and CVD. Specifically, the research has focused on the acute biological response to a stressor. However, humans do not require an external stressor to provoke such responses; we are quite capable of storing the memories of those experiences and replaying them later, often over and over again. Moreover, some theorists, including the authors, have come to the conclusion that it is this chronic reexperience of past stressors that is the more important cause of illness. The effects of such 'replays' are often of lesser magnitude than that of the original stimulus, but a 30 mmHg increase in the BP over a period of a few minutes or an hour is not nearly as damaging to the cardiovascular system as a small change – just 2 or 3 mmHg – that is sustained over months or even years. Thus, the role of cognition, with a focus on perseverative cognition (e.g., rumination, worry), has begun to be seen as an important area of study, not supplanting but certainly augmenting the reactivity

models. A large body of research now shows that dysfunctional cognitive and emotional self-regulation, such as keeping one's anger in and ruminating about it, often long into the future, exercises pejorative effects on BP regulation, as well as other biological systems including the hypothalamic–pituitary axis, sympathetic–parasympathetic balance, and endothelial function.

Conclusion

It is unequivocal: Stress, and the way one copes with it, plays a critical role in cardiovascular health and psychological well-being. The effects of stress on the biological systems that are implicated in poor cardiovascular health are well documented. In addition to acute effects, the chronic sequelae of perseverative cognition and rumination are also implicated in the development of HTN and CHD.

Glossary

Coping Physical or mental efforts made to manage perceived demands of a stressor.

Health Resilience, toughness.

Illness Sickness that has been diagnosed.

PAC Pituitary adrenocortical response system – evaluation of a threat triggers physiological responses resulting in cortisol release; a long-term stress response.

SAM Sympathetic adrenal medullary system – evaluation of a threat triggers physiological responses resulting in catecholamine release; a short-term stress response.

Stressor An external event deemed as a challenge or threat.

Stressor appraisals The perception that an impending or ongoing personally relevant event is taxing one's resources for coping with the event.

We all experience stress but only some of us will become sick because of it. This article begins with a brief history of how philosophers and scientists have thought about stress and illness, and how stress is physically and psychologically manifested. Next, we consider that although understanding physiological responses to stress helps us to understand how stress might lead to illness, it does not help us to define what stress is. Finally, specific links between stress and illness are examined, with an eye toward factors that can help organisms build resilience against stress.

Brief History of the Interaction of Mind and Body

Most present-day thinkers studying the body's adaptation to its environment believe that the mind and the body interact and that they are intimately linked to influence our ability to adapt to stressful situations. These beliefs were not always so prevalent. In the mid-1600s, the Western world was offered Descartes' mechanistic approach, in part, a product of the 'time of machines.' It suggested that the mind and the body were separate both in substance and in their distinct functionality. At that time in history, this conceptualization of mind-body dualism permitted investigation (dissection) of the human body (the 'machine') without concern for affecting the mind which held the soul (the 'ghost in the machine'). Although our knowledge of the physical functioning of the human organism increased greatly, there was no consideration of how the mind could influence or be influenced by the machine.

Cartesian dualism offered a philosophical separation of the mind and the body that allowed for an investigation of the machine, but it posed barriers for thinking about how the mind and the body may be functionally integrated. The father of American psychology, William James, believed that the body and the mind together have an adaptive relationship with the environment, even though they are physically different. In American psychology, however, the study of the mind became untenable for psychologists, largely because of John Watson's directive that as a natural science, psychology should focus on investigating only those things that were observable. Consequently, examination of mental states was unworthy of study because the mind is inherently unobservable. The study

of the interaction of the mind and body processes did not reemerge until the 1960s, when Schachter and Singer offered a neo-Jamesian model of emotion. Their research demonstrated that people would interpret their physiological arousal depending upon the situation in which they found themselves. Given physical arousal and a happy context, people were more likely to interpret their physiological symptoms as indicating happiness. Conversely, given arousal and an angry context, people were more likely to interpret their arousal as indicating anger. Subsequently, some scientists suggested that the physiological experience need not rise to the level of psychological awareness to influence thoughts and behavior. Research on nonhuman animals revealed that immune system suppression could be learned, demonstrating that awareness was not needed to influence physiological functioning. In human research, evolutionarily significant pictures (i.e., spiders and snakes) were presented below levels of awareness. Research participants had physiological and psychological distress responses to these stimuli, despite their lack of awareness of the pictures.

At present, we know that the body is comprised of multiple systems that coordinate with one another, and these systems are affected by the mind. The traditional biomedical model reflects a separation of mind and body. The model's focus was on pathogens that cause disease and their treatment. Conversely, the more recently developed biopsychosocial model considers the interplay of biological, psychological (e.g., thoughts, emotions), and social factors on health and illness. This model best explains how stress and illness can be linked. There have been three main approaches to studying stress and illness. The physiological approach focuses on physical disease and its mechanisms, the environmental approach focuses on external stimuli, and the psychological approach focuses on cognitive and emotional processes. Given this brief history of thinking about the interaction of the mind and the body, we now turn our focus toward understanding how these three main approaches have evolved.

Physiological Stress Responses

The body has multiple systems that allow for layered stress responding, making the organism quite adaptable to

environmental changes. Major historical contributors to present-day thinking about stress reactions, Cannon and Selye, believed that perceptions were the key to setting off physiological changes. We begin with a description of Cannon's contributions to understanding basic, so-called 'fight-or-flight' reactions to stress and then discuss Selye's investigation of chronic stress responses. These physiological responses, along with immune system functioning, provide a direct route through which perceptions of threat (below or above levels of conscious awareness) affect the body and influence physical illness.

Walter Cannon, a physiologist, coined the term 'fight or flight' to describe sympathetic nervous system (SNS) responses to stress that quickly prepare the organism for attack, defense, or escape. The most immediate response includes neural-induced physiological changes, including pupil dilation (to bring in more light), increased heart rate (to get more blood to the muscles for use), and hormonal changes including secretion of adrenalin (to increase cardiovascular and respiratory functioning for muscle mobilization and to reduce digestive functioning). These widespread and quick effects are beneficial as energy is mobilized throughout the body in preparation for vigorous muscle activity, such as would be needed to fight or flee. This is the sympathetic-adreno-medullary response system (SAM).

Physiologist Hans Selye refined our language about stress, referring to the external stimulus as the 'stressor,' and the physiological response as 'stress.' For Selye, stress was a non-specific biological response caused by all noxious stimuli. He focused on nonhuman animal stress responses of the hypothalamic-pituitary-adrenocortical (HPA) axis. Because of its anatomy and functioning (via the bloodstream), the HPA axis tends to be a slower stress response system compared to the SNS. Upon the perception of threat, the brain's hypothalamus signals the anterior pituitary to secrete adrenocorticotropic hormone (ACTH), which travels to the adrenal cortex (atop the kidneys) signaling it to secrete glucocorticoids, including cortisol. Cortisol not only travels throughout the bloodstream to mobilize the body's energy resources, but is also used as an anti-inflammatory. Having sustained energy and protection from injury would be helpful, for example, when an organism is fleeing from a hungry tiger and twists its ankle. Thanks to cortisol, running from the tiger can be sustained for some time without suffering too much pain and swelling. This stress response was dubbed the 'general adaptation syndrome.' Selye's model stated that adaptation to a stressor has three stages beginning with 'alarm,' the fight-or-flight response, then 'resistance' as the stressor continues, which includes physiological secretion of cortisol. The last stage is 'exhaustion,' the physiological breaking point where organisms might suffer depression or even death. As stressors continue, the physiological response sets the stage for diseases of adaptation. Selye was the first to show that stressors (both positive and negative) have a direct impact on the functioning of the body, and that this impact was driven by the HPA axis and cortisol specifically. This is the pituitary adrenocortical response system (PAC).

Another physiological system that has been more recently investigated in the domain of stress is the immune system. The immune system is the body's defense against foreign invaders and also has implications for stress and illness. When immune system functioning is reduced, organisms are more susceptible

to infection, and injuries are slower to heal. In the mid-1970s, researchers discovered that rats could learn to suppress their immune functioning, suggesting that the mind could affect this physiological system. The field of psychoneuroimmunology emerged soon thereafter, examining the interactions of the psychological, nervous, endocrine, and immune systems with health and illness.

Defining Stressors and Stress Responses

Understanding the physiology of stress responses may help us to understand how the body responds to potential or ongoing threats, but it does not help us to define stress. Given the idea that the body has a nonspecific response to noxious stimuli, psychologists began to investigate how conditions, called life events (e.g., death of a spouse, losing a job), relate to the development of later illness. Overall, this research was not promising because life events were not consistently or strongly related to the development of illness. Although the physiological stress response can prepare people for mobilization, people have different interpretations about the same stressor and will have different ideas about how to cope with the stressor – perhaps via approaching, attacking, or withdrawing. This (and nonhuman) research demonstrated that it is not the objective event but the interpretation of the event that is important for stress responses. It should be noted that while people can interpret the same stressor differently, there are some objective stressor characteristics that increase their potential for stress responses, such as unpredictability, uncontrollability, and negativity.

Richard Lazarus, a clinical psychologist, suggested that stress responses involve a transaction between the person and the situation, and that the person's interpretation of the event was more important than the event itself. Stress responses were determined by the interaction between evaluations of the personal importance of a situation (called primary appraisal) relative to evaluations of the coping resources available to manage the situation (called secondary appraisal). Over time as a stressor unfolds, a person will reassess the importance and relevance of the stressor as well as potential coping resources. Lazarus investigated minor life events, or more precisely, daily hassles (e.g., losing car keys), and found that if these events were interpreted as negative, then stress responses increased. Investigations of daily hassles revealed that they were better predictors of later illness than major life events. Psychological processes are important aspects of our stress responses and influence the development of illness. These influences can be direct, through physiological reactions, or they can be indirect, by altering our behaviors.

Mechanisms Linking Stress to Disease

A direct link between stress and illness occurs through physiological stress responses generated by perceptions of or in anticipation of a stressor. Repeated or continued exposure to a stressor can cause wear and tear on the body. Stressor evaluations of threat (personal relevance coupled with low coping resources) have been related to enhanced fight-or-flight

response. This type of response (when pronounced or frequent) could, for example, aggravate irritable bowel syndrome, cause headaches, or damage cardiovascular health (e.g., coronary artery disease). Repeated or chronically high levels of cortisol responses can increase susceptibility to various diseases and delay the body's healing processes. Excessive cortisol secretion may be an important link to reducing immune system functioning, leaving the body susceptible to colds and other respiratory infections.

Disruption of the normal functioning of these systems can foster mental health problems such as anxiety and depression. Loneliness, depression, and chronic stress, such as caring for a person with Alzheimer's, have been linked to lowered immunity. Research has shown that reducing negative stress (i.e., threat) can improve immune functioning to some degree. There are also behavioral effects that indirectly link threat and illness. When people experience high levels of threat, they may engage in poor health behaviors, such as increased cigarette smoking, alcohol consumption, poor diet, inactivity, and sleep disruption. These unhealthy behaviors can cause the body to function more poorly and reduce immune functioning in particular.

Vulnerability to Stress-Induced Illness

We all experience stressors, but most of us do not develop stress-related illnesses. The diathesis-stress model best characterizes who will succumb to the effects of stressors. The addition of stressors to an already existing personal vulnerability (e.g., biological, genetic, or personality trait) is more likely to result in illness. This model helps us to understand why some people who experience stress get sick and others do not. These so-called stress moderators (personal and social vulnerabilities) can influence exposure to and appraisals of potential stressors, as well as perceptions of coping resources.

There are stable aspects of people that influence their interpretation of the environment in similar ways over time. These stable aspects are personality traits. Optimism is one trait that characterizes the tendency to be hopeful and have positive expectations for the future. One might expect that those who are highly optimistic would have better health outcomes, which they do. Conversely, people who demonstrate hostile tendencies, who are cynical, mistrusting, and suspicious of others, are more likely to suffer poor health outcomes. Compared to those who are less hostile, those who are highly hostile are more likely to interpret situations as competitive and believe that others have negative intentions. When interpreting situations in this way, those who are highly hostile experience greater cardiovascular reactivity and other neuroendocrine responses which pose repeated degradation of the cardiovascular system. Neuroticism is the tendency to experience negative emotions and has repeatedly been found to be detrimental to health. People who are high in neuroticism interpret many of the situations they find themselves in as threats. Evaluations of threat have been consistently related to deleterious cardiovascular responses and worse performance on tasks. However, those high in hostility and neuroticism are not doomed to future illness.

Although there are stable intrinsic variables that can lead to illness for some individuals, there are also stress moderators

that can provide protection. The social context is important to consider for health and illness. Our social networks include the number of people we have for support and how often we use this network. The more people we have in our social network, and the more often we utilize their support, the better our health. Social support can have a direct effect on health by providing a form of assistance, through the good (no stress) and the bad (stress present) times. Having more social ties is linked to greater longevity and better health. However, a smaller network used frequently can still supply beneficial social support. The health effects of low social support are best demonstrated by those who are socially isolated. People who are lonely or isolated suffer more illness. Isolation and loneliness happen for many reasons. Those who are high in hostility may be difficult to be around and provide support to, and research suggests that this appears to be the case. Those who are highly hostile should seek help to change how they interact with the world, to experience less stress reactivity, and garner more social support.

Social support can facilitate coping mechanisms when stressful events occur. People in our social support network can be found in different places (e.g., work, spiritual community, school) and likely provide different functions. Some people might help to give you more confidence to deal with stressors. Others might provide helpful information and/or financial resources. Still, others might be a good source of listening so that you can talk about your stressful experiences, and thereby reduce your negative emotional stress response. It is important to note that not all social support is beneficial. For example, being around people who engage in hostile communication is detrimental to psychological health and can exacerbate psychological symptoms.

Social support can also indirectly affect health by fostering healthy behaviors. Those who have more social support are more likely to engage in health behaviors such as using seat belts and eating healthier. Of course, people can get together to eat more poorly too! Good social support can foster other healthy behaviors such as exercising together and taking better care to obtain health screenings. Engaging in health screenings can help people get the feedback they need to maintain a healthy body or to find problems early and seek treatment. Social support is one way to help us withstand the inevitable stressors we will face, but there are other ways to build up our resilience to stress.

Building Stress Resilience

Vulnerabilities can act as catalysts and actually increase harmful stress effects. However, personal resources and vulnerabilities interact with the stress process. Social support and other resources (such as dispositions like optimism) act as assets when we encounter stressful situations, decreasing the negative effects of stress. They may provide us benefits by exposing us to fewer stressors, helping us to appraise stressors as less threatening, enhancing our coping capabilities, and reducing our physiological stress reactivity. There are many ways to reduce the negative effects of stress. There are also ways to build up our stress tolerance, which can prevent experiencing stress in the first place. Stress tolerance will help our mind and body to be more resilient when faced with stressors.

Several effective stress reduction strategies are offered by the research and experiences of clinical psychologists and health psychologists. One technique includes relaxation training, which includes a combination of breathing exercises, mental imagery, and release of muscle tension. Progressive muscle relaxation is another technique that focuses on the tensing and relaxing of the major muscle groups. Various techniques implemented in cognitive behavior therapy can help to alter how we interpret our world. Psychologists work with clients to help them become aware of and change health-damaging beliefs and behavior. Therapy may focus on changing irrational beliefs that foster catastrophic interpretations of stressful encounters, or focus on increasing the confidence that one can effectively solve stress-related problems, or perhaps to change beliefs that foster hostile interactions with the environment.

Other effective stress reduction strategies stem from eastern cultures and include massage, acupuncture (which is particularly effective for reducing some types of pain such as lower back pain), and mindfulness meditation. Mindfulness meditation involves being still and observing one's thoughts nonjudgmentally. This type of meditation has demonstrated benefits for cardiovascular health and lowering anxiety levels. It may work through reducing stress-related reactivity at the outset, by reducing perceptions of threat. Exercise is another proven way to foster positive psychological and physical health.

Summary

It is clear that the mind and the body are linked. The body can influence the mind, the mind can influence the body, and

the mind and the body interact across different levels to influence how we relate to others and our environment. Repeated stressful interactions can have negative costs for both the mind and the body. A lack of personal awareness of the effects of stressors on our physiological and psychological functioning can exacerbate at worst, and continue at best, our deleterious interactions with the environment. However, there are effective ways in which we can boost our ability to respond to stressors and our tolerance for stress.

Studying

M Rabinowitz and J Z Ingber, Fordham University, New York, NY, USA

© 2012 Elsevier Inc. All rights reserved.

Glossary

Constructed outcome The expectation of acquiring a deeper level of understanding of the material, for the purposes of making inferences and connections to the material being acquired.

Distributed rehearsal The spacing of rehearsal of materials out over different time periods and contexts.

Interpreted outcome The expectation to be able to know the gist of what is being presented – exact wording is not required.

Massed rehearsal The rehearsal of materials in the space of a single, prolonged time period.

Mastery-oriented goal The aim or attempt to master or learn a new skill.

Metacognition A person's ability to know about and monitor his or her cognition.

Performance-oriented goal The aim or attempt to strive to do well – score highly, in reference to others.

Studying An intentional and effortful activity that has as its goal the learning or mastering of some new information or skill.

Verbatim outcome The expectation to be able to repeat back or recognize what was repeated.

Zone of proximal development A concept developed by the Soviet psychologist Lev Vygotsky, defined as the difference between what a child can accomplish independently and what can be accomplished with help from an experienced adult or mentor.

For most people, the word is not associated with pleasant feelings. Studying is an intentional and effortful activity that has as its goal the learning or mastering of some new information or skill. Studying is different from other types of tasks because it is often performed as an isolated and unsupervised activity. Unlike learning in classrooms, studying occurs while working alone and usually, the manner in which the activity is carried out is often executed without directions or feedback from others. As such, the success or failure of the studying activity is often attributable specifically to what the person is doing while studying.

The activity of studying actually begins during the first year of life when infants begin to show evidence of using intentional memory strategies and try to learn language. Studying behavior then evolves rapidly as one enters and progresses through the school years and educational demands increase. As people grow older and complete formal schooling, the activity of studying tends to decline as reliance on prior experience (e.g., real-world knowledge) becomes the predominant strategy for everyday activities.

As with any skill, people vary in terms of how well they execute the skill. Some of the factors that affect the efficacy of studying and their relation to the basic psychological processes that underlie them are presented. (Readers are encouraged to investigate these processes in more detail in the other sections of the encyclopedia.) Also, some recommendations as to how to study more effectively are provided.

Attention

Perhaps because studying is not perceived to be an enjoyable activity by many, people tend to study while also engaging in a secondary activity; for example, listening to music, watching television, texting friends, etc. Although we like to think that we can and should multitask (e.g., engaging in multiple tasks at

work, talking on the cell phone while driving, and even walking), the reality is that research from the area of attention shows that our cognitive system is not designed to do that very effectively. Research and experience has shown that one attribute of our cognitive system is that we have limited attentional resources; that is, we can only attend to a limited number of things at one time. To the extent that people pay attention to one thing (television), they are not paying attention to another (studying) – or vice versa. Research has shown that performance drops off significantly on a primary task when people multitask; the ability to acquire new skills suffers, the number of errors increases, and the time needed for mastery increases. The implication of the constraint of limited attentional resources is that when a person has the goal of studying, he or she should not attempt to multitask.

Interestingly, a second feature of attention leads to a different and slightly contradictory implication. Attention is selective as well as limited. Studying requires staying focused on one thing and this in turn requires effort. These demands lead to a number of consequences including fatigue, decreased motivation, and boredom. The mind has a tendency to wander or get distracted. Current research has shown that the tendency to become distracted actually increases with the amount of effort required by the task; the more effort required, the greater the tendency to become distracted. Studying requires a significant amount of effort! Because it requires effort, it is important to avoid condensing study into single extended periods of time and to create an environment that limits the possibility of distractions.

The suggestion to refrain from studying for extended periods of time in one sitting is supported by research from a number of different research areas. First, research looking at practice indicates that people with an exceptional ability to acquire new skills (experts) use spaced practice: they practice as much in total as other people who are good, but they tend to space out their practice over time (shorter sessions more

number of times a day). Because successful practice is effortful and requires focused attention, there is even evidence that people who are very successful are more likely to take naps after or between practicing! This suggestion is also supported by memory research on the effects of massed versus distributed practice. Many experimental findings demonstrate that massed rehearsal (rehearsing materials all at one time) is not as effective as distributed rehearsal (spacing rehearsal out over different time periods and contexts). People exhibit better memory performance with spaced as compared to massed rehearsal. Finally, research on memory has similarly revealed that the ability to remember something is very context specific; that is, we are able to retrieve information given specific retrieval cues. Information that a person clearly knows may not be retrievable unless the correct retrieval cue is provided. Studying all at one time and in one context limits the number of retrieval cues available. Spreading out studying over time and contexts increases the number of retrieval cues and thus makes the ability to recall something when needed more likely.

The second implication posited was to study in an environment that limits distractions. For example, it is often useful to have white noise (noise that will not demand attention but rather blocks out sounds that might be distracting). Examples of white noise would be the recordings of ocean waves or birds chirping quietly. It is also advisable to study in different places – not study in the same place each time. The research on context-specific memory has shown that studying in multiple locations actually improves retrieval.

So then, studying should not be done while working simultaneously on a secondary task, it should be spaced out over time – no cramming, and conducted in an environment with minimal distractions. All of these suggestions seem intuitive but few people actually follow them. These are suggestions for the context of studying but what should a person do when they actually sit down to study?

One way of thinking about studying is to regard it as a problem-solving task – an ill-defined problem-solving task. An ill-defined problem-solving task is one in which the goals are vague, the manner in which the task should be accomplished is unclear, and indicators of accuracy in task completion is not obvious. The ill-defined problem-solving task contrasts with a well-defined problem-solving task where the goals are well defined (the problem-solver knows when the goal has been reached) and the procedures necessary to achieve the goal are clearly stated.

Goal-Setting

A problem-solving task is defined as a goal-oriented task, where problem-solving people are trying to attain a specific goal. In describing goal-setting behavior, a distinction has been made at a general level between mastery- and performance-oriented goals. With a mastery-oriented goal, the person attempts to master or learn a new skill. With a performance-oriented goal, the person strives to do well – score highly, in reference to others. Research suggests that people who adopt mastery-oriented goals are more likely to try harder and persist in a task than those who adopt performance-oriented goals. However, performance is not always associated with goal type.

While it is hoped that most students study to understand a topic and not solely to perform well, this practice is not always appropriate. Success ultimately depends upon what will be tested. A student can study for comprehension and be tested for rote memory – being able to repeat back what was presented. One distinction that has been made regarding possible outcomes is between verbatim, interpreted, and constructed outcomes. A verbatim outcome is akin to rote memory – to be able to repeat back or recognize what was repeated. Acquiring foreign language vocabulary is one example, but a verbatim outcome is often exemplified by learning specific dates of historical events. An interpreted outcome only requires one to know the gist of what is being presented – exact wording is not required. A constructed outcome entails a deeper level of understanding, because it involves making inferences and connections to the material being acquired. Studying for an interpreted outcome does not lead to quality performance when being tested for a verbatim outcome and vice versa. It is important to know the information that will be used or tested and to adopt a studying strategy that compliments the intended outcome of that information (verbatim, interpreted, or constructed), which will reveal how information is applied. As stated earlier, when people sit down to study, they often do not know how the knowledge is going to be assessed or how it needs to be used.

Studying Strategies

Studying strategies are very often not taught in schools. Many times, students are just told that they are required to study something but not directed on how to go about doing so. Once again, studying is a problem-solving task. Students need to figure out what is the goal and how to accomplish it. Thus, students are left to their own devices to figure out how to do it effectively. Many students seem to be adept at figuring out how to study but many fail; that is, they spend a lot of time trying to study but what they do is not effective.

Alternatively, on the other end of the continuum, some teachers or parents are very prescriptive as to how to study. They demand that students study using a specific strategy. When given directions for studying, students are often told something like ‘this is how you should do it,’ or ‘this is a good studying strategy.’ The problem with this is that, as will be shown, there is no such thing as a *general* good studying strategy. A good studying strategy in one context might be a very poor studying strategy in another.

A distinction made within the problem-solving literature is between weak and strong strategies (or processes). A weak strategy is one that may be applied broadly to many different types of tasks but lacks the specificity for a particular task, meaning that success (achievement for the goal) is not guaranteed. A strong strategy, on the other hand, is one that is designed to work explicitly on a given task and because it is so specifically designed for a given task, it affords a high level of success. The problem with a strong strategy is that it does not necessarily work well for other tasks – it is not generalizable. Thus, if the task demands change slightly, the strong strategy may not work as well.

As mentioned before, studying is often seen as an ill-defined problem-solving task. A person often does not know

what the goal is (how he or she is going to be asked to use the knowledge), whether or not they have mastered the knowledge, or how they should go about the task itself. Given these characteristics, it is often impossible to develop a strong strategy to accomplish the task. People are forced to rely on weak strategies – strategies that are better than nothing but do not guarantee success.

An example of a set of strong strategies is using mnemonics to memorize something. There are a whole host of memorization strategies (called mnemonics) that have been developed to aid memory. Some of the more common ones are called the link mnemonic, the method of loci, and the keyword mnemonic. There are many books available on improving memory that describe the steps needed to be taken to use these strategies. The important point here is that mnemonic techniques (1) work very well for memorizing information and (2) are very detailed in terms of the process of using them effectively. They are designed very specifically to overcome problems with encoding and with retrieval. The problem with them is that they are limited in terms of what they are good for – they allow you to remember the materials in a very specific way with accuracy. However, they are not good for facilitating comprehension or for allowing alternative pathways of retrieval.

Contrast this description with that of a weak strategy. One example of a weak strategy would be subgoalting, a process in which a person breaks up a large goal into smaller composite goals. It breaks up that task into manageable components and allows the person to incrementally set and meet goals. A subgoalting strategy works for a wide variety of tasks. Other examples of weak studying strategies include relating information to prior experiences, trying to relate or integrate information from one source with another, trying to visualize or draw pictures of the information to be learned, trying to think of things from multiple perspectives, etc. Each of these strategies can be used in a variety of contexts and for a variety of tasks and have been shown to improve learning and comprehension. But when do you use each? It is not clear when a person should rely on one strategy or another. Also, unlike the mnemonics mentioned earlier, the steps required to go through to execute the strategy are not well specified. How are you supposed to go about relating something to your prior experiences? What should you specifically do when applying these strategies? The mnemonic strategies mentioned above have very detailed step-by-step descriptions of what to do. Weak strategies, in contrast, are general guidelines for how to go about studying. Different people would try to implement them in different situations – not always appropriate – and in different ways with differing outcomes. These weak strategies are very good processes and can be used in a variety of different situations. However, because they are general, they cannot be specified in great detail nor do they always work for what you are trying to accomplish.

A second point to be made about studying strategies is that people have been shown to not be very good at choosing the most effective strategy for a given task. An interesting research finding relevant to the issue of strategy choice is that apparently students prefer to use strategies that they perceive to be easy to use and require little effort on their part. These strategy choices are often independent of whether the strategy will help them or not. Given a choice between a strategy that is easy to use (requires little effort) but does not help learning much and

one that is more difficult to use (requires more effort) but is more effective, students often choose to use the one that requires less effort.

The implications of this discussion are that (1) people need to rely on a repertoire of different studying strategies to be successful, and they need to be flexible in their choice and use of strategies; (2) approaching a task with a preconceived strategy of how you are going to accomplish it could be just as harmful as having no strategy at all. Good learners tend to be flexible learners, adapting or creating strategies to meet the demands of the given situation. Finally, (3) people need to be aware of whether or not they are mastering the material.

The Importance of Self-Testing

Metacognition refers to a person's ability to know about and monitor his or her cognition. Are you on task? Are you doing things that will help you attain your goal? Is your strategy working? An interesting finding from the research on metacognition is that people are often not very accurate in assessing what they know and what they do not know. For example, when given a choice to study items that students knew versus items they were not as comfortable with, the students often did not allocate their study time very effectively – they did not concentrate on items that they did not know. Also, as illustrated above, people often are not aware if their strategies for learning are working. For this reason, it is important that people test themselves while studying. Research on self-testing shows that there are two benefits to doing this. The first is that it obviously gives a person information about what he or she knows and what he or she does not. Second, the research also indicates that it is a good study strategy for enhancing the ability to retrieve information later. Engaging in self-testing improves memory performance more than if a person just repeatedly studied the material.

Discussion

As can be seen from the preceding presentation, studying is not an easy task to master. It requires intention and a lot of effort. It is often an unguided activity and people often do not get feedback as to whether they are being successful or not. To confound things even more, there is no simple and best method for studying. People may need to try lots of different strategies and be willing to change their strategies depending on the demands of the task.

Very often people are not taught how to study. Starting in elementary school, students are often given assignments to study and they are left to figure out how to do it by themselves. As stated earlier, studying could be thought of as a problem-solving task where the student needs to figure out the best way of achieving the goal. On the other hand, when students are given hints on how to study, they are often told to do it in a formulaic way, being told that there is a set and best way to study. This type of instruction might be more harmful than no instruction at all. The point made earlier is that the student needs to be flexible in their studying behavior, adapting the activity to the specific goals of the task at hand.

So how do people become successful at studying? Again, some people just figure it out for themselves but most need guidance. One suggestion is at least early on, have the beginning learner (a young child) study with someone who is more skilled (a parent). In his theory of development, Vygotsky used the following illustration to show how children learn a number of tasks. Emphasizing the concept of the 'zone of proximal development,' he presented the context of a young child working on a jigsaw puzzle with a parent. Initially, it looks like the parent is doing most of the work in solving the problem and the child is just watching or making random decisions. Gradually, as the parent talks about what they are doing, the child takes more and more responsibility for solving the puzzle. After a period of time, the child is doing most of the work on the puzzle, internalizing the social processes initially exhibited by the parent and the parent can sit back and watch. Unfortunately, studying, as we stated earlier, is often seen as an activity that a person works on independently. If the beginning student has the opportunity to view and work with a more experienced student (one who exhibits the skills described in this section), the child will have the opportunity to learn and internalize the skills that are being displayed. Initially, as with the jigsaw puzzle, it would seem like the more-experienced person is doing most of the work, but gradually, the less-experienced person would take over more of the responsibility for the task and learn the skills that would make him or her successful.

Subjective Culture

H C Triandis, University of Illinois, Champaign, IL, USA

M Gelfand, University of Maryland, College Park, MD, USA

© 2012 Elsevier Inc. All rights reserved.

Glossary

Cultural assimilator Books or computer-based cross-cultural training devices to assess the degree to which individuals make correct (isomorphic) attributions of others' behavior.

Cultural complexity The degree to which societies are simple, with few roles, versus complex, where there are many roles.

Individualism and collectivism In collectivist cultures, the theme is centrality of the ingroup; in individualist cultures, it is the centrality of the individual. Similar contrasts include terms such as sociocentric,

group-oriented, *Gemeinschaft*, or interdependent culture versus idiocentric, or individual-centered, individual-oriented, *Gesellschaft*, or independent culture.

Subjective culture Subjective culture includes *shared* ideas, theories, and political, religious, scientific, economic, and social standards for judging events in the environment. Subjective culture includes also *shared* memories and ideas about correct and incorrect behavior, stereotypes, and the way members of the culture value entities in their environment.

Tightness and looseness The degree to which societies have strong norms and little tolerance for deviance from norms.

Introduction

People in every culture (defined by the conjunction of language, location, and history) have a characteristic way of viewing their social environment. Culture is to society what memory is to individuals; it consists of what 'has worked' in the past, and helped a group adjust to its environment, and therefore was worth transmitting to future generations. Another definition of culture is shared understandings made manifest in act and artifact. In short, it includes both what people do and what they make. Yet another definition is that culture is the human-made part of the environment. The human-made part of the environment can be split into material culture (tools, dwellings, food, clothing, pots, machines, roads, and the like) and subjective culture (categorizations, beliefs, attitudes, and the like).

Subjective culture includes *shared* ideas, theories, and political, religious, scientific, economic, and social standards for judging events in the environment. Subjective culture also includes *shared* memories, and ideas about correct and incorrect behavior, stereotypes and the way members of the culture value entities in their environment.

The elements of subjective culture are linked to social behavior. *The Analysis of Subjective Culture* explores the elements and the links as well as the description of the cultures of several countries, and also the cultures of African and Hispanic Americans.

Theory

The basic element for the study of culture is *categorization*. What stimuli are treated as equivalent by members of a culture? Members of each culture have unique ways of categorizing experience. For example, who is a member of my ingroup? In some cultures, it is those who are born in the same place, or belong to the same tribe, race, social class, religion, or who

are blood relatives. In other cultures, it is people who 'think like I do.' The two categories might overlap, but they are not the same. Both etic (universal) and emic (culture specific) elements define a category. By studying how people categorize experience we learn a great deal about their culture.

Members of each culture have unique ways of *associating* one category with another. For example, is 'socialism' referring to a political party, an ideology, or both? Are 'fathers' in this culture assumed to be severe or lenient with respect to children of different ages? In addition, cultures differ in the kinds of perceived antecedent-consequent relationships that people use (e.g., if you have 'hard work' then you have 'progress'; if you have 'progress' then you have 'health'), *attitudes* (e.g., is 'socialism' good or bad, would members of the culture support a socialist party?), *beliefs* (e.g., 'socialism' results in good health or in an impoverished society), *expectations* (e.g., if there is socialism then there is happiness, poverty or both), *ideals* (e.g., widows should not be cool or passionate), *memories* (e.g., I remember the names of each of my cows), *norms* (e.g., members of this society give their seat to old people), *role perceptions* (e.g., the mother-son role is warmer than the father-son role in this culture), *stereotypes* (e.g., lower class people are not intelligent), *tasks* (e.g., to make this tool one has to first get some redwood), *values* (e.g., 'security' is all important).

Later work by Triandis resulted in a model linking *behavioral intentions* (e.g., I intend to do X) and *behavior* (X), which included also *norms* (most people I respect think I should do X), *self-definitions* (e.g., I am the kind of person who does X), *habits* (e.g., I frequently do X), and *facilitating conditions* (e.g., I am highly aroused to do X, I am capable of doing X; the situation calls for me to do X). Facilitating conditions are so important that at times the situation takes over and people do what the situation demands even when the other factors require a different behavior. The theory of reasoned action was combined with elements of the 1980 model to form the unified theory of behavior of Fishbein and colleagues.

Sample Findings

Stereotypes

A number of studies produced data dealing with stereotypes. For instance, representative samples of the two largest cities in Greece provided one set of such data. The American data were obtained by employing 32 interviewers, who interviewed samples of convenience. A total of 750 Greeks and 435 Americans responded to items in the following format:

	In general, Greeks tend to be	
Systematic	— — — — —	Unsystematic

During face-to-face interviews, respondents pointed to the place on the line that represented their position on the scale. The attributes on which these judgments were made were provided by focus groups in the two cultures; they consisted of the attributes frequently used by focus groups in both cultures.

The Behavioral Differential

An adaptation of the semantic differential called the 'behavioral differential' was developed. It involved the presentation of a complex stimulus person such as 'A black 35-year-old male physician' and under this stimulus were presented scales defined by a particular behavior, for example:

Would	— — — — —	Would not
	Invite this person to dinner in my home	

In each study, complex stimuli were generated according to a factorial design. They could vary in race, occupation, religion, nationality, age, gender, and even in personality attributes.

The Role Differential

Another adaptation of the semantic differential was the role differential. The format consisted of a role relationship and a behavior such as:

	Male-female	
Would	— — — — —	Would not
	Let go first through a door	

The responses of the N participants from each culture were summed, so that a data set consisting of 100 roles by 30 scales was obtained in each culture. Factor analyses of the 30×30 matrix (based on 100 observations per scale) from each culture showed that four factors emerged in all cultures. They were: *association-dissociation* (defined by behaviors such as help, reward, advise, stand up for, be interested in, be eager to see, and respect versus grow impatient with, be indignant with, argue with, infuriate, fear, be prejudiced against, and exclude); *superordination-subordination* (defined by command, advise, treat as subordinate, inspect the work of, feel superior to versus

apologize, ask for help from, be dependent on, accept commands of); *intimacy* (kiss, cuddle, love, marry, pet, cry for); *hostility* (throw rocks at, fight with, quarrel with, exploit, cheat). Each role relationship can be defined, then, as a point in a four-dimensional space, and one could state that in this culture the mother-son role is more associative, subordinate, intimate, and less hostile than it is in that culture. In addition to the four etic factors, the data set of each culture produced emic factors. For example, the Greeks produced a factor called 'ingroup concern for consensus,' the Americans an 'envy' factor.

The study found that roles are perceived similarly within cultures but quite differently across cultures. The data suggested that some cultures use much association and intimacy and low hostility within ingroups while in other cultures participants express some hostility within ingroups and emotional distance from ingroup members. Some cultures see a large difference in behavior when the other person is a member of the 'ingroup' versus a member of the 'outgroup' while in other cultures this contrast is not nearly as pronounced. An ingroup in Greece was defined as a group of individuals about whose welfare a person is concerned, with whom the person is willing to cooperate without demanding equitable returns, and separation from whom leads to anxiety. As we discuss below, these kinds of data eventually resulted in the identification of *collectivism* and *individualism*, as well as an emphasis on *vertical* versus *horizontal* relationships in different cultures.

The Antecedent-Consequent Method

Twenty concepts (anger, courage, fear, laughter, freedom, peace, truth, punishment, crime, knowledge, power, progress, success, wealth, death, defeat, love, respect, sympathy, trust) were used in this study. They were concepts that previous work by Osgood and his associates had found easy to translate. In addition, Osgood provided the semantic differential profiles of these concepts in Greece, India, Japan, and the United States.

In Step I, the participants were asked to complete sentences by using these two formats:

If you have ____ then you have X; If you have X then you have _____. The most frequently given antecedents (As) and consequents (Cs) from each culture were noted. An attempt was made to identify As and Cs that were culture-common, as well as As and Cs that were unique to each culture. In Step II, the format required placing an X on one of five lines. Participants selected the 'best' answer that completed sentences such as (e.g., If there is ____ then there is MURDER. Revenge____, Hate____, Insanity, ____, Theft____, Fear ____). The five answers were selected so that one answer was culture-common, and the other four were unique to each of the four cultures of the study. The order of the answers from the four cultures was counter-balanced, requiring several forms of the questionnaire in each culture. Similarly for Cs the format was as follows: If there is a MURDER, then there is ____ Imprisonment____, Grief____, Execution____, Disgust ____, Police action____. Again one of the five responses, selected from Step I, was culture-common and the others were unique to each of the four cultures of this study, and the answers were counter-balanced, requiring several forms in each culture.

The antecedent–consequent method provided information about the themes that were especially important in each culture. They presumably reflect central values of the culture. The central values of Americans were individual progress, self-confidence, good adjustment, status, peace of mind, achievement, and joy. The central values of the Greeks were civilization, glory, victory, love, and appreciation by others. The central values of Indians were increased status, glory, and social well-being. The central values of the Japanese were serenity, aesthetic and general satisfaction, self-confidence, responsibility, peace, advancement, and good adjustment.

There were some culture-common themes, but the culture-unique themes stand out. The individualism of Americans, with their emphasis on individual achievement and adjustment, is different from the collectivist emphasis of the Greeks on love and on being appreciated by others, as well as the Greek ‘nationalist’ themes such as civilization, glory, and victory. The Indians showed much emphasis on status, as well as glory. The caste system makes India one of the most status-conscious cultures. The Japanese have a unique emphasis on aesthetic satisfaction and serenity. Perhaps Zen Buddhism is reflected in this response pattern.

Role Perceptions

In all cultures, role perceptions are patterned according to (1) ingroup roles, (2) outgroup roles, (3) conflict roles, and (4) status (high–low, equal, low–high). Numerous culture-specific findings were obtained. For example, there is much higher solidarity in high-to-low status ingroup roles in Greece (3.0) than in India (1.5) or the United States (1.7). On the other hand, solidarity in such roles toward outgroup members is very low in Greece (0.4) as compared to other cultures (about 1.0). However, this difference did not appear in roles of equal status, but it reemerged in low-to-high status ingroup roles (Greece, 2.8 and India, 1.6); the United States was similar to Greece (2.8).

One study examined if the information obtained from each of the ‘probes’ into culture by the various methods leads to similar conclusions. If there is consistency across the methods it would indicate that the methods have concurrent validity. The study argued that the data from each of the methods can be summarized by using certain themes. For example, the Greek data indicated much more contrast between behaviors toward the ingroup and outgroup members than was found in the United States. This turned out to be a major characteristic of collectivist cultures. The traditional Greeks (of the 1960s, when the data were collected) defined their universe in terms of the triumphs of their ingroup over their outgroups, while for Americans this world view was of little or no importance. In Greece, relationships with authorities and social relations in general reflected the ingroup–outgroup relationships. The 2010 demonstrations in Greece provide an example of the conflict between the people and the authorities.

Another study examined the stereotypes of Americans that Greeks had and of Greeks that Americans had. Americans saw the Greeks as *emotional*, *rigid*, with *poor working habits*, *inefficient*, *competitive*, and *suspicious* (e.g., are you going to be my ingroup member or an outgroup member?), but also as

sociable, *charming*, and *witty*. A representative sample of 800 Greeks, from the large cities of Greece, saw Americans as *arrogant*, *sly*, *suspicious*, and *competitive*, but also as *emotionally controlled*, *systematic*, and *flexible*. The Greeks admired American *cold efficiency* but they thought of Americans as *well-oiled machines*. The emphasis on Greek sociability, and spending much time with friends, contrasted with the American emphasis on getting things done and the admission of loneliness. This reflects the Greek collectivist placing of social relationships in center stage, while American individualism keeps a distance from ingroup members, which may also result in loneliness.

Both geography and history shape subjective culture. Greece is cut up into small segments because of the numerous mountains and islands, and this results in ingroups that are linked to a place. The 350-year-old Ottoman occupation required knowing who could be trusted (i.e., who was ingroup). Furthermore, competition for scarce resources made it difficult to be nice outside the ingroup.

Much of what was found in these studies later became the bedrock for individualism–collectivism research. For example, the study found that cooperation occurred only within the ingroup, and relationships with outgroups were competitive. The Greeks often defined themselves as *philotimos*. This means, literally, ‘friend of honor.’ Foreshadowing the large literature on culture and self, Triandis found that the Greek self-definition depended on the way ingroup members saw the person; thus individuals had relatively little control of their self-esteem. By contrast, American self-definition depended on the way individuals saw themselves, which provided more control, and hence their self-esteem was high. This contrast reflects the high levels of self-esteem observed in individualist cultures as opposed to collectivist cultures. Consistent with the collectivist–individualist contrast, the concept of MYSELF was rated (on semantic differential scales) ‘stronger’ by Americans than by Greeks, but the concept of MY RELATIVES was rated stronger by Greeks than by Americans. Finally, Greeks perceived emotions in *context* to a greater extent than did Americans, an attribute that later proved to be a key characteristic of collectivist cultures. For example, CHEATING was completely unacceptable for the Greeks when the target was an ingroup member, but was perfectly okay if the target was an outgroup member.

On the whole, the American data, obtained through different methods, indicated great emphasis on achievement and efficiency. The Greek data indicated great emphasis on interpersonal relationships and social control (e.g., they approved of severe punishment). The Greek emphasis on intimacy and self-sacrifice within the ingroup is a challenge for Americans who are unprepared to be so intimate and self-sacrificing, making cross-cultural social relationships difficult.

In all, *The Analysis of Subjective Culture* was one of the first systematic attempts to examine how key social–psychological concepts formed a syndrome to explain cultural differences.

Applications

The 1972 study was followed by studies by Triandis and Marin and colleagues and used the same theoretical framework and methods with black, white, and Hispanic participants.

Black Subjective Culture

Using survey research methodology, Triandis examined black and white hardcore unemployed, working class, and middle class samples. The studies examined *stereotypes* (e.g., is a mother intelligent?), *behavioral intentions* (e.g., would you date a black policeman?), *role perceptions* (e.g., would a mother hit her son?), *job perceptions* (e.g., are truck drivers well paid?), and *consequences of behavior* (e.g., is getting a good job likely to lead to satisfaction?). The samples made a total of 4600 judgments.

The results are too numerous to summarize here, but there are some broad findings and themes that stand out. For example, the hardcore unemployed black sample stood out from the other samples. In short, the subjective cultures of economically sufficient/stable blacks and whites, men and women, and people of different ages are not especially different. But the hardcore black unemployed see the world very differently from the way the other samples do. Often, the working class blacks had a point of view rather similar to the view of middle class whites. When the black hardcore shared a point of view with another sample it was usually the other black samples.

The concept of '*ecosystem distrust*' was developed to summarize the perceptions of the black hardcore unemployed. Ecosystem distrust means that most entities in one's environment – people, things, institutions – cannot be trusted. Most entities are seen as potentially harmful, and the individual does not see the self as able to improve the situation. In addition, a person cannot trust the dependability of relationships between what one does and the consequences of the action. Consider the connection between *to finish high school* and *to get a good job*. While the employed samples saw a clear connection, the hardcore unemployed did not. In general, the hardcore saw positive events not connected with positive outcomes and negative events unconnected from negative outcomes, while the other samples saw clear connections. There was also more suspicion of others and more distrust and rejection of authorities by the black hardcore unemployed than by the other samples. Blacks who are doing well under the current system were rejected by the black hardcore. Thus black policemen, black teachers, and the like did not receive good ratings.

It is likely that ecosystem distrust is due to the lack of resources. Imagine a parent who promises a toy, but is unable to deliver it. The child is likely to distrust future promises. Imagine a person who gets paid \$100, is arrested, and the police assumes that the funds were stolen, and confiscates all but \$20 (and tells him 'shut your mouth, otherwise you will be in real trouble'). Under these conditions, it is easy to see why there is less trust of people, suspicion of the motives of others, rejection of authority figures, a low degree of certainty that events will be followed by specific consequences, a sense of individual powerlessness, and a sense that if one is not extremely careful one will get into trouble. A person with this perspective is likely to believe that good behavior will not lead to good outcomes. In fact, the environment is seen as being chaotic, unpredictable, and capricious. One can make the case that this perspective is functional in a chaotic environment. The data also showed that receiving respect from others is more of an issue in the black than the white subculture. For example,

the black samples indicated that it was more appropriate to *call* someone *Mr.* than did the white samples. The black hardcore unemployed believed that it is important to have a good 'pose' so that others will see one as stronger and better than one is. They were ambivalent about I, MYSELF and rated this concept as less *important* than the other samples. They valued 'power' more than they valued 'being nice.' This may also be functional in their social environment.

The culture of family relations also varied across the groups. Blacks expected less formality in ingroup roles than did whites. Giving and taking of orders in family relationships were rated as less appropriate by the black than by the white samples. The role perceptions showed that the hardcore unemployed blacks saw more conflict in ingroup relationships than did the other samples. For example, they saw a higher probability that *a father would hit a son*. Also, the hardcore associated *friends* with *can be bad for you*, *teachers* with *unimportant* and *do not deserve respect*, *ministers* were seen as *exploitative*, and they *should be avoided*. In addition, the hardcore did not have a clear view of what one has to do in order to get a reward. For instance, they did not see that one has to complete high school in order to go to college.

In sum, the lack of clear connections between events and outcomes suggests the perception of a chaotic, untrustworthy environment by the black hardcore unemployed, which is not found in the white unemployed or the working class blacks or the middle class samples. In more modern terminology, the hardcore was extremely individualistic, while the middle class had a more balanced perspective, using both collectivist and individualist conceptions. Work by Oyserman and colleagues also found African Americans to be more individualistic than European Americans. More generally, the findings built on *The Analysis of Subjective Culture*, and were viewed within a theoretical framework in which the environment is linked to culture which is linked to behavior.

Hispanic Subjective Culture

Later work by Marin and Triandis summarized 20 studies of Hispanic subjective culture, based mostly on samples of recruits in the US Navy, who had Hispanic names and self-identified as Hispanics, compared to random samples of recruits who did not self-identify as Hispanics. Additional samples of high school students were obtained in Puerto Rico and El Paso, Texas. The data were examined to see if the origin of the person from Central America, Cuba, Mexico, Puerto Rico, or South America changed the results, and if the high school students provided different data from those obtained from the Navy recruits. In general, the subjective cultures of the participants from the various regions of the Americas and the subjective cultures of Hispanic high school students and recruits were similar.

However, the subjective culture of the non-Hispanic recruits was different from that of the Hispanic recruits. There was a definite relationship between level of acculturation (e.g., number of years in the United States, preference for use of English rather than Spanish, mostly watching English TV) and similarity between the Hispanic and non-Hispanic subjective cultures. In fact, the elements of subjective culture that

were most clearly linked to acculturation were the ones that made Hispanic culture distinct from non-Hispanic culture.

Again, there are too many findings to mention here in detail, but some themes were identified. For example, the Hispanics see more positive relationships (e.g., *less argue with, fight with*) and less superordination (e.g., *discipline, give orders to*) in family roles than the non-Hispanics. There is more *love, intimacy, and nurturance* and more *avoidance* of interpersonal competition in the Hispanic ingroup than in the non-Hispanic ingroup data.

A number of behaviors were rated more probable by the Hispanics (e.g., *be sensitive, simpatico, loyal, dutiful, gracious, conforming*) than by the non-Hispanics, but some were rated more probable by the non-Hispanics (e.g., *be sincere, honest, conservative, moderate*).

(e) Perhaps the most interesting finding was that the Hispanics had the *simpatia* concept. They saw more positive behaviors (e.g., *admire, respect*) than did non-Hispanics in positive situations (e.g., cooperative roles), and less negative behaviors (*criticize, give orders to*) in negative situations (e.g., in a confrontation) than did the non-Hispanics. The emphasis on harmony and nonconfrontation is an important aspect of Hispanic subjective culture and has also been found in other collectivist cultures.

In sum, Hispanic subjective culture is collectivist. There is an emphasis on the ingroup, that is, the self is perceived as an aspect of the ingroup, ingroup goals are given priority over personal goals, doing one's duty is more important than having fun, and one stays with the group even if one is not too pleased with it. By contrast, non-Hispanics are individualists. They define the self as independent and autonomous from the ingroup, they give priority to personal over group goals, they give more weight to attitudes than to norms as determinants of their behavior, and if they do not like their group they try to leave it.

Cross-Cultural Training

The Analysis of Subjective Culture was used to develop training programs to help expatriates better adjust to other cultures. After a culture is analyzed, the information can be placed in 'culture assimilators' which are books, or computer-based cross-cultural training devices. Assimilators consist of about 100 episodes that reflect a problematic interaction between members of two cultures. For example, an episode might be that an American teacher notices that a Hispanic child does not look at her when she is talking. Under each episode, in the format of a multiple choice test, are four or five attributions that could explain what is happening in the episode. The trainee is asked to select one of the attributions, and then receives feedback. Some of the attributions are incorrect, and when the trainee selects one of them he/she is asked to try again. When the correct attribution is selected, the feedback explains the cultural difference. In the example above, the cultural difference is that in the United States children are expected to look at a teacher who is talking; but in the Latino countries one is 'insolent' if one looks at a high status person in the eye, and the proper behavior is to respectfully look down.

The attributions are pretested with samples from the two cultures, and when members of the host culture select an attribution that is rarely selected by members of the trainee's culture, there is something to teach. The effect of this training is that trainees learn to make '*isomorphic attributions*,' that is, attributions that are more or less like the attributions that are usually made by members of the host culture in the particular situation. Trainees randomly assigned to a training and a no training condition show some improvement. The trained feel more comfortable when they are in the host culture.

Assimilators vary in quality, and it has been found that people learn better when the episodes provide feedback organized around cultural syndromes such as individualism and collectivism. Although people learn much about another culture, they do not change their behavior enough to be really successful in the other culture. Changes in behavior require clinical interventions and behavior shaping. Nonetheless, this application is reported in several handbooks concerned with cross-cultural training.

Extension to the Study of Individualism and Collectivism

The Analysis of Subjective Culture set the stage for a number of decades of research on culture and psychology that ultimately placed culture in the mainstream of the field. One important research direction it sparked was the investigation of individualism–collectivism as a cultural syndrome – that is, elements of subjective culture which are organized around a theme. In collectivist cultures, the theme is the centrality of the ingroup; in individualist cultures, it is the centrality of the individual. One could use other terms, such as sociocentric, group-oriented, *Gemeinschaft*, or interdependent culture versus idiocentric, or individual-centered, individual-oriented, *Gesellschaft*, or independent culture. All these terms contrast the centrality of the group with the centrality of the individual, and in each of the two sets of terms, the concepts can be considered equivalent.

In the decades since *The Analysis of Subjective Culture*, much research has documented the importance of individualism and collectivism for social–psychological phenomena in terms of the focus of attention, emphasis on different attributes, self-definitions, goals, emotions, cognitions, attitudes, norms, values, ingroups, social behavior, organizational behavior, and language and communication.

When culture is the unit of analysis, individualism and collectivism are the poles of one dimension. But when individuals are the unit of analysis, collectivism and individualism are often unrelated. Thus it was useful to use different terminologies for the two kinds of data. Triandis proposed the use of 'allocentrics' and 'idiocentrics' to correspond to collectivism and individualism. There are both collectivist and individualist cognitions present in every individual, and the tendencies are elicited by the *situation*. There are allocentrics and idiocentrics in every culture. The fit between culture and personality is very important. Allocentrics in collectivist cultures and idiocentrics in individualist culture are well-adjusted, but allocentrics in an individualist culture find that they do not have enough relationships, so they join

communes, unions, associations and the like. Idiocentrics in collectivist cultures feel oppressed by the requirements imposed by ingroups, and when they have an opportunity they leave such cultures.

Other cultural syndromes include cultural complexity and cultural tightness–looseness, or the degree to which societies have strong norms and little tolerance for deviance from norms. Gelfand's research has shown that tightness and collectivism are largely independent dimensions, correlated at ~ 0.4 . Thus, there are collectivistic cultures that are tight (e.g., Japan), collectivistic cultures that are loose (e.g., Brazil), individualistic cultures that are tight (e.g., Austria) and individualistic cultures that are loose (e.g., the United States). Tightness is positively correlated with population density (as far back as 1500) and negatively correlated with the amount of resources that societies have, suggesting that strict adherence to rules is in part an adaptation to environmental factors as *The Analysis of Subjective Culture* suggested. Tightness is also associated with more autocracy and less openness of the media, as well as more conservative attitudes as rated on the world values' survey. Crime and divorce rates are much lower in tight as compared to loose societies.

An Extension to the Study of Self-Deception Across Cultures

Triandis recently examined what aspects of subjective culture are prone to self-deception. Self-deception occurs because humans often use their hopes, needs, and desires to 'construct' the way they see the world. For instance, stereotypes are examples of self-deception (I know with certainty what the attributes of this group are). But almost all elements of subjective culture may be influenced by hopes, needs, and desires, and thus may contain a trace of self-deception. The self-deceptions of collectivists tend to glorify the ingroup, while the self-deceptions of individualists tend to glorify the individual.

Some examples of self-deception: (1) When the French revolution started, on 14 August 1789 with the storming of the Bastille, Louis XVI wrote in his diary only one word: 'Rien.' In other words, nothing happened! Had he avoided this self-deception he might have saved his neck from the guillotine. (2) "We will be greeted as liberators in Iraq" (John McCain); (3) "the West will convert to Islam" (bin Laden); (4) "Allah loves those who commit suicide for religion" (Al-Qaeda writings published by Ibrahim).

There are cultural differences in self-deception. In some cultures, self-deceptions are very common, while in others they are not. The nonacceptance of the Darwinian theory of evolution can be used as a clue to the tendencies toward self-deception. Nonacceptance in Scandinavia is about 20%, in Central Europe about 30%, in the United States 45%, in Turkey 60%, in Egypt it is 92% (*The Economist*). Much conflict is due to differences in the subjective cultures and the self-deceptions of various groups which result in different ways of constructing the way people see the world. The future of the planet may depend on further analyses of the subjective cultures around the globe in order to increase understanding, promote well-being, and decrease violence.

Summary

There are many ways to study cultures. One way is to study their subjective cultures. This article presents the elements of subjective culture that may be studied, and also a sample of findings from studies of subjective culture. Applications of such studies include methods of cross-cultural training that make the interaction of people from one culture with people from another culture more effective. Extensions of the work on subjective culture increased the understanding of collectivism and individualism and the distribution of self-deception across cultures.

Glossary

Backward mask A stimulus, usually a meaningless letter string or image, presented immediately following a critical stimulus to eliminate its afterimage.

Dissociative paradigm A research methodology used in subliminal perception research that seeks to find a dissociation between measures of conscious and unconscious responses to stimuli. Participants will be unable to consciously recognize the stimuli that are presented to them, but will be unconsciously influenced by them.

Limen Threshold.

Mere exposure effect The tendency for repeated exposures of a stimulus to enhance a person's attitude to that stimulus.

Objective measure of awareness Measures of conscious awareness that rely on an individual's ability to discriminate between stimuli that were presented versus not presented.

Semantic priming The presentation of a particular stimulus (a 'prime') intended to facilitate responses to a subsequent, semantically related stimulus. For example, being exposed to the word 'bread' will make an individual faster to recognize the word 'butter.'

Subjective measure of awareness Measures of conscious awareness that rely on an individual's self-reports of their perceptual experiences or conscious processing.

Subliminal Below the threshold of consciousness.

Supraliminal Above the threshold of consciousness.

Tachistoscope A device used to present stimuli for short, but very precise, durations.

One of the most long-standing controversies in psychology concerns the existence of subliminal perception: whether it is possible to perceive something even when we do not have the subjective experience of perceiving it. Though the study of subliminal perception began in the 1800s, scientific attitudes toward it have vacillated between acceptance and denial. Additionally, the broader public, including the media and government officials, have been concerned about the possibility of individuals being influenced and manipulated without their conscious awareness.

The study of subliminal perception has intrigued scientists mainly for the insight it provides into consciousness. First, research on subliminal perception provides a way of testing whether conscious and unconscious processes are fundamentally different from one another. Does a particular stimulus, when presented subliminally, have different effects than when it is presented so that people are consciously aware of it (i.e., supraliminally)? Second, this research allows scientists to investigate the nature and function of consciousness, such as whether consciousness is necessary for some process or effect. Finally, presenting stimuli subliminally allows scientists to rule out demand or other active strategies on the part of experimental subjects as alternative explanations for their effects.

Definition

One of the primary controversies regarding subliminal perception has been how to define it. The word itself was introduced by Johann Herbart and comes from the Latin word *limen*, meaning threshold. Thus, subliminal perception, strictly speaking, is perception below the threshold of consciousness. What is meant by the terms 'threshold' and 'consciousness' have been enduring matters of debate.

Methodology

Subliminal presentation of stimuli hinges on presenting the stimuli in such a way that the stimulus is registered by the appropriate sensory system and activates its corresponding representation, but the activation is minimal enough that the stimulus does not reach conscious awareness. The amount of internal activation of the representation is a result of the duration of the stimulus and of its intensity.

The vast majority of research on subliminal perception has focused on visual stimuli. Initial research manipulated intensity by using very weak stimuli: stimuli that were too far away, too faint, etc., to be consciously perceived. As technology advanced, with the arrival of first the tachistoscope and later computers, research shifted to involve very briefly presented stimuli.

For how long should a stimulus be presented to be subliminal? Unfortunately, even after stimulus characteristics are taken into account, there is no absolute threshold that can be universally recommended: thresholds for a given stimulus vary both intra- and interpersonally. One method of handling such variability is to set thresholds uniquely for each individual. In such a threshold-setting task, researchers typically present subjects with stimuli for different durations. After each presentation, subjects indicate whether they saw anything or not. (While subjects may be able to report seeing 'something,' they generally cannot report exactly what they saw.) With such tasks, care must be taken in selecting the durations for which stimuli are presented and the order in which these durations are used. For example, if stimuli are presented at consistently shorter durations, as in a standard simple staircase procedure, subjects are likely to predict the duration of the next stimulus. An alternative method is to use a fixed duration brief enough to be subliminal for most subjects, using an awareness check on these same subjects to ensure the stimuli were indeed subliminal.

The appropriate duration for a given stimulus, in addition to being determined by characteristics of the stimulus and the subject, will also depend on whether the stimulus is presented foveally or parafoveally, and whether it is masked. Foveal presentation involves presenting stimuli in the center of a person's visual field, or at foveation, whereas parafoveal presentation involves presenting stimuli on the periphery or fringe of the field. The foveal visual field extends from 0 to 2 degrees of visual angle from the focal point of attention, with the parafoveal visual field extending beyond this, from about 2 to 6 degrees of visual angle.

To fix subjects' eye gaze, researchers usually begin by presenting a fixation point, followed by the stimulus. For foveal presentation, the stimulus is presented at the same location as the fixation point. For parafoveal presentation, researchers need to determine the parafoveal area of the screen, so the stimulus can be presented within that area. Calculating this area involves taking into account the distance between a subject's eyes and the screen: the farther away the subject is from the screen, the greater the area on the screen that falls within the foveal region.

Parafoveally presented stimuli may be presented for longer periods of time while remaining subliminal than foveally presented stimuli. However, it is important to ensure that the subject's visual focus is on the desired fixation point; otherwise, a parafoveally presented stimulus can become a foveally presented stimulus. Thus, researchers often vary the delay between presentation of the fixation point and presentation of the stimulus, as well as the location in which stimuli are presented, to prevent subjects from anticipating the stimulus and shifting their attention accordingly.

Brief presentation of a stimulus is usually not enough to guarantee subliminality because a visual stimulus tends to persist in the visual iconic memory store for a time after it has physically disappeared. This persistence is akin to the afterimage that is seen after viewing a bolt of lightning. Researchers use the technique of backward masking to erase or overwrite this afterimage: they present a pattern mask, typically a random letter string or other meaningless stimulus with the same structural characteristics as the critical stimulus (e.g., a random letter string for a word stimulus, a scrambled set of facial features for a face stimulus), immediately after the critical stimulus.

Subliminal presentation is often embedded in a particular task requiring some sort of response to keep subjects alert and engaged, as opposed to passive viewing. Additionally, the use of such a task ensures that the subjects' attention stays fixated on a particular location. A routinely used task for parafoveal presentation is a vigilance task wherein subjects must indicate which side of the screen the 'flash' (the subliminal prime-mask presentation) occurs. The onset of these flashes (i.e., the time between trials) is also varied to further maintain attention.

Historical Background

Early research on subliminal perception took a psychophysical approach, searching for thresholds of sensory experience. Peirce and Jastrow, in the late 1800s, were probably the first to empirically demonstrate subliminal perception. In their study (which was also the first properly randomized

experiment), subjects (actually Peirce and Jastrow themselves) were asked to distinguish between two objects of similar weight or between two similar pressures, to indicate which of the two was heavier or greater, respectively. In addition to making forced-choice discriminations, they also rated their confidence in their judgments on a 0–3 scale, where '0' denoted absence of any preference for one answer over its opposite, so that it seemed nonsensical to answer at all. Peirce and Jastrow found that even when subjects reported 0 confidence, they could still accurately discriminate between the two alternatives at well above chance levels.

A few years later, Sidis presented subjects with cards one at a time, each containing a single printed letter or digit. The subjects were so far away from the cards that they often reported seeing only a dim, blurred spot, or even nothing at all. However, the subjects performed better than chance not only at reporting whether the card contained a letter versus a digit, but also at guessing its precise identity. Stroh and colleagues found similar results with auditory stimuli: subjects were able to identify whispered letter names at better than chance levels under conditions where they reported not hearing any sound.

In these studies subliminal perception was demonstrated via a dissociation between two measures of conscious awareness: a subjective measure that used self reports, and an objective measure that used a measure of discriminative abilities. According to a subjective measure (e.g., asking whether subjects were aware of the primes), subjects did not appear to have been consciously aware of the stimuli. According to an objective measure (e.g., forcing subjects to guess which of two stimuli was presented), subjects appeared to have perceived the stimuli. This dissociation between subjective and objective measures was taken as evidence of subliminal perception.

A few other studies in this domain were published in the first half of the twentieth century. However, what was more notable was the outbreak of claims of subliminal influences on behavior in the mid-1950s, particularly by advertisers. In September 1957, James M. Vicary and Francis Thayer announced that they had presented messages such as 'Eat popcorn' and 'Drink Coca-Cola' for 1/3000 of a second during movie screenings in Fort Lee, New Jersey. They claimed that these subliminal presentations had increased popcorn sales 58% and cola sales 18%.

An outcry in the popular press followed, and both the US Congress and the Federal Communications Commission debated the legal and ethical implications of subliminal advertising. The practice of subliminal advertising was subsequently banned in the United Kingdom and Australia, and by American networks and the National Association of Broadcasters in 1958. However, Vicary's attempts to duplicate his claims under controlled conditions were unsuccessful, and in 1962 he admitted to lying about the experiment and falsifying the results. Nonetheless, the public seemed more convinced than ever of the possibility of subliminal perception and persuasion.

Meanwhile, the scientific community was meeting such claims as Vicary's with skepticism. In his 1960 critique of the scientific literature on subliminal perception, Eriksen argued against the use of subjective measures as valid measures of awareness. He stated that subjective measures were insufficient because they might not, or did not, represent an exhaustive measure of all relevant conscious experiences. Instead,

subjective reports might reflect subjects' response biases: subjects might partially or even fully perceive the stimulus, yet claim they had not seen it for various reasons. For example, a statement that a subject did not 'see' a stimulus may reflect the subject's preconceived ideas about the value of a particular conscious experience for making decisions, rather than a true absence of relevant conscious experiences. Thus, Eriksen argued that such subjective reports should be replaced by an objective measure, namely forced-choice discrimination. By this standard, a stimulus would be said to be subliminal only if subjects forced to choose which of two (or more) stimuli that were previously presented performed better than chance.

This represented a major shift in both theory and methodology for researchers working on subliminal perception. Previously, correct forced-choice performance had been assumed to reflect the perception of stimuli in the *absence* of conscious awareness. Now, according to Eriksen, correct forced-choice performance was assumed to reflect the *presence* of conscious awareness. This meant that researchers were now left with the problem of finding new indirect measures of subliminal perception.

Marcel was the first researcher to report the results of experiments showing evidence for subliminal perception while using an objective measure of awareness. In the 1970s and 1980s, he provided two types of experimental evidence for subliminal semantic processing. First, subjects who could not detect the presence or absence of a masked word were nonetheless semantically influenced by that word in their later responses. For example, subjects subliminally presented with the word 'salt' who were then asked to choose between 'pepper' and 'lotus,' chose 'pepper' more often. Second, he provided evidence for semantic priming with subliminal primes. In this paradigm, a prime word is first presented subliminally, and then a target word (to which subjects must respond) is presented supraliminally. Marcel found that target words were responded to more quickly when they were preceded by a semantically related prime word than by an unrelated prime word, even though the primes were presented subliminally. Such research was considered particularly surprising because it demonstrated higher-level processing of subliminal stimuli. Subsequently, other researchers replicated these effects not only with words but also with pictures.

However, as the supporting evidence accumulated, so did the skepticism and criticism. In 1986, Holender published a detailed review of masked priming, concluding that the findings were problematic in a variety of ways, including lack of reliability and poor assessment of whether stimuli were actually presented subliminally. Again, the identification of serious methodological flaws caused great doubt as to the existence of subliminal processing.

These cycles of new evidence, followed by skepticism, particularly skepticism as to the subliminality of stimuli, continue to be a recurring theme in the literature on subliminal perception. By now, the mere existence of subliminal perception has been firmly established. What continues to be controversial to this day is how deeply subliminally presented stimuli are processed, and, as a consequence, how much they can affect people's attitudes, judgments, and behavior. The evidence for simpler forms of subliminal processing is considered to be strong. For example, there is much evidence that subliminal

stimuli are processed orthographically (i.e., in terms of letter identities and positions). But researchers disagree as to the extent that higher-level subliminal processing, such as semantic processing, occurs.

Neurological Evidence for Subliminal Perception

What is the chronology of subliminal perception? Where does a stimulus go, if it is perceived without reaching consciousness? Some insight can be gained from naturally occurring forms of subliminal perception. Area V1, the primary visual cortex, plays a central role in visual perception, detecting the basic elements of a visual stimulus (e.g., orientation). Nearly all signals from the retina pass through this area before proceeding to the other areas specialized for different aspects of visual processing. Patients with partial or total damage to V1 have a loss of vision in part or all of the visual field. However, some of them can still make accurate judgments and discriminations about visual stimuli presented to the 'blind' area. This condition, the ability to respond appropriately to visual stimuli in the absence of conscious visual experience, is known as blindsight. Blindsight represents an organic form of subliminal perception. The most thoroughly studied blindsight patient is DB, whose right occipital cortex, including most of V1, was removed surgically. DB reported no conscious visual experience in an area of the lower left quadrant of the visual field. However, he could detect whether or not a visual stimulus had been presented to this area and could also identify its location, though he insisted he was just 'guessing.'

One issue in the study of blindsight, as with the study of subliminal perception in general, is determining whether patients truly have no conscious visual experience in their 'blind' area. Studies that require patients to report on stimuli in the 'blind' area are subject to the same critiques as subliminal perception research that uses subjective criteria. Rafal and colleagues sidestepped this problem by running a study that did not require patients to report on characteristics of the 'unseen' stimulus. They found that blindsight patients were slower to respond to a light presented to the intact part of the visual field when another light was simultaneously presented to the blind area – even though they could not consciously detect the latter light. Thus, a light not producing any conscious awareness nevertheless interfered with visual performance on another task.

Blindsight is not a homogenous phenomenon; patients vary greatly in their preserved visual abilities and subjective experience. The precise brain mechanisms involved in blindsight remain unclear and probably vary from patient to patient as well. Possibilities include subcortical mechanisms, residual functioning within V1, and the cortical visual system.

In contrast to research on blindsight, which focuses on stimuli that cannot activate a particular brain region (because that region is lesioned), research on subliminal perception has mostly explored which brain regions are actually activated by subliminal stimuli. Such activation has been used to determine both what types of processing are possible with subliminal stimuli, and whether the effects of subliminal stimuli are driven by different patterns of brain activation than those of supraliminal stimuli. In 1998, Dehaene and colleagues were the first to show that subliminal stimuli can cause detectable neural activity

not just in brain areas involved in sensory processing, but also in areas associated with motor programming of responses. Subjects classified numbers between 1 and 9 as smaller or larger than 5. These target numbers were preceded by subliminal number primes that were also smaller or larger than 5. Subjects were faster when both the prime and the target belonged to the same category (e.g., prime 1, target 4) than when they belonged to opposite categories (e.g., prime 1, target 6), indicating that they had processed the subliminal prime on a semantic level. The researchers also recorded event-related potentials (ERPs) during the task and found evidence of prime-induced covert motor activation (measured via differences in lateralized readiness potentials (LRPs)): participants unconsciously prepared the motor response appropriate to the subliminal prime. Moreover, the temporal resolution of ERPs enabled the researchers to determine that the subliminal prime itself induced this preparation. These results were replicated by other researchers using arrows as stimuli, and were also demonstrated using functional magnetic resonance imaging (fMRI) to measure motor cortex activation.

Other researchers have utilized neurological techniques to look for evidence of semantic processing of subliminal stimuli, using ERPs to compare semantic priming effects for subliminal versus supraliminal primes. With supraliminal primes, semantic priming produces an attenuation of the N400, an ERP component thought to index semantic processing. The evidence for subliminal primes producing similar modulation is mixed, with some more recent experiments showing an effect.

More consistent results have been found with subliminal repetition priming and fMRI. In repetition priming, visual recognition of a target word is facilitated when it is preceded by the same word, and as a result, neural activity is decreased in certain word-processing areas of the brain (contended to reflect tuning of cortical representations). Researchers have found evidence for such repetition priming even when the prime word is presented subliminally. Subliminal repetition priming has also been found when the prime and target are orthographically different, such as when they are written in the two different Japanese writing systems of Kanji and Kana, and when the prime and target are only semantically related (as opposed to being the exact same word). In such research, neuronal activity was found to be decreased in the left middle temporal gyrus, a region thought to be involved in semantic processing of words and objects.

fMRI has also been used to demonstrate emotional processing of subliminally presented faces. In these experiments, subjects saw subliminally presented fearful or fear-associated faces followed by a clearly visible neutral face that also served as a backward mask. Two studies found that the processing of these emotional faces was associated with increased activity in the amygdala, a brain structure integral to the processing of emotional stimuli, relative to neutral stimuli. Since then, these studies have been replicated with faces as well as other types of stimuli, including words.

Downstream Effects of Subliminal Perception: Attitudes and Judgments

Initially proposed by Zajonc in 1968, the mere exposure effect posits greater liking of a stimulus as a result of greater exposure to the stimulus. Experiments have demonstrated that the mere

exposure effect is highly reliable and, furthermore, that it does not depend on conscious awareness of the exposure. In fact, subliminal mere exposure effects seem to be stronger than typical mere exposure effects. In one experiment by Kunst-Wilson and Zajonc, subjects were first subliminally exposed to several irregular polygons, five times each. Later, they were given pairs of polygons, one that had been subliminally presented and one that had not been previously presented at all. Subjects were asked to make two judgments: which one had been presented previously, and which one they liked better. Although subjects were no better than chance at determining which polygon had been presented previously, they showed an increased liking for the previously presented polygons.

Other research has shown mere exposure effects with subliminal faces. In an experiment by Bornstein and colleagues, subjects were subliminally exposed to a photograph of one of two males. In a later phase of the experiment, both men pretended to be research subjects and engaged in a task with the actual subject. When the two men disagreed during this task, the subject sided more often with the man whose photo had been subliminally presented in the first part of the experiment, and also reported liking that individual more.

A more complicated method of altering individuals' attitudes toward stimuli is evaluative conditioning, a way to transfer valence from one stimulus to another. In this method, a target stimulus is repeatedly paired with a negatively or positively valenced stimulus, and the target eventually acquires the same negative or positive valence. Evaluative conditioning has been demonstrated even when the negatively or positively valenced stimuli are presented subliminally. For example, in experiments conducted by Murphy and Zajonc, subjects were shown a series of clearly visible, unfamiliar Chinese ideographs. Immediately after seeing an ideograph, they rated how much they liked it. For half of the subjects, each ideograph was preceded by either a subliminally presented smiling face, or a subliminally presented scowling face. For the other half of the subjects, each ideograph was preceded by either a smiling or a scowling face that was presented supraliminally (for 1 s). When the faces were presented subliminally, subjects liked ideographs that had been paired with smiling faces more than ideographs that had been paired with scowling faces. This effect vanished when the faces were presented supraliminally.

Subliminally presented stimuli can also affect judgments about both others and the self. In an experiment by Bargh and Pietromonaco, subjects engaged in an unrelated task in which words were presented subliminally. Either 0%, 20%, or 80% of the words were related to the trait of hostility. Afterwards, subjects read a paragraph about a fictitious person ('Donald') who behaved in an ambiguously hostile way. The impression subjects formed of Donald was influenced by their subliminal exposure to the words: the more hostile words subliminally presented earlier, the more negative the impression of Donald became. Similar results have been found in later experiments with other traits such as kindness, and with subliminally activated social stereotypes, including stereotypes activated by subliminal presentation of photographs. In an experiment by Baldwin and colleagues, Catholic undergraduate women rated themselves more negatively on a series of traits after subliminal exposure to a photograph of the pope, but only if they were relatively religious.

Another question that has emerged from research on subliminal priming is whether the processes set in motion by subliminal priming are equivalent to those involved when a concept is activated consciously. To investigate this matter, McCulloch and colleagues subliminally primed one group of subjects with words related to forming an impression of a person (e.g., judge), and gave another group conscious directions to form an impression (e.g., think about what kind of person this is). All subjects then read a series of behavioral sentences, and later were given a surprise cued recall task. Those in the subliminal priming group had recall of behaviors equivalent to those in the conscious impression formation condition. Thus, in this case, subliminal presentation of words relating to impression formation presumably activated similar cognitive operations as conscious instructions to form an impression.

Downstream Effects of Subliminal Perception: Behavior

Though evidence of subliminal stimuli affecting judgments and attitudes is intriguing, it does not necessarily follow that such stimuli will also affect individuals' overt behavior. Indeed, a lengthy literature in social psychology has demonstrated far less correspondence between, for example, attitudes and behaviors than might be expected. Effects of subliminal stimuli on behavior are also more controversial, as the issue of subliminal advertising and persuasion fall under this heading.

In the past 20 years, social psychologists have repeatedly demonstrated that the same subliminal stimuli that can affect judgments and attitudes can also affect overt behavior. Bargh proposed that stimuli, including subliminal stimuli, can influence behavior directly, via a perception-behavior link that bypasses conscious thought. In one experiment, Bargh and colleagues asked subjects to complete a long, boring task on a computer. During the task, subjects were subliminally exposed to photographs of either Black or White faces. (Previous research had shown that exposure to Black names or faces activated the concept of hostility, part of the Black stereotype.) Then, after many trials, an error message appeared, and the experimenter informed subjects they would have to start the task again from the beginning. Subjects' reactions to this news were recorded with a hidden camera. Judges (blind to condition) who viewed these tapes indicated that subjects subliminally exposed to Black faces responded in a more hostile manner than subjects exposed to White faces.

Though plausible alternatives to the direct perception-behavior link have been proposed in the last decade, the more fundamental idea that subliminally presented stimuli can affect behavior has not been questioned. However, it is important to note that this type of research involves behavior that is both natural and appropriate to the particular situation involved. In fact, most models of such subliminal effects emphasize that these effects would not occur if they were inappropriate to the situation at hand. In other words, subliminal priming cannot cause people to do what they would not naturally do. These effects are also assumed to be transient, lasting minutes at best.

However, not all subliminal priming effects are assumed to be transient. In addition to the direct, perception-behavior route, subliminal perception also affects behavior through an

indirect route, via goal activation. The representation of a goal consists of the means by which the goal operates or is carried out. Therefore, activating a goal representation will lead to the activation of its corresponding means, which in turn will result in the greater likelihood of the means being carried out. According to Atkinson and Birch's dynamic theory of action, goal-directed action tendencies increase in strength over time until the goal is acted on. Thus, in contrast to other forms of priming, in which construct activation decreases over time so priming effects are transient, the effects of goal priming actually increase over time.

Goals can be activated by a variety of primes. For example, people that are closely associated with particular goals can serve as primes for these goals. In one experiment, Shah used the names of significant others as primes for an achievement-related goal. Subjects were initially asked to provide the name of a significant other who would most want them to possess an achievement-related goal, and the name of a significant other who would care the least about this. Subjects were subliminally primed with either of the two names or a control prime (i.e., a random letter string). Subjects were then given an anagram task designed to measure goal-striving. Subjects subliminally primed with the name of the significant other who cared the most that they possess the goal persisted longer on the anagram task and found more correct solutions than those in the control group, and those primed with the name of the person that cared the least persisted less and found fewer correct solutions than those in the control condition. In sum, the subliminal activation of a goal can lead to not only better performance, but also persistence, another distinct feature of goal pursuit.

These sorts of behavioral and motivational effects differ from the single most controversial area within the domain of subliminal psychological processes: subliminal persuasion. The line between the previously described effects and the area of subliminal persuasion is fuzzy, but one key difference is that subliminal persuasion generally involves causing people to do things they cannot or would not normally do. Various people, beginning memorably with James Vicary in 1957, have made grandiose yet largely unsubstantiated claims about the effectiveness of subliminal persuasion. For example, in the 1980s, self-help audiotapes were very popular in the United States, despite the lack of rigorous scientific research on their effectiveness. When various researchers decided to test the claims of such tapes, they found that the tapes were ineffective. In one experiment, Greenwald and colleagues tested two tapes, one designed to improve memory and the other designed to improve self-esteem. Subjects were given one of the two types of tapes and were asked to listen to their tape daily. However, the experimenters switched the labels on half of the tapes. In other words, some subjects received a memory tape that had been mislabeled as self-esteem improvement, some subjects received a self-esteem tape that had been mislabeled as memory improvement, and the remaining half of subjects received correctly labeled tapes. After 5 weeks, the subjects completed self-esteem and memory tests and also indicated if they believed the tapes had been effective. The subliminal tapes had no effects on either self-esteem or memory, but there was an effect of subjects' expectations on whether they thought the tapes were effective. That is, subjects who thought they had listened to a self-esteem tape thought their self-esteem had

improved, and subjects who thought they had listened to a memory tape thought their memory had improved, regardless of which tape they had actually received.

What separates such tapes from the previously described research on subliminal effects on behavior, so that the tapes were not influential? One obvious difference is that subliminal self-help tapes claim to present long messages, such as phrases or entire sentences. Research by Greenwald and colleagues has demonstrated that individuals cannot process an entire sentence when it is presented subliminally. In one experiment, Greenwald and Liu subliminally presented two-word sentences to subjects. For each sentence, the meaning of the sentence differed from the meaning of the individual words. For example, the sentence 'enemy loses' has a positive meaning, but it consists of two words, 'enemy' and 'loses,' that are negative in meaning. The effects of the subliminally presented sentences were driven by the meaning of the individual words rather than by the meaning of the entire sentence.

Strahan, Spencer, and Zanna proposed that even presenting single words would not be sufficient for subliminal persuasion. They pointed out that a person's goals and motives are critical for subliminal persuasion to occur. Subliminal priming can be used to prime goal-relevant cognitions, but this priming needs to be combined with a motive to pursue the goal, for subliminal persuasion to occur. In one experiment, Strahan and colleagues brought subjects into the lab supposedly for a study on marketing research. All individuals were asked to refrain from eating or drinking for a few hours before the session. Once they arrived, half of subjects were given water to drink, and the other half were not. Thus, the latter group of subjects was thirsty and the former group not. Then all subjects completed a task on computer in which they were subliminally presented with either thirst-related words (i.e., thirst and dry) or neutral words (i.e., pirate and won). Finally, all subjects were asked to taste-test some beverages. Only subjects who were thirsty and had been subliminally presented with thirst-related words showed subliminal persuasion: they drank more of the beverages than the other subjects.

Can such persuasion be carried over to actual consumer choices? Strahan and colleagues found that their subliminal persuasion effects also led subjects to prefer products that were advertised as fulfilling their goal. For example, subjects who were thirsty and had been subliminally primed with thirst-related words preferred a beverage advertised as thirst-quenching over another beverage. Karremans and colleagues took this research a step further, proposing that if individuals already have a particular motive, they will be persuaded by subliminal priming of a brand that can satisfy that motivation. In one experiment, half of the subjects were given a very salty candy to consume to make them thirsty. Then all subjects completed a task on the computer in which they were subliminally presented with either the brand name of a beverage ('Lipton Ice') or nonwords made by scrambling the letters of the brand name ('Npeic Tol'). Finally, subjects were asked to indicate which of two brand name beverages they would choose if they were offered a drink right now. Subjects who were thirsty and had been subliminally primed with Lipton Ice were the only ones to choose Lipton Ice more often than the alternative. Hence, you can subliminally lead a horse to water only if it is thirsty in the first place. It is when people

are in a motivated state that specific subliminal primes can affect choice.

One of the last media outcries regarding subliminal priming was in the political sphere. In 2000, the word RATS was flashed very briefly in tandem with images of Al Gore before the entire word 'bureaucrats' was presented onscreen in a television commercial sponsored by the Republican National Committee. Could briefly presenting a negative word in combination with an image of a person indeed color the impression of that person? The scientific community largely dismissed this as unlikely for numerous reasons, the least of which was because a single pairing of a negative word with a well-known person is not likely to produce a change in the preexisting attitude toward that person.

Relevance to the Real World

Why should individuals perceive and be influenced by stimuli that do not reach conscious awareness? The processing capacity of consciousness is greatly limited: consciousness can only deal with a very small percentage of all incoming information. We would be unable to function if we were guided only by the information to which we could consciously attend. Being consciously aware of a stimulus redirects focal attention to that stimulus and decreases the amount of attention available for peripheral stimuli. Efforts to consciously 'take it all in' tax not only our attentional resources, but our self-regulatory resources as well. The depletion of our self-regulatory stores in turn has deleterious effects on our behaviors and judgments. Luckily for us, much of the time, we need not consciously attend to stimuli for adaptive behavior or accurate judgments to occur.

Glossary

Altruistic suicide In Durkheim's theory of suicide, altruistic suicide is committed by people with strong interpersonal ties who commit suicide in order to help others, such as a soldier throwing himself on a hand grenade in order to protect his fellow soldiers.

Anomic suicide In Durkheim's theory of suicide, anomic suicide is suicide by someone who has not adopted the prevailing norms and values of the society, such as an alcoholic, threatened with the loss of family relationships and failure in his or her career.

Chronic suicide Self-destructive behavior whose impact shortens the life span of the person, such as alcohol or drug abuse.

Egoistic suicide In Durkheim's theory of suicide, egoistic suicide is suicide by someone who does not

have strong social ties, such as an elderly widower living alone.

Fatalistic suicide In Durkheim's theory of suicide, fatalistic suicide is suicide by people who are strongly regulated by the social norms and customs and commit suicide because they are 'supposed to,' as in sati in which Indian widows throw themselves on their husband's funeral pyre.

Focal suicide Behavior that intentionally (and sometimes unintentionally) destroys a part of the body, permitting the organism to survive, such as blinding oneself intentionally or losing a limb in a piece of industrial equipment.

Parasuicide A term suggested by European scholars to refer to self-destructive behavior in which the person intends to survive and, in fact, does so. This behavior is more commonly called attempted suicide.

The term *suicide* can be used both narrowly and broadly. In the narrow sense, suicide refers to the actions of people who possess a mature concept of death and who kill themselves intentionally. In order to choose death, a person must understand what death entails. This criterion, therefore, rules out suicide as a possibility in animals, in young children, and in those who are mentally retarded, for such individuals may not have a mature concept of death. Most children, for example, think of death as like a temporary sleep from which it is possible to return. The criterion of having an intent to die rules out some psychiatrically disturbed people whose intent to die is in doubt. For example, a psychiatric patient may hear voices commanding the patient to jump in front of a train. In responding to such hallucinations, the patient may not intend to commit suicide.

However, scholars have begun to use the term suicide in a much looser sense in recent years. This broader use of the term permits the suicidal desire to operate in a covert, unconscious, and partial manner, as described in Sigmund Freud's psychoanalytic theory. In this view, the suicidal impulse may manifest itself in partial ways that do not necessarily lead to immediate death. For example, people with self-destructive lifestyles, such as drug abusers and alcoholics, can be viewed as suicidal (*chronic suicides*), as can those who injure or destroy part of themselves intentionally or accidentally (*focal suicides*). Many people, especially the elderly, refuse to take the medication necessary for their continued physical health, while others may refuse to eat. These indirect life-threatening behaviors can be seen to have suicidal motivation.

While sociologists tend to adopt the narrow definition of suicide, psychologists and psychiatrists tend more often to adopt the broader definition, perhaps because they encounter so much nonfatal self-destructive behavior in the patients

whom they treat. Biologists are also using the term suicide more often these days to describe self-destructive behavior in animals.

Many individuals make self-destructive acts but survive. They may take an overdose of a medication, which fails to kill them, or they may cut their wrists but not bleed to death. Sometimes survival may be planned (as in a person who knowingly takes one-half of the lethal dose of a medication) or unplanned (as in a person who runs a car engine in a closed garage but is quickly discovered by an unexpected caller). This behavior is usually called *attempted suicide*, in contrast to an act where the person dies, which is called *completed suicide*. Some investigators have pointed out that many attempted suicides do not intend to die and, thus, the term attempted suicide is inappropriate. Such individuals may be communicating distress to significant others in their life by their suicide attempt, or perhaps they are ambivalent in their decision to die. (Many suicide attempters, however, do admit to some intent to die even though their suicide attempt is not lethal.) *Parasuicide* has been proposed as an alternative term and is still used, particularly in Europe, but researchers have switched to using the term *deliberate self-injury*, a term that eliminates the presumption of suicidal motivation. Attempted suicide, however, is more serious than *self-mutilation* (a behavior in which people inflict mild harm on their bodies, usually motivated by frustration or boredom).

Recently, feminist scholars have objected to the terms attempted and completed suicide since these terms suggest that the behavior more commonly found in men (completed suicide) is the only possible goal of the behavior, and that women typically attempt to achieve this goal but fail to do so. They have suggested that the terms be replaced by fatal and nonfatal suicidal behavior.

Epidemiology of Suicide

Accuracy of Suicide Rates

It has been well documented that coroners and medical examiners often fail to certify suicides correctly. For example, in a study of deaths in one county in Ireland, investigators found an actual suicide rate of 13.1 per 100 000 per year rather than the officially reported rate of 5.8, and this undercounting of suicide has been documented in many other regions of the world.

Despite this, it has also been noted that the relative ranking of suicide rates of nations is similar to the relative ranking of suicide rates of immigrants from those nations to countries such as the United States and Australia, where their deaths are certified by the same coroners and medical examiners. Thus, though the underreporting of suicide may affect the *absolute* suicide rate of a particular group, it may not change the *relative* suicide rates of different groups by much.

Incidence of Suicide

The completed suicide rate in the United States in 2006 (the latest year for which complete statistics are available) was 11.1 per 100 000 inhabitants per year. There were 33 300 suicides, which comprised 1.4% of all deaths. It is estimated that there are 25 suicide attempts for every completed suicide in the United States, which means that about a further 832 500 Americans made suicide attempts in 2006.

Community surveys of the suicidal history of people reveal a wide range in the estimates of prior suicidal behavior. The percentage of residents who report having attempted suicide in their lives is usually in the range of 2–10%, and for reports of having thought about committing suicide is in the range of 10–50%. This percentage differs from community to community, and depends on the country studied and on the way in which the question is phrased.

Variations in Rates of Completed Suicide

In almost every nation of the world, men have higher suicide rates than women. For example, according to the World Health Organization, in the United States in 2002, the rates were 17.9 (per 100 000 per year) for men and 4.2 for women, in Japan in 2004, 35.6 and 12.8, respectively, and in France in 2003, 27.5 and 9.1, respectively. The relative difference between the suicide rates of men and those of women is less in Asian nations than elsewhere. In a rare reversal of this gender difference, mainland China has recently reported a higher suicide rate for women than for men (14.8 and 13.0, respectively, in selected urban and rural areas in 1999).

The variation in suicide rates by age differs from nation to nation. Typically, suicide rates increase with age, sometimes peaking among middle-aged people and at other times continuing to increase among the old-age group. In the United States, the suicide rates of men increase steadily with age whereas the suicide rates of women peak in middle age. However, among the less privileged groups in wealthier countries (such as native Americans) and among women in poorer countries (such as Thailand), suicide rates tend to peak in young adults.

The 1970s witnessed a rise in the suicide rates of those aged 15–24 in many nations of the world, including Canada, the

United States, and most European nations. The late 1980s witnessed a rise in the suicide rates of the elderly. Between 1950 and 2000, there has been a change in age distribution of suicide cases worldwide. The middle-aged and older (45+) people, who constituted 60% of suicides in 1950, accounted for 45% of self-inflicted deaths in 2000. Conversely, the younger people aged 5–44 years currently account for 55% of suicides (vs. 40% in 1950). Globally the highest suicide rates for males and females are among those aged 35–44 years.

The nations with the highest suicide rates in the world are Lithuania (with a rate of 30.9 in 2006), the Russian Federation (30.1 in 2006), and Kazakhstan (26.7 in 2006). The nations with the lowest suicide rates are Islamic countries in the Middle East (e.g., Kuwait 2.0 in 2002). (Retrieved from www.who.int, May 29, 2010.)

Societal Suicide Rate

The suicide rates of societies remain quite stable over time. The relative suicide rates of nations 50 years ago are similar to the present rates, despite changes in the absolute size of the rates. For example, Hungary, with one of the highest suicide rates, also had one of the highest suicide rates in the world at the beginning of the last century and between the two World Wars, and Hungarian immigrants to the United States have one of the highest suicide rates of all immigrant groups.

The stability of the societal suicide rates means that it is meaningful to inquire whether the characteristics of the society are associated with, and perhaps cause, the suicide rate.

Social Causes of Suicide

Emile Durkheim in his book on suicide published in 1897 suggested that two broad social characteristics of a society determined its suicide rate: the degree of social integration (i.e., the degree to which people are involved in social relationships) and the degree of social regulation (i.e., the degree to which people's desires and attitudes are governed by the societal norms). Durkheim felt that suicide would be especially common where social integration was very weak (leading to *egoistic* suicide) and where social regulation was very weak (leading to *anomic* suicide). These suicides are committed by people who are relatively socially isolated and whose values are less often congruent with the prevailing social norms.

To a lesser extent, Durkheim felt that the other extremes of social integration and social regulation might also cause some suicides: too strong a level of social integration leading to *altruistic* suicide (where individuals kill themselves to help others) and too strong a level of social regulation leading to *fatalistic* suicide (where individuals feel so oppressed that suicide is chosen as a means of escape). Later sociologists have, on the whole, disregarded these latter possibilities, claiming that such suicides are rare in modern societies. They have proposed simply that suicide rates are higher where social integration and social regulation are weak.

Possible indices of these social characteristics are indeed associated with suicide rates, over nations of the world, over regions within nations, and over time. For example, suicide rates are typically associated with the divorce rate, the extent of

migration within the nation, and alcohol consumption, and with unemployment (positively) and church attendance (negatively). Interestingly, where these indices of a lack of social integration and regulation are strong, suicide rates are higher in all groups in the society. For example, in regions where divorce rates are high, suicide rates are higher in the single, married, and divorced, indicating that social integration and regulation are broad characteristics of the *whole* society.

Another variable associated with suicide rates is unemployment, an indicator of hard economic times. Suicide rates tend to be higher in times when unemployment rates are higher and, among individuals, suicide rates are higher in the unemployed.

Publicity and Suicide

A great deal of recent research has shown that temporary changes in the society's suicide rate can be brought about by short-term social events. Political, civil, and religious events, such as presidential elections, national holidays, and religious holidays are linked to lower overall mortality rates (a 'death dip') and lower attempted and completed suicide rates.

The phenomenon in which a book, play, song, or film is linked to increase in the incidence of suicide is called the Werther Effect after the publication of Goethe's *The Sorrows of Young Werther* in 1774, which purportedly led to young lovers committing suicide in imitation. According to anecdotal evidence, there have been other such 'epidemics,' such as the rash of suicides in young Jewish females after the publication of Otto Weininger's 'Sex and Character' in 1903 and an alleged increase in suicides in the 1930s related to probably the best known song concerning suicide, 'Gloomy Sunday,' the 'Hungarian suicide song.' An earlier recorded epidemic occurred in the early 1700s in Japan in relation to kabuki plays, which often presented thwarted love followed by the suicides of the lovers as a common plot.

Suicides of people considered as celebrities may be linked to increased suicide rates in members of the general population, especially in individuals of the same gender, age, and race as the deceased. For example, the suicide of a celebrity, such as Marilyn Monroe in 1962 or a fictional character in a television soap opera, typically leads to an increase in the suicide rate and sometimes attempted suicides in the following 7–10 days, particularly in those similar to the suicide in age and sex.

This imitation effect in suicide is apparent in the existence of suicide venues, places where people go in large numbers to commit suicide, such as the Golden Gate Bridge in San Francisco and the Eiffel Tower in Paris. The 1980s and 1990s also saw the documentation of clusters of suicides occurring in communities, for example, among teenagers in small towns, on some Native American reservations, in some Australian Aboriginal communities, and among some groups of Pacific islanders.

Over the last decade, there have been concerns raised regarding the negative impact of the Internet on suicidal ideation and behavior, especially among adolescents and young adults. Such concerns are related to online availability of suicide manuals and descriptions of lethal methods, and the risk of a virtual 'Werther effect' ('copycat cybersuicides'). Also, there have been reports of suicide pacts initiated over the Internet. In some cases, however, involvement in suicide-related

websites and online forums might have a preventive effect and help people cope with their problems as the Internet can create a sense of community and provides empathic listeners.

Causes of Individual Suicide

Psychiatric Disorder

The most notable personal characteristic associated with suicide is psychiatric disturbance. Persons with an affective disorder (in particular, a major depressive disorder) have a very high suicide rate. Those with schizophrenia and those who are substance abusers also have high suicide rates. It has also been documented that particular personality disorders (i.e., chronic maladaptive lifestyles) are associated with a higher risk of suicide and suicide attempts, in particular, borderline personality disorder.

Depression can refer to a mood as well as a particular psychiatric disorder, and the mood of depression is strongly associated with and predictive of suicidality. In those suffering from any psychiatric disorder, the level of depression predicts the degree of suicidality. Aaron Beck has suggested, further, that one component of depression is particularly useful as a predictor of suicidality, namely, hopelessness, a feeling that life will not get better in the future.

Biochemical and Genetic Factors

Biochemical and genetic factors have been shown clearly to have a role in the etiology of psychiatric disorders. For example, studies of twins and adopted children have shown that both affective disorders and schizophrenia have a genetic component. The neurotransmitter serotonin seems to play a role in affective disorder while dopamine seems to play a role in schizophrenia.

This association of suicide with psychiatric disorder makes identification of biochemical and genetic factors for suicide per se difficult. It has proven difficult to show that biochemical or genetic factors play a role in suicide above and beyond increasing the likelihood of psychiatric disorder which itself increases the risk of suicide.

Medical Illness

The increasing frequency of long-term debilitating medical illnesses (such as Alzheimer's disease, AIDS, and cancer) has led to the documentation of many suicides committed by people dying of these illnesses or afraid of what their condition will be like as the disease advances. Some people commit suicide motivated by the fear that they might develop these conditions. The fact remains, however, that the vast majority of people suffering from these illnesses do die from the illness rather than suicide.

Childhood Experiences

Several childhood experiences have been found to increase the later risk of psychological disturbance and suicide. Among these is the loss of parents (through death or divorce) in the first 15 years of life. Although loss of a parent in the first 6 years of life is thought by many developmental psychologists to be especially traumatic, many eventual suicides have lost a parent during the period when they were 6–14 years of age

and have failed to resolve and complete the mourning process. In some cases, the suicide can be motivated in part by a desire to be reunified with the lost parent after death (as in the case of the American poet Sylvia Plath).

The experience of physical and sexual abuse as a child increases the risk of later self-destructive behavior, and dysfunctional families of all kinds (including those with parents who have psychiatric disturbance or who are substance abusers) also increase the risk of later self-destructive behavior. However, researchers have not yet shown that these experiences lead to suicide per se rather than merely increasing the severity of psychological disturbance, which in turn increases the risk of suicide.

Interpersonal Relations

Suicidal behavior, especially among adolescents and young adults, is often triggered by interpersonal friction and loss. Although suicide in the elderly is more often the result of long-term psychological distress, elderly men seem less able to cope with the loss of their spouse than elderly women. The significant others of potentially suicidal people sometimes harbor hostile and death wishes (both conscious and unconscious) toward them, and this increases the risk of suicide.

Recent Stress

Most of those who experience a psychiatric breakdown have experienced a recent high level of stressful life events. Similarly, those who attempt and complete suicide are generally found to have experienced a particularly high level of recent stress in the past year and to have had this stress level increase markedly in the weeks prior to the suicidal behavior.

Psychological Factors

Several personality traits have been associated with suicidal behavior, including a depressed mood, low self-esteem, a belief that what happens to you is outside of your control, poor problem-solving skills, and irrational thinking patterns.

Psychological factors or vulnerabilities can exacerbate the impact of other risk factors such as medical illness or recent stress and thus increase the risk of suicide. One of the strongest predictors for suicidal thinking and behavior is hopelessness, that is, a state of negative expectancies concerning oneself and one's future. Studies conducted by Aaron T. Beck and his colleagues have shown that hopelessness may predict as many as 91–94% of suicides in both outpatient and inpatient populations and that hopelessness is a better predictor of suicidal ideation and behavior than depression itself. According to Beck's cognitive theory of depressive schemata, in some individuals the level of hopelessness escalates during the depressive episode, later subsides with the course of the illness, and is indicative of the level of hopelessness during subsequent episodes. There are, however, individuals in whom high hopelessness seems to be a stable (trait) characteristic, such as people with personality disorders or people abusing alcohol, who are chronically suicidal.

Other psychological risk factors for suicide include aggression and impulsivity, poor problem-solving skills, cognitive

rigidity (i.e., 'all-or-nothing' thinking), and perfectionism. Also, the experience of psychological suffering and pain (or 'psychache') is a strong correlate of elevated suicide risk.

Edwin Shneidman described the psychological state of a person in suicidal crisis using '10 psychological commonalities of suicide,' that is, patterns of emotion, behavior, and cognition, which precede suicide. Although every suicide is different, there are certain common intercorrelated characteristics which can be found in almost all cases of suicide:

1. *The common purpose of suicide is to seek a solution.* For a person experiencing unbearable psychological pain, suicide seems to be the only and the best solution to his/her problem ('Suicide was the *only* thing I could do' or 'It was the answer to my problem').
2. *The common goal of suicide is cessation of consciousness.* The goal of suicide is not to die, but to stop the stream of consciousness which is filled with pain and suffering.
3. *The common stimulus of suicide is unbearable psychological pain, that is, psychache.* Psychological pain is different from depression and may be subjectively experienced as excessive feeling of guilt or shame, unbearable loneliness, great humiliation, or overwhelming anxiety. The sources of *psychache* are frustrated psychological needs.
4. *The common stressor in suicide is frustrated psychological needs.* Although there is a wide range of psychological needs, there are five major clusters of frustrated needs found in suicide cases: 'thwarted love,' 'grief,' 'excessive anger,' 'fractured control,' and 'avoidance of shame.'
5. *The common emotion in suicide is hopelessness-helplessness.* Although a person contemplating suicide may experience a range of emotions, the dominant emotions are hopelessness and helplessness. Shneidman disagreed with the widespread belief (originating in psychoanalytic theories of suicide) that suicidal behavior stems from hostility and aggression.
6. *The common cognitive state in suicide is ambivalence.* Quite contrary to common beliefs, suicidal people do not unequivocally want to die; they just cannot continue living with the unbearable psychological pain.
7. *The common perceptual state in suicide is constriction.* Constriction or 'tunnel vision' leads to narrowing of options and, in a suicidal crisis, dichotomous 'either-or' and 'all-or-nothing' thinking prevails. Interpersonal relations or personal values, such as family or religion, also lose their importance.
8. *The common action in suicide is escape.* For a person in crisis, suicide becomes an escape from the difficult life situation and from unbearable psychological pain. Thus, suicide can be defined as an ultimate escape. It is final and irreversible.
9. *The common interpersonal act in suicide is communication of intention.* People thinking about suicide usually communicate their intentions to others. Such communications are important warning signs of suicide, and if taken seriously, may lead to getting the necessary help and support.
10. *The common pattern in suicide is consistency of lifelong styles.* Suicide hardly comes as a surprise. It is closely related to and a consequence of a particular lifestyle. The way people react to difficulties and problems across their life span is a good long-term indicator of suicide risk.

Protective Factors

Sufficiently strong protective factors can balance out the negative impact of risk factors and thus reduce the risk of suicide. It may come as a surprise that research to date has focused mostly on identification and measurement of risk factors, neglecting the study of what helps people cope with life adversities and crises. It should be stressed that protective factors are not necessarily the opposites of risk factors (e.g., employment – unemployment) or their absence (e.g., good health – illness).

Protective factors are quite diverse and range from individual characteristics and beliefs to the features of the environment and culture. On the individual level, these include hopefulness, reasons for living, resilience, problem-solving and coping-with-stress skills, plans for the future, and constructive use of leisure time. Religiosity, spirituality, a sense of purpose and meaning to life, and personal beliefs that exclude suicide as an acceptable solution to life's problems can help people cope and, thereby, prevent suicide. Employment and good physical and mental health are other important protective factors. In the case of psychiatric disorders, early identification, the availability of effective and appropriate treatment, as well as the propensity to seek treatment and maintain it when needed, might counterbalance the negative impact of psychopathology.

Among protective factors on the interpersonal level are the availability and suitability of social support from family and others, involvement in stable and significant relationships (including marriage), responsibility for children and parenthood, especially having children under the age of 18 living at home. Certain features of the environment and culture might protect against suicide, such as religious and cultural beliefs that oppose suicidal behavior and support coping and resilience. Also, restricted access to lethal means of suicide (e.g., guns, toxic substances) is one of the most effective protective factors.

Psychological Autopsy

The tragic paradox of suicide research is the absence of the very person who is the subject of the study. It has been suggested that there is a continuum of suicidality and an overlap between the groups of people who think about suicide, those who make suicide attempts, and those who die by suicide. Therefore, a study of suicide ideators and attempters might shed light on fatal suicidal behavior. However, this approach has been questioned, and there are significant differences between those who attempt and those who complete suicide, starting with sociodemographic characteristics such as age and gender. In general, suicide attempts are more frequent among females and young people, completed suicides among males and the middle-aged and the elderly.

The psychological autopsy is a method developed by Edwin Shneidman, Norman Farberow, and Robert Litman which involves gathering information about the deceased from reliable sources in order to reconstruct his or her life in order to identify life events and other risk factors preceding suicide. Psychological autopsies are combinations of

interviews with people who were close to the deceased and knew him or her well (e.g., family members, friends, colleagues, medical professionals) and analysis of information contained in medical files, hospital notes, criminal files, and other documents. This method was initially developed to help coroners ascertain the mode of death (i.e., suicide, accident, homicide, or natural death) in a case of equivocal death. Currently, it is widely used to study proximal (triggering) and distal suicide risk factors such as life events, psychopathology, physical health, social support, recency of contact with health professionals, personality, and other psychological and socio-demographic variables. Psychological autopsies also allow the identification of patterns of behavior and communication which precede suicide and thus may be considered as suicide warning signs, for example, making final arrangements, talking about suicide, expressions of hopelessness, and preparing the means of suicide (such as collecting pills or buying a gun).

Preventing Suicide

There have been two major methods of preventing suicide in the past. First, the treatment of those with psychiatric disorders, and in particular depressive disorders, by medication and by psychotherapy, can prove useful in reducing the risk of suicide. A program in the Swedish island of Gotland to train physicians in the detection of depression and the prescription of appropriate medication reduced the suicide rate there.

A second method for preventing suicide has been the establishment of suicide prevention centers. In many countries (such as the United States) these centers are set up independently by different kinds of groups, while in others there is a centralized and uniform organization (such as the Samaritans in the United Kingdom). These centers typically establish crisis counseling services, using the telephone as a medium for communication, which are available 24 h a day and 7 days a week. Clients in distress can call and discuss their problems and search for alternatives to suicide as a solution for their problems. Some centers also have walk-in clinics for face-to-face contact, some have outreach services that can visit people in the community, and others have organized groups for those who have experienced the suicide of a loved one and are finding it hard to cope with the loss.

Recently, it has been noted that elimination of lethal methods for suicide, often inadvertently, can result in a reduction in the suicide rate. Domestic gas companies in many countries (such as the United States, England, and Japan) switched from highly toxic coal gas to less toxic natural gas for economic reasons, but the switch has virtually eliminated suicide by domestic gas. Emission controls on cars (which reduce the toxicity of the exhaust) reduce the lethality of cars for suicide. Several investigators have suggested, therefore, extending this tactic to other methods and have advocated, for example, reducing the amount and toxicity of prescribed medications, reducing the availability of guns, and fencing in bridges and subway platforms from which people jump. There is the possibility that some potential suicides will switch to an alternative method for suicide, but the evidence suggests that not all will do so.

Surviving the Suicide of a Significant Other

Surviving the suicide of a loved one appears to be especially traumatic for people. Not only is there the loss of the person, but there is often a feeling of stigma associated with the death. The survivors feel guilty for not recognizing and responding to the suicide's distress. Often, neighbors and friends do not know how to react to the survivors and withdraw, so that the survivors feel rejected and isolated.

In addition, many suicides commit suicide at home where they are discovered by their loved ones, often horribly disfigured (especially if they used a gun for their suicide). This trauma can haunt survivors for the rest of their lives and is similar to the trauma in those who witness murder and war. A posttraumatic stress disorder is not uncommon.

Furthermore, the risk of suicide in the relatives and especially the children of suicides is greater. For example, Ernest Hemingway's father committed suicide, and Ernest and two more of the six children also killed themselves.

Is Suicide Immoral?

The morality of suicide has been a subject of debate for many thousands of years. There are those who set up a clear principle, such as 'Thou shalt not kill,' and apply it to every situation. For these, suicide is immoral. There are others who place more importance on other principles, such as freedom of choice for autonomous individuals. For these people, suicide may be moral.

Utilitarian ethicists weigh the harm and the good from alternative actions and suggest minimizing harm and maximizing good. The problems here are that the weights are often subjective, and we can argue about for whom we should minimize the harm and maximize the good – the suicide, the survivors, or the society.

Suicide is, however, not illegal in many countries (including the United States), though assisting someone else to commit suicide may, in some jurisdictions, be a crime. Attempting suicide in such a way as to endanger the health and safety of others may be an offense, either in the criminal code or the public health code. However, contrary to popular belief, insurance companies in many countries do pay the full amount for suicides who bought the policy more than 2 years before their death (e.g., in the United States).

Can Suicide Be Rational?

There has been a great deal of debate over whether suicide can be rational, especially as many of those dying from chronic diseases commit suicide or ask for help to do so. Some argue that suicide can never be rational for the suicide is almost always psychiatrically disturbed or, at least, psychologically distressed. If they could be helped through this period, their

desire to live could be rekindled. Others argue that people are capable of weighing the disadvantages and advantages of continued life quite appropriately and of making a rational decision to die.

There are two issues here. First, are the premises of the suicidal person rational and, second, is the reasoning, given their premises, logical? Typically, the reasoning of suicidal people (other than those who are grossly psychotic) is quite logical. It is the rationality of the premises that we dispute. However, these are subjective. Pain (physical or psychological) which is bearable for one person may be unbearable for another. The only sensible resolution is to permit each of us to decide what is bearable for ourselves.

Surprise

R Reisenzein, University of Greifswald, Greifswald, Germany

© 2012 Elsevier Inc. All rights reserved.

Glossary

Belief The mental state of holding a proposition to be true; one of the basic kinds of propositional attitude.

Emotions Mental states experienced as (typically positive or negative) feelings that typically seem to be directed at specific objects, and are more or less frequently accompanied by physiological arousal, expressive reactions (e.g., facial expressions), and characteristic actions. Examples are joy, sadness, hope, fear, anger, pity, guilt, and pride.

Expectation In common parlance, a belief regarding a future state of affairs. In the theory of surprise, 'expectation' is used more broadly, as a synonym of 'belief.'

Misexpected and unexpected Surprise is caused by unexpected events. Unexpected events cover two cases: those that are misexpected, and those that are unexpected in the strict sense. An event is *misexpected* if it conflicts with a preexisting, specific, and usually explicit belief concerning this event. An event is *unexpected in the strict sense* if it is inconsistent with the person's background beliefs.

Orienting response (OR) The OR is usually defined as a probabilistic syndrome of behavioral and physiological reactions, evoked in particular by novel or significant stimuli. Although the reactions characteristic for the OR and those characteristic for surprise overlap, the OR must be distinguished from surprise.

Schema According to schema theory, human perception, thought, and action are to a large extent controlled by complex, organized knowledge or belief structures called schemas. Schemas can be regarded as informal, unarticulated theories, or as sets of beliefs, about objects, events, event sequences (including actions and their consequences) and situations.

Startle reaction A reflex-like defensive response elicited by abrupt, intense sensory input, such as a pistol shot. The startle reaction consists centrally of a rapid muscular response beginning with the closure of the eyes that may extend to the body, but it also includes a variety of physiological changes. Although surprise is a frequent secondary reaction to startling stimuli, the startle reaction and surprise are entirely different phenomena.

Surprise A peculiar state of mind, usually of brief duration, caused by unexpected events of all kinds. Subjectively, surprise manifests itself centrally in a characteristic feeling; objectively, it may manifest itself in a variety of behaviors and physiological changes. It is argued that underlying these phenomena is an evolved mechanism whose function is (a) to detect discrepancies between cognitive schemas and newly acquired information, and (b) if they are detected, to instigate processes that enable the short- and long-term adaptation to them.

Pretheoretical Characterization of Surprise

Common-sense psychology conceptualizes surprise as a peculiar state of mind, usually of brief duration, caused by unexpected events of all kinds, ranging from unexpected sounds and lights to unexpected social events (e.g., the outcome of an election), to unexpected turns in novels and unexpected puns of jokes.

Subjectively (i.e., from the perspective of the surprised person), surprise manifests itself centrally in a phenomenal experience or 'feeling' with a characteristic quality, that can vary in intensity from just-noticeable to intense. In addition, the surprised person is often aware, at least if she observes herself carefully, of a variety of surprise-related mental and behavioral events: She realizes that something is different from usual or other than expected; she notices that her ongoing mental processes and actions are being interrupted and that her attention is drawn to the unexpected event; she may feel curiosity about the nature and causes of this event; and she may notice the occurrence of spontaneous epistemic search processes (attempts to make sense of the event).

Objectively (i.e., from the perspective of the outside observer), surprise may reveal itself – depending on circumstances – in any

of a number of behavioral indicators, including: interruption or delay of ongoing motor activities; orienting of the sense organs to the surprising event; investigative activities such as visual search or questioning others; spontaneous exclamations ('Oh!') and explicit verbal proclamations of being surprised; and a characteristic facial expression consisting, in full-blown form, of eyebrow-raising, eye-widening, and mouth-opening/jaw drop. Intercultural studies suggest that people from different cultures consider this facial display to be characteristic for surprise; this points to an evolutionary origin of the expression. Psychophysiological studies suggest that surprising events may also elicit a variety of bodily changes, similar to those characteristic for the orienting response (OR), such as a temporary slowing of heart rate and an increased activity of the eccrine sweat glands (see section on '[The Orienting Response](#)'). As to the brain processes that underlie surprise, research is limited; again however, the available evidence suggests that the neurophysiological events characteristic for surprise overlap partly with those characteristic for the OR. In particular, electrophysiological studies suggest that the so-called P300a component of evoked brain potentials elicited by rare deviant stimuli may also be characteristic for (some forms of) surprise (see section on '[The Orienting Response](#)'). Brain-imaging studies suggest that both unexpected stimuli and

rare deviant stimuli activate a large network of cortical and subcortical regions in the brain, suggesting a ‘whole-brain response’ to unexpectedness that would fit well with the theory of surprise detailed below, as well as with theories of the OR. As to the brain processes selectively associated with surprise, a recent study points to processes in the lateral prefrontal cortex.

Scientists can use the various external indicators of surprise (self-reports about surprise, action delay, brain responses, etc.) to infer the presence and intensity of surprise in their research participants. It must be noted, however, that the behavioral manifestations of surprise (e.g., the facial expression of surprise, or physiological reactions) occur by no means in all surprise-eliciting situations and are in general only loosely associated with one another. Although progress in brain-imaging techniques may eventually provide researchers with a precise, objective measure of surprise, for the time being the most direct indicator of surprise remains the person’s self-report about the presence and intensity of the feeling of surprise, typically measured using a rating scale (ranging, e.g., from 0 = not at all surprised to 10 = extremely surprised).

A Short History of Research on Surprise

Descriptions of surprise as a mental and behavioral phenomenon, as well as first attempts at theory-building, date back as far as Aristotle (about 350 BC). Among the first to discuss surprise in modern times were the philosophers David Hume and Adam Smith in the eighteenth century. Their ideas were taken up and elaborated further when psychology was established as an independent discipline in the nineteenth century. By 1920, most of the questions about surprise that are discussed today had already been formulated, and even first experimental studies had been conducted. However, during the subsequent, behaviorist era of psychology (about 1920–1960), research on surprise came largely to a standstill, to be taken up again only following the so-called ‘cognitive revolution’ of the 1960s. At that time, aspects of surprise first came to be discussed again under the labels ‘*orienting response*’ and ‘curiosity and exploration.’ Surprise as an independent phenomenon was first discussed anew by evolutionary emotion theorists Silvan Tomkins and Carroll Izard. Referring back to Darwin, these authors proposed that surprise is a basic emotion that serves essential biological functions. One of these functions – surprise as an instigator of epistemic (specifically causal) search and a precondition for learning and cognitive development – came to be particularly emphasized by developmental psychologists. This suggestion was subsequently taken up by social psychologists interested in everyday causal explanations, who emphasized unexpectedness as a main instigator of spontaneous causal search. In the 1980s, cognitive psychologists, including cognitively oriented emotion theorists, became interested in surprise. Since that time, research on surprise has steadily increased and is carried out today by researchers in several different subfields of psychology, as well as in neighboring fields such as artificial intelligence. Topics addressed by contemporary research on surprise (part of which is carried out under different labels such as ‘spontaneous attention,’ ‘OR,’ and ‘curiosity’) range from the relation of surprise to spontaneous attention capture, to the conditions of the facial expression of surprise, to the role

of surprise in advertising. Because surprise is involved in many different psychological phenomena, research on surprise is relevant for many areas of psychological investigation. These include belief updating and learning, the diagnosis of knowledge structures in children, spontaneous attention, automatic versus controlled processing, emotions, humor, the psychology of music, and esthetic appreciation.

Theories of Surprise: The Cognitive-Evolutionary Model

Classical psychological theories of surprise are formulated exclusively on the ‘intentional level’ of system analysis familiar from common-sense psychology, using concepts such as *belief*, *expectation*, *attention*, and, of course, *surprise*. Only in recent times have there been attempts to move beyond this level of analysis to the level of the underlying mental mechanisms, or the cognitive architecture. The aim of these newer, ‘process models’ of surprise is to provide a deeper understanding of the causal generation of surprise, its nature, and its functional role in the architecture of the mind, by describing (at least in outline) the information-processing mechanisms that underlie the experience of surprise and surprise-related mental events and behaviors. To illustrate, we describe in some detail the *cognitive-evolutionary model of surprise* proposed by Meyer and coworkers, which is the result of an attempt to integrate and elaborate the modal views of previous surprise theorists, as well as previous psychological analyses of humans’ reactions to unexpected events, within the framework of schema theory. This model has formed the basis of some recent empirical research on surprise in psychology, as well as inspired a computational model of surprise proposed by artificial intelligence researchers. The cognitive-evolutionary model of surprise is depicted in simplified form in [Figure 1](#).

Schema theory assumes that human perception, thought and action are to a large extent controlled by complex, organized knowledge (or belief) structures, called schemas. Schemas can be regarded as informal, unarticulated theories, or as sets of beliefs, about objects, events, event sequences (including actions and their consequences), and situations. Schemas serve the interpretation of present and past, and the prediction of future events, and thereby the adaptive guidance of action. To be able to fulfill these functions, a person’s schemas or informal theories must be at least approximately correct. This in turn requires – because knowledge of the environment is usually incomplete, and because the environment can change – that schemas are continuously monitored for their compatibility with newly acquired information and, if necessary, are appropriately updated. According to the cognitive-evolutionary model of surprise, the surprise mechanism plays a crucial role in this context.

The surprise mechanism is assumed to consist at its core of an innate, hardwired information-processing device that continuously compares, at an unconscious level of processing, the currently activated cognitive schemas (which may be regarded as constituting the person’s working-memory model of her present situation) with newly acquired information (new beliefs). As long as the ‘schema-discrepancy detector’ registers congruence between schema and input – colloquially, as long as events conform to expectations – the person’s informal

Figure 1 A cognitive-evolutionary model of surprise. After Meyer W-U, Reisenzein R, and Schützwohl A (1997) Towards a process analysis of emotions: The case of surprise. *Motivation and Emotion* 21: 251–274.

theories are supported by the evidence, and there is hence no need to revise them. Rather, the interpretation of events and the control of action take place largely automatically and effortlessly. In contrast, if a discrepancy between schema and input is detected, and if the degree of schema discrepancy (unexpectedness) exceeds a certain threshold, a ‘surprise reaction’ is elicited (see [Figure 1](#)): Ongoing information processing is interrupted, processing resources are reallocated to the unexpected event, and the feeling of surprise is generated ([Figure 1](#)). These processes enable and prepare the subsequent analysis and evaluation of the unexpected event plus – if this analysis suggests so – immediate reactions to this event and/or the updating, extension, or revision of the schema or schemas that gave rise to the discrepancy ([Figure 1](#)). The evolutionary function of the surprise mechanism is to (1) detect schema-discrepancies and (2) if they are detected, to prepare and instigate processes (of event analysis and schema update) that enable the immediate and long-term adaptation to unexpected events. Let us look at the processes postulated in [Figure 1](#) in more detail.

Detection of Schema-Discrepancies

The assumption that surprise is caused by the detection of schema-discrepancies is an explication of the common-sense psychological assumption – which is accepted by nearly all classical and modern surprise theorists – that surprise is elicited by *unexpected events*, that is, by events that disconfirm, contradict, or violate an expectation. However, to cover all cases of surprise, this idea is given an extended interpretation in the theory that includes the following assumptions: (1) The ‘expectations’ that are disconfirmed by surprising events are not restricted to beliefs about the future; rather, ‘expectation’ is used as a synonym of ‘belief.’ This assumption is necessary to take account of the fact that surprise can also be caused by disconfirmation of beliefs about the past (e.g., one is surprised that the train departed an hour ago) and about atemporal states of affairs (e.g., one is surprised that a particular theorem follows from the axioms of a theory). (2) The concept of ‘unexpectedness’ covers two cases: *misexpectedness*, and *unexpectedness* in the strict sense. An event is *misexpected* if it conflicts with a preexisting, specific, and usually explicit belief concerning this event. For example, Mary is waiting for Bob in her office; hearing a knock at the door, she expects Bob to enter, but Bill enters instead. This event elicits surprise because it is *misexpected*. In contrast, an event is *unexpected in the strict sense* if it does not conflict with an explicitly held belief (at least none that was active, that is, in the person’s working memory

at the time when the surprising event occurred), although it is inconsistent with the person’s background beliefs. For example, even if Mary does not expect anybody in particular to visit her, she will be surprised to see Bill walk into her office if she believes that Bill is currently attending a conference abroad. (3) The explicit or implicit beliefs whose disconfirmation causes surprise can be acquired in several different ways: They can be gradually built up through personal experience during an extended period of time (e.g., during many days in her office, Mary learns that Bob usually visits her at noon); they can be conveyed through verbal communication (Bob informs Mary that he will come to visit her at noon); and they can be inferred from other beliefs through reasoning processes (e.g., Mary reasons that, because Bob has promised to visit her the next time he is in town, and because he is in town today, he will probably visit her today).

Any plausible cognitive theory of surprise must take account of these facts. This means in particular that such a theory needs a suitably general and flexible account of the internal representations that serve as a reference against which an event is classified as ‘discrepant.’ This account must allow to represent beliefs about past, present, and future states of affairs; as well as beliefs about concrete events and abstract states of affairs; it must allow to explain how both *misexpected* and *unexpected* events can be classified as ‘discrepant’; and it must be able to accommodate different sources of belief acquisition (e.g., cumulative personal experience over an extended period of time, and explicit verbal information). The schema concept promises a description of adequate breadth: Surprising events are those not consistent with currently activated schemas, irrespective of the existence of a concrete expectation, and irrespective of the origins of the beliefs encoded in the schema. Schema theory postulates that schemas become activated as a result of current experiences, that may include the unexpected event itself. The activated schemas then serve as a reference against which experiences are compared; events that deviate from the currently activated schemas elicit surprise.

Interruption, Reallocation of Processing Resources, Event Analysis, and Schema Update

Usually the individual is engaged in some other activity when an unexpected event occurs. To permit the undisturbed processing of the unexpected event, these ongoing cognitive and motor activities are temporarily interrupted by the surprise mechanism, and the available processing resources are redistributed, now favoring processes that serve the analysis of the

event and the updating of currently activated schemas. The focusing of attention on the unexpected event amplifies information relevant for the updating process and simultaneously attenuates potentially interfering information from other sources. It should be noted that, although turning attention to the surprising event as a prerequisite for updating is in most cases adaptive, it is not always so, because there are situations in which even the shortest interruption of momentary activity can have disastrous effects. This is the case when the uninterrupted continuation of ongoing activities is vitally necessary, as may be the case for a fighter pilot or a cat burglar. From the perspective of the cognitive-evolutionary model of surprise, these occasional negative side-effects of surprise are the price that has to be paid for a mechanism that is overall adaptive in enabling the coping with unexpected events.

According to the cognitive-evolutionary model of surprise, the subsequent analysis and evaluation of the surprising event typically comprises the following subprocesses: the verification of the schema discrepancy (did one see or hear right; did one draw the correct conclusion from premises?); the analysis of the causes of the unexpected event (why did it happen?); the evaluation of the unexpected event's significance for well-being (is the event congruent or incongruent with one's desires; does it signal danger, or an unexpected opportunity?); and the assessment of the event's relevance for ongoing action (can one ignore the event, or does one need to respond to it?). Additional event appraisals, such as an assessment of the moral significance of another person's unexpected action, can also occur in special situations. Once the appraisals of an unexpected event (e.g., regarding its causes or action relevance) have been computed, they are stored as part of the schema for this event. As a consequence, the analysis of subsequent instances of the same or similar kinds of events can be substantially abbreviated.

The analysis and evaluation of the surprising event is usually a precondition for adaptive schema (or belief) update. A schema update may consist in the correction, restructuring, or extension of relevant schemas. Appropriate schema update enables the individual: to predict and possibly, to control (bring about or prevent) future occurrences of the schema-discrepant event; to avoid the event if it is negative and uncontrollable; or to ignore the event if it is irrelevant for further action. The long-term function of surprise is thus to ensure the adaptation of the individual by enabling and instigating processes that result in the updating of action-guiding schemas. To the degree that schema revision or belief update can be equated with cognitive development and learning, it follows that surprise should have an important function for the development of cognitive structures and learning. In agreement with this conclusion, many developmental psychologists consider surprise to be an important factor for children's cognitive development. Similarly, several learning theorists conceive of learning as a process in which an individual's schemas are brought into line with new input that deviates from the schemas. This suggests that at least one central form of learning – namely belief updating – occurs only if newly acquired information is unexpected and hence surprising. Surprise theory thus suggests a strongly 'localist' approach to belief updating.

The Behavioral Manifestations and the Experience of Surprise

The cognitive-evolutionary model of surprise assumes that the described mental processes are causally responsible, alone or in combination, for the various behavioral manifestations of surprise (if they occur): the interruption or delay of ongoing motor activities, investigative activities, facial and verbal expressions of surprise, and peripheral physiological reactions. For the greater part, these behavioral manifestations of surprise are probably adaptive processes that, in one way or another, subserve the major function of the surprise mechanism: the short- and long-term adaptation to unexpected events. For example, investigative motor actions are in the service of epistemic analysis, and eyebrow-raising may, as Darwin argued, facilitate the visual exploration of unexpected events in some situations. In addition, eyebrow-raising could serve to communicate the person's surprise to others, thereby soliciting their help in explaining the unexpected event. Indeed, a deliberately produced, stylized form of the surprise expression – raising the eyebrows to form an enquiring look – is frequently used as a nonverbal request for information in everyday conversation. In this way, the facial expression of surprise (and likewise surprise vocalizations) may assist the updating of beliefs by recruiting informational support from the social environment.

The subjective experience or 'feeling' of surprise can be regarded as the manifestation in consciousness of the encountered discrepancy between activated schema and newly acquired information. Because the intensity of experienced surprise is closely related to the degree of unexpectedness of the eliciting event, the feeling of surprise could simply be the conscious awareness of the signal produced by the schema discrepancy detector. (According to the model, this signal is characterized by a specific quality that codes the fact that a schema discrepancy has occurred, and an intensity that codes the degree of the schema discrepancy.) However, the subjective experience of surprise could include additional elements, such as a direct phenomenal awareness of mental interruption.

According to the cognitive-evolutionary model of surprise, the feeling of surprise has an informational as well as a motivational function. Its *informational function* consists of informing the conscious self (the person) about the detection of a schema discrepancy. This assumption relates to theoretical views of consciousness that stress the importance of consciousness for planning: Whereas the routine execution of simple activities may be carried out without conscious control, the generation of action plans for exceptional situations requires conscious processing. Seen from this perspective, the surprise signal acts on the one hand as a 'deautomatizer' that interrupts routine processes and calls for, as well as prepares, conscious processing; on the other hand, the surprise signal enters conscious processing (in the form of the surprise feeling) as information about the occurrence of a schema discrepancy. In addition to its informational function, the experience of surprise can also be ascribed a *motivational function*, for it is likely the feeling of surprise that triggers the conscious analysis of the surprising event, or at least provides an initial impetus for this analysis. The reason for this is probably that the information that something unexpected happened elicits curiosity. Hence, the motivational effect of the surprise feeling may be based on its informational effect.

The Theoretical Definition of Surprise

The cognitive-evolutionary model of surprise allows to replace the pretheoretical characterization of surprise by a more precise, theoretical (i.e., theory-based) definition. As evident from [Figure 1](#), the schema-discrepancy signal is the ‘causal hub in the wheel of surprise’: it is the direct or indirect cause of all subsequent mental processes postulated in the model (the feeling of surprise, interruption and attentional shift, event analysis, and schema revision), as well as of the various behavioral manifestations of surprise. Because of its central causal role, the schema-discrepancy signal suggests itself as the best candidate for the scientific referent of surprise. Hence, presupposing the correctness of the cognitive-evolutionary model of surprise, surprise can be theoretically defined as follows: *Surprise is the signal that is the immediate output of the schema-discrepancy detector.*

Surprise, the Startle Reaction, and the Orienting Response

The Startle Reaction

Surprise must be distinguished from the so-called *startle reaction* elicited by sudden intense sensory input. The startle reaction differs from surprise in terms of its causes, its topography, and its function.

Whereas surprise is elicited by the appraisal of unexpectedness (the detection of a schema discrepancy), startle is a reflex-like reaction to abrupt, intense sensory input, such as a pistol shot. ‘Abruptness’ in this context does *not* mean unexpectedness, but primarily a sudden onset and fast rise of the intensity of sensory input. For example, an acoustic stimulus (a tone or noise) with a high peak intensity will elicit startle only given a short rise time (in the range of some 10 ms), but not when it rises gradually. Furthermore, whereas the intensity of surprise is determined by the degree of unexpectedness, the magnitude of the startle reaction is mainly determined by the intensity of the sensory input. Because of these differences in eliciting conditions, a sensory stimulus that elicits startle (i.e., one with abrupt onset and high intensity) need not cause surprise (if it has been announced beforehand, or presented repeatedly); and a sensory stimulus that elicits surprise (i.e., one that is unanticipated or contrary to expectations) need not cause a startle response (if it is of low intensity, or if its intensity rises gradually). However, surprise is a frequent secondary reaction to startling stimuli because these stimuli are often unexpected as well. It is probably for this reason that the ordinary language word ‘startle’ can also be used to refer to some forms of surprise.

Surprise and startle also differ in terms of the typical behaviors associated with them. The startle reaction consists, centrally, in a specific pattern of facial and bodily muscle movements, varying considerably in completeness, which spreads from the head over the rest of the body. Its initial and most reliable component is the reflexive closure of the eyes; but if the reaction is more intense, it may include additional facial movements (lowering of the eyebrows and a horizontal stretching of the mouth) and postural changes: A forward motion of the head and neck, hunching of the shoulders, pronation of the lower arms, flexion of the fingers, bending of the elbows and

knees, contraction of the abdomen, and a forward motion of the trunk. These muscular reactions are accompanied by diverse physiological changes including an increase in skin conductance, blood pressure, and heart rate, plus an initial holding of breath followed by accelerated respiration. With the exception of the skin conductance reaction, these physiological changes are different from those attributed to surprise. Likewise, the postural changes characteristic for startle are quite untypical for surprise, and the facial changes that occur in startle (closure of the eyes, lowering of the eyebrows, stretching of the mouth) are even opposite to those characteristic for surprise (widening of the eyes, raising of the eyebrows, dropped open jaw). In addition, the temporal onset of the startle reaction differs from that of surprise: Whereas surprise needs at least 200–300 ms to develop in response to a sensory input (e.g., an unexpected tone), the startle reaction occurs with very short latency, with its earliest components appearing at some 40 ms after the onset of a startle stimulus.

Correlated to these differences in elicitors and response, the functions of surprise and startle are different: Whereas the function of surprise is to assist the updating of schemas or beliefs, the startle reaction is – as suggested by the short latency and topography of the described muscular response pattern – essentially a first-line defensive reflex against injury from a predator or a blow. In line with this conclusion, the neural pathways underlying the startle reaction have been determined to consist of a brain-stem reflex system that exists, in similar form, not only in humans but also in variety of animal species.

The Orienting Response

The OR is typically defined as a probabilistic syndrome of responses, evoked in particular by novel and significant stimuli, that includes a variety of behavioral and physiological components, the latter being of primary interest to most researchers of the OR. Although the reactions characteristic for the OR and those characteristic for surprise overlap, the OR must be distinguished from surprise.

The conditions that evoke the OR have been classified into three broad categories. The first category, *novelty* (the quality of an event or stimulus of being new), can be subdivided into (1) novelty of a stimulus or an elementary event, (2) novelty in a sequence of events, and (3) novelty in the patterning of stimuli. For example, a tone that is presented for the first time in an experiment is novel in the first sense; a tone that deviates occasionally from a sequence of regular tones (a so-called ‘oddball stimulus’) is novel in the second sense, and a melody that deviates from one heard before would be novel in the third sense. The second category, *conflict*, refers to situations in which an ambiguous stimulus leads to the activation of conflicting response tendencies (e.g., in a difficult perceptual discrimination task). The last category, *previous conditioning*, includes high-importance stimuli (e.g., one’s own name or a warning call like ‘watch out’), which have acquired their significance as a result of the individual’s learning history. In contrast to the startle response, the OR does not require an increase in the intensity of stimulation to occur. In fact, an event evoking an OR can consist of the occurrence, as well as the change, and even the removal (or omission) of a stimulus (e.g., the omission of a tone in a regular series).

Although there is overlap in the typical procedures used to induce either the OR or surprise in humans, they are not identical. In particular, not all events that elicit an OR also elicit surprise. A novel stimulus, as defined above, may well cause surprise, the reason being that novel stimuli are often also unexpected; however, novel stimuli can also be expected (e.g., an oddball stimulus that has been announced beforehand, or has been presented repeatedly), in which case they do not elicit surprise. And stimuli from the 'conflict' or the 'previous conditioning' categories of OR elicitors need not be unexpected, and hence surprising at all. However, it is possible that all events that cause surprise also trigger an OR (or a special form of the OR), in which case the physiological changes that occur in surprise could consist of the physiological aspects of the OR.

The behavioral components of the OR include movements of the sense organs toward the source of the eliciting stimulus, as well as an interruption of overt actions, accompanied by an increase in general muscle tonus. The physiological components of the OR comprise (1) an increased sensitivity of the sense organs, manifested in the lowering of sensory thresholds; (2) vegetative changes (a decrease of heart rate and respiration rate, an increase in skin conductance, and two opposing vascular changes, vasoconstriction in the limbs and vasodilation in the head); and (3) changes in the electroencephalogram in the direction of faster activity with a lower amplitude, indicative of an increase in cortical arousal or wakefulness.

As to the specific brain processes that underlie the OR, it has been found that novel events evoke a cortical response that differs in waveform from that caused by regular events. More specifically, this research (which has mostly studied the electrocortical responses to simple auditory or visual oddballs) has identified three characteristic components of the event-related brain potential evoked by these oddballs. The first is the so-called mismatch negativity, a negative peak around 200 ms after stimulus onset, which is thought to reflect the preattentive, automatic detection of the sensory (e.g., acoustic) change. The second is the P300a component (a positive peak around 350 ms after stimulus onset) that seems to reflect the involuntary attention switch to the oddball event. Third, the so-called reorienting negativity (a negative peak around 500 ms after stimulus onset), is thought to reflect the voluntary attentional reorienting to the task at hand. Brain-imaging studies found that oddball stimuli elicit widespread activity in diverse, spatially distributed cortical and subcortical systems. To the degree that these brain responses also occur in response to unexpected events, they would indicate that surprising stimuli elicit a 'whole-brain response' that would fit well with the function attributed to surprise. As to the brain processes selectively associated with surprise proper (the output signal of the schema-discrepancy detector), recent research suggests that they may be localized in the lateral prefrontal cortex.

Is Surprise an Emotion?

Common-sense classifies surprise as an emotion. In contrast, in scientific psychology, the question of whether or not surprise is an emotion is controversial: Some emotion theorists regard surprise not only as an emotion, but even as a basic

emotion; others regard it as an emotion, but not a basic one; and yet others do not classify surprise as an emotion at all, but as a cognitive state (although one that may play an important role in the process of emotion generation, e.g., by preparing the individual for the evaluative appraisal of events).

Surprise is typically considered a basic emotion by proponents of an evolutionary approach to emotions, in particular the adherents of the theory of 'discrete basic emotions.' Basic emotion theorists believe that the innate core of the human emotion system consists of a small set of modules – the basic emotion mechanisms – each of which developed in evolution as a solution to a different, recurrent adaptive problem. Surprise, they argue, fits this definition of basic emotions. Some theorists assume, in addition, that basic emotions are innately linked to communicative signals, in particular to facial expressions. Inasmuch as surprise is indeed associated with a specific facial expression, it would also qualify as a basic emotion according to this criterion.

Two main arguments have been advanced for *not* regarding surprise an emotion: (1) in contrast to paradigmatic emotions such as joy or fear, the feeling of surprise is *per se* hedonically neutral, rather than pleasant or unpleasant; (2) corresponding to, and explaining, this difference in feeling tone, surprise does not presuppose the appraisal of the eliciting event as positive (motive congruent) or negative (motive incongruent). The claim that surprise is hedonically neutral rests on the observation that the experience of surprise can be pleasant (e.g., surprise caused by an unexpected present), unpleasant (e.g., an unexpected failure), as well as neutral (neither pleasant nor unpleasant; for example, surprise about an unexpected solution to a quiz problem). This observation suggests that feelings of pleasantness and unpleasantness are not a necessary component of surprise, but result from processes different from those that elicit surprise. These other processes, that are responsible for the hedonic tone of surprise in those cases where it is either pleasant or unpleasant, can be construed as appraisals or evaluations of the significance of what is happening for one's well-being; specifically, the evaluation of the surprise-eliciting event as positive (motive congruent) or negative (motive incongruent). This appraisal of motive consistency, if it occurs at all, usually takes place in parallel to, or quickly after the onset of surprise, and it results in pleasant or unpleasant feelings that blend with the feeling of surprise in consciousness, thus endowing the experience of surprise with a positive or negative hedonic quality. This hypothesis allows to explain the differences in feeling tone in different instances of surprise. It also explains why some authors have come to think that surprise, like other emotions, is intrinsically hedonic or evaluative.

Although the proposed differences between surprise and paradigmatic emotions must be acknowledged, it is not clear whether they are great enough to exclude surprise from the realm of emotions. For one reason, surprise appears to be an essential ingredient of several unquestioned emotional states, such as disappointment and relief; and the intensity of most emotions is enhanced if their elicitors occur unexpectedly. For another reason, it can be argued that the cognitive mechanism that produces surprise (a mechanism that compares newly acquired beliefs to preexisting beliefs) and the mechanism that produces hedonic emotions (presumably, a mechanism that compares new beliefs to preexisting motives or desires)

have similar properties and are closely intertwined in their operation: They are both automatically and unconsciously operating mechanisms that 'supervise' representations (beliefs and desires, respectively); they seem to operate on the same inputs (newly acquired beliefs); and their outputs may be integrated at an unconscious level of processing (e.g., the signals of unexpectedness and desire-incongruence may be unconsciously integrated into the emotion of disappointment). If these assumptions are correct, they would constitute good theoretical reasons for (re-)classifying surprise as an emotion. In any case, however, surprise needs to be considered in theories of emotion, even if it is not regarded as an emotion itself.

Synesthesia

J Simner, University of Edinburgh, Edinburgh, UK

© 2012 Elsevier Inc. All rights reserved.

Glossary

Associator synesthete A synesthete who experiences his/her synesthetic concurrent (e.g., colors) in the mind's eye.

Concurrent The sensory or conceptual experience triggered by the synesthetic inducer.

Grapheme–color synesthesia The experiencing of synesthetic color triggered by (hearing, reading, saying, or thinking about) letters and/or digits.

Higher synesthesia Synesthesia triggered by high-level conceptual stimuli (e.g., word meanings).

Inducer The stimulus that triggers a synesthetic concurrent.

Lexical–gustatory synesthesia The experiencing of synesthetic flavor triggered by (hearing, reading, saying, or thinking about) words.

Lower synesthesia Synesthesia triggered by low-level sensory/perceptual stimuli (e.g., auditory pitch).

Ordinal linguistic personification (OLP) synesthesia The experiencing of synesthetic personalities and genders triggered by ordered sequences such as letters, numbers, days, months, etc.

Projector synesthete A synesthete who experiences his/her synesthetic concurrent (e.g., colors) projected outside the body.

Synesthete A person with developmental or inherited synesthesia.

Introduction

Synesthesia (UK spelling: synaesthesia) is an inherited condition that gives rise to unusual experiences that have often been described as a 'merging of the senses.' For synesthetes, everyday activities such as reading, listening to music, speaking, etc. give rise to extraordinary sensations, such as colors or tastes. Synesthete JW, for example, experiences a 370-Hz single piano note as both an auditory phenomenon and as a dark yellow colored form in her visual field. Synesthete MM has specific sensations of flavor, which flood her mouth whenever she hears proper names (e.g., 'John' tastes of cornbread). Synesthete SD sees colors in his visual field in response to the tastes of food, and so the taste of rice, for example, triggers the color blue. In many cases, these experiences are as perceptually real as veridical sensations, although they are not considered hallucinations: synesthetes are almost always aware that these perceptions are not part of the outside world, but that they are inherently paired with the triggering stimulus. For example, synesthete JS sees colors when he reads letters and digits (known as grapheme–color synesthesia), and, although these colors are projected onto the written typeface, he is fully aware that the print itself is black on white. He knows, moreover, that individual letters and digits trigger individual color experiences, and that these colors are superimposed by his own mind. Synesthesia research has a broad appeal, and the cause of these unusual sensations has been of interest to psychologists for the last 200 years. In recent decades, however, the field has experienced a considerable renaissance of interest, and provided a contemporary source of study for scientists across a range of different psychological and neuroscientific disciplines.

Variants of Synesthesia and Phenomenology

Each variant of synesthesia is characterized by the pairing of a particular type of triggering stimulus (known as the 'inducer')

with a particular type of synesthetic experience (known as the 'concurrent') (Table 1). In the pitch–color variant, for example, the inducer and concurrent are musical pitch and colors, respectively. So for pitch–color synesthetes, hearing music at various pitches gives rise to the visual experience of colors. Another particularly common variant is known as sequence–space synesthesia (or visuo-spatial synesthesia) in which sequences such as numbers, letters, days of the week, or months of the year are visualized as occupying particular spatial arrays. Synesthete IB, for example, sees the months of the year as occupying a running-track shape, at chest height in front of the body. Synesthetic forms, colors, and other sensations are experienced either in the 'mind's eye,' or can be projected out into the space around the body. This distinction in the nature of the concurrent has been captured by the terminology of psychologist Mike J. Dixon and his colleagues as 'associator' and 'projector' synesthesia, respectively. Synesthesia has a wide range of different manifestations depending on the particular combination of inducer and concurrent, and at least 50 different manifestations have been recorded to date. The most common synesthetic concurrent is that of color, and this accounts for 95% of all synesthesias found in one recent prevalence study. Nonetheless, synesthetes can experience a range of different sensations, including taste, flavor, odor, texture, shape, touch, sound, and even bodily pain, and many other modalities of sensation have also been reported as concurrents. In lexical–gustatory synesthesia, for example, reading, saying, or even thinking about words triggers accompanying flavor sensations. These sensations are experienced either as similar to veridical flavor (e.g., the word 'jail' tastes of bacon in the mouth) or as an overwhelming association between the inducing word and the food type (e.g., the word 'jail' automatically evokes the notion of bacon). These food experiences are not generic simple tastes of bitter/salty/sweet, etc., but are complex sensations that are rich in detail. Synesthete JG, for example, experiences a complex flavor from the name 'Adrian,' which she describes as the taste of

Table 1 Classifications of synesthesia according to whether subclass definitions are based on the nature of the inducer (triggering stimulus) or the nature of the concurrent (resultant synesthetic sensation)

Inducer	Concurrent
<i>Lower synesthesia</i> : sensations are triggered by low-level, perceptual aspects of the stimulus. For example, for a lowercase letter–color synesthete: the color of <i>a</i> ≠ the color of <i>a</i> (because <i>visual/perceptual</i> properties determine color)	<i>Projector synesthesia</i> : synesthetic experiences are projected out into the world, in locations similar to real-world perceptions. For example, projector letter–color synesthetes might see colors projected onto the written typeface
<i>Higher synesthesia</i> : sensations are triggered by high-order, conceptual aspects of the stimulus. For example, for an uppercase letter–color synesthete: the color of <i>A</i> = the color of <i>a</i> (because <i>conceptual</i> properties determines color)	<i>Associator synesthesia</i> : synesthetic experiences are ‘known,’ or seen ‘in the mind’s eye,’ or in some internal space. For example, associator letter–color synesthetes might see colors only in the ‘mind’s eye.’

lettuce coated with Caesar salad dressing. Like all flavor experiences, synesthetic flavors can also incorporate texture and temperature, so for synesthete JIW, for example, the word ‘jail’ generates the experience of (specifically) cold, hard bacon.

Lexical–gustatory synesthesia demonstrates that the inducer to synesthetic experiences need not be a purely sensory stimulus. Synesthesia can be triggered by words, and indeed, linguistic units are the most common type of inducer. One recent study showed that 88% of synesthesias were triggered by language units such as words and graphemes (i.e., letters and digits). Importantly, it is often the abstract linguistic quality of these language units, rather than their purely sensory features (i.e., how they sound/look) that triggers the synesthesia to arise. One recent study from our lab showed that lexical–gustatory synesthesia, for example, is triggered by the abstract semantic meaning of words, rather than by the sensory features of their sounds and spellings. Together with psychologist Jamie Ward, I demonstrated that words can trigger synesthetic flavors even when the synesthete is in a tip-of-tongue state. Tip-of-tongue state is the familiar experience that we all encounter when we are unable to recall a known word from memory. In our study, we were able to place synesthetes in a tip-of-tongue state by showing them pictures of unusual objects (e.g., a metronome, a platypus). Like all people in a tip-of-tongue state, the synesthetes knew the meaning of these words but were temporarily unable to say their names. Importantly, we found that synesthetes began to taste the word even before they could say it. One synesthete, for example, tasted Dutch chocolate while struggling to retrieve the word ‘phonograph.’ Another felt the sensation of crumbly biscuit while struggling for ‘tambourine.’ The fact that synesthetes could sense their synesthetic flavors even though they could not remember how to pronounce the triggering word suggests that it is the word meaning, and not its sound or spelling that elicits the synesthetic sensation. In turn, this shows that synesthesia is far more than a simple ‘merging of the senses,’ and that its inducers can include complex higher order units of language.

Despite the astonishing range of different synesthetic experiences, all variants appear to share certain key characteristics. Synesthetic sensations are automatic and cannot easily be repressed. One simple demonstration comes in a type of Stroop-type task, in which grapheme–color synesthetes are shown letters in colored font and are simply required to name the color of the font. Synesthetes are particularly poor at this task if font colors clash with their own synesthetic colors. For example, a synesthete would be slow and error

prone when describing a red 7 if their own synesthetic color for 7 is, for instance, green. Hence, although the task requires them to say ‘red’ (the color of the font), they have an implicit notion that 7 should be green. Another key characteristic of synesthesia is the consistency of inducer–concurrent pairings, which tend to remain constant across the synesthete’s lifetime. Hence, when asked to describe their synesthetic experiences (e.g., A = red; B = yellow, etc.) synesthetes are typically close to 100% consistent in retests across many months or even years. In one recent study, we were able to show that the synesthetic associations of one lexical–gustatory (word–taste) synesthete had remained consistent across almost three decades, since they were first recorded in 1979. This trait of consistency has been used to distinguish synesthetes from malingerers, since nonsynesthetes are considerably less consistent in recalling invented associations simply by memory alone. In laboratory tests, nonsynesthetes tend to be only around 20–40% consistent over time, even if they are retested after only a few weeks. In contrast, synesthetes will always report the same experiences, and this is because they are apparently ‘reading off’ these experiences in real time, rather than relying on explicit recall from learned memory.

Although many variants of synesthesia give rise to experiences of sight, sound, smell, taste, and touch, there are also variants that trigger nonsensory concurrents. For example, the variant of synesthesia known as ordinal linguistic personification (OLP; also known as sequence–personality synesthesia) is triggered by archetypal inducers such as letters, numbers, day, and other sequences. The concurrent, however, is not color or taste, or any other sensory phenomenon, but is instead the overwhelming impression of a gender or personality type. For example, an OLP synesthete may not think that the number 7 is green, but rather, that it is a maniacal old man who shouts at his neighbours. Alternatively, they may feel that the letter F is a middle-aged woman who likes to gossip with friends, or that Tuesday is a young man who yearns for adventure, while November is a self-centered empty-headed boy. Such descriptions can be found in scientific reports dating back to the nineteenth century (see section [History of Synesthesia Research](#)), and are remarkably consistent across synesthetes from different centuries and different continents. Hence, the inducers to this type of synesthesia tend to be the linguistic units of ordinal sequences (e.g., letters, numbers, days, months) and these give rise to a range of complex concurrents, including gender (e.g., female), personality (e.g., shy), physical appearance (e.g., thin), occupation (e.g., businessman), cognitive

attributes (e.g., clever), and relationships to other inducers (e.g., A might be the mother of B). Such relationships tend to hold within, but not across, sequences (e.g., A might be the mother of B, but not of 7) and tend to hold only between units that are proximal (e.g., A might be the mother of B, but not of Q).

The OLP variant significantly co-occurs with other types of synesthesia, suggesting again that it is indeed a bona fide manifestation of the condition, with a shared neurological basis. OLP also possesses the key characteristics of synesthesia, being involuntary, highly consistent over time, and automatic. This automaticity can be seen in Stroop-type tasks (see above) where synesthetes are required to ignore their synesthetic sensations for the purpose of the test. One such study in my own lab required an OLP synesthete to ignore her synesthesia, and to simply read names silently from a screen (e.g., Michael, Anna, John, . . .). For every name, she was asked to press a button to indicate whether it represented a male or a female (e.g., John = male). This ostensibly simple task was rather challenging for the synesthetes because each name had been deliberately chosen by us to begin with a letter whose synesthetic gender posed a conflict. For example, although 'John' is a male name, the letter J for this synesthete is female. As a result, the synesthete was far slower and error prone in this task than a group of nonsynesthete controls, simply because she could not ignore her conflicting synesthetic genders.

The OLP variant shows that synesthetic concurrents can involve not just sensory experiences (colors, tastes) but also higher level cognitive features (e.g., personalities), just as variants such as lexical-gustatory synesthesia have shown the same for inducers (which can be either sensory percepts such as sound, or higher level cognitive units such as word meanings). The distinction between low-level sensory triggers and high-level more conceptual triggers has been captured in the terminology of neuroscientists V.S. Ramachandran and Edward Hubbard as lower versus higher synesthesia. This lower/higher distinction can be seen even within variants. Take, for example, grapheme-color synesthesia: synesthetes can experience color from either the low-level visual form of letters (e.g., their curves and intersections) or from their higher level category or class. Hence, lower synesthetes would experience different colors depending on the particular way in which a letter was drawn (uppercase vs. lowercase; italics vs. upright font, etc.), while higher synesthetes would experience the same color across every instance of that letter, irrespective of its visual form (because all of these visual instantiations represent the same category of letter).

Individuals with synesthesia are likely to have more than one variant. Hence a pitch-color synesthete might have different colors not only for the sounds at various pitch but also for different timbres of music (e.g., a sine wave might be overall less saturated in color than a piano tone at the same pitch). Indeed, even rather different types of synesthesia can coexist in the same individual. Synesthete ES, for example, experiences colors in response to both tones and tastes in the mouth, while Synesthete AP has grapheme-color synesthesia, day-color synesthesia, a sequence-space mental number line, and OLP synesthesia, and she also experiences tactile sensations of shape in response to tastes in the mouth (taste-shape synesthesia). Certain patterns have been detected in the clustering of synesthesias within individuals. For example, synesthetes who

experience concurrents of color, but not those who experience taste, are significantly likely to also have sequence-space synesthesia. Such cluster findings are now being verified in very large populations of synesthetes and might speak to the way in which the condition is inherited (see section [Prevalence and Inheritance of Synesthesia](#)).

History of Synesthesia Research

Synesthesia has fascinated psychologists since the earliest days of the nineteenth century, when a young Austrian doctoral student named Georg Sachs published the first case study about this unusual phenomenon. Sachs wrote of his own experiences of 'seeing' colors when hearing music, and when thinking about simple sequences such as numbers, days, and letters. He submitted his findings in Latin in his bound doctoral thesis in 1812, but died shortly after. His work fell into relative obscurity until the twenty-first century, when a revival in synesthesia research over the last 20 years brought about renewed interest in the condition. In that short time, a huge body of work has demonstrated the psychological, neurological, developmental, and genetic basis of synesthesia, and taken Sachs' seminal work in a direction he might never have imagined. At the same time, there has been a revival of interest in historical writings, many of which are surprisingly current. The Swiss psychologist Theodore Flournoy, for example, wrote an extensive book on synesthesia in 1893, which he termed at that time 'Synopsis,' and which describes many examples of the condition which have, in more recent works, been reexamined in great detail (e.g., OLP synesthesia). Another seminal work appeared in *Nature* in 1880, written by the eminent scientist Francis Galton, cousin of Charles Darwin. Galton described the experiences of individuals with 'visualized numbers,' which we now recognize as a type of sequence-space synesthesia. Many of these historical works cluster around the final two decades of the nineteenth century, when early interest in synesthesia was at its height, and scientists such as Flournoy, Galton, and their contemporaries Mary Calkins, W.O. Krohn, Ferdinand Suarez de Mendoza, and others were disseminating information about synesthesia throughout Europe and the United States. Suddenly, however, as quickly as it had arisen, the condition fell out of public consciousness. John Watson's seminal work of 1913 had described a new landscape of psychological study known as Behaviorism, in which there was no place for the investigation of internal experiences such as synesthesia. As a result, there was relative silence in the field of research regarding synesthesia for the next 70 years, until a neurologist named Richard Cytowic began a revival following a chance conversation with his neighbor. Having invited Richard Cytowic for dinner, the neighbor apologized for the lack of 'points' on the chicken, and Cytowic recognized this description of taste-shape correspondences as a variant of synesthesia. Many years of writing and research followed, and others, too, began their own research programs. Two other notable events transformed synesthesia science into the vibrant field it is today. First, a simple behavioral test devised by the Cambridge researcher Simon Baron-Cohen and his colleagues in 1987 allowed researchers for the first time to verify the genuineness of synesthetes' reports, by showing that their

associations (e.g., A = red, B = yellow, etc.) are significantly more consistent over time than those invented by controls trying to 'fake' the condition. Second, and the most significant event, perhaps, was the advent of brain imaging techniques, which have allowed us to see for the first time not only how the brain acts when experiencing synesthesia, but also how the very wiring of the brain permits these extraordinary sensations to be produced. The last 20 years have produced an astonishing set of insights into this condition, and the branches of synesthesia research now provide information regarding synesthetic behavior, genetic inheritance, neurological roots, cultural influences, and developmental path. In this article, I describe the most recent findings on the prevalence of synesthesia and on studies showing the inheritance and genetic roots of the condition.

Prevalence and Inheritance of Synesthesia

Synesthesia was once thought to be extremely rare, although estimates of prevalence have ranged from 1 in 250 000 to 1 in 6. Until recently, the most reliable figure had been based on the response rate from a newspaper advertisement in 1996, which called on synesthetes to come forward for a study in Cambridge, United Kingdom. Twenty-eight synesthetes responded from a circulation figure of 55 000, giving an estimate of prevalence of 1 in 2000. We now know, however, that this was a vastly underestimated figure: for every synesthete who responded, a further 85 did not. Recent studies no longer rely on self-referral, and have shown the true prevalence of synesthesia to be closer to 1 in 23. In two recent studies from our lab, several thousand members of the general population have now been randomly sampled and individually assessed for synesthesia with objective tests of genuineness. These show that synesthesia is present in at least 4% of the population, the majority of which have a small core of subtypes, which are overrepresented among synesthetes. In particular, the most common variants are triggered by linguistic sequences such as days, letters, and numbers, and give rise to synesthetic experiences of color and form. Less common experiences are of flavor, odor, touch, sound, and other sensations (see section [Variants of Synesthesia and Phenomenology](#)).

Early investigations based on self-report such as the advertisement study in Cambridge had suggested that female synesthetes may be six times more common than males, but this again appears to be a fallacy based on self-referral: it is known that women are more likely than men to report their atypical behaviors, which means that women likely dominated in self-reporting, but not in synesthesia, *per se*. Later estimates based on the more reliable random sampling method now show that women and men have synesthesia in almost equal numbers. Nonetheless, it is yet possible that women may slightly outnumber men by a small degree of around 1.5:1. However, sample sizes are, as yet, too small to confirm this bias statistically. Other sex differences might also be found in the study of familial transmission patterns, which appear to show a rarity of father-to-son transmission. In other words, while women with synesthesia have both sons and daughters with the condition, fathers are followed most often by synesthesia in the daughter only. This particular pattern of transmission led researchers to suspect a genetic influence with a dominant,

possibly X-linked, mode of inheritance. However, a whole-genome scan and fine-mapping linkage study has now revealed evidence of linkage only to chromosomes 2q24, 5q33, 6p12, and 12p12. In other words, this study, at least, found no support for a role of the X chromosome, and may indeed have provided the first documented cases of male-to-male transmission. Nonetheless, no explanation has yet been given for the comparative scarcity of male-to-male inheritance, and the possibility remains that the apparent male-to-male cases reported in this study in fact involve synesthesia passing through the mother's line without her having expressed the trait. Nonetheless, this discovery of genetic inheritance is a pivotal moment in synesthesia research, and has added enormously to our understanding of this condition.

Despite the genetic influences in synesthesia, the condition also involves a component of learning. First, and most obviously, many of the triggers for synesthesia are learned cultural symbols, such as letters and words. This suggests that some predisposition for synesthesia must necessarily interact with stages in development during literacy acquisition (see section [Neurological and Developmental Roots of Synesthesia](#)). More subtly, however, the learning component of synesthesia can be seen when considering data from very large groups of participants. It had been thought for some time that synesthetic sensations were highly idiosyncratic, since synesthetes often disagreed on their synesthetic pairings (e.g., A might be red for one synesthete but green for another). However, when very large numbers of synesthetes were compared in 2005, systematic patterns emerged to suggest more similarities than differences. For example, although the letter A can be any color, it is significantly likely to be red. B is likely to be blue, L is likely to be yellow, and so on. These shared preferences stem from shared subconscious 'rules' that each synesthete is following, even without awareness. For example, high frequency letters are significantly likely to be paired with high frequency color terms, and with more saturated and luminant colors. Hence, A is likely to be vibrant red, while V is likely to be a pale purple. Since grapheme–frequency is a learned feature of language arising from exposure to a language environment, its role in dictating synesthetes' colors again illustrates the place of learning in synesthetic development. Moreover, learning can be seen in other variants also. For example, the personality types found as concurrents in OLP synesthesia tend to reflect the society that was contemporary to the report. Older studies mention 'society girls' and 'housekeepers,' while these historical character types tend not to be found in modern accounts. Again, therefore, learning and experience appear to influence the synesthetic sensation.

One final point to note about the inheritance of synesthesia is that its transmission is not tied to any particular variant. For example, a mother who sees colors with letters can give birth to a son who tastes words. This suggests that heritability governs the predisposition for synesthetic cross-talk in a very general sense (see section [Neurological and Developmental Roots of Synesthesia](#)). Nonetheless, recent studies appear to suggest that certain variants of synesthesia may cluster together, at least within individuals (and so possibly also within families). This suggests, in turn, that synesthesia may not be a single heritable trait, but rather that it might be a grouping of several different cluster phenomena, each one underpinned by its own genetic

code. Very large-scale studies of synesthesia clustering, such as those being carried out by David Eagleman and colleagues via the online forum synesthete.org might hope to shed light on the subclasses and inheritance of synesthesia.

Neurological and Developmental Roots of Synesthesia

Synesthesia has a genetic mode of inheritance, and this inheritance is assumed to give rise to a predisposition for increased cortical communication. The roots of this communication may be functional or structural, in that the synesthete brain may have, respectively, extra connections that are not present in nonsynesthetes, or a disinhibition of the normal connections found in all people. One argument in favor of the latter is that certain hallucinogens such as lysergic acid diethylamide (LSD) can trigger a temporary state of synesthesia. The rapid onset of such experiences after consumption might appear to argue against a structural account of extra connections, simply because the time frame would not allow for the growth of new pathways (but might fit with the unmasking of existing ones). Nonetheless, the type of 'synesthesia' triggered by drug use is very different from developmental synesthesia in that it is temporary, inconsistent, and low-level (i.e., simple sensory crossings between sound and vision, for example, but not the complex, discrete experiences of grapheme-color synesthesia, etc.). This suggests, in turn, that mechanisms are likely to be different between developmental and acquired variants.

In contrast, there has been direct empirical evidence for structural differences in the brain of synesthetes. Neuroscientists Romke Rouw and Steven Scholte used diffusion tensor imaging (DTI) to examine the brains of grapheme-color synesthetes and controls. DTI provides an indication of the brain's white matter connectivity, by tracking the movement of water molecules (since this movement is more restricted in areas of high connectivity). Rouw and Scholte found that the brains of grapheme-color synesthetes contained greater structural connectivity in several areas, including regions close to V4, an area of the cortex known to be involved in color processing. The degree of this extra connectivity correlated with the strength of the synesthetic experience, since projector synesthetes (who experience strong synesthetic colors projected into space) had greater connectivity than associator synesthetes (who experience colors only in their mind's eye). This finding is consistent with studies using functional magnetic resonance imaging (fMRI), which indicates the degree of blood flow in the brain and demonstrates which brain regions are engaged during specific tasks. Neuroscientist Julia Nunn and her colleagues were the first to use fMRI to show that synesthetes' brains behave differently to controls when exposed to stimuli that can induce synesthesia. For example, various fMRI studies now show that area V4 is activated when synesthetes see graphemes or words. Studies show activation, too, in parietal areas, which may be involved as the synesthete brain 'binds' together the inducer and concurrent. Other studies have also suggested activation in frontal regions, although the role of such areas in synesthesia is, as yet, poorly understood.

If the gene mutation associated with synesthesia causes extra connectivity in the adult brain, how might this hyperconnected state develop? Daphne Maurer and colleagues have proposed the neonatal synesthesia hypothesis, suggesting that the adult

state of synesthesia bears a close resemblance to the infant state in all people. All humans are known to be born with excess connectivity, which is pruned over time by the normal process of cell death known as apoptosis. Maurer and colleagues suggested that synesthesia may represent a failure in this apoptosis, leading to a highly connected adult brain in synesthetes. However, their elegant theory remains, on the whole, untested in a neuroscientific sense, simply because neuroimaging techniques and testing environments have not yet allowed us to easily track the developing brains of child synesthetes. The question of synesthesia's development had also been underaddressed in behavioral work. The reasons for this are likely to stem from the difficulty in finding and recruiting child synesthetes. Some studies have achieved this by gathering self-referred samples via contacts with adult synesthetes whose children also have synesthesia. However, this approach may lead to biased samples, whose characteristics are not representative of child synesthetes as a whole. First, such children come from families with highly motivated parents (i.e., they are motivated enough to have contacted researchers) and from families where the synesthesia is known and so is likely discussed in family environments. It is likely that synesthesia may develop differently in such circumstances, being perhaps highly reinforced, or influenced by the experiences of other family members (e.g., young children may adapt their colored letters to resemble those of their parents, if these are discussed from an early age).

For all these reasons, my own lab initiated a research project 4 years ago, which aimed to find an 'untainted' sample of child synesthetes and to track their development over time. To this end, we individually tested over 600 children aged 6–7 years, to first identify the synesthetes among them, and then to track the real-time development of these synesthetes in comparison to the development of their nonsynesthete peers. Our longitudinal approach has allowed us to demonstrate, in a very real sense, that synesthesia 'grows' over time. Hence, although adult synesthesia is characterized by a fixed pattern of unchanging paired associations (e.g., if A is red for any given synesthete, it is always red) we were able to show that this systematicity is an acquired trait, with a protracted development. For example, the average child synesthete at the age of 6.5 years has only around 30% of fixed colors for the letters of the alphabet and digits 0–9. Twelve months later, at the age of 7.5 years, this has grown to around 55%. We have now returned to these children aged 10.5 years and seen, once again, a more stable system than was previously found. Perhaps the most remarkable finding for us was that grapheme-color synesthesia was present and visible (to the trained eye) in children as young as 6 years, who had only very recently begun recognizing the letters of the alphabet. This suggests to us that the predisposition for synesthetic mapping is very quickly 'called into action' whenever the necessary environmental stimuli are encountered.

Costs and Benefits of Synesthesia

Synesthetes often take pleasure in their synesthetic sensations, and many profit from them in artistic pursuits. It has been demonstrated that there is a significant tendency for synesthetes to spend time engaged in the creative arts, especially as these

relate to their synesthesia. For example, synesthetes who see colors from music are more likely than the average person to play a musical instrument. Synesthetes also score higher than nonsynesthetes in certain tests of creativity. For example, when people are asked to provide a missing link between word triplets such as elephant – lapse – vivid (answer: memory), synesthetes score significantly higher than the average person. Indeed, a growing body of evidence suggests that synesthesia may give superior abilities in a range of cognitive and perceptual tasks. Grapheme–color synesthetes, for example, have better skills in color awareness than the average person; they can better differentiate between subtle shades of color and can better recall test colors from memory when asked whether these colors were the same or different to colors seen previously. Some grapheme–color synesthetes (perhaps those with strong projector-type experiences) are able to detect hidden patterns in visual ‘pop-out’ studies: Ramachandran and Hubbard (2001) showed that their synesthete JS was able to detect a matrix of Hs forming a triangle shape, embedded in a background of distractor letters (Fs and Ps). This is a difficult task for nonsynesthetes because the black graphemes are perceptually similar and the triangle formed by the matrix of Hs is ‘lost’ in its background (see Figure 1). For synesthete JS, however, the Hs were seen as green, which made the triangle shape stand out among the distractor letters (which were yellow and red). Other variants of synesthesia, too, come with advantages. Sequence–space synesthetes who experience mental time lines are significantly better than the average person in dating events that took place in the past. In one study from our lab, a group

of these synesthetes were shown 120 world events of international news (e.g., the release of Nelson Mandela) and cultural significance (e.g., ‘The Godfather’ wins Oscar for best film) and were asked to write the date that each event occurred. The average person is around 8 years, on average, away from the correct date for each event, while synesthetes were only 4 years away. Synesthetes were also better than the average person when recalling events that had taken place within their own life. When asked to recall autobiographical facts from nine different years (e.g., 1984; 1997) the average person recalled on average 39 facts in 9 min, while the average synesthete recalled over 70 facts. Hence in both public and autobiographical memory recall, synesthetes outperform their peers.

It has been important to rule out motivational biases in any study where synesthetes perform exceptionally well. It has been suggested that as synesthetes are recruited as a special population, they may simply try harder. For this reason, studies claiming benefits for synesthetes also provide ‘control’ evidence that the same set of synesthetes also scores normally in tests where no exceptional abilities are predicted. For example, synesthetes with mental time lines might be expected to perform well on tests of event recall, but not, for instance, on tests of reading words. This is indeed the pattern of results found. Synesthetes might also be expected to perform well on visual imagery tests (given that their mental time lines are a form of mental imagery) and, as predicted, they do indeed perform well in this domain. Grapheme–color synesthetes have also shown enhanced visual imagery skills, as well as better memories when recalling lists of digits. The latter is likely because they are able to use their color associations to provide an aid to recall. For example, when recalling a list of digits, the synesthete might remember that the digits appeared in a sequence that was red, blue, green, yellow, etc., and be able to recall those digits on the basis of their color.

It is unclear whether this ability of grapheme–color synesthetes for enhanced digit recall extends to all grapheme–color synesthetes, or just to those who have learned to somehow profit from their sensations. Indeed, it has been suggested that an extreme ability to profit from synesthetic experiences may be at the root of the Savant syndrome. Savants are individuals with a developmental disorder (often autism spectrum disorder; ASD) who have a high ability in one area that sharply contrasts with their overall limitations. This ability is sometimes so refined that it would be considered phenomenal or genius even in a person without cognitive disabilities. Prodigious savants can recall, for example, sequences of more than 20 000 digits, or can remember exactly what they were doing in great detail on every day of their life extending back to early childhood. Research suggests that savantism may arise from the coincidental co-occurrence of synesthesia and ASD (or other neurodevelopmental disorders tied to obsessive traits). The synesthesia would give a predisposition for elevated memory recall, while the obsessive traits tied to ASD may create a compulsive drive to rehearse these skills. Over time, the savant ability would emerge. Evidence comes from the study of savants, many of whom do indeed have synesthesia and describe using their synesthesia to perform their phenomenal memory feats. For example, Daniel Tammet, a savant with phenomenal digit recall abilities, who has written an autobiography about his experiences, describes using his synesthesia

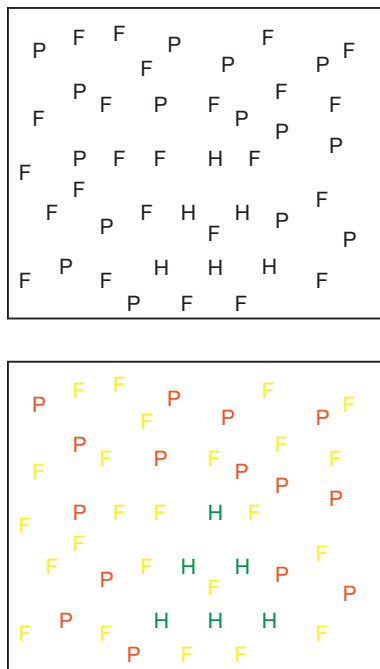

Figure 1 Top: A matrix of Hs forming a triangle shape embedded in a background of distractors (Ps and Fs). Controls find it difficult to identify the geometric shape. Synesthete JS is able to easily spot the triangle because for him Hs are seen as green, while background is red (P) and yellow (F). Below: The same matrix shown in the color associations of synesthete JS.

to create a 'number landscape.' Each digit has its own color, texture, and height, and these digits combine to create a visual landscape that can be mentally navigated when he recalls astonishingly long strings of digits.

Synesthesia, then, clearly provides the opportunity for cognitive and creative benefit; the extent to which it can be exploited differs from individual to individual. However, synesthesia is a multivariant condition, and in some cases, can present certain obstacles to the synesthete, as well as benefits. Indeed, synesthesia has a complex profile of benefits and costs, which manifest differently depending on the particular variant. For example, despite the assets described above for sequence-space synesthetes with time lines, those with number lines are slightly slower than the average person when performing certain types of mental calculation. It is known that subtraction and addition rely to some extent on spatial memory, while multiplication relies more heavily on verbal recall. Sequence-space synesthetes may over-rely on spatial memory, and so are slightly slower than the average person on multiplication tasks, but show no difference in addition or subtraction.

As another potential cost, lexical-gustatory synesthetes (who experience tastes from words) report significant problems maintaining attention when performing day-to-day tasks such as reading and speaking. This can pose problems in the workplace and in social environments, and indeed, in any place where words are exchanged. This is because every word uttered can trigger an overwhelming sensation of flavor that floods the mouth. Some of these tastes are pleasant (e.g., chocolate) but can arrive in such intensity that they distract attention. Other tastes are inherently unpleasant (e.g., mucous, earwax) and can make conversation an extremely challenging task. Other synesthetes show different types of difficulties. Grapheme-color synesthetes exhibit poor memory for letters and numbers presented in colors that conflict with their synesthetic sensations. For example, when asked to recall the numbers 5, 8, 2, and 6 presented in red, purple, orange, and green ink, respectively, a synesthete may show poorer abilities than the average person if their own synesthetic colors are, (for example) yellow, white, blue, and pink. This conflict between real-world colors and synesthetic colors not only impairs memory but can also cause a sense of malaise. Synesthetes report discomfort when viewing colored letters and numbers that clash with their own synesthetic sensations and this fact might have important implications on the ways in which synesthete children are taught at school. Many classrooms have colored alphabet charts, and some literacy systems are based on the careful pairing of colors with letters. For children with synesthesia, this approach could pose a significant challenge to learning.

Concluding Remarks

After falling into relative obscurity during the mid-twentieth century, synesthesia research has emerged again as a vibrant field of study, and psychological, biological, and neuroscientific investigations over the last 20 years have shed light on the roots of this unusual condition. Imaging studies have shown how the brain functions when experiencing synesthetic sensations, and how these sensations arise from the very structure of the synesthetic brain. Genetics studies have traced its roots in

the human genome, and familial inheritance studies have mapped its transmission through families. Cognitive psychological studies have uncovered a rich world of complex 'rules' governing the types of experiences generated by synesthesia, and developmental studies have been able to track the emergence of synesthesia in real time. Synesthesia is a condition of unique interest to a broad range of scholars, from neuroscientists, psychologists, philosophers, linguists, etc., to anyone wishing to understand the relationship between inner experience and the outside world. The experiential 'reality' of synesthetic tastes, textures, colors, odors, flavors, shapes, and other sensations experienced by synesthetes allows us to see, in a very direct way, that our understanding of the outside world is greatly reliant on internal mental processes, and can be idiosyncratically constructed. Moreover, synesthesia's blending of sensory experiences with cognitive constructs has forced a redefinition beyond a simple 'merging of the senses,' and has allowed us to better recognize the interplay between perceptual and nonperceptual systems.

Glossary

Ambiguity The property of having more than one meaning.

Anaphor A linguistic expression entirely dependent on another linguistic expression for its interpretation: for example, *himself* in 'John injured himself' is dependent upon *John*.

Argument Semantically contentful expression in an argument position.

Argument position Subject position, direct object position, indirect object position, etc. in a sentence.

Embedding The process of inserting one phrase or sentence inside another.

Grammar A theory of a language.

Language A computational system enumerating, for each of an infinite set of expressions, a full array of phonetic, semantic, and structural properties.

Parameter A two (or more) valued choice determining a general property distinguishing one type of human language from another.

Principle A property common to all human languages.

Syntax is concerned with the structural properties of languages. The term 'syntax' is used ambiguously to refer to both the structural properties and the branch of the field of linguistics concerned with investigating them. Included in this topic are the regularities governing word order as well as the grouping of words into larger units relevant to semantic and phonological interpretation. How these regularities are represented in the mind of the speaker, how they arise in the mind of the speaker, and how they are put to use in the production and comprehension of sentences are the psychological aspects of these issues.

Phrase Structure

A person who knows a language knows a huge number of words, including properties relevant to their pronunciation and semantic interpretation. In addition to this 'lexicon,' he or she has command of a productive system for the appropriate arrangement of words into sentences, the syntax of the language. Given the fact that brand new sentences are routinely used and understood, it could not be true that the syntax of a language consisted merely of a list of sentences which are memorized in the course of language acquisition. Rather, a set of processes, syntactic rules, must be involved in this creative use of language.

The computational system including these syntactic rules determines mental representations expressing not only the sequencing of words, but also their grouping into hierarchical structural units intermediate between word and sentence. Even a simple sentence such as (1) is not just a sequence of three autonomous words:

(1) The man left

The and *man* are closely associated in a way in which *man* and *left* are not. The former pair of words constitutes a unit based on the noun *man*. We can see this in a number of ways. First, that sequence can be substituted for by a 'pro-form,' in this case a pronoun:

(2) He left

No comparable substitution is possible for the sequence *man left* in example (1). Further, an adverb modifying the sentence can be inserted between *man* and *left*, as in (3), but not between *the* and *man*, as in (4):

(3) The man obviously left

(4) *The obviously man left (* indicates an ungrammatical sentence, a sequence of words that is not a sentence of the language under investigation)

This same structural grouping is evidenced in the phonology. A longer pause is possible between *man* and *left* than between *the* and *man*, again indicating that the sequence *the man* constitutes a unit while the sequence *man left* does not. There is a division of sentence (1) into two major parts, or 'constituents.' The first constituent, based on a noun, is called a 'noun phrase' (NP). The second constituent, based on a verb, is called a 'verb phrase' (VP). A typical English sentence like (1) consists of an NP followed by a VP, roughly corresponding to the traditional division of a sentence into subject and predicate. (5), a 'phrase structure (PS) rule,' is a shorthand way of stating this property of English sentences in a 'top-down' fashion:

(5) S[entence] → NP VP

A simple NP, in turn, consists of a noun (N) preceded by a 'determiner' (*the*, *a*, etc.) or not ('John left'), and a VP consists of just a verb (V), among many other possibilities:

(6) a NP → (Det) N (parentheses indicate an item that may or may not be present)

b VP → V

c V → left, etc.

d N → man, etc.

e Det → the, etc.

These can be thought of as part of the system of implicit knowledge underlying the procedures for the analysis and for the production of sentences. (This knowledge can also be characterized in a 'bottom-up' fashion taking lexical items as input, with, e.g., a determiner and noun merging to form an

NP, this NP merging with a V to form a VP, and so on. This ultimately eliminates PS rules, as in much current work in syntax.) The structure that the rules in (5) and (6) determine for sentence (1) can be represented by the 'phrase structure tree' in (7):

Such a diagram represents the linear and hierarchical properties of the sentence. Two standard relations defined on such structures are 'precedence' and 'dominance.' In (7), NP precedes VP, V, and *left*, but does not precede Det, *the*, N, S, etc. NP dominates Det, N, *the*, and *man*, but does not dominate VP, V, S, etc. Another way of representing precisely the same information is the 'labeled bracketing' in (8):

(8) [_S [_{NP} [_{Det} The][_N man]] [_{VP} [_V left]]]

Phrase structure trees and labeled bracketing representations are both widely used in the syntax literature. A structural representation (in either format) is called a 'phrase marker.'

In addition to very simple VPs containing only a verb and nothing else, there are also VPs that contain NPs, as in (9):

(9) The man saw the woman

(10) allows for this additional possibility of a 'direct object' for the verb:

(10) $VP \rightarrow V(NP)$

As in (6a), the parentheses are to be understood as allowing, but not demanding that the enclosed material occur in a structure. Taken together, (5) and (10) correctly assert that just the same kinds of sequences of words that can be subjects of sentences can be objects of sentences because it is the constituent NP that occurs in either position.

Constituent structure analysis provides part of an account of the creative use of language. There is no limit to how long a sentence of English (or any other human language) can be. Thus, given a sentence of any length, a speaker can always create a longer, novel one. Infinitude and structure are two 'principles,' properties common to all human languages. One of the major ways in which ever longer sentences can be constructed is by 'embedding' one sentence inside another. We have already seen a VP consisting of just a V and also one consisting of a V followed by an NP. In addition to these possibilities, the material following the V can be an entire sentence:

(11) The child thinks [_S the man left]

In (11), the 'direct object' of the verb is not an NP but rather is our original sentence, (1). The structure of (11) is represented in (12):

An additional VP rule of the standard sort allows for this possibility:

(13) $VP \rightarrow V S$

Now the structure in (12) can be produced by application of rule (5) followed by, among other things, application of rule (13), followed by another application of rule (5). Then, the usual rules for NP and VP can apply. This process can be continued indefinitely, with rule (13) introducing an S which, by rule (5), introduces (in addition to another NP) another VP, and so on. Systems of phrase structure with this property are called 'recursive.' It is important to note that with the addition of the simplest possible rule for generating structure (12), namely rule (13), the system of rules (the 'grammar') becomes recursive. Thus, with just the rules we already have, (12) can be further embedded to produce a still more complex sentence such as (14).

(14) The woman knows the child thinks the man left

The structure of (14) is as in (15):

Recursion thus provides finite means for generating an unlimited number of sentences. Given the interpretation of syntactic rules as pieces of a speaker's knowledge, this is crucial, in light of the finite character of the human brain.

The VP structures considered so far all contain a V. Similarly, the NP structures contain an N. The hypothesis that this is true more generally – that XP always contains X, for any choice of X (both for all structures of English and cross-linguistically) – is one of a complementary pair of fundamental tenets of what is called 'X-bar theory.' The name derives from a particular notation used for phrase structure rules, as in (16), where the lexical category symbol has a bar over it to represent a structure intermediate between lexical item and phrase:

- (16) a $\bar{X} \rightarrow \dots X \dots$
 b $XP \rightarrow \dots \bar{X} \dots$

By (16), XP always ultimately introduces X into a structure. The complementary claim is that whenever XP is present in a structure, it must be by virtue of (16). XP must have as its 'head' X, and X must 'project' the phrasal category XP. The merge operation briefly discussed above embodies the notion of projection. (In what follows, I will generally abstract from \bar{X} structural details.)

The Lexicon

As noted earlier, VPs occur in a variety of forms (though all of them contain V). We have observed VPs containing just a V, ones containing a V and an NP, and finally, ones containing a V and an S. Examples (17)–(19), repeated from above, illustrate these three respective types of VP.

- (17) The man left
 (18) The man solved the problem
 (19) The child thinks the man left

Left unexpressed so far, however, is the fact that not just any verb can appear in any of these VP types. For example, the verb in (18) would be ungrammatical in the VP of (17):

- (20) *The man solved

Similarly, the verb in (19) is incompatible with the VP in (18):

- (21) *The child thinks the problem

Lexical properties, that is, properties of particular lexical items (words), thus play a major role in determining syntactic well-formedness. In traditional terms, there are transitive verbs, such as *solve*, which require a direct object. Alongside these are intransitive verbs, such as *sleep*, which do not tolerate a direct object:

- (22) *Harry slept the bed

Further, among the transitive verbs, there are those like *solve* which take an NP, but not an S, for a direct object:

- (23) *Mary solved Bill left

And, as just noted, there are those like *think*, which take an S, but not an NP, as direct object. The large lexical category V is thus divided into smaller lexical 'subcategories,' each with its own special privileges of occurrence. The properties of the subcategories are expressed in 'subcategorization frames' such as the following:

- (24) a $\text{sleep} \langle __\rangle$
 b $\text{solve} \langle __\text{NP} \rangle$
 c $\text{think} \langle __\text{S} \rangle$

The categories that appear in the subcategorization frame of a particular verb are called 'complements' of that verb. (24a) is to be interpreted as the requirement that *sleep* can occur only in a \bar{V} that has no complements for the head V, that is, one like (25).

- (25)
$$\begin{array}{c} \bar{V} \\ | \\ V \end{array}$$

A verb with the subcategorization frame in (24b) can only occur in such a \bar{V} as (26).

- (26)
$$\begin{array}{cc} & \bar{V} \\ & / \quad \backslash \\ V & \quad \text{NP} \end{array}$$

And so on. These syntactic properties of verbs follow, in large measure, from their semantic properties. Thus, in a sentence with *solve*, the verb has a semantic function for a direct object to fulfill, while there is no such function in the case of *sleep*. These semantic functions that arguments (direct objects, subjects, indirect objects, etc.) fulfill are called 'thematic (θ -)roles' and are assigned by a predicate to its arguments. It is thus plausible that what is wrong with (20) is that a necessary semantic function has not been fulfilled – a θ -role associated with the verb *solve* has not been assigned. Conversely, the violation in (22) is that there is an argument NP, *the bed*, with no θ -role at all because *sleep* has no θ -role to assign to an object, just one to assign to a subject. These paired requirements on assigners and recipients of theta roles are called the ' θ -Criterion': Every θ -role must be assigned, and every argument must receive a θ -role.

Example (27) illustrates several additional subcategories of verbs. The corresponding subcategorization frames are given in (28):

- (27) a Susan put the book on the desk
 b Oscar convinced Harriet that she was brilliant
 c Richard envies Marie her intelligence
 d Stephen looked at the picture

- (28) a $\text{put} \langle __\text{NP PP} \rangle$
 b $\text{convince} \langle __\text{NP S} \rangle$
 c $\text{envy} \langle __\text{NP NP} \rangle$
 d $\text{look} \langle __\text{PP} \rangle$

As expected, given the \bar{X} schema for phrase structure, other lexical heads besides verbs can also take complements. For example, there often occur pairs of verbs and nouns with similar structure, meaning, and subcategorization, as in the following:

- (29) a John believes that Mary saw Fred
 b John's belief that Mary saw Fred

- (30) a Marion lectured about semantics
 b Marion's lecture about semantics

The nouns in the (b) examples are known as 'derived' or 'deverbal' nominals.

In all of the examples in (24) and (28), the head precedes its complement(s). In fact, that is more generally true in English: heads invariably precede their complements in basic 'unmarked' word order; verbs precede their objects, as do prepositions, etc. This property should thus be factored out of particular lexical entries because a lexical entry contains only what is idiosyncratic about individual lexical

items. However, the property does not hold of all languages. Japanese, for example, is just the reverse of English in this regard: heads invariably *follow* their complements; verbs follow their objects, there are postpositions instead of prepositions, etc. Simple, general differences of this type between languages are called 'parameters.' This particular parameter is known as the 'head parameter,' and it is assumed to be two-valued: a language is head-initial (English) or head-final (Japanese). Learning this structural property of a language involves setting the value of the parameter, on the basis of simple input data.

Syntactic Transformations

The phrase structure rules (arguably reduced to the \bar{X} template plus a specification of a value for the head parameter) along with the lexicon constitute the 'base component' of the syntax. The base component determines the structural representations of an unlimited number of sentences. However, there are sentence types requiring further machinery for an adequate characterization:

- (31) a Which problem did John solve
b This problem, John solved (... but not that one)

Solve belongs to the subcategory of verbs that can occur only in VPs of the form (26) because they have an object θ -role that they must assign. Yet the examples in (31), which both apparently violate this requirement, are grammatical. The key is that in these examples, although *this problem*, or *which problem*, is at the front of the sentence, it functions as the object of *solve* just as if it were in the VP. Considerations of this sort lead to the hypothesis that sentences have not just one structural representation, but (at least) two. For the examples in (31), the PF (Phonetic Form) representation, the more 'superficial' one, determines the pronunciation of the sentence. Another more 'abstract' representation determines the thematic relations of the sentence, and is thus responsible for the satisfaction of subcategorization requirements. In this more abstract representation, the so-called 'D (eep)-structure' of the sentence, the understood direct object will actually be in direct object position in the VP. In the more superficial representation, the so-called 'S(urface)-structure,' the direct object NP is displaced leftwards from the position that determines its θ -role. The D-structure of (31b) is then (32):

- (32) (D-structure of (31b))

Structure (32) accounts for the major θ -relations of (31b), and is consistent with all of the principles and lexical requirements considered so far. It does not, however, account for the structure of the sentence as it is immediately perceived. Rather, the S-structure, in which the direct object has been displaced to the front of the sentence, as in (33), has that function:

- (33) (S-structure of (31b))

A displacement operation of this sort, relating one phrase marker to another, is known as a syntactic 'transformation' (hence, the name 'transformational grammar' for this general approach to syntax). The set of transformations in a given language constitutes the 'transformational component' of the grammar. Schematically, the grammar has the following organization (to be slightly revised below):

- (34) Lexicon – D-structure – Determination of θ -relations

The transformation which relates (32–33) is standardly called 'Topicalization.' (The transformations responsible for (31a) include 'WH-movement'.) The mode of attachment of the fronted NP to the S in (33) is 'adjunction,' a transformational process attaching a moved item (in this case, an NP) to a target category (in this case an S) by creating a 'higher' instance of the target category from which both the moved item and the original target category hang. Example (33) displays left adjunction (i.e., attachment on the left) of NP to S. The structural representation in (33) captures one striking phonological property of sentence (31b): there is a major pause between the fronted NP and the remainder of the sentence, corresponding to the major constituent break created between that NP and the residual S.

Trace Theory

A potential question concerning the position from which movement takes place arises. (33) indicates that that position is totally eliminated by the operation of the transformation, but work begun in the 1970s indicates that a marker of

the previous occupant remains, in the form of a 'trace.' Example (35) represents this second possibility (which is known as 'trace theory'), with *t* a silent trace of the moved NP, *this problem*:

(35) (S-structure of (31b) with a trace)

The arguments for traces are based, among other things, on properties of a particular contraction phenomenon in English and on the patterns of subject-verb agreement, whereby the form of a verb depends on the properties of the subject of that verb ('He *comes*' but 'They *come*'). Three facts are relevant background for the former argument. First, the Topicalization transformation is not limited to direct objects of simple sentences. The displaced item can come from an embedded sentence, as in (36), where the topicalized NP is the direct object of the lower verb, or (37) where it is the subject of the lower verb.

- (36) This problem [_S Mary thinks [_S John solved *t*]]
 (37) This student [_S Mary thinks [_S *t* solved this problem]]

Second, an embedded sentence need not be 'finite,' with a verb in the past tense (like *solved*), or the present tense (like *thinks*). An embedded sentence can also be 'infinitival,' as in (38):

- (38) You want [_S this student to solve this problem]

Third, colloquial English has a contraction process by which *want* and *to* become *wanna* when they are immediately adjacent:

- (39) a You want to solve this problem
 b You wanna solve this problem

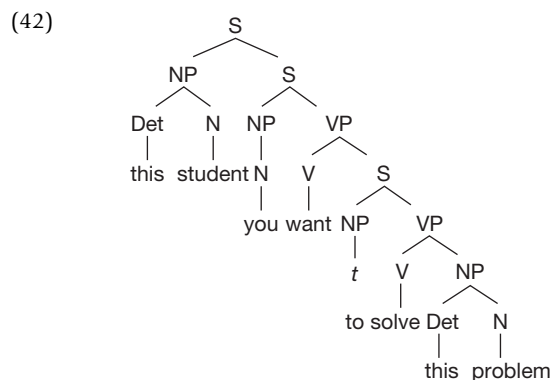

That this process demands adjacency between *want* and *to* is shown by the impossibility of (40), based on (38):

- (40) *You wanna this student solve this problem

The relevant (and surprising) property of *wanna* contraction is that even if *this student* in (38) is displaced by Topicalization, contraction is still blocked:

- (41) a This student, you want to solve this problem
 b *This student, you wanna solve this problem

Though there does not seem to be anything intervening between *want* and *to* in (41a), hence, nothing to prevent contraction, under trace theory, there is, in fact, something intervening – the trace of the moved NP, *this student*. (42) represents this hypothesis:

The same array of facts obtains with WH-movement:

- (43) Which student do you want to solve this problem?
 (44) *Which student do you wanna solve this problem?

Again, the trace of the moved phrase blocks the adjacency needed for contraction. Even though they are silent, traces are evidently real, as far as the syntax and/or phonology are concerned. One question remains, though. The θ -Criterion requires that even in (39b), where contraction succeeds, the lower clause must have a subject. Somehow, the trace is visible to the contraction process, but the silent subject in (39b) (standardly called PRO) is not. One traditional account posited that in the latter instance, the subject is simply deleted and therefore completely removed from the representation.

Properties of subject-verb agreement provide a second source of evidence for traces. Generally, such agreement is a strictly local process, relating elements within the same S, for example, *they* with *think*, and *he* with *likes* in (45):

- (45) *They think* [_S *he likes* psychology]

Agreement with a more distant NP is impossible:

- (46) **They think* [_S *he like* psychology]

However, when Topicalization or WH-movement has taken place from the subject position of an embedded finite sentence, apparent long distance agreement obtains:

- (47) *This student*, they think [_S *likes*/*like it]
 (48) *Which student* do they think [_S *likes*/*like it]

This dependency between a moved NP and a distant verb can be reduced to standard local agreement on the assumption that movement leaves a trace, and that the trace of a moved NP has the same agreement features (for person and number) as the moved NP. This is illustrated in (49):

- (49) *Which student* do they think [_S *t likes*/*like it]
 3rd person 3rd person
 singular singular

Constraints on Transformations

As just seen, the Topicalization transformation can move an NP to the front of its own sentence as in (31b), and can also move an NP out of its own sentence to the front of the next

'higher' sentence as in (36), (37), (41a). In fact, an NP can move still farther, as in (50):

- (50) This problem, Mary thinks John said Susan solved *t*

Similarly for WH-movement:

- (51) Which problem does Mary think John said Susan solved *t*?

In fact, movement can be indefinitely far. However, there are certain 'locality' constraints on the operation of these transformations. Consider sentence (52):

- (52) I like this magazine and that book

In this example, the object NP is a 'coordinate structure' consisting of two NPs joined by the coordinating conjunction *and*. But while (53) is a good instance of Topicalization, (54) is entirely ungrammatical:

- (53) This magazine and that book, I like
(54) *That book, I like this magazine and

As (54) illustrates, extraction out of a coordinate structure is prohibited. This is schematized in (55):

(56) is another illustration of the general prohibition:

- (56) *This magazine [_S I think [_S [that book and *t*] impressed Fred]]

Examples (54) and (56) raise in a very clear manner the general question of acquisition of complex knowledge, particularly knowledge of the negative sort. It is not plausible that the child learning English is presented with evidence for the constraint (e.g., via correction). Thus, it is reasonable to conjecture that the relevant bit of linguistic knowledge is innate. If that conjecture is correct, we should expect the constraint not to be particular to English, since, as is well known, any normal human child can learn any human language. Hence, we should expect the constraint to show up in human languages in general. This expectation is confirmed. Of the hundreds of languages that have been investigated, no clear instances have emerged of languages that permit extraction out of a coordinate structure.

Coordinate structures fall into the class of 'islands' (or, as they are sometimes called, 'barriers'), structural configurations blocking extraction. 'Complex NPs,' such as the noun complement constructions of the type seen in (29b) above, also constitute islands, as evidenced by the following contrast:

- (57) Which problem did you announce [_β that John believed [that Mary solved *t*]]
(58) *Which problem did you announce [_β John's belief [that Mary solved *t*]]

When β is a sentence containing another sentence, extraction from the more embedded S is possible (57). But when β is an NP containing an S, such extraction is not allowed (58), a typical island effect. There have been a number of attempts to reduce the entire class of island constraints to one general locality condition on movement known as 'Subjacency.' The term is a 'portmanteau word' combining 'subordinate' and 'adjacency.' Subjacency stipulates that a step of movement can cross at most one 'bounding node' or 'barrier'; from a subordinate domain to the immediately adjacent superordinate one. (Apparent, unbounded movement is then compounded of a series of short movements.) If Subjacency and other general constraints on the operation and output of transformations are factored out of particular transformations, the statements of these particular transformations are correspondingly simplified. In fact, it has been argued that the transformational component can be reduced to one maximally simple, general transformation, 'Move α ' (Move anything anywhere), with all ungrammatical derivations 'filtered out' by such constraints.

Case Theory

WH-movement and Topicalization both have the effect of moving a constituent to a 'non-A(argument) position' to the left of the subject of an S. There are other movement operations that move a constituent into the subject position, an 'A-position.' Consider the following pair of sentences:

- (59) It seems Harry knows the answer
(60) Harry seems to know the answer

Harry in (60) is in subject position at S-structure, as evidenced by the agreement pattern on the verb: 3rd person singular in (60), but 3rd person plural in (61):

- (61) Harry and Bill seem to know the answer

However, given the close semantic parallelism between (59) and (60), especially with respect to θ -relations, their D-structures are assumed to be similar. In particular because *Harry* is the understood subject of *know the answer* in both examples, it must be in the subject position of that predicate in the D-structures of both examples. The D-structure of (59) is identical to the S-structure in relevant respects:

In (62), the subject of the main sentence *it* is not an argument, but rather, an 'expletive,' a place-holder lacking semantic import (unlike the referential *it* in 'It is on the table.'). The

D-structure of (60) is similar, the only differences being that the main subject position is empty, and the embedded sentence is an infinitive:

To derive the correct S-structure, the NP *Harry* raises into the empty higher subject position, as indicated by the arrow in (63). The movement is obligatory in this instance. If *Harry* remains in the lower subject position, the result is ungrammatical, whether or not the expletive *it* occurs as the higher subject:

- (64) *Seems Harry to know the answer
 (65) *It seems Harry to know the answer

This obligatoriness of the movement of the subject has been analyzed as a requirement of abstract 'case.' There are characteristic structural positions that 'license' particular cases, as in the following table:

(66)

Position	Case	Example
Subject of finite sentence	Nominative	<i>He</i> left
Direct object of transitive verb	Accusative	I saw <i>him</i>
'Subject' of NP	Genitive	<i>His</i> belief that Mary solved the problem
Complement of preposition	'Oblique' (in English, indistinguishable from accusative)	near <i>him</i>

In many languages (such as Latin, Russian, German), these case distinctions are overtly manifested as a morphological affix that is attached to the stem of the noun. In English, only pronouns show an overt distinction between nominative and accusative, but Case theory posits that all NPs have abstract case (henceforth, Case), even when it is not phonologically visible. The requirement that all NPs occur in appropriate Case positions is called the 'Case Filter.' The Case Filter is a well-formedness condition on the S-structure level of representation. The NP *Harry* in its D-structure position in (63) lacks a legitimate Case because that position does not license nominative, accusative, genitive, or oblique Case. Movement of *Harry* to the higher subject position salvages the example because that position licenses nominative Case. Such 'Subject raising' is not possible for structure (62), where the embedded sentence is finite:

- (67) *Harry seems [*t* knows the answer]

This, too, has been analyzed in terms of Case: movement of an NP from one Case position to another is prohibited. Metaphorically speaking, movement to a Case position is a 'last resort,' an option taken only if necessitated by the Case Filter.

Case theory has also been used to explain some of the properties of 'passive' sentences, such as (68):

- (68) This problem was solved

The S-structure subject, *this problem* bears the object θ -role assigned by the verb *solve*. Hence, by hypothesis, it must have originated in the object position in D-structure. But as in (63)–(65), movement is obligatory when the verb is in the passive form:

- (69) *Was solved this problem
 (70) *It was solved this problem

Passive verbs apparently lose the ability of the corresponding active verbs to license accusative Case. It has occasionally been suggested that this relates to the fact that passive verbs are not fully verb-like in that they share some properties with adjectives (cf. 'the solved problem'). The morphological process creating a passive verb from an active one neutralizes its verbal properties.

Adjectives, like passive verbs, lack the ability to license Case on an object, as seen in the contrast between the VP in (71) and the corresponding Adjective Phrase (AP) in (72):

- (71) I [_{VP} suspect Harry]
 (72) *I am [_{AP} suspicious Harry]

For (72), another saving strategy is available: a semantically null preposition is inserted to license Case on *Harry*.

- (73) I am suspicious of Harry

Passive verbs differ from adjectives in this respect. The *of*-insertion strategy is not available for the former:

- (74) *It was solved of the problem

Passive verbs are neither fully verbs nor fully adjectives.

Nouns pattern with adjectives with respect to the phenomena just outlined. First, they do not license Case on their objects:

- (75) Susan [_{VP} proved the theorem]
 (76) * [_{NP} Susan's proof the theorem]

Second, the strategy of inserting a semantically null preposition is available. (76), like (72), is salvaged by *of*-insertion:

- (77) Susan's proof of the theorem

Additionally, though, when the subject position of the NP is not already occupied, movement into that position is often available for the object of the head N, a process reminiscent of that seen in passive sentences such as (68) above:

- (78) The theorem's proof
 (derived from [_{NP} — proof [_{NP} the theorem]])

Of the four major lexical categories V, N, A, and P, V and P pattern together (as opposed to N and A) with respect to

licensing Case on an object, while N and A pattern together in triggering *of*-insertion. The lexical categories can be analyzed as bundles of values for binary (two-way) ‘distinctive features’ in such a way as to capture these various properties:

- (79) V [+v, -n]
 N [-v, +n]
 A [+v, +n]
 P [-v, -n]

The ‘Case-licensing’ lexical categories are those specified $-n$. The triggers for *of*-insertion are those specified $+n$. As passivized verbs neither license Case nor trigger *of*-insertion, the formal representation of their ‘neutralized’ status is as a $+v$ category with no specification at all for n :

- (80) Passivized verb [+v]

Logical Form

There are languages, such as Chinese and Japanese, in which interrogative WH-words are not fronted, as they are in English, but remain *in situ* in their D-structure positions. The Chinese sentence (81) contrasts with its English translation in this way:

- (81) [ni renwei [ta weishenme meiyou lai]]
 you think he why not come
 (82) Why do you think [he didn’t come *t*]

Even though *weishenme* in (81) seems not to have moved, the interpretation of (81) is as if *weishenme* had moved, that is, as a direct question about the reason for not coming. Further, the locality effects discussed earlier also seem operational for WHs *in situ* under certain circumstances. For example, when *weishenme* is inside a complex NP, it cannot be interpreted outside of that island, precisely mirroring the island effect on WH-movement:

- (83) *ni xiaangxin [_{NP} [_S Lisi weishenme lai] de shuofa]
 you believe Lisi why come claim
 (84) *Why do you believe [_{NP} the claim [_S that Lisi came *t*]]

(The relevant (and unavailable) construal here concerns the reason for Lisi’s coming. There is no other construal possible either, as neither the noun *claim* nor the verb *believe* takes an embedded question.)

This suggests that (81) and (83), like (82) and (84) respectively, do involve movement, though a kind of movement that has no effects on the phonetic form of the utterances. Given the organization of the grammar in (34), that kind of movement is not possible. But a modification introducing the component of logical form (LF) allows for the possibility of ‘abstract’ movement that does not feed into PF:

- (85) Lexicon — D-structure — Determination of θ -relations
 |
 Transformations
 |
 S-structure
 / \
 PF component LF component
 | |
 Phonological rules Transformations
 | |
 Phonetic form (PF) Logical form (LF)

PF and LF specify aspects of sound and meaning, respectively, insofar as they are linguistically determined. (Even θ -relations can be ‘read off’ LF, if movement processes leave behind traces.) Transformations do or do not have phonetically overt consequences depending on whether they operate between D-structure and S-structure (as in the English WH-movement examples above) or between S-structure and LF (as in the Chinese examples). Language variation of this kind can be stated as a parameter. This parameter distinguishes the languages at the level of S-structure, but at the LF level of representation, in both types of language the interrogative word will be in the position where its semantic scope is determined. The scope of an interrogative ‘operator’ can be an entire utterance, as in the examples considered so far, or it can be just an embedded sentence, as in (86):

- (86) John wonders [what Bill bought]

(86) is not a direct question, but it contains within it an embedded or indirect question. The scope of *what* in this instance is the embedded sentence. In a language without overt WH-movement, the same scope effects arise. In (87), *shenme* (‘what’) is *in situ*, but its scope is the embedded sentence:

- (87) Zhangsan xiang-zhidao [Lisi mai-le shenme]
 Zhangsan wonder Lisi buy what
 Zhangsan wonders [what Lisi bought]
 (Zhangsan wonders for which *x*, *x* a thing, Lisi bought *x*)

LF is the level of representation where this semantic parallelism is expressed.

The semantic notion ‘in the scope of’ thus has structural instantiation at the level of LF. This structural instantiation is characterized in terms of the relation ‘c(onstituent)-command’ defined in (88):

- (88) A category α *c-commands* a category β if and only if β is a sister of α or is dominated by a sister of α .

In (89), A *c-commands* B, C, and D; B *c-commands* A; C *c-commands* D; and D *c-commands* C. No other *c-command* relations hold.

- (89)
-
- ```

graph TD
 S --> A
 S --> B
 B --> C
 B --> D

```

A fronted WH-phrase *c-commands* the clause that it takes as its scope. Similarly, it has been argued that the scope of a quantifier is determined by an LF operation called quantifier raising (QR), which adjoins a quantificational expression to S, leaving behind a trace. The S-structure of (90) is mapped onto an LF like (91):

- (90) John likes everyone  
       (91) [<sub>S</sub> [everyone]] [<sub>S</sub> John likes *t*]

The interpretation of (91) is then straightforward:

- (92) For all *x*, *x* a person, John likes *x*.

‘Scope ambiguities,’ such as that in (93), receive a simple characterization in these terms.

- (93) Every student solved one problem

The relative heights of the raised quantifiers at LF determine the particular quantificational meaning that is assigned to the sentence. (94) represents the reading where every student solved some problem or other, and (95) the reading where there is a particular problem that every student solved. (Identical integer subscripts are assigned to a moved item and its trace.)

- (94) [<sub>S</sub> [every student]<sub>1</sub> [<sub>S</sub> [one problem]<sub>2</sub> [<sub>S</sub> *t*<sub>1</sub> solved *t*<sub>2</sub>]]]  
 (95) [<sub>S</sub> [one problem]<sub>2</sub> [<sub>S</sub> [every student]<sub>1</sub> [<sub>S</sub> *t*<sub>1</sub> solved *t*<sub>2</sub>]]]

Another ambiguity phenomenon that falls in the domain of syntax is a 'structural ambiguity.' Human languages are filled with ambiguity. Some instances of ambiguity are scopal, as seen above. Others are lexical, involving two different words that happen to be pronounced and/or spelled alike. An example is

- (96) Meet me at the bank

where I could intend that we gather after depositing our paychecks or that we get together to go fishing. But many other instances of ambiguity do not depend on homonymous words. Each of the following examples appears to be two different sentences in one, even though the words of each have constant meaning.

- (97) Sue met a singer on the stage

(Was the *meeting* on the stage, or just the *singer*?)

- (98) Susan said John resigned in order to protect his reputation

(Was the *resignation* or the *statement* to protect John's reputation?)

These ambiguities can be captured by positing two different syntactic structures for each two-way ambiguous sentence. For (97), the prepositional phrase (PP) *on the stage* can be inside the direct object NP (where it will modify *singer*) or outside that NP, but still inside the VP (where it will modify *met*). The two structures are in (99) and (100) respectively.

## Binding Theory

Among the imaginable 'anaphoric relations' (relations of referential dependence) among NPs, some are possible, some are necessary, and still others are proscribed, depending on the nature of the NPs involved and the syntactic configurations in which they occur. For example, in (101), *him* can take *John* as its 'antecedent,' while in (102), it cannot. (The antecedent of an expression E is another expression from which E picks up its reference.)

- (101) John said Mary criticized him  
 (102) John criticized him

That is, (102) has no reading corresponding to that of (103), with the pronoun *him* replaced by the 'anaphor' *himself*.

- (103) John criticized himself

A pronoun cannot have an antecedent that is 'too close' to it. In (101), where antecedence is possible, a clause boundary intervenes between the pronoun and antecedent. There is no such boundary between the pronoun and antecedent in (102). Thus, the presence of a clause boundary between the pronoun and antecedent puts them far enough apart to allow a relation of referential dependence and allows the antecedent to 'bind' the pronoun. This is sometimes called Condition B of the Binding Theory.

Conversely, an anaphor requires an antecedent quite close to it ('Condition A'). Compare (101) with (104).

- (104) \*John said Mary criticized himself.

Again, the pertinent locality is, roughly, being in the same clause. An anaphor must have a 'clause-mate' binder.

Distance in this sense does not always suffice to make antecedence possible. In (105), a clause boundary intervenes between *he* and *John*, yet an anaphoric connection is still impossible.

- (105) He said Mary criticized John

Importantly, it is not the linear relation between the pronoun and the name that inhibits anaphora. This is evident from consideration of (106), in which *he* once again precedes *John*, yet anaphora is possible.

- (106) After he entered the room, John sat down

The generalization covering (101) and (105)–(106) is approximately as in (107):

- (107) A pronoun cannot c-command its antecedent.

In (105), the c-command domain of the subject pronoun is the entire sentence. As the putative antecedent is included in that domain, the anaphoric interpretation is inconsistent with the generalization (107). In (106), on the other hand, the domain of the pronoun is the clause embedded in the adverbial phrase, which does not include the antecedent *John*.

In fact, Conditions A and B also involve c-command. For the former, the anaphor must not only be near its antecedent, but it must also be c-commanded by it. When the potential antecedent is buried in another phrase, the result is unacceptable.

- (108) \*John's mother criticized himself

Conversely, a pronoun with bound interpretation is fine in this position:

(109) John's mother criticized him

### Summary

In summary, syntax concerns the structural aspects of sentences, including the way words are grouped into phrases, and those phrases into still larger phrases, and the way those phrasal units are manipulated and interpreted. There are universal aspects of syntax (infinitude, structure) and parametric ones (such as the order of head and complement). Exactly which syntactic properties are universal and which are subject to variation continues to be a rich area of research.

# Temperament and Individual Differences

J Kagan, Harvard University, Cambridge, MA, USA

© 2012 Elsevier Inc. All rights reserved.

## The Meaning of Temperament

Each individual possesses a large collection of biological and psychological properties that influence how the person will react in a particular situation. The biological properties include genes and the chemistry and anatomy of the brain. The psychological properties include diverse types of representations of past experience and the feelings that are linked to them. Although all humans possess these biological and psychological properties, they vary in the frequency and intensity of particular feelings, behavior, and desires because of variations in their life experiences and biological properties.

Temperamental bias is based on biological properties. Most scientists define a temperamental bias as a biologically based susceptibility for particular feelings and actions, usually appearing during infancy or early childhood, that experiences sculpt into a large but nonetheless limited number of personality traits. The settings in which the individual develops determine the specific traits that will be expressed. However, the local context in which the individual is behaving at the moment selects for expression one particular combination of biological and psychological properties from the larger number of possibilities. This means that when the context changes, a different combination could be selected. A person who is normally quiet and conforming to authority in the work place might be talkative and dominating at home.

## Origins of Temperament

A temperamental bias can be created by at least four different biological mechanisms: (1) an inherited neurobiology, (2) season of conception, (3) maternal stress or illness during fetal development, or (4) events during the first year or two that affect the still developing brain. Although an inherited neurobiology is believed to be the most common source of a temperamental bias, the other three factors can be influential.

For example, fetuses conceived in the northern hemisphere during the spring or fall months, when the hours of daylight are increasing or decreasing at a faster than usual rate, are exposed to decreasing (in spring) or increasing (in fall) levels of maternally secreted melatonin, which affects the developing brain. Therefore, a fetus with a particular genetic vulnerability to a low or high melatonin level could develop a temperamental bias if conceived during the fall or spring months. Children in the northern hemisphere who were conceived in the fall are biased to become shy and are at a slightly greater risk for depression disorder during adulthood. By contrast, adults conceived during the spring months are at a slightly higher risk for developing a drug addiction or becoming schizophrenic.

## Neurobiology

The human brain contains over 150 different molecules, each associated with a variety of receptors varying in density and location in the brain. The very large number of possible combinations of molecular concentrations and receptor distributions means that the number of possible brain profiles that could create a temperamental bias is much larger than the types of behavior psychologists observe. One way to categorize the large number of possible human temperaments relies on three criteria: (1) is the temperamental bias due primarily to a neurochemical profile or a feature of brain anatomy? (2) is the temperament due to a heritable set of genes or the result of prenatal or early postnatal events?, or (3) does the biological basis for the temperament influence primarily the limbic parts of the brain, which regulate feelings, or frontal lobe sites, which regulate impulsive behavior? Eight temperamental types emerge if each feature is divided into two opposing categories (see [Table 1](#)). Each of the eight cells in [Table 1](#) can contain many different temperaments.

Extremely irritable or minimally irritable infants who inherited a chemistry that affected limbic structures would be assigned to cell 1, but equally irritable infants who were born to mothers exposed to the flu virus during their pregnancy would be assigned to cell 2. Some children diagnosed with attention deficit or conduct disorder who inherited a chemistry of the frontal lobe that led to a compromise in the control of impulsive behavior would be assigned to cell 5, but equally restless or disobedient children born to a mother who was stressed during pregnancy would be assigned to cell 6. Children who display many tantrums because of a compromised anatomy in one of the limbic structures would be assigned to cell 3, but would be assigned to cell 7 if the cause was an inherited compromise in frontal lobe sites.

It is important to appreciate that a child's experiences shape the initial bias into a variety of forms that vary across cultures and historical eras and are always influenced by the child's gender, ethnicity, and social class. Thus, the pattern of behavior and emotions displayed by older children is usually influenced more by differences in experience than by their temperamental bias. Because young infants have not yet been exposed to much variation in experience, temperamental bias is more easily observed in the first year.

## Infant Temperaments

Infants vary little in behavior that appears to originate in their temperament. The most obvious are the reactions displayed to uncomfortable states of pain, cold, and hunger. Infants vary in the intensity and duration of crying as well as in the ease of

**Table 1**

|                           | <i>Mainly neurochemical</i> |                      | <i>Mainly anatomical</i> |                      |
|---------------------------|-----------------------------|----------------------|--------------------------|----------------------|
|                           | <i>Inherited</i>            | <i>Not inherited</i> | <i>Inherited</i>         | <i>Not inherited</i> |
| Variation in emotionality | 1                           | 2                    | 3                        | 4                    |
| Variation in impulsivity  | 5                           | 6                    | 7                        | 8                    |

being soothed. They also vary in their reactions to unexpected events that are not painful, such as new foods, sounds, or sights. Once again, some infants are active and others passive; some cry and others remain calm. Infants also vary in how they react to frustrations, such as losing a nipple they were sucking or being unable to retrieve a toy. Finally, infants vary in the frequency of babbling, smiling, and limb movements when they are simply lying in their crib with no intrusion into their perceptual space.

Mary Rothbart, an acknowledged expert in infant temperaments, suggests that there are four basic temperaments that vary in intensity. One type refers to a bias for the unpleasant emotions of fear, anger, or sadness. A second bias, called surgency, refers to behavior that accompanies pleasant states, especially smiling and babbling, and the tendency to approach unfamiliar people, objects, or settings. A third temperament biases infants to soothe easily when they are upset, although these infants do not always show behavioral signs of pleasure. The fourth bias refers to the regularity of eating and sleeping; some infants establish a regular rhythm while others do not.

The relation between the brain's neurochemistry and behavior that has a temperamental foundation is complicated and, therefore, not well understood. For example, serotonin is an important molecule that usually suppresses neuronal excitability. Thus, it is reasonable that infants and children with lower concentrations of serotonin are usually distressed more easily than others. However, the duration of serotonin activity is affected by the concentration of another molecule (called the serotonin transporter) that reduces the level of serotonin in the synapses of select sites. The gene that is the origin of this molecule has several alleles that determine the level of expression of this gene. Two of these alleles are called short and long because of the variation in their DNA string. The short allele is associated with less expression of the gene and, therefore, less transporter. As a result, serotonin remains active in the synapse for a longer time. However, this condition usually leads to a reduction in the number of serotonin receptors and, therefore, an overall reduction in serotonin activity. One consequence is greater excitability of the amygdala. Although this brain state should be correlated with a susceptibility to fear or anxiety, unfortunately the psychological consequences of possessing the short or long allele depend on the person's ethnicity, gender, culture, and life history. Possession of the short allele has different psychological consequences in Caucasians and Asians.

Opioids are a class of molecules that influence temperament. These molecules modulate the neurons in the medulla that receive information from the body and transmit it to the cortex. A high density of opioid receptors in the medulla

reduces the likelihood that changes in the body will pierce consciousness. Thus, a person with fewer receptors will be more aware of subtle changes in heart rate and muscle tension.

Oxytocin and vasopressin contribute to temperament bias. The males in a strain of mammals related to mice, called prairie voles, pair bond to a female after an initial series of matings, but the related strain of montane voles does not pair bond. This dramatic difference in behavior appears to be due to differences in the density of receptors for vasopressin in a brain site that contributes to the intensity of pleasure associated with sexual behavior. Oxytocin activity is increased when mothers are nursing and caring for their infants. If variations in vasopressin and oxytocin levels or receptor densities have similar outcomes in humans, some husbands will be faithful to their wives and some mothers will develop unusually close emotional bonds with their infants.

Dopamine and the density and distribution of its varied receptors also contribute to brain states that are the bases for temperamental bias. One psychological state, which humans interpret as pleasure, occurs when a person receives a desired event that was unexpected. This experience leads to a surge of dopamine in a structure called the ventral striatum. There is a complementary relation between the usual level of dopamine in the cortex and the level of dopamine in the ventral striatum. The lower the tonic level in the striatum, which could be due to a higher level in the cortex, the greater the increase in dopamine activity in the striatum when an unexpected event occurs, and the greater the probability the individual will experience an intense feeling of pleasure. By contrast, individuals with tonically higher levels of dopamine in the striatum will experience a smaller increase in dopamine activity and presumably derive less pleasure from the same experience.

Unfortunately, the current immaturity of our knowledge frustrates any attempt at the moment to posit a strong relation between any neurochemical profile and a temperamental bias. For example, a gene or cluster of genes rarely accounts for more than 5–10% of the variation in human behavior that has been studied. No single gene from a set of over 300 000 in a sample of close to 4000 adults accounted for more than 1% of the variation in five different personality traits measured with a questionnaire because most psychological traits are due to a particular life history shaping the pattern of temperamental bias into different forms. Although there can be a close relation between a set of genes and the brain states it produces, there is a much weaker relation between a brain state and the psychological state of an individual.

### **Variation in Reactions to the Unfamiliar**

Two temperaments that have been studied more extensively than others refer to the variation among infants and children in their reaction to unexpected changes in the immediate sensory surround (called stimulus novelty), and to events that deviate from their knowledge (called conceptual novelty). Both types of novelty automatically alert infants and young children and provoke them to try to relate the event to the setting and their knowledge. Every human, like every animal, anticipates a narrow range of events in a given setting. An adult wearing a clown costume unexpectedly entering a room in which a child is

playing falls outside this range and, therefore, automatically elicits a vigilant state, body immobility, and, in a smaller proportion, a scream of fear. This behavioral profile is usually called fear to novelty. Many animal species vary in their tendency to avoid or approach unfamiliar objects or places. Because the heritability of the variation in this trait in two breeds of dogs was significant but modest, we can be certain that experiences are also influential.

### High- and Low-Reactive Infants

The amygdala and the prefrontal cortex usually participate in the infant's reactions to unexpected or unfamiliar events. Some neurons in the amygdala are part of a system that alerts other parts of the brain to the presence of an unfamiliar event. One of these sites is the prefrontal cortex, which evaluates whether the event is a potential threat. Other locations in the amygdala initiate behavioral or physiological reactions intended to protect the individual from possible danger. Four-month-olds born with a chemistry that produced an especially sensitive amygdala are likely to thrash their arms and legs and cry when they are exposed to unfamiliar events that pose no danger (e.g., moving mobiles or the sound of human voices).

One team of scientists recorded the behavior of 450 4-month-old infants exposed to colorful moving mobiles, taped human voices, and a cotton swab that had been dipped in dilute alcohol. About 20% of the infants, called high-reactive, thrashed their arms and legs, lifted their back from the seat on which they rested (called an arching reaction), and cried on a substantial proportion of the trials. Another 40%, called low-reactive, were usually still, rarely cried or arched their back, and occasionally babbled or smiled. These two temperamental groups developed different personalities as they grew.

The high-reactive 1- and 2-year-olds were more fearful and timid to unfamiliar events, such as the placement of electrodes on their chest or the sudden appearance of puppets with flashing lights. The low-reactives were minimally fearful to these same events. At age 4, the children from these two temperaments played with two other unfamiliar children. Twice as many high- as low-reactives were shy, quiet, and remained close to their mother; more low-reactives played and talked with the other two children. When these same children were 7 years old, one of every two high-reactives, compared with only one of ten low-reactives, showed signs of anxiety such as a reluctance to sleep without a night light, to stay overnight at a friend's house, or a distinct fear of large animals or storms.

The high-reactive 11- and 15-year-olds were less exuberant and less relaxed than the low-reactives and the two groups worried about different experiences. The high-reactives worried about meeting strangers, entering crowds, visiting an unfamiliar city, or the unpredictable events of the future. Low-reactives worried primarily about their grade record and their performance on the athletic field. Not surprisingly, the high-reactives described themselves as serious and tense, whereas the low-reactives described themselves as happy and relaxed most of the time.

These two temperamental groups differed during the adolescent years in four biological measurements that reflect

the excitability of the amygdala and the circuit connecting the amygdala with the prefrontal cortex. The high-reactives showed a larger brain reaction to unfamiliar scenes, such as an infant's head on an animal's body, implying greater neuronal excitability to the unexpected. They also showed greater activation in the right compared with the left frontal lobe; the former is more likely when individuals are experiencing an unpleasant state. Two important differences involved the cortical thickness in two sites in the prefrontal cortex. The site in the ventromedial prefrontal cortex contributes to conscious feelings of tension that might be interpreted as anxiety and sends projections to the neurons that produce arching of the back. The high-reactives had a thicker cortex in this region on the right side; the low-reactives had a thinner cortex. A second site in the orbitofrontal cortex sends fibers to a small group of cells that inhibit the part of the amygdala responsible for the behavioral and biological signs of fear. The low-reactives had a thicker cortex in this area on the left side, whereas the high-reactives had a thinner cortex.

However, only one of four adolescents from the high- or low-reactive temperamental groups maintained over the first 15–18 years the behavioral and biological signs that were expected for their infant temperament. But very few children from either group developed a personality and biology that was characteristic of the other temperament. This fact means that a temperamental bias eliminates many more possible outcomes than it determines. The probability that a high-reactive infant will not become a consistently exuberant, sociable, fearless child with a minimally excitable amygdala is very high; that prediction was confirmed for about 90% of the high-reactives. However, only 20% of high-reactives became adolescents who were extremely shy and anxious and showed signs of amygdala excitability. By contrast, over 90% of low-reactives were not unusually anxious to unfamiliar events and did not show signs of amygdala excitability, but only 40% were consistently sociable, exuberant, and had a minimally excitable amygdala. Other scientists at the University of Maryland who observed similar temperamental groups have reported very similar results. Such a bias is related to the differences between introverts and extroverts and is reminiscent of the ancient distinction between a melancholic and a sanguine temperament.

### Temperament and Gender

Although the behavioral differences between males and females are affected by culture, a small number of traits separate most males from most females across continents and millennia because of differences in genes and neurochemistry that create temperamental bias. Boys in most societies engage in more vigorous activity involving the large muscles, prefer competitive games with a winner and a loser, and more frequently display physical aggression toward peers and disobedience toward adults. Most girls, by contrast, play with a smaller number of peers in relationships defined by emotional closeness and are more often anxious over possible physical harm or social rejection. Similar differences have been observed between male and female monkeys and chimpanzees. Male monkeys prefer to play with toys that have wheels rather than

plush animals or dolls because they can push the former objects. Female chimpanzees are less impulsive, less aggressive, and gentler with other animals; male chimpanzees are more active, more excitable, and more likely to dominate another animal.

The students of the anthropologists John and Beatrice Whiting studied the behavior of 4- and 9-year-old children in six different societies. In most cultures, girls were more nurturing of others; boys were more aggressive. Males were more concerned with their power and dominance over others than with the depth of their social relationships. Females were more often threatened by a dilution in the quality of their relationships with others.

### **The Biology of the Sexes**

The most robust sex difference is that males are more variable on most traits than females. More boys than girls have extremely high or extremely low scores on tests of cognitive abilities and more boys than girls are unusually tall or unusually short.

The sexes differ in the concentration of the two sex hormones, testosterone in males and estrogen in females. The surge in testosterone during the fetal development of boys slows the growth of the left hemisphere relative to the right. This condition produces more males with a dominant right hemisphere and allows more males to perform at very high levels of competence on the psychological functions mediated by the right hemisphere, especially the nonverbal talents of spatial reasoning, musical composition, and painting. The surge of testosterone also leads to a slightly larger cluster of neurons in a part of the hypothalamus that contribute to sexual arousal. Males, compared with females, usually have their first sexual experience earlier, have more sexual partners, and are more aroused by pictures of unclothed members of the opposite sex. Testosterone also suppresses the brain circuits that mediate fear and inhibits the contraction of the facial muscles that are used in smiling. Males of every age and in every culture smile less often than females.

The ratio of the lengths of the second to the fourth finger (the length of the index finger divided by the length of the ring finger and called the 2D:4D ratio), which is inherited, is a rough index of the amount of testosterone to which the fetus was exposed. Boys and men have slightly smaller ratios than girls and women. Girls with a more masculine ratio have a feminine identity but are more athletic than the typical girl. Men with very masculine ratios have greater muscle strength, faster running speeds, more sexual partners, and often have a broad upper face with a prominent jaw and large chin. The men who work on the trading floors of large investment firms are under extraordinary pressure to make decisions involving large amounts of money. The men who earn their clients the most money must control their anxiety because this emotion can lead to vacillation or impulsive decisions. The men who are the most successful in this stressful setting had extremely masculine finger ratios; the men who made less money had less masculine ratios.

The sexes also differ in the activity of oxytocin and vasopressin. Oxytocin activity, which is greater in females, in part because estrogen enhances its activity, mediates the

bonding of mothers to infants and of friends to each other. Hence, girls and women are more concerned with maintaining close emotional friendships. Vasopressin activity, which is enhanced by testosterone and is greater in males, mutes fear, raises the threshold for pain, and, in animals, facilitates aggression.

Dopamine, a fifth molecule contributing to sex differences, has many different functions and six distinctive receptors. It was noted earlier that one function is to mediate a feeling of excitement, often interpreted as pleasure, when a desired but unlikely event is anticipated or occurs. Addicted gamblers observed in a casino playing black jack showed larger rises in dopamine than nonaddicted men. When pathological gamblers were given a drug that suppressed dopamine, they reported that gambling had lost much of its pleasure.

Because the female brain binds dopamine to one of its receptors more effectively than the male brain, most female brains have fewer dopamine receptors ready to be activated. In addition, estrogen reduces the activity of the molecule that absorbs dopamine from the synapses; hence, dopamine remains active for a slightly longer time in female than in male brains, especially in the ventral striatum. These facts imply that the surge of dopamine in the striatum that accompanies an unexpected, but wished for, event will activate more dopamine neurons in men than in women and presumably create a more intense feeling of pleasure in males. However, these biological differences between the sexes are always inserted into a social fabric in which males and females interact with each other and use these encounters to arrive at conclusions about themselves.

### **Temperament and Ethnicity**

There is a strong relation between the geographical distance separating two human groups and the magnitude of difference in their genomes. Thus, Africans, Asians, South Americans, North Americans, and Europeans differ in a small number of genes that could contribute to temperamental bias. The proportion of humans possessing the allele that leads to greater expression of the gene for the molecule that modulates brain serotonin activity (the long allele discussed earlier) is highest among Africans (about 80%) but lowest among Japanese (about 20%).

Comparisons of the psychological and biological differences between Asians from China and Japan and Caucasians from Europe and North America have been studied more extensively than others. Asians and Caucasians differ in about 25% of the genes in regions that control the expression of the genes responsible for the proteins that make body organs. Alcoholism is far less common among Asians than among Caucasians because Asians inherit alleles that interfere with the liver's metabolism of alcohol. Asians are more sensitive than Caucasians to the setting in which a person behaves, as well as to the context in which an object or event occurs. More paintings and photographs composed by Asian, compared with Caucasian, artists depict many objects or animals in the backgrounds of scenes illustrating the central object. European and North American artists usually place the person or object of significance in the foreground and add fewer additional details.

Over the past 1000 years, Caucasians in western Europe made every person's skills, beliefs, and feelings the primary

features of their identity. Asians, by contrast, made every person's social roles and obligations to others the central feature of self. European and North American Caucasians regard every individual as an entity with fixed traits acting on others in the world. Asians regard every person as a collection of distinct roles that have to be altered to accommodate to the specific people with whom they are interacting.

The likelihood of temperamental differences between Asian and Caucasian infants is supported by observations of young infants. Asian newborn infants are calmer, less likely to struggle, less likely to remove a cloth on their face, and more easily consoled when they cry. But Asian infants smile and laugh less often and, when older, stay closer to their mother in an unfamiliar room containing unfamiliar children.

One possible contribution to these behavioral differences is the gene controlling the molecule that affects serotonin activity. As noted earlier, Asians possess the allele that leads to a prolonged presence of serotonin in the synapse, but lower tonic levels of serotonin activity. Serotonin contributes to some of the behavioral signs of pleasure, such as smiling and laughing, and activates a receptor for dopamine in places that mediate body movement. Thus, the infrequent thrashing of arms and legs and minimal emotion shown by Asian 4-month-olds could be due, in part, to possession of this gene.

Geographically distant human populations also differ in facial shape. Asians have the flattest faces of all human groups: the forehead, jaw, and nasal protuberance are less prominent in Asians than in Caucasians or Africans. One team of biologists bred a small number of tame silver foxes with other tame animals and in <20 generations all the offspring were tame. These tame foxes were less fearful and had shorter snouts – that is, flatter faces. Domesticated pigs, cattle, and horses also have shorter snouts than their less tame, wild relatives. The fact that Asians have flatter faces than Caucasians or Africans implies that, from a biological perspective, Asians may be the most domesticated humans. It may not be a coincidence that loyalty to one's family and social groups is a cardinal ethical value in Asian societies.

## Temperament and Mental Illness

A person's temperament influences the psychiatric categories for mental illnesses. Paul McHugh has suggested that there are four major families of mental disorders, and three are influenced by biological conditions related to temperament.

The patients in the first family, more often male than female, have profound deficits in attention, memory, reasoning, language, or states of consciousness, and are usually diagnosed as schizophrenic, bipolar, or autistic. Even though the symptoms of each of these diagnoses can be caused by more than one set of conditions, these symptoms are most likely to have a biological foundation that can be detected in the first 10 years of life.

The patients in the second family, more often female than male, report chronic or intense bouts of anxiety, depression, or both. These patients have phobias, posttraumatic stress disorder, panic disorder, obsessive-compulsive disorder, anorexia, or serious depression. Each category contains symptoms with different origins and different heritabilities. However, the

symptoms of this family are more often the result of an imbalance in brain chemistry rather than a compromise in anatomy.

A critical feature of the symptoms of this family is excitability in the set of connected brain structures that include the amygdala, the anterior cingulate cortex, and the prefrontal cortex. Individuals with high levels of excitability in this circuit are vulnerable to exaggerated emotional reactions when they have to select the best action among a number of alternatives and are not sure which one to choose.

The patients in the third family are addicted to drugs, alcohol, or gambling or have difficulty inhibiting sexual or aggressive urges and sustaining attention when it is adaptive. These symptoms are more common among males than females. Many patients in this family show compromised functioning in sites in the prefrontal cortex that facilitate the regulation of inappropriate action. The genes and brain molecules that affect the integrity of the prefrontal cortex differ from those that influence the amygdala and the anterior cingulate.

Historical and cultural conditions, and their associated ethical values, have a greater influence on the prevalence of illnesses in the third family than on the incidence of symptoms in the first two families. This claim is obvious for homicide. Mothers in many parts of the less developed world kill their newborn if they cannot feed it, and some mothers kill their infant daughters if they believe they will be unable to afford a dowry when their daughter is ready to marry. None of the mothers in these cultures is regarded as mentally ill by the majority in their society.

The fourth family contains patients whose symptoms are due, primarily, to the life history and current circumstances, rather than to a special temperamental vulnerability. These symptoms are more common among the poor and marginalized in every society.

The important point is that bouts of anxiety or depression can occur in patients who belong to any of the four families and these emotions can be the product of different combinations of genes, temperament, culture, and life history.

## Summary

Although temperamental bias has some power, the person's life history, and, especially, the social class and the background, usually have a greater influence on later personality than the initial bias. Individuals in every society vary in power, status, wealth, and privilege and those who believe they have less privilege are vulnerable to anxiety, envy, anger, depression, self-doubt, or a blend of two or more of these emotions despite no special temperamental bias. Societies with a very large difference between the privileged and less privileged will have more members of the latter group who are vulnerable to intense emotions compared with societies with minimal differences.

The historical era and culture also shape the traits of individuals born with a distinctive temperament. The changes in America and Europe over the last century that brought technology, education, and an economy based on information rather than agriculture have created new beliefs, values, and emotions that were not present 2000 years ago. The important point is that the setting in which an individual lives selects from the same pattern of temperaments the personality traits

that will be adaptive. An adolescent who had been a high-reactive infant who lives in a small village and knows everyone will be better adapted than a high-reactive in a large city. A low-reactive adolescent is at higher risk for criminal activity if he lives in a large city than in a small town.

Third, adolescents born with different temperaments find it relatively easy to control how they appear to others, but have more difficulty controlling their vulnerability to specific feeling states of tension, worry, or depression. Humans can learn to suppress the urge to avoid a certain place or object, but are less able to change their feeling tones.

Temperaments contribute to the substantial variation in the intensity of anxiety, shame, or guilt that can accompany the contemplation or commission of an action that violates a moral standard. Adolescents who were high-reactive, for example, experience more intense guilt than low reactives when they fail to honor their moral imperatives.

There is a serious gap between a measured brain state and the individual's thoughts, feelings, and intended actions. The brain is a tightly interconnected set of structures affected by many molecules that, in turn, influence complex patterns of excitation and inhibition. Therefore, there cannot be a determinant relation between a brain profile produced by an event and a psychological outcome across a large number of humans because the event is imposed on the person's usual brain state, which differs across individuals, and evokes distinctively different associations in different individuals. Thus, the final brain state that is measured can be the result of varied combinations of initial brain states and unique associations.

The current interest in human temperaments will lead to a more extensive study of the feelings and emotions of humans,

which are harder to measure than their behavior. Emotions are analogous to the hidden molecular structures responsible for the color or shape of plants and animals. At the moment, scientists do not possess procedures sensitive enough to measure with great accuracy either the quality of a person's conscious feelings or their brain states. However, future investigators will be more successful and these victories will provide a more profound understanding of the reasons for the differences among humans in their usual emotional reactions and the variation in the serious symptoms of chronic anxiety, depression, addiction, callousness, and cognitive impairments.

### Glossary

**Antiterrorism** Defensive measures taken in place to protect a series of prospective targets from terrorist attacks.

**Counterterrorism** Preventive, offensive, and defensive measures – including military action, law enforcement, intelligence, conflict prevention, and political compromise – taken to deter or respond to the threat of terrorism.

**Extremism** The willingness to employ violence in the service of a set of radical or fundamental beliefs.

**Fundamentalism** A set of political beliefs which insist on strict adherence to a literal interpretation of the essential beliefs of a political ideology or faith.

**International terrorism** A terrorist attack which is funded, directed, or conducted across state boundaries by an

organization or state which seeks to use the violence for foreign policy advantage.

**Jihad** Literally meaning ‘struggle,’ refers to a religious duty of Muslims. It has been interpreted to mean nonviolent struggle (i.e., for nonviolent political reform, or an individual seeking to live a pious life) and to mean violent struggle against those who threaten the faith (holy war). The term ‘jihadi’ has been applied to those who engage in, or seek to engage in, violent struggle.

**Radicalization** The process by which an individual adopts a set of transformative ideas about political or social change.

**Terrorism** The use of indiscriminate violence on a target for some criminal, political, or idiosyncratic reason, with the primary objective of spreading fear to a population beyond the immediate target of the violence.

### Defining Terrorism

There is no single or universally accepted definition of terrorism, though it is widely acknowledged to be a type of political violence which uses indiscriminate attacks (or the threat of indiscriminate attacks) to spread fear to an audience beyond its immediate target. But beyond this basic description, the very nature of the terrorist act remains contested. For example, some scholars have argued that terrorism should be seen as a coercive act, designed to extract concessions from a target; others see it as a form of symbolic communication – the ‘propaganda of the deed’ – employed to illustrate a political cause. Others have argued that some kinds of terrorism – for example, suicide terrorism – cannot be explained solely with reference to some instrumental calculation of advantage, but must rather be explained with reference to the psychological characteristics and needs of the perpetrator. Still others argue that terrorism is a social act, conducted on behalf of an ascribed group and motivated by the incentives and pressures arising from an individual’s membership in groups or social networks. Whether terrorism is considered a tactic, a strategy, a form of symbolic communication (or some combination thereof) varies substantially across the literature; whether the motive for terrorism arises from a hard-nosed calculation of costs and benefits, or from a psychologically motivated desire to act on behalf of one’s group, (or both) remains a subject of intense debate.

The reasons for the lack of a consensus on terrorism are many, not the least of which is that the study of terrorism cuts across multiple academic disciplines. Psychologists, political scientists, sociologists, criminologists, and historians have all highlighted different aspects of the phenomenon, depending on the focus of their discipline. The result has been a

proliferation of definitions of terrorism. A survey conducted in 1988 by Alex P. Schmid and Albert J. Jongman found 109 separate definitions of terrorism, all highlighting different aspects of the phenomenon. This problem has been exacerbated by the vast increase in scholarly and popular literature on terrorism since the September 11th attacks. The emergence of popular literature on terrorism – some of it highly sensationalistic and unserious about its subject – has muddied the waters and made it more difficult to develop a consensus around a precise, analytically rigorous definition of the concept. Further complicating matters is the fact that the term ‘terrorist’ is a pejorative that actors often try – sometimes with success – to attach to their enemies. Given that the term is employed differently across disciplines, used carelessly in popular discourse, and deployed rhetorically to both delegitimize and condemn one’s enemies, it is hardly surprising that reaching an academic consensus on a definition has proven to be difficult, though some scholars, governmental agencies, and international organizations have made notable attempts.

Efforts to formulate a consensus definition of terrorism have run aground because there are at least four major areas where scholarly opinion on the subject is divided: (a) the essential characteristics of terrorism; (b) the difference between terrorism and other forms of political violence, especially insurgency; (c) the possible victims of terrorism (civilians or agents of the state); and (d) the possible agents of terrorism (e.g., substate actors or states). First, any well-formed concept in social science must have a cluster of conceptual attributes that are considered necessary (or in rare cases, sufficient) for its definition. For example, following a definition proposed by J. David Singer and Melvin Small in the correlates of war (CoW) project, interstate war has traditionally been defined as a violent conflict that involves sustained combat, at least two

organized combatants, and a minimum of 1000 battle fatalities per annum. While this definition has been critiqued and modified, it remains a widely accepted benchmark within the study of interstate war. By contrast, there is little consensus on the essential characteristics of terrorism that would distinguish it from other forms of political violence. In Schmid and Jongman's survey of scholars, disparate elements such as violence, political motive, the projection of fear, the use of threat, the organized nature of the attack, the indiscriminate selection of victims, the desire for publicity, the extra-normality of the violence, and the psychological effect of anticipated reactions were cited in varying frequencies by a range of experts as essential to the definition. Even the notion that terrorism must involve some kind of actual violence commanded support from only 84% of respondents, because the threat of an attack, if it induces fear or panic in an audience beyond the proposed target, may be sufficient to count as an act of terrorism.

Second, efforts to develop a precise definition of terrorism have run into difficulty when distinguishing terrorism from other forms of political violence. Although it is often treated as an entirely unique phenomenon, terrorism is little more than a specific type of political violence, which shares a number of important characteristics with other types of political violence such as insurgent attacks, targeted killings, and even genocide. For example, insurgent violence – such as attacks against military installations of an occupying power – shares some obvious similarities with terrorist attacks in that both are forms of asymmetric warfare which employ surprise to coerce an enemy. Similarly, targeted killings and assassinations are often designed to convey a political message, much in the same way that terrorism conveys a message of fear. The similarities between terrorist attacks, insurgent violence, and targeted killings – and the fact that these types of political violence are so often deployed concurrently within the same theater of war – have led many observers to blur the distinction between them. Indeed, one of the chief problems with the literature on terrorism since the September 11th attacks has been a conflation of terrorism with insurgency, with scholars attributing the causes, effects, and remedies of one to the other.

But while terrorism may share some important similarities with insurgent attacks and targeted killings, there are some key differences as well. First, terrorism is necessarily indiscriminate in that it aims to kill large numbers of people. As a form of violence, it is nonselective in that the perpetrator is typically indifferent to who the victims are. As Paul Wilkinson has pointed out, terrorism is most effective when it raises the prospect of random, arbitrary, or indiscriminate targeting in the civilian population, for this maximizes fear and convinces the wider audience that they may be struck 'like lightning in the dark' (p. 52). This is different in insurgent attacks and targeted killings, which can often be more discriminate and selective in execution than terrorism. Always mindful of the need not to alienate the civilian population, insurgents – particularly those who hope to topple a regime and assume control over a government – are often reluctant to employ too much indiscriminate violence for fear of backlash. Insurgents attack to keep pressure on a regime and to sow chaos, but they are often selective about whom they attack (representatives or agents of the state) and make efforts to convince the civilian population that they are on their side. There are cases in which

insurgents resort to terrorism frequently to sow chaos in the society (such as Iraq from 2003 to present), but there are many other cases where insurgents rarely employ the tactic (such as the Fuerzas Armadas Revolucionarias de Colombia (FARC) in Colombia) or deploy it selectively (such as the Front de Libération Nationale (FLN) in Algeria). Although terrorism and insurgency are overlapping conceptual categories, sharing many similar characteristics, it is a mistake to equate terrorist activity (which is by definition indiscriminate) with insurgent activity, which is not always indiscriminate.

Third, terrorism tends to have a wider communicative purpose than more selective forms of violence. Much of political violence is about communication – that is, signaling intent or capacity to harm – to other actors in a conflict. For example, insurgents use symbolic attacks to demonstrate their power and send a threatening message to the existing regime. Governments and rebel groups often use targeted killings to 'send a message' to a specific group. But the projection of fear with these other types of political violence is often different in scope than it is with most terrorist attacks. The purpose of terrorism is to send a message to a wider audience that anyone can be targeted at any time; in this respect, the message of fear is boundless and applicable to all those who take notice of the attack. By contrast, targeted killings, reprisals, and other forms of low-intensity violence are often accompanied by messages which are coded, subtle, and intended for only a specific group in the population. The insurgent, for example, does not want to threaten all members of the population in a state that he hopes to control, but only those actively supporting the regime. Similarly, targeted killings between governments and rebel groups – for example, between Israel and Hamas operatives in Gaza – are conducted in a tit-for-tat fashion, with little public acknowledgment or effort to communicate a message to the general public about the meaning of the violence. This is very different in purpose than that of the terrorist, who seeks to use violence in a demonstrative fashion to broadcast a message to a wider population. Indeed, the historical record suggests that terrorists are keenly attuned to their public message and spend much of the efforts insuring that their message, however abhorrent, is conveyed through the media. In contrast to other forms of political violence in which the message is limited in scope and secondary in purpose to the attack, with terrorism the public projection of fear is central to the purpose of the act.

Another important debate around the definition of terrorism concerns who can be understood as a victim of terrorism. Some definitions of terrorism limit the potential victims to civilians, implying that attacks against those deemed combatants must be considered an act of war rather than of terrorism. Such a position is designed to emphasize the indiscriminate nature of terrorist violence, specifically the fact that its coercive power arises from its promise of harm against civilians. The fact that terrorists knowingly violate the principle of noncombatant immunity means that terrorism can therefore be defined in Alex Schmid's words as the 'peacetime equivalent of war crimes.' Similarly, restricting the victims of terrorism to non-combatants implies that armed groups can attack those deemed as combatants (e.g., military personnel in a war zone) without being accused of terrorism. This restriction is designed not only to limit the careless use of the term 'terrorism' but also to imply that actors may be able to employ

violence against an oppressive regime or an occupying power without incurring the label 'terrorist' provided that they do not deliberately target civilians. In other words, restricting the definition of terrorism to noncombatant victims enshrines the legitimate right of resistance for armed groups under occupation or waging wars of self-determination provided that they do not resort to attacking civilians.

Critics of this view have argued that such a distinction is untenable because it is hard to determine who counts as a combatant in many cases. For example, it is not clear how off-duty military personnel or civilians working for an occupying government would be classified. Would they be considered combatants for supporting the regime or the occupation or noncombatants because they were not actively supporting military operations against the terrorist group? Terrorist organizations themselves tend to adopt an expansive definition of their victims, often arguing that all those who pay taxes are as guilty as those who are firing weapons in a war. This distinction between combatants and noncombatants, while important to legal experts, may have no purchase with terrorist organizations conducting the violence. Finally, restricting the use of the term 'terrorism' to attacks against noncombatants would appear to exclude some key events which were clearly intended as terrorism, such as the bombing of the US Marines barracks in Beirut in 1983. A definition which excludes attacks against combatants from the universe of terrorist attacks would not classify this act – conducted via truck bombs, by a known terrorist group (Islamic Jihad), and killing 241 US military personnel – as an act of terrorism.

The final controversial issue concerning the definition of terrorism relates to whether the state may be a perpetrator of terrorism. Some scholars have explicitly limited their definitions of terrorism to exclude the state as a perpetrator of terrorist violence, arguing that only substate actors can be considered 'terrorists.' Proponents of this view argue that to admit that the state can be a terrorist is to open a Pandora's box in which anything a state does in the context of an armed conflict that harms civilians and induces fear can be deemed an act of terrorism. This is particularly important given that governments often employ psychological warfare as a means of intimidating opponents; for example, the US invasion of Iraq in 2003 was accompanied by a range of psychological warfare tactics designed to 'shock and awe' the Iraqi government into surrendering. Also, as Bruce Hoffman argues, states often take some steps to observe the laws of war, particularly the principle of noncombatant immunity, which terrorists often deliberately violate. Proponents of this view argue that to include state and nonstate violent action under the category of terrorism is to classify so many heterogeneous acts as 'terrorism' that the term itself becomes meaningless.

Critics of this position argue that excluding the state as a potential perpetrator of terrorism is problematic for two reasons. First, ruling out the possibility of 'state terrorism' by definitional fiat appears to let states off the hook. As Paul Wilkinson and others have noted, the states are by far the greatest perpetrators of terror on their own populations, as examples such as Nazi Germany and Stalin's purges in Russia can attest. Indeed, the origin of the term 'terrorism' is the use of terror tactics by the French state following the Revolution. As advocates of critical terrorism studies (CTS) point out, this

exclusion appears to privilege state actors, holding them to different moral and legal standards than their nonstate opponents. Second, some states deliberately resort to terror tactics designed to terrify the population in an armed conflict. For example, the Allied bombing of German cities such as Dresden was acknowledged inside the British government to be a form of 'terror bombing.' It is hard to insist that such an act – which involves violence, the projection of fear, and clear communication of threats – bears no parallel with similar tactics by nonstate groups.

## History and Trends in Terrorism

Terrorism has a long history. The term itself arose during the French Revolution, in the Reign of Terror (1793–1794), when thousands of supposed 'enemies of the Revolution' were put to the death by the Jacobins. But the actual employment of terror tactics predated this example by centuries. In the ancient world, weak rebel groups would often resort to surprise attacks to weaken their enemies and terrify their supports. The Sicarii (first century) was a splinter group of the Jewish Zealots that used surprise dagger attacks to kill their enemies (usually supporters of the Roman Empire) in public places to terrify the population. Similarly, the Ismaili Shiite Assassins (also known as the Hashishin), who operated in the eleventh to thirteenth century, also conducted highly selective murders in public spaces to send a message to opposing factions. The similarities of these attacks to modern-day terrorism lie in the surprise of the attack and the communicative function of the violence, though these groups were far more selective in their victims than modern-day terrorist groups.

David C. Rapoport has identified four major waves of terrorism in the modern era. The first major wave came with the antistate revolutionaries of the nineteenth century. The intellectual father of these movements was Carlo Pisacane, an Italian radical who led a rebellion against the Bourbon kings and called for the symbolic use of violence – the so-called 'propaganda of the deed' – to spread the message of the group. In his view, violence was didactic, designed to not only inform the people about the cause but also to rally the masses in support of it. This belief in the demonstrative power of violence was picked up by a number of subsequent revolutionary actors in the late nineteenth century. Prominent among them was the Narodnaya Volya (People's Will), a Russian revolutionary group which called for constitutional reform of czar's regime. The Narodnaya Volya killed select members of the Czarist regime in Russia, including Czar Alexander II, as a way of rallying the Russian people to their cause. While they were eventually destroyed, their model proved influential with a number of other groups, including Black Hand, a Serbian radical group responsible for the assassination of Archduke Franz Ferdinand in 1914. Another important descendant of this first wave of revolutionary terrorism was the Anarchist groups, many of whom formed local chapters to threaten the overthrow of their governments. While most of their efforts were unsuccessful, anarchists were successful in assassinating several high-profile political leaders, including French President Marie-Francois Sadi Carnot in 1894 and American President William McKinley in 1901.

The second major wave of terrorist movements emerged during anticolonial revolts in the first half of the twentieth century and later partisan movements during the second world war. Among the earliest revolutionary/terrorist movements to form in the twentieth century was the Irish republican army (IRA), which formed in 1919 to oppose British rule in Northern Ireland. Terror was again in evidence during the second world war, as the Nazis often called the partisans in Greece and Yugoslavia 'terrorists' and used terror tactics to destroy these movements and keep the population subservient. Following the end of the second world war, terrorist violence appeared in campaigns in Palestine, Kenya, Cyprus, Algeria, Angola, and Mozambique. Here, it proved successful in accelerating the departure of colonial powers, even though it was widely condemned. Particularly notable among these cases were the Irgun, which bombed the King David Hotel in 1946 to force the British to withdraw from Palestine, and the FLN which selectively used terrorism against the French military and settlers in order to convince Paris to allow Algeria to declare its independence. The ideology of these revolutionary movements was often nationalist and Marxist or some combination thereof. Popular tactics during this wave of terrorism included kidnapping and hostage-taking, as well as some criminal activities like bank-robbing.

The third major wave of terrorism (1960s–1970s) was marked by its international scope and focus. This was facilitated by a number of important factors, not the least of which was the advance of media technology which allowed attacks by terrorists, along with their messages, to be broadcast instantly to much of the world. Seminal events in this wave of terrorism include hijackings of five airliners in 1970s by the Popular Front for the Liberation of Palestine (PFLP) and the Black September incident, when PLO terrorists killed 11 Israeli athletes at the 1972 Olympic Games in Munich. This example was followed by a number of Marxist groups in Western Europe (such as the Red Army Faction and Red Brigades) as well as national secessionist movements (such as the PKK in Turkey). The idols of this movement were revolutionaries like Che Guevara, and also prophets of the use of demonstrative violence such as Carlos Marighella, whose 1969 *Minimanual of the Urban Guerrilla* became enormously influential. Despite their emphasis on the need for violence as a form of revolutionary provocation, terrorists in the third wave of terrorism did not seek high levels of casualties, but rather saw the violence as a form of spectacle and symbolic communication. They were also often supported by state sponsors, such as the Soviet Union and Iran, in order to further the foreign policy objectives of those states.

The fourth wave of terrorism began following the end of the Cold War and has continued to the present day. There are three trends noticeable in the current wave of terrorism. The first is that the contemporary wave of terror is motivated by religious or transcendent sentiment, in many cases an uncompromising interpretation of Islam, but often married to practical objectives. Notable examples of this motive include Hamas in the Palestinian territories, GPSC in Algeria, Hezbollah in Lebanon, as well as al Qaeda and its branches in North Africa, the Middle East, and Asia. But it is worth pointing out that religious terrorism is not confined to Islam; the early twenty-first century has seen a significant increase in membership for the Christian

identity movements and fundamentalist Hindu and Jewish groups. The second major trend clearly evident in this wave of terrorism is an increasing casualty rate for attacks. Whereas terrorists in the third wave wanted, as Brian Jenkins remarked, a 'lot of people watching, not a lot of people dead,' terrorists in the fourth wave appear to want both. The fourth wave of terrorism has become bloodier, with extremist groups like al Qaeda proving willing to kill large numbers of people in pursuit of their objectives. The first indication of the increasingly indiscriminate nature of terrorism in this wave was the Aum Shinrikyo group's chemical weapons attack on a Tokyo subway in 1995. Subsequent terrorist spectacles – such as the 1998 bombings of US Embassies in Kenya and Tanzania, the September 11th attacks, and the Madrid bombings (2004) – and the increasing use of tactics like suicide bombings and improvised explosive devices (IEDs) – have led to much higher casualties. Moreover, terrorist organizations have proven willing to kill large numbers of civilians in so-called 'soft targets' in order to achieve their objective. The siege of a primary school by Chechen separatists in Beslan, North Ossetia, which led to the death of 377 people, including 186 children, is an illustrative example. Similarly, the willingness of groups like al Qaeda in Iraq (AQI) to launch indiscriminate attacks on civilian targets is remarkable, for contrary to the approach of many insurgent or guerrilla groups, it appears less concerned with winning the support of the population than with fomenting chaos and civil war. Finally, terrorist organizations within this wave have been less dependent on state support and have relied more on fundraising, often from religious charities and criminal activity than their predecessors. The fourth wave of terrorism is a dangerous evolution of the phenomenon because it is largely comprised of entrepreneurial and self-organizing groups committed to the use of indiscriminate violence on a large scale.

### Types and Tactics of Terrorism

As the history of terrorism indicates, there are many different types of terrorism, many of which have unique features and characteristics. As a rule, terrorist acts demonstrate common characteristics based on two criteria: (a) their motive and self-ascribed source of legitimacy (e.g., religious, ideological, separatist) and (b) the type of perpetrator (state vs. nonstate). The motive of a terrorist organization matters for a number of reasons, not the least of which is that it shapes the goals that the organization pursues and its tactics. National-separatist terrorist organizations – that is, those focused on liberation of their home countries or regions – tend to have limited goals and be more selective in their employment of violence. Their goals are, as Paul Wilkinson described them, 'corrigible' because they are focused on reforming the system to meet their political demands, even if their demands are as extreme as outright secession from the state itself. For example, the Irish Republican Army used terrorist violence against Unionist Protestants and British officials at various points during its campaign, but only on occasions resorted to the indiscriminate attacks on civilians (e.g., the Canary Wharf bombings in 1996). Ideological and religious groups – such as the anarchists, Red Brigades, and al Qaeda – tend to be motivated by more

expansive goals, and seek the overthrow of the existing system. In this respect, they are revolutionary, for they are seeking not just the inclusion of specific political demands within an existing system but also the fundamental transformation of the system itself. For this reason, they tend to be less selective in their use of violence, and more willing to resort to suicide bombing and other mass-casualty attacks than their national-separatist counterparts.

There are a number of hybrid organizations which demonstrate features of both the national-separatists and religious-ideological archetypes. For example, Hamas is a terrorist organization committed to the violent destruction of Israel and its explicit source of legitimacy is Islam. Its leaders see themselves as leading a religiously motivated resistance movement. At the same time, however, Hamas has proven to be occasionally pragmatic in its willingness to forswear tactics like suicide bombings during its periods of cease-fire with Israel, and may be willing to be politically more accommodating in the future. Similarly, Hezbollah – literally the Party of God – is a religious terrorist organization that formed as a resistance movement during the Israeli occupation of Lebanon. While it employs terrorism and sees itself as an organization which draws strength and legitimacy from Islam, it has also been willing to negotiate cease-fires with Israel and participate in normal politics in Lebanon. On the other side, some national-separatist organizations like the LTTE (also known as the Tamil Tigers) are willing to employ tactics (such as suicide bombings) predominantly used by religious organizations.

Beyond this principal distinction lie two additional types of nonstate terrorism. The first is single-issue terrorism, which consists of individuals or small groups committed to the use of violence over a single policy issue. These organizations are highly ideological, but also more discriminate in the use of violence than traditional revolutionary organizations like the Anarchists. Examples of single-issue terrorist groups include the animal liberation front (ALF) and the earth liberation front (ELF). These groups employ attacks on targets of symbolic importance – for example, bombings of logging industry sites or medical facilities involved in research on animals – but are typically more careful to ensure that casualties are nonexistent or limited. Additionally, there is what might be called ‘idiosyncratic’ terrorism – violence conducted by individuals for causes without popular support or even acknowledgment. A signature example of idiosyncratic terrorism is Theodore Kaczynski (also known as the Unabomber), who sent 16 bombs to civilian targets (usually universities or airlines) between 1978 and 1995 in protest to modern society’s reliance on technology.

The second major category, state terrorism, can be broken down into three categories. Traditional state terrorism occurs when a government uses violence and repression to eliminate its enemies and keep the rest of the population in check through the use of fear. Examples of traditional state terrorism include Nazi Germany and the Soviet Union under Stalin, and also more recent cases such as Cambodia under Pol Pot and Afghanistan under the Taliban. State sponsorship of terrorism occurs when a government offers funds, weapons, or political support to a terrorist organization in order to further the government’s foreign policy objectives. Iran’s support of Hezbollah in Lebanon is a classic case of direct state sponsorship. State

sponsorship of terrorism can also be indirect if the government does not adequately stop its population from supporting a terrorist movement (i.e., United States’ reluctance to crack down on funding for the IRA in the 1970s, or Saudi Arabia’s unwillingness to stop charitable fundraising in support of al Qaeda) or if the government lacks the capacity or will to uproot and destroy the terrorist organization (i.e., al Qaeda and the Taliban in Afghanistan). Finally, prostate terrorism consists of nonstate actors who act on behalf of a government (i.e., militias and defense forces). In some cases, they are supported by the state (e.g., death squads in Guatemala) and in others tolerated or even opposed by the government they claim to support (e.g., the Ulster Volunteer Force (UVF) in Northern Ireland). [Table 1](#) identifies the types of terrorism along both of these dimensions, as well as key features of attacks within each type.

It is important to stress that these types of terrorism are conceptual distinctions which are often less clear in practice. As noted, some organizations cut across multiple boundaries. For example, Hezbollah is a state-sponsored terrorist organization that has features of both religious and national-separatist organizations. Groups like the IRA have in some cases claimed to be nationalists but have employed religious iconography and flirted with ideological movements, including Marxism. Classifying terrorist groups into these types is a useful first step for research but often raises more questions than it answers.

### What Makes a Terrorist? Approaches and Advances in the Study of Terrorism

Both in popular discourse as well as in academic inquiry, the kinds of questions that are frequently asked about terrorism often focus on the motives of the terrorists themselves. For instance, it is not at all uncommon to hear questions such as ‘why would someone engage in terrorism?’ or ‘what makes someone a terrorist?’ More recently, these questions have been supplemented with questions of process – ‘how’ does someone become a terrorist? Further, the question of how someone leaves terrorism behind, as articulated by scholars such as John Horgan, both in terms of the underlying motivations as well as the practical matters, is of increasing interest to both researchers and practitioners alike.

Historically, research in the still-developing field of terrorism studies had sought to establish key factors and elements that when considered in summation might effectively serve as the ‘profile’ of a terrorist. However, and in relatively short order, the sheer magnitude and difficulty of such a task was made clear, and empirical evidence to establish such a profile has yet to be established. In fact, the current consensus in the discipline is that a search for a profile based on some specific combinations of variables is destined to be a wasted and fruitless effort. While it is possible to start an analysis at the occurrence of a terrorist action or event and work backward, this type of analysis can only give a limited understanding about a particular set of perpetrators, motives, and circumstances. This type of analysis may also provide insights about the interpersonal and group dynamics that were especially influential on a given actor at a given point in time. However, trying to use an understanding of particular terrorists, and particular

**Table 1** Types of terrorism

|                             | <i>Description</i>                                                                                             | <i>Types of goals</i>                     | <i>Common tactics</i>                                                      | <i>Select examples</i>                                                |

| <i>Nonstate terrorism</i>   |                                                                                                                |                                           |                                                                            |                                                                       |
| National-separatist         | Armed groups who seek either autonomy or independence from an existing state                                   | Reform of existing government or policies | Bombings, assassinations, reprisals                                        | IRA, ETA, Irgun, FLN, PKK, Tamil Tigers, PLO                          |
| Religious                   | Armed groups who use fundamentalist interpretations of faith to challenge regimes or policies                  | Transformative and/or pragmatic           | Bombings, especially suicide bombings, assassinations, symbolic attacks    | Hamas, Hezbollah, al Qaeda, Christian Identity groups                 |
| Ideological (revolutionary) | Armed groups who seek the overthrow of an existing regime to produce fundamental political change              | Transformative                            | Bombings, assassinations, symbolic attacks                                 | Anarchists, Red Army Faction, Baader Meinhof, Red Brigades            |
| Single issue                | Small groups or individuals committed to reform of a single moral or political issue within the existing state | Reform of policies or social practices    | Bombings, symbolic attacks, targeted assassinations                        | Earth Liberation Front, animal rights groups, antiabortion terrorists |
| Idiosyncratic               | Small groups or individuals organized around a set of highly personalized beliefs or goals                     | Variable                                  | Bombings, symbolic attacks                                                 | Unabomber                                                             |
| <i>State terror</i>         |                                                                                                                |                                           |                                                                            |                                                                       |
| State terrorism             | Government which engages in systematic violence against its own population or that of another state            | Repression and/or elimination of enemies  | Assassinations, reprisals, torture, detention, psychological warfare       | Nazi Germany, Soviet Union (under Stalin), Cambodia (under Pol Pot)   |
| State-sponsored terrorism   | Governments which support or subsidize terrorist organizations in other states                                 | Weaken foreign enemies                    | Provision of material aid (such as weapons or funds) and political support | Iran's support of Hezbollah and al Asqa Martyr's Brigade              |
| Prostate terrorism          | Armed groups who use violence in support of a state's policies                                                 | Support of status quo                     | Assassinations, reprisals, symbolic violence                               | Ulster Volunteer Force, armed Israeli settler groups                  |

events, to generalize in a way that affords predictive value in identifying potential future terrorists has been largely unsuccessful. Part of this difficulty is due to the fact that predicting whether a specific individual will engage in violence or criminality is exceedingly difficult, if not impossible. Thus, in the field of terrorism studies, the most comprehensive analyses have been able to identify a compelling range of preconditions that have the distinct potential to increase the likelihood of terrorism, without affording specific predictive ability with regard to specific actors or specific situations.

Obtaining data and evidence to address the question of how someone becomes active in terrorism is fraught with problems and challenges as well. First, the nature of the problem of terrorism makes it inherently difficult to study. Because of its very secretive and illegal nature, identifying a specific actor who would harm noncombatant civilians is not feasible, especially in the context of research. Second, while there has been a massive increase in the publication of books and articles about terrorism, it is still relatively small as an area of academic research and topic specialization. Finally, the gap between the open source information available to academic researchers focusing on terrorism and classified information presents additional difficulties for establishing a comprehensive and holistic understanding of the phenomenon.

An additional feature of terrorism that further complicates its study is the dynamic nature of the topic under consideration. For instance, one may be interested in understanding motivations for terrorism, in a broad sense. However, there are

a multitude of reasons for involvement that are likely to change over time. It is becoming increasingly well recognized within the community of terrorism researchers and scholars that the reasons that one would become involved in terrorism are likely to be very different from the reasons that one would remain engaged in terrorism. As an example, imagine a situation in which an individual seeks to become involved in activities to support the global jihad. At several stages in this process, the individual will likely have to participate in a range of more mundane sorts of activities that may not seem to him to be particularly exciting or enticing. However, also along this path, that individual is likely to make new acquaintances, or share key experiences with some friends with whom he initially started his involvement. At this point, motivations are likely to have some core elements of wanting to avoid disappointing friends, which may serve to compel a continuation of their activities and training – less for reasons of hatred for an abstract out-group, and more for reasons of affiliation and affection for members of their in-group. These motivations can be readily understood from a group dynamics perspective, but hold somewhat less cache when the goal is to uncover the key factors that make someone a terrorist.

As in so many other forms of interpersonal and intergroup violence such as genocide, some of the key factors that have emerged from the study of terrorism suggest the importance of many mundane processes of influence, compliance, and obedience, to name but a few. When considered together, these rather normal processes can lead to potentially

devastating actions and consequences. To date, there have been some significant advances that have applied classic and current work from a range of disciplines including psychology to the study of radicalization in the context of terrorism in particular.

### Individual and Group Level Factors in Radicalization and Terrorism

From a psychological perspective, there is little evidence to suggest that terrorists have abnormally high levels of mental illness or psychopathology; in fact, research on the topic has shown no difference between terrorists and other members of the population. What does emerge from this research is that terrorists have purpose, intent, commitment, and conviction. In addition to research addressing individual-level psychological factors, a wide range of external factors such as global poverty, inequalities in health care, education, and access to the basic requirements of food, water, and shelter have been researched as well. In general, structural factors such as those mentioned here may constitute background conditions in which recruiting, indoctrinating, and motivating individuals toward terrorism may become increasingly likely. However, this is not necessarily true for all terrorists, or even all types of terrorism.

Some scholars have examined the link between grievances and traumatic experiences and the development of terrorism. This area of research has been able to examine interview data with people who had been involved in terrorism, and has provided rich narrative detail in which very personal accounts can be used to supplement the more commonly employed methods of examining macrolevel trends or incident databases. Interview data capture a significant depth of experience and the reasons for involvement in terrorism as recollected by the actors themselves. However, there are critical limitations in broadly applying findings from retrospective accounts and narratives to other actors, situations, and contexts. Thus, while interview data have not served as a solid empirical basis for developing valid and reliable predictive models, they have provided a veritable treasure trove of insight about recurring themes in individual-level factors in terrorism.

### Stage Models of Terrorism

Several psychological models posit that there are a series of stages or levels that individuals progress through as they become increasingly radicalized toward terrorism. Fathali Moghaddam's 'staircase model' posits that terrorism can be viewed as sequential progression from lower floors to higher floors on a staircase that gets increasingly narrow the further one progresses. Clark McCauley's 'pyramid' model positions terrorists as the apex of a pyramid composed of a general population, passive supporters, and active supporters. Here, terrorists are a very small portion of the overall population the pyramid represents. Both of these models offer a conceptual foundation for distinguishing between those who may passively or actively support terrorism, and those who might take a more direct role. However, it should be noted that the process by which one becomes radicalized toward terrorism is most often viewed as fluid and dynamic.

### The Power of Social Networks in Radicalization and Recruitment

Of central importance to understanding the modes of recruitment and radicalization is the way in which individuals and small groups become radicalized toward the use of violence. Marc Sageman studied what he termed 'the global salafi jihad' and uncovered critical aspects of the core membership of the al Qaeda terrorist network that linked individuals together into small groups, through the sharing of core formative experiences (e.g., time spent in Afghanistan in the period of the Soviet invasion and occupation), as well as through some more mundane – yet important – daily experiences. One of the key findings in this analysis was that small group dynamics had a very important role in the radicalization process. In fact, the detailed descriptions that Sageman provides of the global jihad, including its networks, and more detailed biographical characteristics of its membership show that the experience of poverty, lack of educational achievement were not causal factors for those who became jihadis. In fact, this group appeared to be fairly well educated, and from a middle to upper-middle socioeconomic status. One thing that this analysis of those involved in the global jihad illustrates is the importance of context. Certainly, some of the background characteristics and motivational factors for those who get involved in the global jihad will differ from those who get involved in more local-level groups. For example, Ariel Merari notes in his review of suicide terrorism that in fact, among Palestinian suicide terrorists, the socioeconomic profiles correspond to those of the general Palestinian population, and that suicide terrorists even had slightly higher levels of education. In sum, much of the available data serve to contradict some popular assumptions about what causes people to engage in terrorism, while emphasizing the importance of social bonds and interpersonal relationships.

### The Importance of Leaders

There are several key examples of groups that have strong, charismatic leaders who have been essential to both the structure and function of the group. In Sri Lanka, the largely Nationalist-Separatist Liberation Tigers of Tamil Eelam was led by Velupillai Prabhakaran, and successfully mounted a protracted campaign against the Sri Lankan government, including a significant series of suicide attacks, from the mid-1970s until their ultimate defeat in 2010. In Peru, The Sendero Luminoso (or 'Shining Path') was led by Abimael Guzman, who also went by the moniker of 'Presidente Gonzalo.' After Guzman's capture and arrest in 1992, the group was essentially stripped of its capacity to pose a serious and continued threat to the Peruvian government. In Turkey, the Kurdish workers party (PKK) was led by Abdullah Ocalan, whose leadership was an essential component of the groups cohesiveness. And in Japan, Shoko Asahara led Aum Shinrikyo, a cult-like group that demanded total loyalty from its members, and most infamously mounted a sarin gas attack against the citizens of Tokyo, Japan, by targeting its subway system. Interestingly, the choice of sarin reflected Asahara's idiosyncratic interest in using poisons. Following the 1995 attack, a series of arrests of Aum Shinrikyo's members, including Asahara, left the group in disarray. In 2000, the group changed its name to Aleph, and has

fractioned as a result of disagreements within factions of the group and a lack of clear leadership of the kind that Asahara offered, and the absolute loyalty he demanded. Each of these leaders represents a very distinct type of organization; however, the commonality that these groups share is that the leadership was a core element of each group's ability to function. Thus, continued consideration of the dynamic relationship among leaders and followers will complement the developing interest in emergent social networks, and the potential for 'leaderless' terror networks.

### The Role of the Media

It has long been noted that terrorist organizations thrive on access to the media. British Prime Minister Margaret Thatcher famously observed that terrorists require the 'oxygen of publicity' in order to succeed and spread their message. For this reason, terrorist organizations have been particularly attuned to the needs of traditional media (such as newspapers, television, and radio) in order to maximize the impact of their attacks. As Brian Jenkins has argued, 'terrorism is theater,' with terrorist organizations in some cases planning their most spectacular attacks to have maximum media impact, especially on television. The visual imagery of terrorist attacks – for example, a hijacking or a hostage video – amplifies the effect of the violence and has a dramatic impact on media coverage. The hijacking of TWA Flight 847 proved a case in point, with the media broadcasting an average 28.8 news segments per day during the duration of the crisis. Similarly, the events of September 11th commanded days of television coverage and made Osama bin Laden a household name virtually overnight. While the coverage of terrorist events is rarely positive, it often dramatizes the events themselves and focuses on the human interest aspect of the crisis, thus reinforcing the notion – as the terrorists intended – that such attacks can occur anywhere at any time. The unintended effect of the volume of media coverage is to amplify the fear that would be the natural result of the terrorist act. The clever use of the television and radio media by terrorist organizations also places enormous pressure on governments to respond, which may in turn goad them into over-reaction. The advent of so-called 'new media,' including the internet, has further transformed the way that terrorist organizations can interact with their supporters and the wider public. The nonhierarchical structure of internet communications – that is, the fact that anyone can post a message without going through an editor or even a filtering process – offers an unprecedented opportunity for terrorist organizations to communicate their message to the public. This could be clearly seen in the raft of video and audio messages issued by bin Laden, Ayman al-Zawahiri, and other leading figures in al Qaeda. Such videos, posted on file-sharing sites and other open forums, are difficult to track and counter, as they can spread rapidly to multiple sites across the internet. A wide range of terrorist organizations, including the Tamil Tigers, Hamas, and Hezbollah, have now set up official or quasi-official web sites, often with sophisticated internet content, chat rooms, and well-produced videos to disseminate their messages. On top of these web sites are a range of unofficial but supportive web sites, often located in little-noticed host servers located throughout the

world, where supporters of the organization can discuss their activities and exchange information. Counterterrorism officials also believe that web sites, chat rooms, and blogs can be used tactically for the dissemination of operational orders to cells planning an attack.

The internet has also been used for radicalization of potential recruits and for popularizing terror attacks to a wider audience. The low-cost barriers to entry on the internet have facilitated the rise of a number of charismatic figures who offer religious and historical instruction of often dubious quality, as well as a compelling interpretation of events, to a wide audience of potential recruits. For example, the Yemeni-American cleric Anwar-al Awlaki has recorded numerous audio and video recordings of his sermons, which demonize the West and exhort Muslims to engage in terror attacks against the United States and its allies. These recordings of his sermons are widely available on the internet, and there is some evidence that those engaged in terror attacks – including the 9/11 attacks and the failed Christmas Day bombing of Northwest Flight 253 in 2009 – have been directly influenced by his call to action. The internet has also proven to be successful in popularizing terror attacks, often with graphic imagery, to generate sympathy and produce new recruits. The Iraqi insurgents, for example, often posted videos of beheadings online; a number of European terrorist suspects reported being influenced by graphic images of fighting in Afghanistan and Chechnya. Terrorist organizations have also recently proven highly innovative in their use of more sophisticated forms of 'new media.' For example, al Qaeda has produced a number of online Arabic and English language magazines, often with high production values, in a deliberate appeal to youth recruits. One of the most striking recent trends has been the production of nasheeds, online songs, and music videos that often emulate Western rap and hip hop styles, in an effort to glorify the actions of those who participate in violent jihad and encourage others to follow suit.

### Conclusion

The study of terrorism is a growing area of focus, as threats continue to develop, evolve, and change. In this field, there are multiple conceptualizations of terrorism that are often reflective of differing missions. Governments, agencies, academics, nongovernmental organizations, and others will likely continue to face the inherent challenges of working across these areas, while developing the background and capacity to face emerging threats such as so-called 'cyber-terrorism' which would ostensibly target critical infrastructures through finding and exploiting key vulnerabilities. If current trends persist, research in terrorism will continue to cross disciplinary boundaries to develop a more cohesive and coherent understanding of the multifaceted problem of terrorism.

### Glossary

**Cognition** Thought or mental processes involved in perception, attention, memory, judgment, decision-making, problem-solving, or other mental operations.

**Formative assessment** Instrument or procedure conducted prior to and/or during a course that assesses students' skills for the purpose of planning instruction for those students.

**Metacognition** Thought or mental processes involved in the monitoring and/or strategic regulation of other cognitive processes.

**Summative assessment** Instrument or procedure conducted following course instruction that assesses

students' mastery of the knowledge and/or skills taught in the course.

**Test** An instrument (along with a set of procedures) that results in a score, capturing information about the knowledge, skills, attitudes, or other attributes of an individual or social group.

**Test-wiseness** An examinee's ability to use characteristics of the test and/or test situation independent of the construct(s) being measured to improve his or her observed score.

**Validity** The degree to which test scores serve as an appropriate indicator of interpretations made with respect to the proposed uses of a test.

### Introduction

Recent years have seen a rapid growth in the number and variety of assessments administered in educational, psychological, and vocational settings throughout the world. In some countries, children as young as 5 years old begin taking tests in school and grow up regularly taking many different types of assessments for much of their lives. The importance of testing should not be underestimated as test scores are used by parents, educators, school admission counselors, potential employers, psychologists, or test takers themselves to make decisions regarding an individual's educational and career development or clinical status. And the results from tests, aggregated across groups, are also frequently used to shape public policy in a number of countries. The incidence, regularity, and importance of testing can either directly or indirectly influence the behaviors of examinees in myriad ways that may, in turn, impact test performance and the interpretation of test scores.

Behaviors that enable individuals to perform to the best of their knowledge and capabilities in a test situation help to ensure that the test serves as a valid indicator of the construct intended to be measured. By the same token, test validity may be compromised when individuals either underperform in the assessment (say by succumbing to high levels of anxiety and stress) or overperform (say by applying test-taking strategies that enable them to successfully guess correct answers). It is therefore critical to better understand both how testing shapes behavior and how behavior influenced in the test situation.

Test developers, test administrators, and test takers may limit such considerations to specific behaviors displayed in the context of a test situation. However, test behaviors encompass a wider range of human thought and actions that extend well before or after an examinee takes a particular assessment. That is, prior to taking a test, certain factors may affect the behavior of individuals as they anticipate and/or prepare

for an upcoming assessment just as certain factors influence behavior during test situations. Moreover, taking a test influences the subsequent behavior of an individual.

The purpose of this article is to provide an overview of the topic of test behavior, focusing primarily on testing in educational settings, though the principles are broadly applicable to all testing applications. Our aim in writing this article is to paint test behavior with a fairly broad brush, such that we do not get too involved in the details of research studies or theoretical discussions. (The curious reader can find a number of references, at the end of this article, that we have selected to address these issues.) So, we first define some broad distinctions and key terminology related to test behavior.

Next, we discuss important factors, highlight key empirical findings, and raise general questions about the aspects of behavior associated with testing. Specifically, this article is organized according to the types of behavioral factors assumed to operate in the test situation, which include physical, cognitive, metacognitive, individual difference, and social factors. In discussing each factor, we consider behaviors that occur in anticipation of, during, and following a test situation, as well as emphasize the reciprocal relationship between testing and behavior. Just as testing can impact behavior, advances in our understanding of behavior can influence the manner in which tests are developed and administered as well. We end with a set of conclusions and some suggestions for future research directions that the reader might profitably explore.

### Tests: Types and Purposes

To address the general question of how testing influences behavior, it is necessary to consider particular characteristics of the test situation itself. First, what type of test is being administered? Tests come in many different forms, depending upon the purpose of the assessment. In the classroom,

instructors may provide students with formative or dynamic assessments, which may include quizzes or other tasks designed to gauge students' knowledge and understanding of a particular subject matter and guide subsequent instruction. To the extent that such tests are used to identify and correct knowledge gaps and misunderstandings, they are also referred to as diagnostic assessments. By contrast, static or summative assessments, such as end-of-chapter, final, or standardized state tests, are designed to measure what students have learned in a particular domain through the course of instruction. These are but one of a series of taxonomies available for testing. For example, within the above mentioned assessment, tests may also be norm-referenced, which means that an individual's performance is measured in relation to that of a reference group (e.g., individuals of the same age, grade level, or socioeconomic background). Alternatively, criterion-referenced assessments measure individual student performance against a particular standard, which is typically defined by educators and policy makers as a task or body of knowledge that students are expected to perform or possess.

Additional test characteristics that may impact behavior are the format of the test questions and the physical and/or social conditions of the test situation. For instance, how individuals prepare for and react to taking a multiple-choice test may differ in myriad ways from their preparation and reaction to tests containing short answers or essay questions, often referred to as open-ended or constructed response tests. How individuals behave in relation to a test situation may also depend upon the modality of test presentation (e.g., aural vs. visual, computer vs. paper-and-pencil), test-takers' responses (e.g., oral vs. handwritten vs. keypad), and whether time limits are generous or strict.

It is important to consider contextual factors as well. Are students testing themselves in an informal self-guided manner, or are they being given a more formal assessment designed and administered by others? Is the test given to individuals in a private or public setting? Is the test administered to individuals alone or is it done in collaboration with other test-takers? Is the test taken in the same location where students originally learned the subject matter in which they are being assessed? Are the consequences of successful or poor performance on the test perceived to be great (high-stakes test situation) or relatively insignificant (low-stakes test situation)? These are some of the questions that underscore the intricacies of how specific features of test situations may influence behavior.

Of course, just as the specific type, format, or context of a test may affect behavior, so too it is necessary to specify what aspects of behavior and its underlying mental processes are influenced by testing. Behavior, broadly defined, is neither a monolithic construct nor is it limited to observable, external responses, but rather, it encompasses a wide range of physical, mental, and even social factors. These factors include (1) physical or physiological factors, which refer to the physical state of the test taker as well as the physical conditions of the testing environment; (2) cognitive factors, which typically refer to mental activities such as human perception, attention, and memory; (3) metacognitive factors, which refer to the mental activities associated with individuals' attempts to monitor their own knowledge, understanding, and skills in a particular domain; (4) individual differences, which include psychological

constructs such as personality, emotion, interest, and motivation; and (5) social factors. Of course, this typology of factors is by no means exhaustive; however, it provides a useful framework for highlighting some of the complicated effects that testing can produce on the different measures of test-takers' thoughts and actions.

### Physical and Physiological Conditions

Ask almost any parent or educator or consult any one of the numerous guidebooks and Web sites that offer test-taking tips, and they will invariably tell you that to best perform on a test, examinees must feel comfortable, relaxed, well-fed, and rested. The common presumption is that individuals who are ill, tired, hungry, or otherwise uncomfortable will perform poorly on a test. This is, for instance, why examinees are often advised to get a good night's sleep and eat a nutritious meal replete with protein and carbohydrates before a test. This is also why many assessments are administered in quiet environments that provide adequate lighting, ventilation, moderate temperatures, and comfortable seating.

Despite the common acceptance of these practices, numerous studies have actually shown that physical conditions that may be somewhat uncomfortable or even distracting to examinees have little or no impact on the test performance. This is especially true in high-stakes test situations. For many test takers, moderate changes in noise levels and temperatures may increase their arousal, which may, in turn, enhance test performance.

What is less well known is the subtle ways in which the physical and temporal context of a test situation may influence behavior. For instance, there is some (albeit limited) empirical evidence showing how individuals vary in terms of their sleep and wake schedules and how this may impact test performance in meaningful ways. Morning people who are most alert during the early periods of the day may perform worse on a test administered in the late afternoon. Conversely, evening people may perform worse on a test given too early in the morning.

Laboratory and classroom-based studies have also corroborated the notion that examinees may best prepare for a test by practicing older tests under physical conditions that are similar to those of the upcoming test. For example, in a famous psychology experiment, divers studied lists of words while standing on a beach as well as underwater, and then they attempted to recall the words in either environment where the lists were originally learned, or in the alternative environment. It was found that lists learned underwater were best recalled underwater, and vice versa.

Researchers have posed similar questions of learning in educational settings. Should students be tested in the same classroom in which they learned the subject material to be tested? Is it important for students to be in the same mood or physical condition during testing as they were in during learning? To date, there is some evidence to suggest that the physical context and mental state in which a person prepares for an upcoming test does matter, but the impact of these factors is often found to be fairly small, so definitive answers to these questions await future research.

## Cognitive Processes and Strategies

From the moment individuals are informed that they will be given a test, or when they decide to take a test of their own accord, examinees begin to engage in anticipatory thoughts and actions that may occur minutes, days, or even years prior to actually taking the test. This is especially true for high-stakes assessments where test scores play an important role in decisions that affect the academic and career prospects of test-takers. Whether and how individuals prepare for upcoming tests can have a significant influence on performance outcomes. Moreover, performance in test situations depends and may have an enduring impact upon a variety of conscious and unconscious mental processes involved in perception, attention, memory, problem-solving, judgment, and decision-making.

### Test Expectancy

The starting point in the process of test preparation is becoming familiar with the form and contents of the upcoming test. Thus, when individuals are informed about the exact type of test they will receive on the subject that they have been asked to learn, they focus better on their preparatory study on important information. As a result, final test performance will be improved relative to examinees who have a vague idea of the upcoming assessment. Indeed, students often ask their instructors at the beginning of a course about what type of exams they should expect. But, does it really matter if students are told that they will be given a multiple choice, short answer, or essay exam, even if they end up taking a different type of test?

The answer to this question depends upon the context. In one set of studies, participants were asked to study lists of words with the expectation of taking a final test of their memory. While one group of participants expected a final recall test (e.g., write down as many words as you can remember from the study list), another group expected a recognition test (e.g., was this word on the previously studied list or not?). It was found that the expectation to take a recall test produced superior memory performance on final tests of both word recall and recognition than the expectation to take a final recognition test. However, the advantage of expecting a recall test cannot be generalized because it has failed in classroom settings with educationally relevant study materials and test formats. Instead, examinees tend to perform best on the specific type of test they expect to take, be it a multiple choice, short answer, or essay examination.

How knowledge of the upcoming test is utilized by examinees to prepare for the test depends upon a host of other factors, including (1) the perceived stakes of the test; (2) examinees' current knowledge in the domain to be tested; (3) examinees' self-assessment of their own knowledge and skills; and (4) the personality of the examinee. For example, the psychological expectation of taking high-stakes assessments may, at one extreme, compel some examinees to devote years of time and effort to test preparation, whereas others at the other extreme may take the test with little or no advance preparation. By contrast, even when examinees anticipate a low-stakes assessment, such as in-class quizzes that count relatively little toward final course grades, conscientious or highly

motivated students may still spend considerable time reviewing notes or old exams beforehand.

### Test Preparation

When examinees do know what to expect, how should they best prepare for the upcoming test? In general, individuals who repeatedly practice or are taught the skills and information to be assessed well in advance of the upcoming test will perform better than examinees who have not engaged in such preparatory activities. These activities include taking practice on similar tests or old forms of the specific upcoming test. In addition, this involves learning test-wisness skills – strategies that enable examinees to maximize performance in a wide variety of test situations. For example, if a test-wise student is unsure of an answer to a multiple-choice question, a rational strategy might be to eliminate one of the distractors in that question if it appears to be the correct answer for another question in the test.

Researchers have identified test-wisness strategies that are independent of test construction. These include using time well, avoiding avoidable errors, and using deductive reasoning. Test-wisness strategies that are dependent upon the test construction also exist. These include answering questions by taking the construction of other questions into consideration, taking into account the intent of the test creator and using cues (such as answer length) to help determine the correct answer. Research has demonstrated that students high in test-wisness tend to perform better on tests. While the benefits of coaching in test-wisness skills are considered applicable to many test situations, their effectiveness in specific situations often depends upon the test takers' knowledge and skills within the assessed domain, as well as their knowledge of the design and purpose of the test. Also note that in many high-stakes situations, the efficacy of these test-wisness strategies may be diminished as assessment developers are instructed to avoid precisely the elements that are being coached (e.g., to keep all answers at a similar length, to avoid giving away information in other items).

In terms of learning the particular domain of knowledge and set of skills to be tested, two general theoretical principles derived from laboratory studies of human learning and memory are worth highlighting: transfer appropriate processing and encoding specificity. According to these principles, practicing the types of problem-solving strategies and mental operations under the same conditions as the upcoming test will enhance final test performance. Conversely, any mismatch between learning and testing conditions may lead to poorer performance, such as might be the case of a teacher who encourages students to engage in study strategies that promote a deep conceptual understanding of the subject matter, but then gives students a multiple-choice test that emphasizes recognition of isolated facts.

Just as one of the best ways to prepare for a test is by practicing taking similar, older tests, testing can also have positive effects on learning and subsequent test behaviors. Numerous studies in the psychology literature have shown that testing not only assesses a person's knowledge but can also transform it by rendering it more resistant to forgetting over long term as compared to restudying the information. This finding, known as the testing effect, has been

demonstrated in educational settings using a wide range of study materials among various test-taking populations. More importantly, taking a test may bestow additional benefits on subsequent learning. Testing can provide students and instructors with rich feedback regarding their own strengths and weaknesses that, in turn, will aid future study and instruction by identifying areas that require more study or instruction time and effort, as well as areas that are well learned, and therefore, require less attention. This is the primary aim of formative assessments. In addition, there is some empirical evidence that testing can enhance the long-term retention of non-tested information that is conceptually related to previously tested knowledge, as well as permit better transfer of learning by improving performance on future tests that assess new knowledge domains.

### Biases and Heuristics in Responding

Despite an individual's conscious efforts to prepare for and perform well during a test, actual test performance may be unwittingly influenced by psychological factors that are difficult to overcome. In particular, naïve strategies or cognitive biases can have a significant impact on human performance in various judgment and decision-making tests. One naïve strategy, or heuristic, students often use, and one that is often taught to them by their parents and teachers, is to stick to their 'first instinct.' Previous research has demonstrated that three out of four students believe that changing one's answer usually leads to the choice of incorrect answers.

Not only do students hold this belief, research has demonstrated that a large percentage of college professors also believe that it is better to stick to one's first answer than to go back and change it. This conventional 'wisdom,' however, is wrong. A change answer is more likely to be correct than was the original answer. Nevertheless, most students tend to continue to believe that sticking to one's first answer is a wise strategy. Why does this occur? Recent research has found that one reason people hold this erroneous belief is that answers that are changed from correct to incorrect produce frustration and are thus more memorable than answers that are changed from incorrect to correct. As such, students tend to overestimate the frequency of the incorrectness of answers that have been changed.

### Metacognition

In contrast to the accepted wisdom of what individuals should do to learn specific content and prepare themselves for test situations, many studies have found that individuals demonstrate poor ability to judge what are the best learning strategies to adopt; how well they know, understand, or remember subject matter; and how to best allocate their study time and effort. Left to their own devices, people tend to select the easiest, least effortful learning techniques and apply them in an inefficient manner.

Of course, the accuracy of metacognitive judgments or self-assessments varies considerably across individuals, with some people being much better attuned than others to their general strengths and weakness, as well as to identifying specific gaps

in knowledge and understanding. The accuracy of self-assessments also varies with respect to domain. For instance, people are usually overconfident in their ability to perform tasks that assess their knowledge and comprehension of subject matter, but they tend to be underconfident in their ability to perform sensory or perceptual tasks.

Who tend to assess themselves most accurately? Perhaps not surprisingly, good students tend to be more accurate in their self-assessments than do poorer ones. That is, good students tend to be able to more accurately predict the grades that they will receive on future tests. In contrast, poorer students tend to be overconfident about the grades they will receive. Although one might predict that poor students' overconfidence would be remediated when they receive disappointing feedback about test scores, this does not seem to be the case. Research has demonstrated that poor students remain very overconfident even after they receive negative performance feedback.

The fact that poor students tend to be overconfident can have important implications for their test-taking behavior. While good students with accurate self-assessments will have a good idea of just how much they should study poor students will tend to spend an insufficient amount of time studying because they are overconfident. This may lead poor students to continue to perform worse in tests than their peers with more self-awareness.

Inaccurate self-assessments have detrimental effects not only on those students who overestimate their ability but also on those who underestimate their ability. One recent line of research theorized that both students who have a tendency to overestimate their test performance and those who have a tendency to underestimate their test performance are motivated to practice ineffective study strategies so that their future test performance will be less diagnostic of their actual ability. Put in another way, those who underestimate themselves do not want a poor test performance in the future to confirm their negative self-view. Thus, they practice self-handicapping strategies (purposely placing obstacles in the way of performance) when studying for tests to avoid this confirmation. In essence, the self-handicapping allows them to tell themselves that their poor test performance was a result of self-handicapping rather than low ability. Furthermore, those who overestimate themselves do not want a poor performance in the future to threaten their inflated self-view. Thus, they also practice self-handicapping when studying for tests. These predictions have been verified in both experimental and nonexperimental studies. In general, these studies suggest that both overestimators and underestimators (a) choose to study in a noisy, rather than a quiet, study environment and (b) spend less time studying than do students who are accurate in their self-assessment. Thus, the former tend to perform worse on subsequent tests and also have lower grade point averages than the latter group of students.

The ways in which students typically study for tests can also lead to overconfidence in estimates of how well a subject has been learned. Research demonstrates that distributed studying (studying over several sessions) leads to better retention of material than does massed studying (studying a lot over a single period). However, students tend to practice massed studying to a much greater extent than distributed studying. Why is this? One reason offered to account for this

phenomenon is that most students are not diligent at planning their study time in advance. Another reason is that students tend to be overconfident in the amount of material they retain when studying in a massed way. Although students do not retain material well with massed studying, they do tend to learn material quickly in massed studying. The problem is that they also forget very quickly. However, students tend to falsely estimate that material that is learned quickly will also tend to be remembered for a long period of time. Thus, they tend to overuse massed studying, which leads to overconfidence in the ability to remember the material they studied when they are taking the exam.

Other researches also demonstrate that students are overconfident about the extent of their understanding of what they have read. For example, several research studies in which students read a passage and are then asked to predict how well they can answer questions about the passage they have just read have been conducted. Next, they are asked to actually answer a series of questions about the reading passage. The correlation between predicted and actual performance tends to be low, providing evidence that students do not fully comprehend the reading. This finding has implications for studying for tests: many students spend an insufficient amount of time on reading materials relevant to the test.

Finally, there is also evidence that confidence can be thought of as an individual difference factor. Thus, some students consistently display more confidence in their chances of succeeding in an exam than do other students. Additionally, male students tend to be more overconfident than female students. As stated earlier, this can have important implications for test preparation behavior, with overconfident students displaying a tendency to understudy for tests.

### Improving Self-assessment

What steps can individuals take to improve the accuracy of self-assessments and thereby develop good test preparation habits? One effective strategy is to teach students to stop periodically and check their understanding of their reading. One possible way to do that would be to give occasional self-quizzes during study times. Quiz questions that were answered incorrectly can be used as cues that a reading passage was not fully understood. Furthermore, students can become more accurate in their self-assessments by comparing themselves to students who achieve good grades. One possible way to do this would be to join a study group that consists of high-achieving students. Finally, another way students can gain a more accurate self-assessment is to have a fellow student rate them. Peer-ratings tend to be highly correlated with teacher-ratings, and thus, can be a useful piece of information for students who desire to accurately assess their level of class knowledge. This information can then let the students know how much they should be studying for the upcoming tests.

### Individual Differences

Behavior is highly context-dependent. For instance, the average person will behave in a much more sociable way while attending a party than while attending a funeral. Indeed, it is not difficult to

imagine that most funeral attendees would be quite shocked to see a person smiling, talking, and generally having a good time while attending the funeral of a loved one. However, although typical behavior changes dramatically between contexts, people can still be differentiated on basis of their typical behavior within contexts. A very outgoing person will tend to be more talkative than a shy person at both a party and a funeral.

The same can be said of students' test-taking behavior. Although students' test-taking behavior is similar overall, there are still important differences between individuals that can predict test-taking behavior. These differences include personality, test anxiety, coping, and cheating.

### Personality

Among researchers, there is now overwhelming consensus that personality consists of five factors and that people vary in how much they display each of these factors. The five factors are (1) openness to experience, (2) conscientiousness, (3) extraversion, (4) agreeableness, and (5) emotional stability. These factors are highly predictive of several behaviors, including test behavior. For example, some personality factors predict procrastination, which in this case means consistently delaying studying for tests. Often, this is accompanied by a sense of anxiety and dejection. Research has revealed that conscientiousness and emotional stability predict procrastination. That is, conscientious and emotionally stable students tend to procrastinate on studying for exams to a lesser extent than students who are less conscientious or emotionally stable. Furthermore, conscientiousness is the single strongest predictor of procrastination among these five personality traits.

Not only do highly conscientious students tend to procrastinate less than their less conscientious peers, they also tend to study more for tests. The finding that conscientiousness predicts grades at all levels of education is now well established in the research literature. This is true with the case of intelligence too. Additionally, none of the other four personality factors comes close to the predictive power that conscientiousness has in predicting test performance.

### Test Anxiety

In addition to feeling anxious about procrastination, students may also feel anxious about the test itself. Much research evidence that suggest that students vary on the amount of anxiety they feel about test situations and that this anxiety can negatively impact test performance has accumulated. Although test anxiety may have its greatest impact during the actual test, it can also have an impact during the test preparation stage and after the test is over. It is generally agreed upon that test anxiety consists of four components: (1) *worry* – cognitive concerns related to poor performance on the test, (2) *test-irrelevant thinking* – thoughts that take one's attention away from the test, (3) *tension* – feelings of distress, uneasiness, fear, and panic during tests, and (4) *bodily reactions* – the tendency of test situations to elicit heightened activation of the sympathetic nervous system.

Students with high test anxiety and are studying for tests may experience a great deal of worry, thoughts that are irrelevant to the test, physical tension, and other negative bodily reactions

(e.g., sweating, increased heart rate) when thinking about the test. As a result, they may find themselves unable to fully concentrate on their test preparation and may practice ineffectual coping behaviors, such as avoiding thinking about the test altogether, to deal with this anxiety. As a result, students with high test anxiety may come underprepared for the test.

Several studies have found that test anxiety is consistently negatively correlated with test performance and that worry and test-irrelevant thinking have a stronger negative relationship with performance than tension and bodily reactions. It is possible that worry and test-irrelevant thinking impair test performance by reducing the amount of cognitive resources necessary to successfully complete a test. For example, working memory and concentration is impaired when students worry about failing the test rather than pay full attention to test items.

Finally, test anxiety may continue to influence student behavior after the test, as highly test anxious individuals will not simply stop worrying about the test once it is completed. Rather, they may continue to worry, feel tensed, and experience negative bodily reactions until they receive their grade (and possibly even after). The worry, tension, and negative bodily reactions they experience after completing a test can serve to further deplete cognitive resources available for subsequent tests, thus creating a vicious cycle whereby anxiety reduces test performance, which in turn creates anxiety and further reduces performance in following tests.

### Coping

Students can use several coping mechanisms to deal with the stress and anxiety that come with taking tests. People tend to cope with stress and anxiety in one of the three ways. *Problem-focused coping* refers to efforts to alter the stressful situation itself. For instance, the stress and anxiety of an upcoming test can be minimized by studying for the test, thus eliminating the stress-inducing power of the test. *Emotion-focused coping* refers to efforts to reduce one's response to the stressful situation. In this case, the stress of an upcoming test can be reduced by imagining all the positives that will come from successfully completing the test – thus, the meaning of the test is reframed from a negative one to a positive one. Finally, there is *avoidance-oriented coping*, in which the stressor is avoided altogether. Thus, the stress of an upcoming test can be avoided by doing something that takes attention away from the test, such as going out with friends or watching television instead of studying.

Although results of research on the relation of coping to test performance are not entirely consistent, some research has found that both problem-focused and emotion-focused coping are positively related to students' test performance. Other research have found that optimism concerning performance in tests is related to problem-focused coping, that pessimism is related to avoidance-coping, and that these relationships are mediated by motivation. Thus, more optimistic students tend to be more motivated to succeed on the test and thus deal with the stress and anxiety of test situations by using problem-focused coping or studying more. In contrast, pessimistic students tend to be less motivated to succeed on the test and thus deal with the stress and anxiety of

test situations by using avoidance-coping or doing things to take their attention away from the test.

### Cheating and Its Correlates

An unfortunate fact of testing is that one behavior that can improve student test scores is cheating. After all, it is often much easier to get an answer correct by peeking at your neighbor's test than by spending hours studying. The decision of a student to cheat is determined by a multitude of factors, and recent research has identified a few of them. For example, research has found that *subjective norms* predict the intention to cheat on exams. Subjective norms refer to how others who are important to you (e.g., family, friends) feel about the behavior. Thus, for example, students are more likely to intend to cheat on exams if their friends also cheat on, or approve of cheating on, exams. Students' sense of *moral obligation*, or the belief that cheating would be morally wrong, also predicts their intention to cheat. Finally, *perceived behavioral control* also predicts cheating on tests. Perceived behavioral control is a student's perceived capability to cheat. A student who believes that he or she can easily cheat without being caught is more likely to cheat than one who believes that cheating without being caught will be difficult.

### Social Factors

Although assessments are typically designed to test characteristics of individuals in isolation from others, social factors can have a significant impact on individuals' test behaviors. For example, the number of examinees taking the same test in one location may affect individual performance due to feelings of competitive motivation aroused (or diminished) in a group setting. Some researchers have observed that in high-stakes test situations, increasing the number of competitors in a test-taking group lowers individuals' motivation and effort, which may worsen performance. By contrast, there is a significant increase in individuals' motivation and effort in small test-taking groups.

Laboratory research has also provided evidence that performance on tests can be harmed by the fear that one will confirm the notions of a negative stereotype that exists about one's cultural group. For example, there is a stereotype that African Americans are intellectually inferior to other ethnic groups. Several studies have indicated that African Americans are concerned that their poor performance on a test will tend to confirm this stereotype. This finding suggests that for an African-American student, taking a test described as a test of intelligence may engender anxiety that can harm test performance.

This phenomenon is referred to as *stereotype threat* and is not unique to African Americans. For instance, Latinos perform more poorly than whites when a test is described as diagnostic of intelligence, and white men perform worse on a math test when they are told that their results will be compared to the results of Asian men. These effects are especially prevalent when a person's attention is called to the negative stereotype. It is important to note that there is very little evidence that stereotype threat effects exist outside of laboratory studies. More research is necessary to determine whether stereotype threat exists in important real-world test situations, such as when students take the SAT or ACT.

## Summary

There are a variety of physical and psychological factors that can determine whether and how individuals prepare for and perform during an upcoming test. The factors include, but are not necessarily limited to, the expectancy of the future test, examinees' perceived and actual knowledge and skill level in the domain to be assessed, and personality characteristics, such as examinees' level of interest, motivation, and conscientiousness, as well as the physical, temporal, and social context of the test situation.

Individuals may best prepare for a test by practicing on similar tests or by solving problems that require the mental operations and skills to be tested under conditions similar to the actual test situation. Examinees may also benefit from familiarizing themselves with test-wiseness skills, depending upon the design and purpose of the test, and soliciting feedback regarding their knowledge and/or skills from peers and educators. Despite an individual's conscious efforts to physically and mentally prepare for and maximize performance during a test, his or her behavior may still be unwittingly influenced by ingrained biases or beliefs. In addition, taking a test itself can both directly and indirectly influence the future thoughts and actions of examinees. Testing can provide examinees with feedback that can promote optimal subsequent study and test preparation, as well as directly improve measures of long-term retention and learning.

In addition, just as testing influences behavior in myriad ways, advances in our understanding of behavior affect test development and administration. As mentioned earlier, the efficacy of test-wiseness strategies may be diminished in many high-stakes situations because assessment developers are instructed to avoid precisely those that are being coached. Test developers also strive to ensure that all test takers can perceive, understand, and solve test questions in the manner in which the questions are intended to be solved. Moreover, recent years have seen increased interest in the development of 'cognitive diagnostic' assessments that are designed to measure test takers' strengths and weaknesses in specific cognitive skills and functions. The challenge of future research in test development is to create assessments that not only advance

educational or psychological measurement, but that in so doing, also promote the most beneficial test behaviors.

### Glossary

**Affect** Feeling or emotion.

**Duchenne smile** A smile, usually elicited during positive emotions, that includes upturned lips accompanied by a crinkling of the skin around the eyes.

**Fixed action pattern** A stereotyped sequence of behaviors that is triggered by a releasing stimulus.

**Gargalesis** Laughter-inducing tickle elicited by a somewhat strong pressure repeatedly applied to certain ticklish areas of the body. This form of tickle cannot be self-induced.

**Knismesis** Type of tickle that is elicited by a light movement across the skin and is not usually associated with laughter. The sensation can be readily produced in the self.

**Ontogeny** Development.

**Reflex** An unlearned, involuntary, automatic response.

Almost everyone has at some time been tickled by a friend or relative. Tickling is a favorite method used by parents to get their infants to laugh and young couples often include tickling in their courting behavior. Given its common occurrence, tickling might seem like a rather simple straightforward social behavior. However, a closer examination of the phenomenon of tickle reveals a number of peculiarities. The fact that a physical touch can produce smiling and laughter – responses that are normally elicited by psychological stimuli such as comedy – is odd, in and of itself. However, it becomes even more puzzling when one considers that despite outwards signs to the contrary, many people report that they do not enjoy being tickled. Another peculiarity is that one cannot make oneself laugh via self-tickling.

The mysterious nature of tickle has been pondered for over two millennia by some of the greatest minds in history including Aristotle and Plato, Galilei Galileo, Francis Bacon, and Charles Darwin. Despite the long history of interest, the empirical research on tickle is rather scant, but has been growing in the last decade or so. This article will discuss both the theories and empirical research that exists on tickling, particularly focusing on issues surrounding the smiling and laughter it induces.

### Two Forms of Tickle: Knismesis and Gargalesis

The English word ‘tickle’ seems to refer to at least two rather distinct, although perhaps not mutually exclusive, phenomena. One is the peculiar sensation, sometimes characterized as a moving itch, caused by a very light movement across the skin. This type of tickle can easily be elicited almost anywhere on the body by moving one's finger lightly across the skin. The annoying sensation can outlast the stimulation by many seconds, and creates an intense desire to rub or scratch the tickled surface (doing so seems to terminate the sensation). Of note, this form of tickle rarely makes people laugh. By contrast, the tickle that causes laughter usually requires a heavier pressure repeatedly applied to specific areas of the body such as the armpits or ribcage. The distinction between these two types of tickle was noted as far back as 1897 by the prominent late nineteenth century psychologist G. Stanley Hall in the *Dictionary of Psychological Medicine*. Hall and his colleague,

Arthur Allin, suggested that the light tickle be called ‘knismesis’ and the laughter-inducing heavier tickle, ‘gargalesis.’ The distinction between these two types of tickle, however, seems blurred when one considers the feet. Deep pressure to the foot produces a sensation of massage for most people, while a somewhat lighter touch often produces laughter.

Knismesis seems clearly different from the arguably more mysterious gargalesis. For one thing, as noted above, knismesis generally does not produce laughter, which in many ways is the most perplexing aspect of tickle. Second, people can readily elicit the sensation of knismesis in themselves, however, they cannot successfully produce gargalesis in themselves (i.e., tickling oneself does not elicit laughter).

Finally, it seems easy to imagine an evolutionary function for knismesis: the annoying sensation prompts one to scratch or rub the tickled spot, thereby removing insects or parasites that might be crawling on one's body.

### Tickling in Nonhumans

Knismesis, the response to very light touch, appears to be widespread across many mammals. The reactions of a dog scratching its side at a flea, or a cat flicking its ear at a mite are commonplace.

Gargalesis may not be as frequent in the natural world as knismesis, but work by primatologists suggests that chimpanzees and at least some other primates such as gorillas tickle each other in the course of rough-and-tumble play, producing what seems to be a nonhuman primate equivalent of laughter. A chimpanzee's laugh sounds different from a human's laugh – it is more of a breathy panting sound. This panting, accompanied by a relaxed open-mouth and quivering lower jaw, appears to be the phylogenetic precursor of human laughter. There is little doubt that tickling can induce such reactions in young apes.

Researchers working with rats have also noted that the rapid movement of human fingers on the back of the neck of juvenile rats causes the rats to emit high-frequency ultrasonic vocalizations. A number of researchers have referred to this as rat tickling, but it is unclear whether it bears any relationship to the tickle response of humans.

## Ontogeny of Tickle

Newborns do not laugh. In fact, babies do not begin showing laughter until around 4 months of age. Their laughter in response to being tickled is even a bit more delayed – usually emerging around 6 months. Various views have been offered on the connection between the development of humorous and ticklish laughter.

One hypothesis is that ticklish laughter is itself a conditioned response that emerges out of other humorous play. Perhaps children laugh when tickled because tickling has always taken place in playful situations in which laughter is already occurring. This repeated pairing could lead to Pavlovian conditioning whereby laughter then becomes associated with tickling movements, even when not paired with other humorous situations. Another possibility is that children laugh when tickled because of the laughter of the tickler which creates some contagious loop (e.g., a parent's laughter causes the child to laugh which increases the parent's laughter, and so on).

In the 1940s, Clarence Leuba from Antioch College came up with a clever way to test whether laughter in response to tickling would emerge even if tickling were never paired with other laughter-inducing play or with laughter from the tickler. His subjects were two of his own babies. From the beginning of each infant's birth, Leuba and his wife deliberately refrained from tickling their children during playful situations. All tickling took place by Leuba while he wore a mask that obscured any possible facial expressions to ensure that the infants would not associate tickling with smiles and laughter. Despite all this, Leuba found that ticklish laughter emerged in both infants around the age of 6 or 7 months. Although this study has limitations, it suggests that laughter from tickling does not emerge because of tickling being paired with other humorous or pleasant stimuli.

Others, such as Alan Fridlund from the University of California at Santa Barbara, have suggested the reverse causal sequence – perhaps humorous laughter emerges from ticklish laughter. Babies differ in the degree to which they respond to tickling. Parents of easily tickled babies are more reinforced for engaging in tickling (i.e., their infants' laughter is a positive experience) which probably leads them to do it more often. Such play then might be extended to include other forms of humorous physical interactions and eventually to mental stimuli, thereby leading offspring to laugh at humor as well. Such a view, however, has difficulty accounting for the fact that ticklish laughter appears to develop slightly later than laughter that emerges from first primitive forms of humor (e.g., playful menacing such as 'I'm going to get you').

## Positive Emotion and Tickle

The fact that smiling and laughter occur during tickling and during humor has led many writers to assume that the two reflect the same positive emotional state. One prominent champion of this view was the father of evolution, [Charles Darwin \(1872\)](#), who noted that "the imagination is sometimes said to be tickled by a ludicrous idea; and this so-called tickling of the mind is curiously analogous with that of the

body" (p. 199). Darwin pointed out several similarities between tickle and humor. First, he claimed that in order for either to elicit laughter, one must be in a pleasant hedonic state. He wrote "in this case, [humor] and in that of laughter from being tickled, the mind must be in a pleasurable condition; a young child, if tickled by a strange man, would scream in fear" (p. 199). Second, he noted similarities in the elicitors of each state, "The touch must be light' in tickle and 'an idea or event must not be of grave import' in humor. Finally, he pointed out that an element of surprise is required to elicit laughter to jokes or to humor. In essence, tickle was simply a physical joke. Many contemporary writers on this topic echo the view that ticklish laughter and smiling are signals of a positive affective state.

My colleague, Nicholas Christenfeld, and I examined the relationship between tickle-induced laughter and humor-induced laughter in the laboratory. Previous research had found a warm-up effect for humorous laughter: jokes that occur later in a series are funnier than those that occur earlier (presumably this is why 'warm-up' comedians give performances on stage before the top comedian does his or her routine). We reasoned that if ticklish laughter and humorous laughter reflect the same psychological state, there ought to be a 'warm-up' effect that transfers from tickling to humor and from humor to tickling. To examine this, subjects watched a videotape composed of the highlights of several comedy routines. They reported finding the comedy humorous and readily laughed and smiled while watching it. The connection between this type of laughter and that of tickling was tested by having a researcher tickle subjects either immediately before watching the comedy tape or immediately after watching the tape. Subjects laughed, smiled, and wiggled when tickled, but they did so to the same extent regardless of whether they had first been 'warmed up' with the comedy tape. Likewise, having just been tickled did not make people laugh more while watching the funny film. The lack of a warm-up effect between humor and tickle lends some support to the hypothesis that tickling-induced laughter is not simply a form of humorous laughter.

Another recent experiment also suggests that the tickle-induced smiling need not reflect positive affect. The proposition that the tickle response is due to humor has been based largely on the assumption that the smiling that is elicited during tickling is indeed the same as that which occurs during amusement. The facial expression that occurs during positive emotion usually includes two muscle movements: the upturned lips or smile (produced by contraction of the zygomatic major), and a crinkling of the eyes (produced by contraction of the orbicularis oculi). This type of smile has been named the 'Duchenne' smile, after a French physician from the 1800s who studied facial expressions and noted the importance of the eyes in conveying positive affect.

To determine whether tickling produces similar facial displays as humor, Nancy Alvarado and I conducted a detailed microanalysis of the facial displays of subjects while they were being tickled. Although Duchenne smiles were sometimes elicited during tickling, the smiling was different from that of humorous smiling in several ways. Some people showed Duchenne smiles while being tickled even though they did not report feeling pleasant emotion (i.e., happy or amused). In fact, for some of these participants, Duchenne smiling was

associated with finding the tickle sensation unpleasant. Moreover, people who said that they generally enjoyed being tickled did not display more Duchenne smiles than people who generally did not like being tickled. The dissociation between smiling and self-reported positive affect during tickle provides some support for the hypothesis that Duchenne smiles during tickling can occur even when people are not feeling positive emotion.

Thus, several findings suggest that ticklish smiling need have no closer an association to merriment and mirth than crying when cutting onions has to sorrow and sadness. However, such a conclusion does not imply that positive emotions never occur during tickling, just that positive affect is not required.

### Sociality of Tickling

A great number of writers across the ages have argued that the interpersonal context, including beliefs about who is doing the tickling and why, plays an indispensable role in whether or not tickling will induce laughter. For example, it is often assumed that the tickling must be done in a playful way with benign intent by someone that is not only known but also liked. Such ideas clearly have intuitive appeal, particularly since they would appear to provide a possible account for one of the greatest mysteries of tickling – why can't one elicit ticklish laughter in oneself? The answer, according to an interpersonal account, is that tickle-induced laughter, at the very minimum, requires the belief that another person is doing the tickling.

So how might one test this idea? One possibility would be to build a fully automatic tickle machine and see if it could make people laugh. At first blush, this might seem to be the perfect way to test whether tickle-induced laughter requires an interpersonal context. After all, if such a machine made people laugh, it would suggest that ticklish laughter does not require another person. However, if people did not laugh in response to the machine, one could never be certain whether the lack of laughter was due to their knowledge that it was a machine or the failure of the device to accurately mimic movements of a human hand.

To get around this problem, my colleagues and I created a 'mock' tickle machine in the laboratory using a robotic-looking plastic hand, a vacuum cleaner hose, and a nebulizer (a device used for asthma) to provide sound effects. Then, in an experiment, subjects were blindfolded and told that they would be tickled twice, once by the machine and once by the experimenter. In reality, the machine was not actually capable of movement. Instead, all the tickling was done by a research assistant, who was hidden under a cloth-draped table near the subject. The assistant was careful to perform the tickling the same way throughout the experiment, thereby allowing assessment of whether the belief that the tickling is being performed by another person is essential to elicit laughter. To decrease the interpersonal context even more, for half of the subjects, the experimenter left the room during the machine-tickle phase.

It turns out that subjects readily smiled, laughed, and wiggled when tickled by what they believed to be a fully automated mechanical device, and did so to the same extent as

when they thought they were being tickled by a person. Furthermore, these reactions were not diminished even when the subjects believed that the experimenter had left the room and that they were entirely alone with the machine. Self-reports of tickle intensity were also the same regardless of who was supposedly doing the tickling. These findings provide rather compelling evidence against the popular notion that ticklish laughter requires the belief that another person is performing the tickling. (Careful probing at the end of the experiment confirmed that subjects truly believed that the machine had tickled them.)

### Automatic Response

As described above, the handful of empirical studies on ticklish laughter suggest that it is not a response driven by positive affect nor does it require an interpersonal context. So what does underlie gargalesis?

The data that exist seem most amenable to the view that gargalesis is a relatively automatic, low-level physiological response. This general view is consistent with the writing of G. Stanley Hall and Francis Bacon and has been advocated by several researchers in more recent times. Findings to date have not revealed exactly what mechanism controls the response but likely candidates are that it is a type of complex reflex or fixed action pattern. In literature on human behavior, the term, fixed action pattern, is sometimes replaced with terms such as species-characteristic or species-typical stereotyped motor pattern requiring a particular releasing stimulus. The boundaries between reflexes and other species-typical behavioral dispositions remain controversial. Reflexes are distinguished from fixed action patterns based on their graded character: the more intense the stimulation the more intense the response. It currently is not known whether ticklish laughter shows an all-or-none character like a fixed action pattern or a graded response to the magnitude of stimulation as with the typical reflex.

If gargalesis is some type of complex reflex or species-typical stereotyped behavior, then why can we not elicit it in ourselves? After all, we can tap our own knees and produce the knee-jerk reflex. There are, however, other reflexes that one cannot elicit in oneself – startle being a prime example. Startle and tickle appear to share some features. Both appear to require some element of unpredictability or surprise – one can no more tickle oneself than startle oneself (at least, not without the use of some external device such as a gun). The two states also produce facial expressions that resemble the types of expressions elicited during emotion, but are arguably not emotional states in and of themselves. The proposition that tickle is a reflex, or other kind of innate stereotyped motor pattern, does not imply that the tickle response is unmodifiable or unaffected by mood or other psychological states. For example, the startle reflex can be potentiated by negative emotion while the opposite effect is produced by positive emotional states and even by a faint warning signal. Despite the name, 'fixed action patterns' also permit substantial variability in behavior.

There is also another explanation consistent with gargalesis being a low-level physiological process and with one not being able to produce it in oneself. Lawrence Weiskrantz and his

colleagues, in a paper that appeared in *Nature* in the 1970s, suggested that the neurological processes observed in vision might provide an answer. When the eyes dart from one focal point to another, the world does not appear to jump because the brain takes into account that it has issued a command (efferent signal) to move the eyes. Weiskrantz and colleagues reasoned that similarly when the brain issues the command to self-tickle, it sends a message to cancel the sensation of ticklishness. Thus, what is sometimes termed exafference (stimulation uncorrelated with a motor command) may be required to elicit the tickle response.

## The Unpleasant Side

Socrates proposed that although tickling could induce pleasure, to a greater degree it elicited pain. Bacon suggested that “tickling is ever painful, and not well endured” (p. 161). There also have been stories across the ages of people being tortured to death using nothing but unrelenting tickle. Whether victims can actually die from tickle alone is not known. However, there is little doubt that prolonged tickling can be highly disagreeable.

Research with college students suggests that even short bouts of tickling can be unpleasant for some people. Detailed coding of the facial displays during tickle, suggest that several movements are similar to those that occur during pain, including wrinkling the nose, raising the upper lip, and grimacing. Furthermore, such facial displays can occur while people are simultaneously smiling.

It is often assumed that tickling is a more pleasant sensation for children than for adults. However, there are several reasons to question this. For one, childhood is often when the displeasure of ‘tickle torture’ is discovered. Generations of children have found that holding one another down and engaging in relentless tickling is an effective way to torment a sibling or playmate. While children sometimes seek out tickling, it may be incorrect to assume this means that the sensation itself is pleasurable. Children also take part in games in which parents play at startling or menacing them. Presumably, such behaviors do not indicate that children enjoy startle or fear. A combination of thrill-seeking and pleasure in tactile contact might lead children to seek out what is still an intrinsically aversive sensation.

## Physiology

The neural mechanisms that are responsible for the tickle sensation are not well mapped out, but touch and pain fibers are two possible candidates. Work on the receptors involved in tickle focuses almost exclusively on knismesis, usually elicited by brushing a piece of cotton wool on the skin of an animal or person. Yngve Zotterman, a pioneer in cutaneous sensation research, used this method on cats while recording action potentials of nerve fibers, and concluded that light tickle depends, at least partially, on pain fibers. Responsiveness to tickle elicited by cotton is also reduced in patients who have had tracts of pain fibers in their spinal cords severed as a treatment for intractable pain. However, gargalesis may rely

on different pathways given that tickle-induced laughter is retained in at least some patients who have lost pain sensation due to similar spinal-cord surgery.

Knismesis seems to also depend on touch fibers: when limb circulation is arrested, sensitivity to touch and tickle is eliminated before pain sensitivity. However, the density of touch receptors is not likely to explain the susceptibility of different body parts to tickle, because the areas most responsive to tickle do not show any obvious advantage in touch sensitivity or in tasks requiring people to tell whether they are being touched on one or two nearby points. For example, the palm is more sensitive to touch than the sole of the foot, but the latter is more ticklish.

Other research has attempted to explore differences in brain activity using the technique of functional magnetic resonance imaging (fMRI) during self-generated and externally generated tickle. Such work has exclusively looked at knismesis which, since it can be produced readily in oneself, is unlikely to inform us much about why we cannot produce ticklish laughter in ourselves. Given the requirement to remain still during fMRI scanning, it is doubtful whether such measures will be a good tool for studying gargalesis as laughter disrupts the imaging.

## Functional Theories

Several theories of why humans may have evolved a tickle response have been offered, although providing evidence for such functional explanations remains a challenge.

One hypothesis is that tickle evolved to promote protection of areas that would be most vulnerable during arm-to-arm combat. The idea is that ticklishness in such areas motivates one to protect these areas and thereby confers an adaptive advantage (i.e., increased ones ability to survive and reproduce). This provides a possible explanation for the pulling away and fending off movements frequently encountered during tickling. However, it does not account for why the hands and fingers, which are quite vulnerable in hand-to-hand combat are not very ticklish, nor why people laugh and smile during tickling.

Another functional account, alluded to earlier, focuses on the smiling and laughter during tickling. Humans find such expressions rewarding which may facilitate bonding between parents and infants. This view, however, does not explain the defensive and withdrawal movements that occur during tickling nor why the sensation of tickle is considered unpleasant by many.

A third possibility draws on different aspects of these views: the disconnection between the inward unpleasant sensation and the outward pleasant expression may be what is adaptive. Tickle may elicit smiling to encourage others to perform the tickling and may elicit discomfort in the one being tickled in order to motivate the developing primate to avoid the tickling. This would promote rough and tumble play that may help the development and acquisition of combat or other skills that have survival benefits. Unfortunately, testing such hypotheses regarding ultimate mechanisms is notoriously difficult. Furthermore, it is always possible that tickle is not an adaptation per se but rather a by-product of a mechanism designed for some other function.

## Final Remarks

Despite 2000 years of speculation on tickle, the paucity of actual research makes it difficult to draw unequivocal conclusions about this enigmatic aspect of human behavior. However, what does seem to be emerging from research is a recognition that tickle is not merely a special case of amusement or joy. Depending on the social setting (e.g., the relationship with the tickler, the tickled person's mood) tickling may be capable of eliciting a variety of reactions, some enjoyable and some unpleasant. But, it is doubtful that the smiling observed in tickling is dependent on the positive or interpersonal aspects of the situation.

The data to date suggest that tickle is most likely a low-level automatic physiological response such as a complex reflex, fixed action pattern, or other species-typical stereotyped motor pattern. It is also possible that tickle may turn out to exemplify some class of phenomena not yet mapped out.

## Touch

**C Spence**, University of Oxford, Oxford, UK

**A Gallace**, Università di Milano-Bicocca, Milan, Italy

© 2012 Elsevier Inc. All rights reserved.

### Glossary

**Attention** Refers to the mechanisms that give rise to a temporary enhancement (or prioritization) of the processing of certain stimuli relative to others.

**Cross-modal interactions** Refer to situations in which the stimulus presented in one modality (e.g., touch) is affected by a stimulus presented in a different modality at around the same time.

**Extinction** The phenomenon whereby the presentation of a stimulus in one modality (e.g., vision) or location results in a person no longer being aware of a stimulus presented in another modality (e.g., touch) or location.

**Haptics** The term used to describe active (as compared to passive) touch.

**Prior entry** The claim that attended stimuli are perceived earlier than unattended stimuli.

### Introduction

Touch is both the largest of the senses and the first of the senses to develop. The skin, in which the majority of the tactile receptors are embedded, accounts for almost 20% of the body mass. That said, the majority of experimental research on the sense of touch has tended to focus on the perception of stimuli presented to the fingertips and hands rather than on the rest of the body surface. It is important to note that 'touch' is really an umbrella term for a number of different sensory submodalities, including everything from temperature and pressure perception through to the perception of vibration and pleasant touch. What is more, the various classes of sensory receptors are not distributed uniformly over the body surface, with certain receptors, such as those whose signal is conducted by the c-tactile (CT) afferents fibers, only being found in hairy skin. The asymmetric distribution of CT afferents, which are thought to code for the pleasant aspects of touch, and which have been shown to respond vigorously to the slow stroking of the hairy skin, perhaps hints at their original role in grooming behaviors. People's sensitivity to different kinds of tactile stimulation also varies substantially over the body surface, and, just as for the other senses, decreases substantially as one ages. Less research has been published over the years on the sense(s) of touch than on the other spatial senses, namely vision and audition; This may, in part, reflect the difficulty associated with mechanically stimulating the skin with anything more complex than the simplest of stimuli, with researchers often using small vibrators or electrocutaneous devices to stimulate participants. Some researchers (in particular, those working with the visually impaired) have also used devices such as the Optacon that allow one to present patterns over restricted areas of the skin surface using arrays of point-like tactile stimulators. There is also a large literature on the tactile perception of surface texture, though that will not be covered in any detail here.

### Information Transfer Through the Skin

Back in the 1960s and 1970s, there was a great deal of interest in the possibility of transmitting information, and even images, via the skin surface. Many researchers were, for example,

actively involved in investigating the possibilities associated with tactile-visual sensory substitution systems. The hope was that such devices might help the blind to, in some sense, 'see' once again. Some researchers even went so far as to suggest that the days of 'tactile television' might be only just around the corner! However, subsequent research soon highlighted the fact that the skin has only a very limited bandwidth for the processing of tactile information as compared to the other senses (e.g., vision and audition). And, although the blind do exhibit enhanced tactile discrimination abilities in certain sensory tasks, their ability to process sequentially presented tactile information does not actually appear to be that much better than that of the sighted, especially when a comparison is made with the tactile/haptic abilities of those sighted individuals who have practiced their tactile discrimination abilities. There have also been occasional case reports of sighted individuals who have had a phenomenal ability to process sequentially presented tactile information.

### Counting Tactile Stimuli

In the general population, however, the average untrained participant can perceive no more than two or three simultaneously presented discrete tactile stimuli when presented to the skin surface. This limitation appears to hold true no matter whether the stimuli are presented to the fingertips or elsewhere on the body surface. It is worth noting here that this limit might be due, at least in part, to some form of automatic pattern organization in the brain (i.e., one is not used to perceiving multiple independent stimuli on one's skin, but rather objects and surfaces.) The one exception to this fairly strict limit (which is significantly lower than that seen for the enumeration of visual stimuli) appears to occur when people try to judge the number of spherical balls they feel haptically in their hands. Under such conditions, people can rapidly estimate the number when as many as six balls are presented to a participant's hands.

### Memory for Touch

In the visual modality, researchers have used the partial report paradigm in order to demonstrate that people may retain some

fleeting access to sensory information that cannot be tapped when a full report procedure is used (i.e., as is typically the case in numerosity judgment studies). Researchers have recently adopted the partial report procedure in order to demonstrate that people may actually retain some access to positional information when as many as five tactile stimuli are simultaneously presented across their body surface (as compared to a maximum of only two or three stimuli in the overt numerosity judgment version of the task). Interestingly, the duration of these rapidly decaying tactile representations appears to be affected by the number of stimuli that happen to be presented (with decay occurring more rapidly as the number of stimuli presented increases).

While a number of studies have, over the years, investigated the constraints on tactile short-term memory, far less research has been directed at the study of longer-term forms of memory in the tactile modality. Indeed, it is worth noting here that the exact nature of the code (e.g., verbal, visual, tactile, or spatial) used by the human brain in order to represent tactile stimuli in long-term (as well as short-term) storage systems remains a matter of debate among researchers. In fact, researchers investigating the brain correlates of tactile memory have shown that tactile memory relies, at least in part, on the same neural networks responsible for the storage of visual information.

### Attentional Constraints on Tactile Perception

Attention constitutes a major determinant of the limitation on tactile perception in humans. To date, the majority of the tasks that were first formulated to study/highlight the attentional constraints on visual information processing have successfully been extended to the tactile modality: These include everything from tactile negative priming, through to tactile distractor congruency effects, and from tactile change blindness through to the tactile attentional blink. What is more, the majority of these attentional limitations on information processing in humans have now also been demonstrated in a cross-modal setting as well, primarily involving interactions between tactile and visual stimuli.

While tactile stimuli are frequently presented to the passive (i.e., unmoving) skin surface of a participant in the laboratory, in real life, one's tactile perception is far more likely to involve active haptic exploration instead. There has been a long debate in the scientific literature between those who believe that active and passive touch are essentially the same and those who believe that there are fundamental differences between these two kinds of tactile perception. The consensus view though currently appears to be that there is far less difference than one might expect. What is certainly true is that a person's ability to perceive tactile stimuli is impaired during the execution of voluntary action. This form of touch blindness (or numbness) has been demonstrated to affect performance both in psychophysical discrimination tasks and in tasks involving tactile change detection. So, for example, in one recent study, participants executed a movement toward a given target stimulus while trying to compare the intensities of two stimuli, one presented to the moving hand and the other to the stationary hand. Tactile sensitivity decreased on the moving hand during movement execution, but not during the movement preparation

and postmovement periods. Results such as these therefore lend support to the view that sensory suppression takes place whenever one executes an action.

### Spatial Tactile Attention

Tactile perception is also affected by spatial attention. People can either voluntarily choose to attend to the tactile stimuli presented to a certain part of their body, or else their attention can be captured automatically by a sudden tactile stimulus that happens to be presented there unexpectedly (e.g., as when someone suddenly taps the back of one's shoulder.) However, such shifts of spatial attention (both endogenous and exogenous) really need to be considered in a multisensory context, since the sudden presentation of auditory or visual events has also been shown to draw a participant's tactile attention to any part of their body that happens to be placed close by. Similarly, the sudden presentation of a task-irrelevant tactile stimulus is now known to give rise to an exogenous shift of auditory and visual attention to the cued location, or side as well. Endogenous spatial attention also appears to be coordinated across the senses such that people find it difficult to focus their tactile attention on one location while attending visually or auditorily to another location. Researchers have now started to investigate how these two forms of tactile spatial attention (i.e., exogenous and endogenous) interact.

Over the last few years, cognitive neuroscientists have made great progress in terms of understanding the neural mechanisms responsible for the orienting (both voluntary and stimulus-driven) of tactile spatial attention. For example, neuroimaging research has highlighted the importance of the parietal cortex as well as the early somatosensory cortex (e.g., SI, SII, and SIII) in the endogenous orienting of tactile spatial attention.

### Attending to the Sense of Touch

However, over-and-above any ability to focus tactile attention on a specific *spatial* location, people can also selectively direct their attention toward the tactile modality (i.e., rather than to the visual or auditory modality, say). In one study on this phenomenon, the participants were presented with a random sequence of tactile, visual, and auditory targets from one of the two locations on either side of the fixation. The participants had to make speeded left/right spatial discrimination responses to the targets regardless of the sensory modality in which they were presented. The three target modalities were presented equiprobably in the 'divided attention' blocks. In the other blocks of trials, the probability of target stimuli being presented in a particular modality (touch, audition, or vision) was increased in order to encourage the participants to focus their attention on that particular sensory modality. Participants responded more rapidly (and somewhat more accurately) to the tactile targets in the 'attend touch' blocks than in those blocks where their attention had been directed to either the auditory or visual modality instead. These results therefore show that people can voluntarily (i.e., endogenously) direct their attention toward touch and that this enhances their ability to respond to tactile stimuli. Interestingly, this and

other studies have now shown that people appear to find it more difficult to shift their attention toward, or away from the tactile modality than they do to shift their attention between the auditory and visual modalities. Other researchers have shown that attending to olfaction (i.e., expecting a smell) can also impair a person's ability to respond to tactile stimuli as well. It therefore appears as though there is some form of shared attentional resources that can be allocated preferentially to the processing of the stimuli presented in a particular sensory modality. The sudden presentation of a task-irrelevant tactile stimulus can also lead to an *exogenous* shift of a participant's attention toward the tactile modality.

Attending to the tactile modality, or to the location at which a tactile stimulus will shortly be presented, speeds up the perceived time of arrival of the attended stimulus as compared to other stimuli presented in a relatively less attended modality or location (this phenomenon is known as '*prior entry*'). There has been a growing interest over the last decade or so in the study of the neural underpinnings of such behavioral effects of attention on tactile perception. Indeed, the results of a number of studies now show that the attentional selection of tactile information can occur at very early stages of neural processing, such as in the somatosensory regions of the parietal cortex (i.e., in S1 and S2).

### Tactile Perception and Attention Following Posture Change

One's posture changes on a regular basis: sometimes, for example, one's left hand may be crossed over to the right of the body while the right hand is placed on the left. Several studies have now demonstrated that both exogenous and endogenous shifts of spatial attention appear to operate on representations of space that are updated whenever one's posture changes. Thus, a sudden tactile stimulus presented to the left hand has been shown to draw a participant's visual attention to the left when the hands are uncrossed, but to the right side of space when the hands are crossed over at the midline. One of the only conditions in which one's brains appear to get confused about the location (and/or timing) of touches presented to the body occurs when the hands are crossed over the midline, and one stimulus is presented to each hand in rapid succession. Under such conditions, participants appear to systematically confuse the two stimuli when they try to report which tactile stimulus was presented first. Interestingly, this appears to reflect a confusion between visual and somatotopic frames of reference for coding the location of tactile stimuli, since the congenitally blind are not confused by this particular postural manipulation. What is more, the sighted show a much reduced crossed-hands deficit if they cross their hands behind their backs (i.e., in a part of space that they normally do not see).

### Tactile Awareness

Over the last few years, there have been many attempts to determine the cognitive and neural correlates of one's

awareness of visual events. By contrast, this topic has received far less interest from those researchers working on touch. The latest research now appears to show that there is a close relationship between spatial processing and access to consciousness of tactile stimuli. For example, decreasing the spatial distance between the hands results in an increase of the time necessary for participants to determine which stimulus is presented first. Similarly, crossing the arms over the midline has been recently demonstrated to be effective in decreasing the perceived intensity of somatosensory stimuli delivered to the back of the hands. But there is still a long way to go to determine with any precision the neural correlates of one's awareness of tactile stimuli, although a few insights have been gained in the last few decades.

Activation of unimodal sensory areas is necessary but not sufficient for an awareness of touch to arise. For example, the neural responses of the primary somatosensory areas have been found to correlate with the physical intensity of the stimuli delivered to the skin but not with a person's awareness of those stimuli. It is now becoming clearer that interactions between primary sensory areas and certain areas of the brain responsible for multisensory and spatial processing (such as the posterior parietal cortex) might play an important role here. Recent debate concerning the neural correlates of tactile awareness relates to the question of whether or not tactile processing can rely on anatomically separated pathways for explicit and implicit information processing, just as has been shown to be the case for visual processing. As far as this topic is concerned, the presence of a phenomenon that can be considered analogous to 'blindsight' in the visual modality has now also been described in touch (i.e., blind touch). This would appear to suggest the presence of independent pathways for the processing of tactile information in the brain. In fact, it has been shown that patients suffering from a loss of tactile sensation (due to a brain lesion) are nevertheless still sometimes able to correctly point the position of a tactile stimulus delivered to their deafferented limb.

### Cross-Modal Interactions Between Touch and the Other Senses

No discussion of the sense of touch would, however, be complete without some consideration of how touch interacts with the other modalities in terms of one's perception of the objects that one hold and feel. Here, the majority of evidence published over the last 70 years has shown that vision tends to dominate over touch in the perception of the size and shape of the objects one haptically interacts with. Vision also dominates over touch in the perception of position and in the perception of the direction of apparent motion. Under certain conditions, the presentation of a visual stimulus can even lead to the extinction of a participant's awareness of (or at least their ability to report) a simultaneously presented tactile stimulus. While such effects have traditionally only been reported in patients suffering from clinical extinction, researchers have recently observed a very similar phenomenon in normal participants. In one recent study, participants were given one response key to press in order to respond to tactile stimuli

and another key to press to respond to visual stimuli. Finally, they also had to respond to the relatively rare occurrence of bimodal target trials by pressing both response keys (or under certain conditions, a third response key). The results showed that participants failed to respond to a number of the tactile stimuli on the bimodal trials while rarely, if ever, missing the clearly suprathreshold tactile stimuli on the unimodal trials. The latest evidence shows that tactile/haptic stimulation can also help resolve ambiguous visual displays such as when viewing the Necker cube, or when experiencing binocular rivalry.

The only areas in which tactile inputs regularly dominate over visual inputs occurs under conditions of intersensory conflict, when people have to judge fine surface textures and when making temporal judgments. So, for example, people will often report that a single visual stimulus presented briefly on the periphery of the visual field as having flashed twice if two or more tactile stimuli are presented at the same time. By contrast, participants have no problem reporting the actual number of stimuli presented correctly when no tactile stimuli are presented.

When the senses of audition and touch are put into conflict, the result generally turns out to be a much more evenly balanced weighting of the two senses than that seen when vision and touch are put into conflict. That said, a number of studies have demonstrated that the perception of surface texture can be modulated simply by changing the sound that people hear when they touch it. Even smell has been shown to influence texture perception: That is, people rate fabric swatches as feeling significantly softer when rubbed between the fingertips while smelling a pleasant fragrance than when smelling an unpleasant fragrance instead. Given that the majority of one's perception is multisensory, and given the ubiquitous nature of multisensory interactions in human information processing, many researchers are increasingly coming to the conclusion that it may not make that much sense to focus all of one's efforts solely on studying tactile perception in a unimodal setting.

### The Affective Aspects of Touch

It is important to note that the sense of touch may be particularly important in terms of its affective contribution to one's sense of well-being. Indeed, the sense of touch has been shown to provide a very powerful means of eliciting and modulating the emotional responses of humans. In fact, it has been argued that interpersonal touch tends to provide the most emotional of one's tactile experiences. However, that said, the study of the more interpersonal and emotional aspects of touch have been rather neglected by cognitive neuroscientists in recent years. Interpersonal touch is important for one's well-being; this is certainly clear from the evidence reported so far. However, researchers will need to try and understand how tactile contact really works in affecting people's behavior. That is, what are the cognitive and neural mechanisms underlying these effects? And how can one exploit these particular characteristics of the tactile modality for applied and clinical purposes? Scientists are now moving toward answering these questions, for

example, by showing that certain parts of the brain, such as the orbitofrontal cortex, respond specifically to 'pleasant touch' or that back-rubbing and hugs induce the release of oxytocin (a hormone involved in social-bonding behavior). Studying the cognitive and neural correlates of interpersonal touch, together with the more cognitive aspects of tactile perception more generally therefore constitutes a particularly important area for future research on the sense of touch.

### Touch: What the Future Holds

In the coming years, research on the sense of touch looks set to grow. This is both because of the increased ability to present complex haptic stimuli offered by haptic virtual reality devices and an ever-growing variety of human-machine interfaces, and because of the increasing stimulation of the sense of touch in modern technology – for example, in everything from mobile phones to touch screen displays, and from cars that vibrate their drivers through to vibrating belts that inform their users of where North lies. Moreover, it is also worth noting that the sense of touch has started to be exploited in the last few years by an increasing number of marketers in order to make their products more appealing to the customer.

# Uncertainty

M Smithson, Australian National University, Canberra, ACT, Australia

© 2012 Elsevier Inc. All rights reserved.

## Glossary

**Ambiguity** A special kind of uncertainty. A concept or proposition is ambiguous if it has two or more distinct possible meanings.

**Fuzziness** A special kind of vagueness that refers to graded degrees of membership in a set.

**Ignorance** A is ignorant from B's viewpoint if A fails to agree with or show awareness of ideas which B defines as actually or potentially valid. Ignorance has a passive sense (being ignorant of X) and an active sense (ignoring X).

**Irrelevance** X is considered irrelevant iff X is considered unrelated to Y. Irrelevance therefore leads to X being ignored when considering Y.

**Nescience** A complete lack of knowledge.

**Risk** Composed of ignorance and the prospect of loss. In economics, risk is composed of probability and the prospect of loss.

**Uncertainty** A special kind of ignorance, namely incompleteness of information. There are nonprobabilistic as well as probabilistic kinds of uncertainty.

**Vagueness** A special kind of uncertainty. A concept is vague if its possible meanings extend over a range on a continuum.

Uncertainty may be defined as a particular kind of unknown, namely incompleteness of information. Incompleteness, in turn, can take various forms, such as simple absence, ambiguity, or even probabilistic uncertainty. Uncertainty, above all, is a mental state, and it can arise either from incomprehension (not understanding an entity or event) or indecision (not knowing what to do). The human sciences have issued two broad streams of theory and research on uncertainty. One of these springs from the psychology of judgment and decision making and behavioral economics. The other stems from sociology and social anthropology. This article incorporates both in its overview. Most of the work on uncertainty has focused on incomprehension although in recent years indecision has been paid more attention, especially in psychology and behavioral economics.

## Concepts and Definitions

Uncertainty is a topic that does not fall neatly within a single discipline. Instead it sprawls across a considerable variety of disciplines, professions, and problem domains. Many disciplines and professions have (often implicit) assumptions and beliefs about the unknown, but these are not integrated with one another. Consequently, there is no cogent, readily identifiable body of literature on uncertainty. It is also difficult to communicate clearly about uncertainty, and the scattered literature on this topic understandably lacks an agreed-upon nomenclature. The absence of a standardized terminology for this domain thwarts sophisticated work.

Nevertheless, several disciplines have proposed terminologies for uncertainty and related concepts. Some have also produced worthwhile distinctions among kinds of uncertainty, and even attempt at exhaustive classification systems. We begin by briefly reviewing these attempts at nomenclature, definitions and taxonomic schemes.

## Terminology and Classification

Let us start by considering a term for the overarching concept in this domain. An early proposal is the German word 'nicht-wissen,' whose English equivalent is 'nonknowledge.' A related, if less common, term is 'nescience' (total ignorance). Outside the social sciences the most popular general term seems to be 'uncertainty.' This is the case, for example, in psychology, economics, and engineering. Still another alternative is 'ignorance' itself, which I will use as the overarching term in this article, taking 'uncertainty' to be a subset term when it is necessary to make that distinction.

A major problem in choosing a name for the unknown and attaching a definition to it is that we cannot avoid making claims to know something about who is ignorant of what. Any claim about ignorance entails a knowledge-claim regarding the nature of said ignorance. A definition that seems to handle these problems reasonably well is as follows: A is ignorant from B's viewpoint if A fails to agree with or show awareness of ideas which B defines as actually or potentially valid. This definition allows B to define what she or he means by ignorance. It also permits self-attributed ignorance, since A and B may be the same person. Most importantly, it incorporates anything B thinks A could or should know (but doesn't) and anything that B thinks A must not know (and doesn't). B's notions about ignorance may be as context-dependent and subjective as required.

The intuition that there might be different kinds of ignorance has motivated a number of scholars to propose various distinctions and taxonomies. One of the most popular distinctions is absence or neglect versus distortion. Another common distinction is reducible versus irreducible ignorance. The term 'negative knowledge' has been proposed to encompass knowledge of the limits of knowing, mistakes in attempts to know, things that interfere with knowing, and what people do not want to know. A fourth distinction in some languages is

between the active voice (ignoring) from the passive voice (being ignorant).

Several taxonomies of ignorance have emphasized distinctions that operate at a meta-level rather than describing the nature of different kinds of ignorance per se. The most popular distinction is between knowing that we don't know (conscious ignorance) and not knowing that we don't know (meta-ignorance). A related distinction is between knowing that we know something versus not knowing that we know it (tacit knowledge).

Some disciplines have produced relatively sophisticated and productive distinctions among special kinds of ignorance and uncertainty. In mathematics, besides at least three major schools of probability theory, several different kinds of uncertainty formalisms have been proposed such as fuzzy set theory, belief functions, and imprecise probability theories.

The most useful high-level distinctions that have emerged from the human sciences are threefold. First, the meta-level concepts of meta-ignorance versus conscious ignorance are crucial. Second, there is the important distinction between ignorance and 'negative knowledge' in the sense of knowledge about the limits of what can or should be known. Finally, the active versus passive voice distinction is important. The active voice (to ignore) shall be referred to as 'irrelevance' and the passive voice (to be ignorant of) as 'error.'

Lower level distinctions among kinds of error that have proven useful are as follows. Error may arise either from incomplete or distorted views, or both. Distortion may consist of a systematic bias or inaccuracy (e.g., under- or overestimation), or confusion (mistaking one thing for another). Incompleteness in kind is outright absence of information, whereas incompleteness in degree constitutes what we shall term 'uncertainty.' Uncertainty, in turn, includes probability, vagueness, ambiguity, and conflict. These are terms we shall explore further.

Aside from a priori distinctions and classifications, how can we assess what other distinctions are worth making, especially those intended to represent localized meanings and usages? I suggest four criteria, namely whether candidate kinds of ignorance or uncertainty:

1. Are consistently distinguished from other kinds when referred to in communication by members of the same linguistic community;
2. Are accorded statuses or roles distinct from other kinds in the same situations or for the same purposes in social interaction;
3. Produce different social consequences for those to whom they are attributed; and/or
4. Are (dis)preferred to other kinds.

These criteria are useful in helping students of uncertainty to remember that lawyers use 'probability' differently from statisticians, that for many people conveying outright misinformation (i.e., distortion or lying) is morally worse than conveying vague or partial information, and so on.

### Schools of Probability

Many reviews of probability theories divide schools of probability into three camps: logical or a priori probability,

frequentist probability, and Bayesian probability. All three schools agree on the probability calculus; where they differ is on the basis and scope of probability. The a priori theory is exemplified in games of chance, where idealized fair gaming devices such as dice and cards are employed for bets on outcomes whose probabilities are known beforehand. Probabilities of this kind are based on the principle of indifference, which defines the probability of an event as the ratio of 'favorable' cases to the number of all 'equipossible' cases.

The frequentist theory begins with the premise that under repeated trials under identical conditions, the probability of an event is estimated by the relative frequency with which it occurs out of the number of trials. According to various versions of the strong law of large numbers, the relative frequency converges to the true probability as the number of trials tends toward infinity.

Neither the a priori nor the frequentist frameworks admit such concepts as the probability of a unique event or a subjective probability. Both approaches limit the scope of probability theory to 'objective' likelihoods of repeatable events. The Bayesian theory does extend probability to subjective appraisals and unique events, by identifying subjective probabilities with degrees of belief that obey the laws of probability. For events whose likelihood can be assessed by accumulating evidence (e.g., via repeated trials), Bayes' theorem is employed to update prior probability judgments on the basis of new (perhaps objective) evidence.

In the 1970s and 1980s, the Bayesian approach gained prominence in fields concerned with the mental representation of uncertainty, such as cognitive psychology, behavioral economics, artificial intelligence, and knowledge engineering. Subjective Bayesians claim their approach ensures that decision makers behave rationally in accordance with their beliefs about event likelihoods. This claim is based on an extensive normative framework for decision making under uncertainty, subjective expected utility (SEU) theory. The central tenet of this theory is that the expected utility of an event is its 'utility' multiplied by its probability. Utility is presumed to be a scalar quantity (e.g., money), and a rational agent chooses the option that maximizes their expected utility. For instance, given a choice between a gamble with probability of 0.5 of getting \$20 and a gamble with probability of 0.25 of getting \$32, the choice that would maximize expected utility is the first gamble ( $0.5 \times \$20 = \$10$ , whereas  $0.25 \times \$32 = \$8$ ).

Until the 1990s, frequentist probability theory dominated statistical theory and applications, partly due to its familiarity for statisticians and partly because of the seemingly impractical computational demands of Bayesian statistical modeling. This state of affairs changed with increases in computing power and the development of Markov Chain Monte Carlo methods for Bayesian models. These developments enabled the application of Bayesian methods to complex models. Currently, Bayesian statistical modeling is increasing in accessibility and popularity.

Uncertainty research in psychology and behavioral economics over the past four decades has featured extensive comparisons between the SEU framework and the ways that humans think about probability (see section 'Perception and Judgment'). For some time, SEU was considered the arbitrator of 'rational' decision making and, therefore, Bayesian probability theory was

the normative standard for uncertainty judgments. As we shall see in section 'Perception and Judgment,' recent developments have shifted away from both of these positions.

### Nonprobabilistic Uncertainty

The claim that there is more to uncertainty than probability has a fairly lengthy history. One of the earliest is Max Black's classic distinctions among vagueness, generality (or nonspecificity), and ambiguity. An earlier distinction was drawn by Keynes and Knight between 'risk' (where probabilities are known) and 'uncertainty' (where probabilities are imprecise or unknown).

During the past four decades there has been a rapid proliferation of alternative frameworks for dealing with uncertainty in formal or mathematical ways that depart from standard probability theory. Fuzzy set theory, rough sets, and fuzzy logic have been developed as frameworks for dealing with vagueness and related kinds of nonprobabilistic uncertainty. The primary claim for fuzzy set theory is that it handles categories (sets) in which items can have partial membership (e.g., a 'reddish' color or a 'tall' person). Likewise, fuzzy logic permits degrees of truth to be attached to propositions.

Probability theory itself has been generalized to incorporate vagueness, mainly by extensions to 'imprecise' probabilities. Formalisms of this kind include possibility theory, Dempster-Shafer belief theory, and several theories of imprecise probabilities that incorporate these two as special cases. The past two decades have seen the establishment of these frameworks on firm axiomatic foundations and an increasing number of applications. Nevertheless, these developments have been controversial at times and there are ongoing debates over what properties generalized probability theories should have.

### Perception and Judgment

Psychology is one of the few disciplines that attempts to account for how people perceive and respond to uncertainty. These accounts have been useful in behavioral economics, management science, risk management, and a host of other areas. Psychological theories about uncertainty fall into two groups: how people manage in an uncertain world, and how people manage uncertainty itself. This section deals primarily with the latter.

There are, broadly speaking, three traditional normative orientations regarding how people deal with the unknown in psychology, and each has its roots in particular theoretical developments. Perhaps the oldest is the 'Knowledge Seeker,' originating in the psychoanalytic canons for the well-adjusted individual and found in most branches of ego psychology. This view extols the person who seeks novel information and experience, is open to full and honest communication, can tolerate uncertainty and even ignorance in the short run in order to gain knowledge, and who is not defensive about prior beliefs.

The second tradition, the 'Certainty Maximizer,' focuses on the debilitating consequences of uncertainty, unpredictability, and uncontrollability for the affective, cognitive, and physiological capabilities of the affected organism. Most of the evidence for this viewpoint originates from research on learning and adaptation. But an entire set of emotion-based theories

also assumes that anxiety is a consequence of uncertainty. Likewise, several social psychological and communication theories of human interaction assume that people are motivated to reduce uncertainty. Thus, there is a natural tension between this tradition and that of the 'Knowledge Seeker.'

The third tradition, the 'Intuitive Statistician-Economist,' originates from psychophysics, perception, and cognitive psychology, and reflects information processing models of cognition. It is primarily concerned with criteria for rationality in judgment and choice, and the dominant normative viewpoints have been the probability theory and a view of humans as being hedonic (seeking pleasure and avoiding pain) by nature. This view has a lot in common with neoclassical economics. 'Rational' decision makers estimate probabilities, quantify utilities, and make choices according to the precepts of SEU. Given this prescriptive benchmark, much of the research in this tradition has focused on judgmental and decisional errors, in the sense of deviations by people from this allegedly rational prescription.

Psychological research on judgment and decision making under uncertainty has stimulated lively debates about the nature of rationality and the extent to which humans can be shown to be rational or irrational. Proponents of the view that humans are not rational fall into the 'heuristics and biases' camp, and their primary claims are that the mental shortcuts to reasoning (heuristics) that people use cause them to fall prey to irrational tendencies (biases). The 'bounded rationality' camp, on the other hand, characterizes human judgment as rational under the constraints of limited time and cognitive capacity, employing 'fast and frugal' heuristics to cope with such constraints. Moreover, some members of this camp claim that many so-called heuristics are adaptive, because they exploit correlated structure in the environment. Finally, in recent times more attention has been paid by some researchers to the role of emotion in guiding judgments and decisions. Their major claim is that emotions may be essential for making good decisions under uncertainty.

### Judgmental Biases and Errors

The 'heuristics and biases' style of research on uncertainty judgments peaked in popularity during the 1980s, with popular treatments appearing in the subsequent two decades. One textbook during this time identified 27 cognitive errors in human judgments about uncertainty. In a few countries, proposals were even mooted to incorporate corrective training in probability judgments into educational curricula.

One class of biases and errors pertains to selective neglect of relevant information. This class includes ignoring or discounting negative and/or disconfirming evidence (confirmation bias), ignoring base-rate information about probabilities in favor of less relevant information (base-rate fallacy), and ignoring sample size in accounting for variation (sample size fallacy).

A second class pertains to judgments regarding random processes. The most famous is gambler's fallacy, an underestimation of the length of runs in random processes coupled with a belief that random variation 'balances out' in a self-correcting fashion. A related phenomenon is the underestimation of subjective confidence interval widths, yielding overconfidence when these confidence intervals are used for prediction. Several studies of gambling behavior have also found that at least

some people believe they have control over random events (e.g., in games of chance). Set against these findings is another collection of studies demonstrating that people are too conservative in readjusting their estimates of an event's likelihood when presented with new evidence (anchoring and adjustment). However, during the 1990s several studies found that humans are able to make fairly accurate short-term predictions of low-dimensional deterministic chaotic processes, from which it was suggested that people respond to random processes as if they are a particular kind of chaotic process.

A third kind of error concerns conditional probabilities and probabilities of compound events. The most famous of these is the 'conjunction fallacy,' a violation of the rule that  $P(A \& B) \leq \min(P(A), P(B))$ . Other well-established examples include the disjunction fallacy and violations of additivity (the rule that probabilities of an exhaustive set of mutually exclusive events must sum to 1).

Finally, framing effects have been found demonstrating that people can be risk-averse in one context but risk seeking in another. The best known of these are described in prospect theory, which holds that people generally are risk-averse under potential gains but risk seeking under potential losses. Some researchers have presented evidence that people's risk attitudes can differ depending on substantive domains (e.g., recreation vs. finance), whether the risk was voluntarily undertaken, and who may bear the consequences.

### Explanations of Probability Judgments

Accounts of and explanations for probability judgments focus on three main topics: omissions and neglect (e.g., base-rate error), distortions or poor estimations, and priming or anchoring of judgments. The 'availability' and 'representativeness' heuristics are primarily attempts to explain why people ignore base-rate information and logical constraints on compound probabilities. The availability heuristic is defined as assessing the probability of an event by the ease with which instances of it can be retrieved, imagined, or associated. The representativeness heuristic is the judgment of probability based on how prototypical an event is of its parent class or how similar it is to such a prototype. Both of these accounts have been criticized for being too vague and not connected to theories of human information processing.

Another type of account that focuses on distortions in probability judgments is a probability weighting model. The original version of prospect theory, for instance, posited that people overweight low probabilities and underweight high probabilities. Rank-dependent expected utility theory provides an alternative probability weighting model, in which the weights are determined by the rank order of the consequences of an event, rather than by how extreme their probabilities are. Probabilities of extremely bad or good events tend to be overweighted. Cumulative prospect theory incorporated the central innovation in the rank-dependent framework, namely the transformation of the cumulative distribution function instead of the density function. A primary goal of both theories is retaining aspects of rationality (e.g., stochastic dominance) while being more descriptively accurate than SEU (e.g., accounting for people being risk seeking in one condition and risk-averse in another).

A third kind of explanation focuses on priming or anchoring of probability judgments. An early example of such accounts is research beginning in the late 1970s on the 'catch-all underestimation bias,' a tendency to underestimate the probability of events that are not explicitly described but instead bundled together into a catch-all category. Support theory generalized this idea to a nonextensional account of probability judgments. The basic premise is that higher probability is given to events that can be 'unpacked' into greater numbers of specific instances or subtypes.

Some recent work has attempted to account for the related phenomenon of 'partition priming.' A sample space partition concerns the division of the space into a set of exclusive events (e.g., two vs. five possible events). Given such a partition of  $K$  possible events and no other information, people invoke the principle of indifference to anchor their probability estimates of each event on  $1/K$ . Experimenters have found that even when a 'correct' partition exists, people can be primed with an alternative partition ( $J$  alternatives, say) to anchor around  $1/J$  instead of  $1/K$ .

### Judgment Research on Nonprobabilistic Uncertainty

There is a scattered literature exploring the psychology of human responses to nonprobabilistic kinds of uncertainty. These include delay (as in delayed outcomes), ambiguity, and more recently, conflict and state space ignorance. Concurrently, there are debates over whether people respond to these alternative kinds of uncertainty just as they do to probabilistic uncertainty or as if these are truly distinct varieties. The following criteria have been proposed for distinguishing among kinds of uncertainty:

1. Normative: Can a case be made that a rational agent would equate one 'kind' of uncertainty with another versus distinguishing between them?
2. Behavioral/consequentialist: Does one 'kind' influence responses independently of another 'kind'?
3. Correlational/predictive: Are orientations toward one 'kind' correlated with orientations toward another? Do different variables predict one kind than those predicting another?
4. Sociocultural: Do social or cultural norms distinguish one 'kind' from another?
5. Neurological: Are different structures in the brain entrained by different 'kinds'? Does damage to one structure disable people from dealing with one 'kind' but still allow them to deal with another?

We shall consider delay first. Behavioral studies of choice under uncertainty operationalize uncertainty in two ways: reward variability and reward delay. The link between reward variability and probabilistic uncertainty is straightforward, but the link with delay perhaps is not quite as obvious. Generally, humans (and other animals) behave as if the consequential magnitude of an outcome is larger if it happens sooner than later. So good outcomes seem better and bad outcomes seem worse, the sooner they occur. The corresponding analogy is that immediacies are certainties and delays are uncertainties. Thus, outcomes are discounted temporally in much the same way that they are discounted probabilistically. Economists

have long maintained that temporal discounting is reasonable (or at least not irrational).

The strongest thesis for a direct analogy between delay and probability is that delay exerts the same kinds of influences that probability does. For example, temporal discounting predicts that people (and other animals) will be risk-averse for delayed gains and risk seeking for delayed losses. Empirical evidence for this parallels findings of similar effects on risk orientation due to probabilistic uncertainty as in prospect theory. That said, there are also recent studies and theoretical developments suggesting that intertemporal effects on decisions do not always parallel the effects of probabilistic uncertainty, and research in this vein has increasingly taken a separate course.

Now let us turn to ambiguity. Ellsberg's classic paper showed that people can be influenced to prefer to bet on a gamble when they know the probabilities exactly or to bet on a gamble when the probabilities are not known exactly, even though according to the standard SEU arguments they should have no preference between those gambles. Usually, people prefer known probabilities when they stand to gain by betting, but may prefer unknown probabilities when they face a prospect of loss. An obvious explanation for this preference pattern is that when probabilities are imprecise people adopt a pessimistic stance toward those probabilities but several other explanations have been promoted, including one that links attitudes toward ambiguity with those toward variability of consequences.

A few recent studies have extended the study of nonprobabilistic uncertainty to include uncertainty arising from conflicting information and from ignorance of the state space (i.e., not knowing about all possible outcomes). There is evidence that conflicting information is responded to as if it differs from other kinds of uncertainty, in that two ambiguous but agreeing messages from two sources are preferred over informationally equivalent, precise but conflicting messages from two equally believable sources. People are conflict averse in the sense that they behave as if conflict is a more consequential kind of uncertainty than ambiguity. Likewise, there are empirical demonstrations that people disprefer state space ignorance to ambiguity. However, a few recent experiments have failed to replicate both sets of findings in their entirety. This is still a new and generally unexplored topic of research.

## Neuroeconomics

Since the mid-1990s, a confluence of research and theory from psychology, behavioral economics, and neuroscience has generated the new subfield called 'neuroeconomics.' While still in its infancy, this area holds the potential to contribute substantially to our understanding of human decision making under uncertainty. One of the most rapidly growing streams of neuroeconomic research focuses on how the brain processes uncertainty. This line of research began when single-unit recording studies in nonhuman primates indicated that neurons can convey information about the expected values of alternatives in a decisional task and neuronal activity can predict an individual's choices.

Neural imaging studies thus far suggest that the area most activated by uncertainty in stimuli is the frontomedian cortex, particularly when probabilities are involved. Some researchers

have also observed that when uncertainty about outcomes cannot be analytically dealt with (e.g., under severe time constraint) then the lateral prefrontal and parietal regions become more active instead of the frontomedian cortical region.

Neuroeconomics and related developments in psychology were launched by two nearly simultaneous discoveries. One was the identification of a 'reward center' in the brain, the key realization being that specific neural structures are recruited when people assess potential consequences of the alternatives in a choice set. The other was the 'somatic marker hypothesis,' which proposes that emotions play an essential role in decision making. Up to the mid-1990s, affect was disregarded by decision researchers or considered a debilitating influence on decision quality. This view changed with the finding that neurotrauma patients with damage to the frontomedian cortex but unimpaired reasoning ability nevertheless were unable to make high-quality judgments and decisions.

Around the same time, some researchers raised the possibility that 'social' uncertainties may differ from uncertainties lacking a social component. The generative studies were conducted on neural activation while subjects play social dilemma games such as Prisoner's Dilemma. An important finding is that activity in some cortical areas is increased during interactions with human opponents but not during similar interactions with computer-simulated opponents. This finding raises the possibility that human responses to uncertainty generated by other humans are distinct from responses to uncertainty from nonhuman sources.

Finally, recent studies comparing brain activity under risky versus ambiguous decisional tasks suggest that the regions activated may depend on the type of uncertainty. One such study found that ambiguity resulted in stronger activation in the lateral orbitofrontal cortex and the amygdala, while risk activated the striatum and precuneus. Behavioral performance on this task in orbitofrontal lesion patients corroborated these claims. Studies that compared risk and ambiguity also have found that preferences toward different types of uncertainty correlate with activation in different brain regions. For instance, activation of the posterior parietal cortex was predicted by risk preference, whereas activation in the lateral prefrontal cortex was predicted by ambiguity preference.

Evidence that different neural structures are activated to deal with different kinds of uncertainty indicates that the 'kinds' are distinct in ways that do not depend entirely on cultural or social factors. Thus, this line of research can fill gaps in our understanding of how and why people think and act as if there are different forms of uncertainty.

## Social Constructions of Uncertainty

Up to this point, we have dealt exclusively with theories and studies of uncertainty that are asocial. These theories implicitly treat uncertainty as if its source is external or intra-subjective. Another tradition approaches uncertainty as being socially constructed. This section deals with that tradition. First, however, we must dispense with a blind-spot concerning uncertainty and its effects. Most popular conceptions of uncertainty have a negative cast to them (e.g., uncertainty is impotence whereas knowledge is power). Of course, there are excellent

reasons in many circumstances to be negatively disposed toward uncertainty. Nevertheless, uncertainty can motivate people positively as well as negatively. People find uses for uncertainty and do not always want to be rid of it. Indeed, they can be motivated to create uncertainty, not only for others but for themselves as well. Contrary to the view of ignorance and uncertainty as primarily negative, human engagement with ignorance or uncertainty is almost always a mixed-motive enterprise.

### **Socially Constructing the Unknown**

It may be very difficult to know anything directly about our own or anyone else's ignorance, but it is not as hard to find out about people's representations and accounts of ignorance. Moreover, those representations and accounts are important because ignorance, like knowledge, is in large part socially constructed. Most of the literature on uncertainty in disciplines such as economics, psychology, and (to a lesser extent) sociology presupposes agreement among all stakeholders on what is known and what is not known. Yet it seems obvious that the behavior of a dugong in waters off Cape York Australia will convey rather different 'information' to a marine biologist and a Torres Strait Island fisherman. They might even agree that each 'knows' different things about dugongs. But on some points they may dispute each other's knowledge and/or ignorance claims, and part of the basis for those disputes will be what 'knowledge' or 'ignorance' can consist of, and indeed what can and cannot be 'known.'

Everyday ideas about the unknown come from two sources: commonsense realism and commonsense sociality. Commonsense realism encompasses everything we believe or think about how the nonsocial world works, including sacred as well as profane domains. Commonsense sociality refers to our beliefs about the social world and includes our theories of mind. Both kinds of common sense are essentially realist. Regardless of the ontological or epistemological positions adopted by scholars and researchers, many laypersons are ontological realists.

Commonsense ontological realism enables us to understand many of the uses people have for uncertainty and how they go about creating and maintaining it or responding to it. The backdrop most of the time includes the assumption that there is an independent reality that provides the true state of any conceivable unknown. For example, it makes no sense to decide whether or not one would like to know the date and manner of one's demise unless one believes that such things are preordained and therefore knowable. A similar basis underpins the economics of attention, the social control of curiosity, and other pertinent social norms and cultural practices governing who is supposed to know what and when they are supposed to know it.

### **Ignorance, Uncertainty, and Social Capital**

Until fairly recently, the social sciences widely shared a 'Pollyanna' perspective, in which the default assumption was that unshared knowledge, miscommunication, and misunderstanding are pathological and in properly functioning social settings would be absent or eliminated. Some early dissidents

from this perspective observed that many important kinds of social interactions and arrangements would be impossible without some unshared perceptions, omissions, secrets, and even deception by the participants. Others pointed to the ways in which unshared information and uncertainty are arranged and manipulated to establish or maintain power relations. For instance, research into the tobacco industry's efforts to manufacture doubt about the hazards of tobacco presents an exemplary case study of the use of pseudoscience by an industrial giant to protect and expand its investments. In this section we review some of the major uses of ignorance and uncertainty and their roles in social life.

Ignorance and uncertainty underpin certain forms of social capital. Four examples are specialized knowledge, privacy, trust, and politeness. The first two exemplify multilaterally negotiated ignorance arrangements as opposed to unilateral ones such as secrecy or deceit. The second pair, trust and politeness, are examples of social relations and modes of social conduct that mandate or even require ignorance.

Specialization is a social ignorance arrangement. Aside from its obvious basis in cognitive limitations and expanding knowledge bases, specialization is an example of risk spreading in three respects. First, no participant has to take on all of the risks of direct learning (vs. vicarious learning which is less risky). Second, the risk of being ignorant about crucial matters is spread by diversifying ignorance. Third, the risks associated with the consequences of bearing knowledge (e.g., responsibility or culpability) also are diversified.

Likewise, privacy also is a socially mandated arrangement involving voluntarily imposed uncertainty and ignorance. Privacy often has been construed as control over access by others to information, mainly about the self. The most common motives for privacy are quite obvious, amounting to freedom from surveillance and exploitation.

There is widespread agreement among scholars that trust carries with it some form of risk or vulnerability. An important component of that risk is a requirement that the truster remains partially ignorant about the trustee. Trust relationships (e.g., friendships) entail a specific kind of privacy. If a person believes another is monitoring them or insisting that they self-disclose or account for their actions, that person will infer that the other does not trust them.

Polite or civil social interaction is another example of social relations that depend on ignorance. In polite conversation, conversationalists do not expect to deal in the truth, the whole truth, and nothing but the truth. Polite conversational strategies include disinformation (e.g., presenting a false impression of approval) and referential abbreviation (particularly vagueness and ambiguity or even outright omission, as in tactful utterances).

The literature on organizations and management has long given uncertainty a prominent place, although the treatment of 'uncertainty' itself has been rather muddled. Classical frameworks for management science during the 1950s and 1960s advised managers to eliminate or absorb uncertainty. The most popular remedies included buffering, smoothing, forecasting, and various forms of strategic planning. These remedies primarily amounted to formulating plans to weather uncertain times and/or strategies for mitigating negative consequences to the organization.

Most of the early findings in studies of how organizations deal with uncertainty could be summed up in the phrase 'uncertainty avoidance.' In addition to protecting the organization, motives for avoiding uncertainty included maintaining control and avoiding discreditation, adverse publicity, or controversy.

The 1970s and 1980s saw a more tolerant view of uncertainty in this literature. Evidence began to emerge that not all managers were risk-averse. Some high-performing managers were found to strategically select uncertain environments in which they could have a competitive edge or scope for entrepreneurship. Likewise, some studies revealed strategies employed by organizations to increase uncertainty for competitors in order to gain an advantage. Finally, critics of conventional control and regulation practices pointed out that tolerance of ignorance and uncertainty has potential benefits for organizations, in the form of a local culture of innovation and entrepreneurship, as well as the kinds of social capital discussed earlier.

### Risk, Uncertainty, and Public Culture

Research on risk perception arose during the 1970s, mainly in response to environmental concerns in Western nations. Much of the initial research was conducted by social and cognitive psychologists, with anthropology, sociology, and allied fields becoming involved during the 1980s and 1990s. There has been relatively little communication or integration between the cognitive psychological and sociocultural approaches to this topic.

Two widely debated sociocultural approaches to risk emerged during the 1990s. The first uses a 'worldview' concept, positing that human attitudes toward risk and danger vary systematically according to cultural orientations, assumed to be individualist, fatalist, hierarchist, or egalitarian. These orientations are held to strongly influence people's risk responses as well as attitudes toward the environment.

The second approach invokes the concept of a 'risk society.' The central claim is that modern technological developments have resulted in the emergence of new all-pervasive and invisible risks, also characterized as beyond the ken of laypeople. The focus of the 'risk society' perspective is on deep and globalized forms of uncertainty and ignorance, arising from major technical and environmental risks (e.g., climate change, pollution, or mass extinctions) and how they have transformed the social landscape in terms of opportunities, threats, benefits, and costs.

A third approach that links psychological and sociocultural approaches is the social amplification of risk framework. The primary subject of this approach is to explain why particular risks become a focus of concern in society while others are ignored. This framework does not deny the reality of hazards but investigates how these are transformed in the public consciousness via their amplification or diminution by psychological and sociocultural processes.

Somewhat related to the social amplification of risk framework is a critical literature that has emerged in the past decade as commentary on the increasingly risk-averse and litigious orientation of some Western societies. Writers and researchers in this vein have documented how risk and blameworthiness have become strongly linked under the rubric of democratic ideals such as accountability and transparency.

### Managing Uncertainty: Tradeoffs and Dilemmas

A crucial mistake in many perspectives that privilege knowledge over ignorance is the failure to realize that knowledge seeking and possession are not costless. The early literature on foraging behavior is pioneering in this regard, taking into account the energy and time costs entailed for an organism to try its luck in a different patch from the one it is familiar with. Information seeking and processing takes time, effort, and cognitive resources. Information seeking can also incur social costs. Directly interrogating someone, for example, is socially inappropriate or risky in many circumstances and prohibitively so in some cultures if the subject of interrogation has sufficiently high status.

Let us consider the tradeoffs involved in possessing information and knowledge, starting at the cognitive level. Ignoramuses are not always worse off than knowledgeable folk; in fact it can be demonstrated that under some conditions they are better off. Imagine for a moment that humans were endowed with the ability and a compulsion to indiscriminately absorb all information that came their way and retain all of it for a lifetime. It is well known that higher cognitive functions such as abstraction or even mere classification would be extremely difficult. Information acquired decades ago would be as vividly recalled as information acquired seconds ago, so older memories would interfere with more recent and usually more relevant recollections. Thus, forgetting is just as important as remembering for adaptively selective information processing. In effect, memory behaves as if it is betting that the less frequently and recently a piece of information has been retrieved, the less likely it is to be needed and therefore the better off the memory is without it.

Recent psychological research on the recognition and fluency heuristics, both of which require partial ignorance, also are instructive. To understand the recognition heuristic, consider the question: 'Which city has the larger population, Pasadena (California), or Pasadena (Maryland)?' If we do not know the populations of those two cities then we must rely on something else we know about them. The recognition heuristic says that if we recognize one city (most likely Pasadena, California) and not the other then we choose the recognized city. In this case we would make the correct choice (as I am writing this, Pasadena California contains about 145 000 people whereas Pasadena Maryland has about 12 000). Several studies have demonstrated that a greater number of correct choices (e.g., which of a pair of German cities has the greater population) can be made by ignorant decision makers (e.g., American university students) than by more knowledgeable decision makers (e.g., German citizens). The fluency heuristic is quite similar, stipulating that the city that is more fluently or rapidly recalled will be the one selected.

However, gaining an appreciation of the mixed-motive nature of engagement with ignorance and uncertainty, there is no substitute for examining some examples of real-world tradeoffs and dilemmas.

- 'Collingridge's dilemma' actually is a tradeoff. The less well-entrenched a system is and the shorter the time it has been operating, the more easily and inexpensively it can be changed; but the greater is our ignorance of its likely effects or problems. By the time ignorance of those

effects has been reduced, it is too expensive and difficult to change the system. In this tradeoff, time is both knowledge and money.

- The 'info-glut' dilemma is a genuine dilemma of the common-pool resource kind. Any stakeholder with an educational or persuasive interest will wish to broadcast its message in a public forum. Too many messages in an unregulated forum, however, may result in the public tuning out messages altogether. The scarce resource in this case is not information or knowledge, but attention.
- 'Mattera's dilemma' is an example of a conundrum in social regulation that has both tradeoff and dilemmatic components. The tradeoff arises from the fact that a regulatory climate favoring creativity and entrepreneurship requires the toleration of ignorance in the service of freedom. Insistence on full knowledge and control eliminates the latitude needed for creativity and entrepreneurship. The dilemmatic component arises from the fact that the greater the attempts to regulate behavior, the more reactive people become and the more they attempt to generate ignorance in the would-be controllers by withholding information or giving false information. If both parties pursue their self-interests then the end result is a system of constraints and controls built on disinformation.
- The 'indemnity' dilemma is a mixture of a collective tradeoff and a public goods dilemma. Play, games, fun, volunteering, and various other public goods require at least some risk-taking. However, a risk-averse public, aided by opportunistic lawyers and profit-oriented insurers, can create a litigious market in which public goods like fun and voluntarism are unaffordable or simply outlawed.

In conclusion, the roles played by knowledge and ignorance are not merely mirror images of one another. Moreover,

ignorance and uncertainty are neither negative nor marginal aspects of the human condition. They are essential to what makes us human.

## Glossary

**Adoption studies** Research wherein a child with one set of biological parents and a different set of psychological parents is studied.

**Biological environmental influences** Events that affect a person biologically but are not encoded into the person's DNA.

**Concordance rates** The frequency with which one twin is diagnosed with an illness, when the other twin is also diagnosed with the same illness.

**Cortisol** The hormone that regulates our body's reaction to stress.

**Genetic influences** The biological blueprints for behavior that are contained in a person's chromosomes.

**Imitation** A theory that states that children may learn to be violent by imitating an adult's aggression.

**Minimal brain dysfunction or minimal brain**

**damage** Very low levels of brain dysfunction, theoretically affecting behavior, emotions, learning, or memory.

**Neurotransmitters** Chemicals secreted by the brain, some of which have been linked to aggression.

**Paranoid misperceptions** Attitudes or belief systems that misinterpret ambiguous circumstances as signs of danger where none actually exists.

**Resilient** The state in which a person is likely to resist developing a disorder.

**Serotonin** One of the monoamines, low levels of which have been implicated as related to aggression.

**Testosterone** One of the *androgens*. A male sex hormone that is associated with aggression.

**Vulnerable** The state in which a person is likely to develop a disorder.

Violent crimes can be as baffling as they are repelling. In England, two 10-year-old boys lured a 2-year-old away from his mother at a shopping mall; they took him down to the local railroad tracks, where they beat him to death and left his body to be run over by a train. In the United States, a group of teenagers shot and killed a man whose car they were stealing – even though the man had willingly handed over his car keys and was not resisting the theft in any way. In Massachusetts, a group of young teenage schoolgirls planned to murder their English teacher because she was too 'strict.'

To understand the causes of violence, it is not always enough to understand the external circumstances that often drive other types of criminal behavior. It is true that violence sometimes results from factors such as an individual's desire for financial gain or from an individual's repeated exposure to violent behavior in his or her social environments. Sometimes, however, it also happens in an apparently motiveless fashion. *Violence is never truly without motive*, but its motives may be so complex and elusive that it *appears* motiveless. In all cases, particularly in cases of violence that appear to have no motive, internal or individual factors may be critical in understanding the cause of such behavior. A variety of different biological and psychological influences and mechanisms have been considered over the years. I summarize them here and attempt to construct a more comprehensive model of the causes of violent behavior.

## Biological Perspectives

### Types of Biological Influences

There exists a mistaken tendency to use interchangeably the terms *biological* and *genetic*. In fact, genetic influences are only

one type of biological influences on behavior. There are (at least) two different types of biological influences: genetic influences and biological environmental influences. *Genetic influences* refer to the blueprints for behavior that are contained in a person's chromosomes. Chromosomes contain deoxyribonucleic acid (DNA), the genetic material a person inherits from his or her biological parents, which is referred to as his or her *genotype*. An individual's *phenotype* is the outward expression of his or her genotype.

*Biological environmental influences*, unlike genetic influences, are events that affect a person biologically but are not encoded into the person's DNA. For example, consider a head injury from a car accident, which subsequently changes the victim's personality. The head injury is unmistakably a biological environmental influence. But no genotype determines that someone will have a car accident; however, such an accident, and its accompanying head injury, can still have an important biological effect on the person's behavior.

### Modern Biological Theories

Some children who are exposed to violent psychosocial environments do become violent; many other children who are similarly exposed do not. This fact has led researchers to hypothesize that some children are *vulnerable* to noxious circumstances, whereas others are *resilient* or *invincible* – that is, resilient children survive and cope well despite terrible circumstances. What makes one child resilient and another child vulnerable? Most recent reviews point to a variety of interventions and settings (family, school, medical care) that help increase resiliency in children. One study pointed out that afterschool and general school participation seems to increase

resiliency. Another possible difference between resilient and vulnerable children is their biology. Perhaps unfortunate genetic influences or biological environmental influences serve to weaken some children – thus making them vulnerable. On the other hand, perhaps positive biological influences strengthen some children – thus making them resilient. The fact that children are differentially vulnerable suggests that biology may be an important difference among violent versus nonviolent people.

Another piece of evidence has emerged that supports the importance of biology as one cause of violence. In the past few decades, researchers have conducted longitudinal studies that track the same group of people over long periods of time, usually years. Several important studies have found that aggressive behavior is (in some children) a stable characteristic from very early childhood until adulthood. Both boys and girls may show that stability of aggression, which seems to increase as the child grows. When a behavior begins very early in life, before a child has been exposed to any psychological environment for a lengthy period of time, it likely that this behavior is strongly influenced by biological factors. Thus, the evidence from longitudinal studies suggests that early biological factors (such as genetic influences or early biological environment) may operate during an individual's entire lifetime to affect his or her tendency to be violent.

In summary, there are two major pieces of evidence that suggest the importance of biology as well as learning: (a) the early emergence of aggressive behavior as a stable characteristic in some individuals, and (b) individual differences in vulnerability to noxious environmental influences (such as having violent parents). The question that remains is: What biological influences are important in making a child more or less vulnerable to poor psychosocial environments?

### Physiology and Anatomy

One type of biological factor that might influence the development of violence is *anatomical differences* between the brains of violent individuals and those of nonviolent individuals – in shape or matter.

One type of anatomical difference that has been studied in relation to violence is the presence of a brain tumor. A brain tumor is an uncontrolled growth mass in the brain. There are two types of brain tumors: those that actively destroy healthy brain tissue, and those that cause problems by compressing brain tissue until it is unable to function normally. Brain tumors, which offer gross (large) insults to brain integrity, undoubtedly cause changes in behavior, including personality changes. A few violent criminals have been found to have brain tumors upon autopsy. Some testing has also found brain dysfunction in forensic populations. One study found a high incidence of focal (i.e., small and localized) abnormalities in the left hemisphere of violent individuals who also tended to be mentally retarded or epileptic or who had suffered from earlier brain damage. A more recent case study noted that in a 16-year-old boy, a tumor was associated with several different behavioral problems, including aggression and mood swings. In general, however, there was no relationship between EEG abnormalities and violent behavior. The pattern of this research suggests that while focal

abnormalities such as tumors might exacerbate violence in some individuals (probably those who have multiple impairments), in general they are not a typical cause of violent behavior. The earlier findings of tumors had caused some excitement in the scientific community; these individuals raised the possibility that extreme, senseless violence may be due, at least in part, to brain tumors that radically affect normal brain function, or that worsen more subtle brain deficits. In reality, however, this scenario would only fit a small number of violent offenders. Most violent offenders do not have brain tumors, and research in this area suggests strongly that brain tumors (and other types of massive brain damage) are not an important factor in the etiology of the bulk of violence. To date, the hypothesis that violence is due to massive brain dysfunction appears to have little support, and autopsies of chronically violent offenders usually find no noticeable (i.e., major) brain damage.

However, not all damage to the brain is massive. Damage to the brain ranges from extremely minimal to extremely major. Most cases of brain damage are at the minimal end of the spectrum, although it is the major cases that are the most noticeable.

### Minimal brain damage

Also called *minimal brain dysfunction*, minimal brain damage does not 'look' like major brain damage. A person with minimal brain dysfunction will not have 'obvious' brain damage; however, minimal dysfunction may affect behavior, emotions, learning, or memory – that is, the more subtle (or 'higher') functions of the brain. For example, although major brain damage might result in severe mental retardation, minor brain dysfunction might result in a learning disability that would not necessarily affect intelligence in any way (e.g., dyslexia). Because we know that minimal brain dysfunction appears to be related to problems such as learning disorders and hyperactivity, it is logical for scientists to be interested in the possibility that minimal brain dysfunction is related to behavioral problems like violence.

### Minor physical anomalies

Interestingly, a series of studies has found a relationship between minor physical anomalies (MPAs) and childhood behaviors related to adult aggression (such as hyperactivity), and criminal violence as an adult. Studies of children with behavior disorders related to delinquency often find that the children have high numbers of MPAs. One longitudinal study followed 170 Montreal (Canada) boys from kindergarten through adolescence; they were examined at age 14, when their MPAs were assessed. This study found that MPAs were related to an increased risk of violent delinquency by age 17, as measured by both self-report and official records, although MPAs were not related to property offending. Another study, which followed children from birth until adulthood, found that subjects with high numbers of MPAs as children were at significantly higher risk of recidivist, violent criminal activity as adults. Another research, taking advantage of more recent and sophisticated imaging scans to examine brain tissue more directly, has found this type of minimal damage in the scans of violent individuals.

### Neuropsychological testing

MPAs are only one indirect way of assessing minor brain dysfunction. A second way is *neuropsychological testing*. Researchers have administered neuropsychological tests to violent criminals, and have found evidence that such individuals often have subtle brain impairments. One study found that a low score on a neuropsychological frontal lobe task predicted aggressiveness among 72 white males. Studies on children have found links between behavior problems, aggression and acting out, and neuropsychological abnormalities. An in-depth study comparing chronic violent offenders to nonviolent offenders found that the violent offenders were significantly more likely to demonstrate a number of indicators of abnormal neuropsychological function, including head injuries, seizures, headaches, hypoglycemia, dizziness, poor coordination, and speech and vision problems. Furthermore, subjects with poor neuropsychological functioning, particularly in the frontal lobe region, are more aggressive when provoked. Hoaken's (2007) study of violent individuals with frontal lobe damage found that such damage appears to affect 'executive functioning' in the brain (which may, in turn, be related to aggression) and the perception (or misperception) of facial expressions. Other studies have also linked frontal lobe dysfunction and antisocial behavior.

### Head injury

A third way of measuring minor brain dysfunction is through studying the medical history of a person to reveal head injuries that did not result in gross brain damage. One study compared 27 control children to 27 children who had suffered brain injuries. The children who had suffered the injuries were significantly more likely to show problems with aggression and antisocial behavior; this was true even for the eight children who showed mild brain injuries. Ommaya and his colleagues studied military discharges and found that individuals with mild brain injuries were much more likely than others to be discharged for 'behavioral' reasons, including criminal convictions. One bizarre case was recently presented at a meeting of the American Academy of Physical Medicine and Rehabilitation. The case involved a 47-year-old graphic designer, having no history of psychological problems or antisocial behavior, who suffered a mild head injury and developed impulsive behavior including property crimes.

Researchers, like Dorothy Otnow Lewis of New York University, have combed the medical histories of some of the most violent people in our society. Lewis and other researchers have found that the medical histories of violent delinquents reveal unusually high levels of head injuries. How does brain injury lead to more aggression? More recent research has begun to suggest pathways. One study noted that pediatric patients with a history of brain injury evidenced more frustration, which in turn led to more aggression. Another study linking brain injury and aggression found that frontal lobe damage and the misperceptions of facial expressions were key.

In summary, although both major and minor brain damage may cause violence, the weight of the evidence suggests that the most important type of brain dysfunction in people who are chronically violent and criminal is minimal brain dysfunction. Although it is almost certain that most people with minimal

brain dysfunction will never be violent, a noticeably high number of repeat violent offenders show some level of brain dysfunction (usually minimal).

### Neurotransmitters

Several psychological disorders, such as schizophrenia, are at least partially caused by too much or too little of one type of neurotransmitter or another. A logical question, therefore, is whether violent behavior is related (at least in part) to the level of certain neurotransmitters in the brains of violent people.

As stated previously, there are many different types of neurotransmitters in the brain. However, monoamine neurotransmitters have been most significantly linked to aggression. Research has linked low levels of serotonin with violence, particularly with impulsive aggression. Of the monoamines, low levels of *serotonin* have been implicated most strongly in recent research. One study of rhesus macaque monkeys found that low levels of a serotonin metabolite were found in dominant monkeys and that levels in general were negatively correlated with aggression. This study pointed out that low levels of serotonin were, in fact, adaptive for some monkeys in that it enabled them to attain a dominant status. Studies in humans, however, have generally failed to note positive results of low levels of serotonin. One study of adolescent boys with conduct disorders (CDs) found a negative correlation between their levels of serotonin and the severity of their violent offending. The study found that this relationship was particularly strong in boys with childhood onset of CDs (as opposed to boys whose CDs did not emerge until adolescence). Another recent study injected both male and female subjects with a serotonin-releasing agent, but interestingly found that although a link between hostility, aggression, and low serotonin was found, it was only noted in male subjects. Stanley et al. (2000) studied serotonin levels in 64 psychiatric patients with a variety of diagnoses. She found that serotonin levels were lower in aggressive subjects – and that this was true for all types of psychiatric diagnoses. The researchers also noted that impulsivity was also linked to serotonin function. This suggested that possibility that aggression and impulsivity may share common biological roots. Yet another study linked serotonin levels to aggression *other* than interpersonal aggression: New and her colleagues found an association between low levels of serotonin and self-injurious, suicidal behavior in a sample of personality-disordered, suicidal subjects.

Other studies have found data that indirectly implicates serotonin function. Davidson and Putnam studied 500 violent individuals through a study of their brain scans and found a high rate of defects in the prefrontal cortex – an area that regulates serotonin function.

### Hormones

Two hormones have been the focus of most research on aggression and criminality: *testosterone* and *cortisol*. Testosterone is one of the male sex hormones, called *androgens*. Both males and females secrete androgens, but males secrete a much greater quantity than do females. Androgens are frequently cited as an important cause of aggressive behavior, particularly intermale aggression. What is the evidence that this is true?

A 1995 study of 692 male prisoners compared those who had committed sexual and violent crimes with those who had committed only property crimes on salivary testosterone levels. Interestingly, the higher testosterone levels were associated both with sexual and violent offending as well as with generally more intractable and confrontational behavior – what might, in another interpretation, be seen as dominance behaviors. Dabbs and Morris (1990) found a wide variety of behaviors marking the high-testosterone males, of which more sexual and violent offending was only one. A more recent study continued this trend, finding an association between testosterone levels and aggression (although this association was noted only in males).

A study of 13 elderly men suffering from dementia, however, found that while testosterone was related to aggressive behavior, it was not found to be related to agitated and confrontational behavior.

In 1996, Terry Banks and James Dabbs, Jr., published a study in which they compared the testosterone levels found in young adult delinquents to levels found in a group of college student controls. The researchers compared 36 students to 29 delinquents, and matched them for age, sex, and race. Some of the delinquents had drug offenses and some had violent offenses. Generally, the violent offenses tended to be milder, although two subjects had committed homicide. Banks and Dabbs found that the delinquent subjects had higher testosterone levels than the student controls. Furthermore, this was true for both male and female offenders.

Again, some inconsistencies emerge. For example, a Spanish study of preschoolers uncovered slightly different findings. Sanchez-Martin et al. studied 28 male and 20 female preschoolers. They examined the children's play behavior via videotaped sessions. The play was 'free play,' that is, not scripted activities. Finally, the researchers measured salivary testosterone in the children. Interestingly, although they did find a significant relationship between hostile aggression and testosterone in male children, they found no such association in female children (unlike Dabbs' research, above). They also found no association between testosterone and the tendency of a child to engage in playful (not hostile) aggression.

Another study of domestic violence also found an association between testosterone and aggression. Soler and colleagues studied 54 men from low socioeconomic backgrounds. They asked these men to self-report on their aggression levels with their domestic partners and a high percentage reported some form of verbal or physical aggression. Further, testosterone levels were significantly correlated with these types of self-reported aggression. Of course, since this study utilizes self-report measures of aggression, it is possible that aggressive men were mistakenly included in the 'low-aggression' group if they failed to report their own violent behavior.

Finally, if high testosterone helps cause aggression, will low testosterone help reduce it? A newer way to study the impact of androgens on aggression is through the forensic use of chemical castration. This process involves the administration of the female hormone medroxyprogesterone acetate (Depo-provera) that decreases the functioning of testosterone (one of the androgens). The theory is that such an administration will decrease a male's sexual drive and permit the release of repeat sex offenders into society. Despite some anecdotal reports of

success in stopping sexual offense recidivism, clinicians have noted that chemical castration does not work in all male offenders and that as many as half are still able, despite treatment, to function sexually. Another study used a different approach: some researchers examined the impact of artificially reducing testosterone levels without castration. This experiment involved eight normal men; so, its findings may or may not be generalizable to violent criminal offenders. Loosen and his colleagues found, interestingly, that some effects were the same for all men, while other effects happened only in some of the men. For example, all eight men showed marked reductions in 'outward-directed' anger, but only half exhibited reductions in anxiety and sexual desire. Neither study really suggests that lowering testosterone, either through castration or through chemical means, is decidedly effective on violent males.

The literature that implicates testosterone as an important cause of violence may seem strong, but research is rarely as clear as it appears at first glance. There are inconsistencies. Some research points to aggression and dominance/hostility as being related to testosterone, and other research fails to find that dominance/hostility measures are related to sex hormones. Some research notes a testosterone-aggression relationship in both males and females; other research finds it only for males. Reducing testosterone demonstrated that in different men it plays different psychological roles, and there is no clear evidence that it might effectively reduce violence in all violent males. Despite this, some consistencies emerge: clearly testosterone may play *some* role in causing aggressive behavior in at least some offenders. What factors might account for the inconsistencies found in the literature above?

Paul C. Bernhardt has suggested that perhaps more than one biological factor must go wrong for testosterone to truly have a deleterious effect. He recently pointed out that although studies have linked high levels of testosterone to aggression, this relationship cannot be a simple one because successful athletes and businessmen also tend to have high testosterone levels, although they are usually not violent individuals. Bernhardt has pointed out that testosterone may be acting in accord with low serotonin in violent individuals, and that it may be this 'double whammy' that results in criminally violent behavior. He points out that serotonin, in addition to being linked to aggression, is also linked to hyperresponsiveness to bad events. Possibly, what is happening is that when a high-testosterone male is thwarted in his dominance attempts – when he fails – then if he 'hyperresponds' to this bad event, he will exude aggression. Thus, Bernhardt's intriguing theory suggests, as many other researchers have, that there probably needs to be more than one system malfunctioning to achieve a truly violent individual.

Another theory suggests that high testosterone levels might have social and psychological implications as well as biological ones, and that a person might need to be exposed to social problems *in addition* to the biological factors to develop a markedly violent tendency. Raine and his colleagues studied 1130 male and female children from the Indian Ocean island of Mauritius as part of a prospective cohort study. They found that children who were taller and heavier at age three – correlates of higher testosterone – were also more aggressive, more fearless, and sought more stimulation

then their peers. Raine speculated that these children might be expected to have suffered socially as well. For example, taller and heavier children might bully more both because they are more likely to have been exposed to more testosterone, and because, being bigger, they find it easier to be bullies. Thus, this study exposes the complex nature of human social interaction and biology. Our biology impacts us all; and in turn, it impacts our ability to socialize with other human beings which in its own turn, helps to determine our own behavior.

One final theory, and one of the most compelling, has to do with the timing of exposure to testosterone. Because higher testosterone is measured in grown men, we assume that it is *then* that it must be making its greatest impact. However, a significant body of research has implicated prenatal exposure to testosterone as a likely source of influence on brain development and thus on behavior. Fetal exposure to high levels of androgens (male-typical range or clinically high range) may affect the tendency to be violent in two ways. First, prenatal exposure to androgens appears to actually lower the tendency of a person to behave in a prosocial manner. Second, levels of prenatal testosterone are theoretically related to levels of MAO, which affects general aggressiveness and feelings of anger and frustration. Like androgens administered to transsexuals, androgens administered prenatally may also affect emotions related to aggression. A series of studies that have examined individuals who were exposed to unusually high levels of androgens prenatally has found that such persons have an increased risk of being aggressive and violent, supporting the notion that it may be androgen exposure during fetal brain development which is most critical. Finally, a fascinating study of twins studied the behavioral differences in females who had a female twin versus a male twin. Theoretically, he expected the female twins who had a male twin to hold more 'masculine attitudes' than females who had female twins. The reason for this, theoretically, was because female twins are exposed to more testosterone in utero if they have a male twin than if they have a female twin. Although there are other possible interpretations of these findings – most notably, the social influence of having a male twin – it remains possible that being exposed in utero to unusually high levels of testosterone can have an effect on brain development.

A second hormone that has been implicated more recently is *cortisol*. Cortisol is the hormone that regulates our body's reaction to stress. It is involved with the immune system and with sex hormones as well. A few studies have linked low levels of cortisol with a tendency to be aggressive. For example, one study looked at 38 boys, aged, 7–12, who had been referred to a clinic for behavior problems. The boys were enrolled in a long-term study and their behaviors were recorded for 4 years, based on reports from their teachers and parents. There were also some reports from the boys themselves and some from their peers. Finally, the researchers also studied levels of cortisol in the boys' saliva. Low cortisol was associated not only with aggression in general but also with boys who were the *most* aggressive and who showed aggressive symptoms the *earliest* during the study years. Boys who had higher cortisol levels were spread across categories – some exhibited symptoms earlier, some later. But of the boys in the low-cortisol group, almost every one exhibited aggressive symptoms by age 10. Thus, while low cortisol levels indicated that a child would

develop an earlier onset of aggression, having a higher cortisol level did not protect from also developing an earlier onset – at least, it only protected some children.

Another study found similar results. Kathleen Pajer and her colleagues studied 47 adolescent girls with CD and 37 controls. They measured cortisol in all subjects, and found that the subjects with CD had significantly lower cortisol levels, relative to the control subjects. This was found even when they controlled for probable confounds such as age and socioeconomic status. Stress may also mediate the relationship between cortisol and aggression, and other research has noted that cortisol levels were significant in explaining discrepancies in twin studies.

In summary, evidence suggests that hormones play a significant, but not a simple, role in determining violent behavior. This is not surprising, since hormones are known to impact many human behaviors, and in every case they have a profound, complex impact which is mediated by a variety of variables – both biological and social.

## Genetics

For decades, researchers have searched for the 'aggression gene.' In one Dutch family with at least 14 men with strong violent tendencies, researchers did find a genetic mutation on the X chromosome. Despite such cases, the majority of researchers agree that violence does not appear to be a behavioral tendency that is transmitted via a simple, directly acting gene. In any case, it is clear that if genetic bases for aggression and violence exist, they are clearly mutable and changeable by a person's psychological environment; the 'old idea' that genetics determines one's behavior *absolutely* is clearly mistaken.

The case for genetics as a cause of aggression and adult criminal violence has to be pieced together from a number of different areas of study. First, we know that children with violent parents do have a higher tendency to be violent themselves. In fact, one study that found that adolescent murderers tend to have violent fathers suggested that genetics might be an important cause of the teenagers' aggression. Despite this earlier research, however, the field needs to make the critical distinction between biological *heredity* versus family psychology. Parents provide a psychological, as well as biological, environment for their children. What do parents teach their children, and what do they pass to them through their genes?

## Twin studies

Twin studies are studies that typically compare identical (monozygotic) to fraternal (dizygotic) twins. Identical twins are the only human beings alive who are genetically identical. Fraternal twins are genetically siblings only; they carry similar genes, as siblings do, but not identical genes as identical twins do. Therefore, if a behavior is found more common in both identical twins and less commonly in both fraternal twins, then one conclusion is that that behavior may be genetically heritable. This is called 'concordance.' Hudziak and his colleagues, who studied 492 twin pairs (comparing identical to fraternal twins), completed one classic twin study on aggression. The researchers surveyed the twins' parents about a broad range of behaviors, including aggression, and then cross-checked to see if aggressive behavior was more commonly

found in both identical twins then in both fraternal twins. Indeed, that was precisely what they found, and the researchers estimated that, in their sample, genetics accounted for 70–77% of the variance in aggression. Another study of twins and triplets found an astonishing 96% heritability among 9- and 10-year olds for antisocial and aggressive behaviors (based on behavior ratings from the subjects themselves, their teachers, and their caregivers). Such a finding suggests a strong genetic influence on aggression.

Another twin study compared 183 monozygotic (identical) with 64 dizygotic (fraternal) twins. They found not only that individual measures of aggression were heritable – that is, more commonly found in both identical twins – but also that the same genotype might produce a variety of aggressive behaviors. Twin studies are compelling, but they suffer from a common flaw: not only do identical twins share genes, but also they often share an environment that treats them similarly. Because of this, identical twins are not the perfect genetics–environment experiment. Another method, which seeks more fully to separate genetics from psychological environment, is the method known as adoption studies.

### **Adoption studies**

Adopted children are children who have one set of biological parents, and a different set of psychological parents. By comparing the children's behavior with that of both their adopted parents and their genetic parents, it is possible to ascertain what behaviors are genetically inherited and what behaviors result from family environments.

Earlier studies, which studied children prospectively in long-term studies, found that adopted-away children are as aggressive as their adopted parents are, rather than as their biological parents are. In a more recent study, researchers used a different design and obtained somewhat different results. Instead of studying child–parent behavioral traits, they studied how similarly siblings behaved. They compared 221 pairs of biologically unrelated siblings to 111 pairs of biologically related siblings. All the children were adopted, but the biologically related siblings should show a higher concordance of aggression and crime if such behavior is genetically heritable.

The researchers found mixed results. While both aggression and delinquency were heritable, aggression was much more heritable than delinquency. Genetics accounted for 70% of the variance in aggression (similar findings to those of the twin studies) but only 39% of the variance in delinquency. This suggests that earlier research, which studied official records of delinquency, might not have been off-target. It is certainly plausible to find different degrees of heritability for aggression *per se*, versus official criminal records of offending – two measures of behavior which are clearly not the same thing. Some researchers have argued that earlier adoption studies do not rule out genetic influences, but rather point out that they are strongly mediated by environmental influences.

### **Heritability of disorders related to violence**

Studying the heritability of disorders linked to violence is an indirect method of studying the heritability of violence itself. Attention deficit disorder/hyperactivity (a disorder with strong

ties to adult violence) may be heritable. Sherman examined 576 twin boys between the ages of 11 and 12 and found that the data demonstrated that hyperactivity, impulsivity, and inattention were behaviors significantly influenced by genetics. Another study compared the biological and the adopted relatives of these children for indications that they, too, had ADHD. They found that while only 6% of the adopted parents had ADHD, 18% of the biological parents of ADHD children exhibited ADHD symptoms.

CDs are another set of childhood disorders that are strongly linked to adult crime and violence. Studies examining this disorder have also found evidence for its heritability. One twin study examining 2682 adult twin pairs revealed substantial concordance for CD among identical twin pairs. Another twin study on the heritability of CDs found similar results. Again, researchers studied 43 monozygotic ('identical') and 38 dizygotic ('fraternal') same-sex twins. They surveyed the twins about their antisocial behaviors and found that behaviors indicative of CDs were more concordant in identical twins. The researchers concluded that these behaviors have a significant heritable component.

Finally, Frederick Coolidge and his colleagues compared 70 identical and 42 fraternal twins between the ages of 4 and 15. They were seeking to uncover the causes of a range of behavior disorders, and found that several of these disorders were significantly more concordant in identical twins. CD was in fact one of the disorders most strongly influenced by genetics – Coolidge estimated that it demonstrated a heritability of 68% (very consistent with past research).

In summary, much of the data on the genetic basis of violence is suggestive of a significant, but not total or direct, heritability. Twin studies are interesting but cannot be definitive, since they do not separate the effects of psychological environment and genetics. Adoption studies are mixed; and studies that are indirect in nature – that is, which do not study violence directly but study other disorders related to it – suggest a heritability index of approximately 70%. In general, the data suggest that there must be a heritable component of violence; perhaps impulsivity, hyperactivity, or aggressive tendencies are genetically transmitted; but clearly, this is not a simple or direct relationship. Even if one were to broadly apply the heritability estimates of 70%, such a number would imply that 30% of the reasons for people becoming violent is unrelated to genetics. As with most behaviors in human beings, no one simple answer suffices.

## **Other Psychological Perspectives**

### **Hostile Interpretation of Ambiguous Events, or Cognitive Distortions**

Are paranoid misperceptions rare among violent individuals? One theory suggests that such biased misperceptions may in fact help explain why some people are violent. Indeed, as the theory goes, under certain circumstances, aggression may be a normal and adaptive response. This may particularly be the case when an individual is faced with hostile or threatening forces, and violence is perceived as a necessary response. Given that a hostile environment might provoke an aggressive response in

almost anyone, some researchers have investigated the possibility that violent individuals are not people who inappropriately choose violence; rather, they are people who inappropriately perceive hostility where most people would not.

Dodge studied aggressive and nonaggressive children, and found that aggressive children have two perceptual tendencies that nonaggressive children lack. Aggressive children were more likely to believe that other people had hostile intentions; and they were more likely to evaluate the results of aggression positively. One study furthered this by comparing reactive to proactive aggression. This study examined how children's cognitions develop and maintain aggression of two different types, and found that hostile biases were particularly characteristic of reactive-aggressive children.

Dodge and colleagues also studied adolescent offenders in a maximum-security prison and found that although these biases were also found in this population, they were only found in undersocialized delinquents. This line of study sheds some light on why it may be so difficult to treat violent offenders. Trying to teach such offenders to be nonviolent may in fact be trying to teach them to react nonviolently to what they perceive to be intensely threatening situations. For example, imagine that you are standing in a field holding a gun, and an elephant is charging toward you at full speed with his tusks aimed right at you. Trying to teach violent offenders to be nonviolent might be like trying to teach them not to shoot that elephant, even though there is every indication that that elephant is deadly.

Other research has noted similar findings. Some of Dodge's later research also found that both moderately and severely aggressive children have a number of problems with 'social cognition,' among them, attributional biases. Another study compared 27 aggressive to 27 nonaggressive boys and examined the way these boys recalled and recognized information. The boys were given a series of ambiguous and unambiguous sentences, and tested for how well they remembered the sentences. Some of the sentences had aggressive content and some did not. The main difference they found between these two groups of boys was that the aggressive boys were significantly better at recognizing the aggressively slanted items. Salzer Burks et al. conducted a longitudinal study, following a group of children from Kindergarten through the eighth grade. In this study these colleagues examined what immediate factors preceded aggression in children. They found that children with biased 'knowledge structures' (i.e., memories which emphasize hostility) process information in a more negatively biased way and are more likely to develop stable negative cognitive biases and stably aggressive behavior.

Other similar studies have found that aggressive children attribute fewer positive intentions to people in problem-solving scenarios and that sexually aggressive men use a 'suspicious schema' in interpreting women's statements. Hoaken, Allaby, and Earle's research went farther and associated the cognitive misperceptions with damage to the frontal lobe, and problems with executive functioning (providing a possible pathway for the misperception of facial expressions, at least). Finally, Downey and Walker looked more closely at this phenomenon and noted that attributional biases did not appear to

mediate the link between high risk and aggression, but rather, appeared to serve as a protective factor against aggression. That is, children who are at high risk for violence – for example, children who have been abused – are not at even higher risk if they also make biased attributions. Rather, those children who do not make biased attributions are at lower risk of becoming aggressive, even if they have been abused. In other words, making accurate rather than biased attributions may be a protective factor that makes children resilient.

Other research has examined different types of violent offenders and has found cognitive misinterpretations and biases that appear to be specific to the type of offense. For example, rather than making general, nonspecific hostile misinterpretations, adults who commit child abuse tend to misinterpret children's behavior. Specifically, they tend to regard children's misbehaviors as more intentional than they really are – possibly paving the way to righteous anger and abuse. Sexually aggressive men, rather than suffering from blanket distortions, may differ from other men primarily in their distortion of women's communications. As research continues into the factor of cognitive distortions, it becomes increasingly likely that violent offenders may be individuals who distort perceptions in such a way that it predisposes them to behave in certain, specific criminal ways.

All violent feelings produce in us a falseness in our impressions of external things. (John Ruskin)

## Visual Motion Perception

S Grossberg, Boston University, Boston, MA, USA

© 2012 Elsevier Inc. All rights reserved.

### Glossary

**Aperture problem** A problem in determining the true direction of motion of an object contour that is faced by any localized motion sensor that detects motion through an aperture-like receptive field.

**Bistable motion** Motion is said to be bistable when the brain periodically switches between two alternative percepts of the same motion stimulus. For example, percepts of moving plaids or of pairs of random dot patterns can alternate between at least two possible percepts.

**Complementary computing** The brain uses parallel cortical processing streams to compute complementary properties of visual inputs. Complementary processes are akin to puzzle pieces that must both be computed, and fit together, to complete a puzzle. For example, visual boundaries and surfaces are computed using complementary computational properties, and need to interact for either of them to be computed properly.

**Directional grouping** This process enables spatially distributed motion signals to be grouped into a coherent percept of object direction and speed. Formotion binding and motion capture preprocess form and motion signals before the stage of directional grouping solves the aperture problem.

**FACADE model** FACADE is a neural model that explains how the visual cortex creates a representation of Form-And-Color-And-Depth which is predicted to be complete by cortical area V4.

**Feature tracking signal** An unambiguous motion direction signal that can be computed at image features, such as object corners.

**Figure-ground separation** This process separates combinations of image features into representations of distinct object boundaries and surfaces.

**Formotion binding** A process whereby form boundaries that are computed in the processing stream from V1 interblobs to V2 pale stripes can select compatible motion signals that are computed in the processing stream from V1 to MT. Interstream interactions from V2 to MT can carry out formotion binding. The selected motion signals can then be further processed to track moving objects in depth.

**Intrinsic and extrinsic terminators** When an object intersects an occluder, the brain needs to determine which of its boundaries belong to the object and which to the

occluder. An intrinsic terminator belongs to the moving object, whereas an extrinsic one belongs to the occluder.

**Laminar cortical circuits** All neocortical cells are organized into layers, often six main layers of cells, with characteristic sublamina, in visual cortex.

**Long-range apparent motion** Long-range apparent motion creates a percept of continuous motion between discrete flashes of light that are separated in space and time. This type of motion percept can create a continuously trackable motion trajectory from moving fragments of object motion behind occluders, much as an animal running at variable speeds behind forest cover can create motion signals that are intermittently experienced.

**Long-range directional filter** The long-range directional filter has a larger receptive field than the short-range directional filter, and one that receives its preferred motion direction inputs from multiple orientations, opposite contrast polarities, and both eyes.

**Motion capture** A process that uses feature tracking motion direction signals to select the same motion direction signals from among the possible ambiguous motion direction signals along contours whose motion directions are ambiguous due to the aperture problem. Motion capture also suppresses the ambiguous motion direction signals.

When no feature tracking signals are available, motion capture enables the strongest ambiguous motion direction signals to determine the perceived object motion direction.

**Motion integration** The process whereby the brain combines spatially distributed motion signals into a coherent percept of object motion.

**Motion segmentation** The process whereby the brain separates motion signals into percepts of distinct moving objects.

**Perceptual grouping** Grouping joins together spatially disparate image features into a coherent representation of an object boundary. Edges, textures, and shading can all be grouped into object boundaries whose structure is sensitive to the spatial distribution of image features.

**Short-range directional filter** The short-range directional filter helps to selectively strengthen unambiguous feature tracking signals, relative to ambiguous motion signals, by pooling such signals within a spatially anisotropic receptive field that is oriented along the pooled direction of motion.

### Motion Integration and Segmentation

#### Aperture Problem

The brain's motion perception system solves the complementary problems of *motion integration* and *motion segmentation*. The former joins nearby motion signals into a single object, while

the latter separates them into different objects. Wallach first showed that the motion of a featureless line seen behind a circular aperture is perceptually ambiguous: given any real direction of motion, the perceived direction is perpendicular to the orientation of the line. This phenomenon was called the *aperture problem* by Marr and Ullman. The aperture problem is faced by

any localized neural motion sensor, such as a neuron in the early visual pathway, which responds to a moving local contour through an aperture-like receptive field. Only when the contour within an aperture contains features, such as line terminators, object corners, or high contrast blobs or dots, can a local motion detector accurately measure the direction and velocity of motion. For example, when the aperture is rectangular, as during the barberpole illusion, moving lines may appear to move in the direction parallel to the longer edges of the rectangle within which they move, even if their actual motion direction is not parallel to these edges. The brain must solve the aperture problem, despite the fact that every neuron's receptive field defines an 'aperture,' in order to detect the correct motion directions of important moving objects in the world. The examples of circular and rectangular apertures, or occluders, provide important cues about how the brain can often do this in the real world.

When an object moves behind multiple occluders, aperture ambiguities can again lead to veridical percepts of its real motion. Despite the fact that the object may be segmented into many visible parts by the occluders, the visual system can often integrate these parts into a percept of coherent object motion that crosses the occluders. Studying conditions under which the visual system can and cannot accomplish correct segmentation and integration provides important cues to the processes that are used by the visual system to create useful and predictive object motion percepts during normal viewing conditions.

### Feature Tracking Signals

To solve the interlinked problems of motion integration and segmentation, the visual system uses the relatively few unambiguous motion signals arising from image features, called *feature tracking* signals, to select the ambiguous motion signals that are consistent with them, while suppressing the more numerous ambiguous signals that are inconsistent with them. For example, during the barberpole illusion, feature tracking signals from the moving line ends along the longer edges of the bounding rectangle of the barberpole compute an unambiguous motion direction. These feature tracking signals gradually propagate into the interior of the rectangle. This *motion capture* process selects the feature tracking motion direction from the possible ambiguous directions along the lines within the rectangle that are due to the aperture problem. Motion capture also suppresses the ambiguous motion signals. When a scene does not contain any unambiguous motion signals, the ambiguous motion signals cooperate to compute a consistent object motion direction and speed.

This article summarizes a neural model of the cortical form and motion processes that clarifies how such motion integration and segmentation processes occur (Figure 1). This 3D FORMOTION model has been progressively developed over the years to explain and predict an ever-larger set of data about motion perception. Comparisons with related models and more data than can be summarized here are found in these archival articles.

### Neurophysiological Support for Predicted Aperture Problem Solution

In addition to model explanations of known data, the model has predicted data that were subsequently reported. In particular, Chey et al. predicted how feature tracking estimates can

gradually propagate across space to capture consistent motion directional signals, while suppressing inconsistent ones, in cortical area MT. Such motion capture was predicted to be a key step in solving the aperture problem. Pack and Born reported neurophysiological data that support this prediction. As simulated in the model, MT neurons initially respond primarily to the component of motion perpendicular to a contour's orientation, but over a period of ~60 ms the responses gradually shift to encode the true stimulus direction, regardless of orientation. Pack and Born also collected data which support the concept that motion signals are used for target tracking. Namely, the initial velocity of pursuit eye movements deviates in a direction perpendicular to local contour orientation, suggesting that the earliest neural responses influence the oculomotor response.

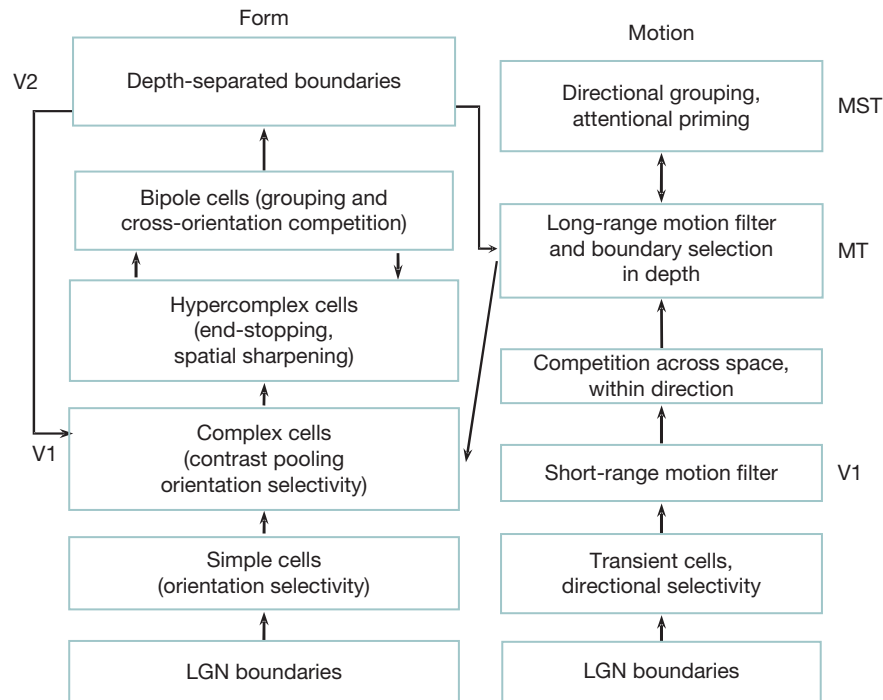

Many psychophysical data also illustrate how feature tracking signals can propagate gradually across space to capture consistent ambiguous signals. Castet et al. described a particularly clear illustration of this. Figure 2(a) summarizes their data. They considered the horizontal motion of both a vertical and a tilted line that are moving at the same speed. Suppose that the unambiguous feature tracking signals at the line ends capture the ambiguous motion signals near the line middle. The preferred ambiguous motion direction and speed are normal to the line's orientation. In the case of the vertical line, the speed of the feature tracking signals at the line ends equals that of the preferred ambiguous speed near the line's middle. For the tilted line, however, the preferred ambiguous speed is less than that of the feature tracking speed. If the speed of the line is judged using a weighted average of feature signals and ambiguous signals, then the tilted line will be perceived to move slower than the vertical line.

To further test this idea, Castet et al. also showed that the ambiguous speeds have a greater effect as line length increases when the line is viewed for a brief duration. These additional data strongly support the idea that feature tracking signals at the line ends propagate inwards along the line to capture the ambiguous motion speed and direction there. Since capture takes longer to complete when lines are longer, the ambiguous motion signals have a larger effect on longer lines. Chey et al. simulated these data, as shown in Figure 2(b).

In addition to simulating data of Castet et al. on how the perceived speeds of moving lines are affected by their length and angle, Chey et al. used similar model mechanisms to also simulate, among other percepts, how the barberpole illusion is produced, how it can be affected by various configurational changes, and how plaid patterns move both coherently and incoherently. In addressing plaid pattern motion, the model provides explanations of when plaid patterns cohere or do not, how contrast affects the perceived speed and direction of moving plaids, and why the movement of so-called Type 2 patterns differs from those of Type 1 patterns. All of these data may be explained by an interaction of figure-ground separation mechanisms in the form cortical stream interacting with motion capture mechanisms in the motion cortical stream.

### Formotion Binding by Laminar Cortical Circuits

As the model name 3D FORMOTION suggests, it proposes how form and motion processes interact to generate coherent percepts of object motion in depth. Among the problems that the

**Figure 2** Effects of line length and orientation on perceived speed of horizontally moving lines. Relative perceived speed for three different line orientations and lengths are shown as percentages of the perceived speed of a vertical line of the same length. Part (a) shows data from Castet et al. (p. 1925). Each data line corresponds to a different line length ( $0.21^\circ$ ,  $0.88^\circ$ , and  $1.76^\circ$ ). The horizontal axis shows the ratio of the speed normal to the line's orientation relative to the actual translation speed. The three data points from left to right for each line length correspond to line angles of  $60^\circ$ ,  $45^\circ$ , and  $30^\circ$  from vertical, respectively. The horizontal dotted line indicates a veridical speed perception; results below this line indicate a bias toward the perception of slower speeds. Part (b) shows simulation results, also for three lengths and orientations. In both cases perceived relative speed decreases with line length and angle from vertical. Simulated lines use slightly different orientations from those in the experiments so that the simulated input conforms to the Cartesian grid. Reprinted with permission from Chey J, Grossberg S, and Mingolla E (1997) Neural dynamics of motion processing and speed discrimination. *Vision Research* 38: 2769–2786.

model analyses are the following form-motion (or *formation*) binding issues, which go beyond the scope of other models: How do form-based 3D figure-ground separation mechanisms in cortical area V2 interact with directionally selective motion grouping mechanisms in cortical areas MT and MST to preferentially bind together some motion signals more easily than others? In cases where form-based figure-ground mechanisms

are insufficient, how do motion and attentional cues from cortical area MT facilitate figure-ground separation within cortical area V2 via MT-to-V1-to-V2 feedback? These processes help to explain and simulate many motion data, including the way in which the global organization of the motion direction field in areas MT and MST can influence whether the percept of an object's form looks rigid or deformable through time.

The model also goes beyond earlier motion models by proposing how *laminar* cortical circuits realize these mechanisms (Figure 3). These laminar circuits embody explicit predictions about the functional roles that are played by identified cells in the brain. The 3D FORMOTION model extends to the motion system laminar models of cortical circuits that have previously explained challenging perceptual and brain data about 3D form perception in cortical areas V1, V2, and V4, as well as about cognitive working memory, sequence learning, and variable-rate sequential performance.

### Intrinsic and Extrinsic Terminators

A key issue in data and models about motion perception concerns the assignment of motion to an object boundary when it moves relative to an occluder. How does the brain prevent motion integration across both the occluder and its occluded

objects? In the example in Figure 4, motion of the left line end corresponds to the real motion of the line. The right line end is formed by the boundary between the line and a stationary occluder. Its motion provides little information about the motion of the line. Bregman and Kanizsa, and more recently Nakayama et al., have discussed this problem. Nakayama et al. use the terminology of *intrinsic* and *extrinsic* terminators to distinguish the two cases. An intrinsic terminator belongs to the moving object, whereas an extrinsic one belongs to the occluder. Motion of intrinsic terminators is incorporated into an object's motion direction, whereas motion of extrinsic terminators is attenuated or eliminated.

The FACADE (Form-And-Color-And-Depth) model of 3D form vision and figure-ground separation proposed how boundaries in 3D scenes or 2D images are assigned to different objects in different depth planes, and thereby offered a mechanistic explanation of the properties of extrinsic and intrinsic

**Figure 3** Laminar circuits of 3D FORMOTION model. See text for details. Reprinted with permission from Berzhanskaya J, Grossberg S, and Mingolla E (2007) Laminar cortical dynamics of visual form and motion interactions during coherent object motion perception. *Spatial Vision* 20: 337–395.

**Figure 4** Extrinsic and intrinsic terminators: the local motion of the intrinsic terminator on the left reflects the true object motion, while the local motion of the extrinsic terminator on the right follows the vertical outline of the occluder.

terminators. The 3D FORMOTION model proposed how FACADE depth-selective figure-ground separation in cortical area V2, combined with depth-selective formotion interactions from area V2 to MT, enable intrinsic terminators to create strong motion signals on a moving object, while extrinsic terminators create weak ones. The model starts with motion signals in V1, where the separation in depth has not yet occurred, and predicts how V2-to-MT boundary signals can select V1-to-MT motion signals at the correct depths, while suppressing motion signals at the same visual locations but different depths.

### Form and Motion Are Complementary

What sort of depth does MT compute? The prediction that V2-to-MT signals can capture motion signals at a given depth reflects the prediction that the form and motion streams compute *complementary* properties. The V1–V2 cortical stream, acting alone, is predicted to compute precise oriented depth estimates in the form of 3D boundary representations, but coarse directional motion signals. In contrast, the V1–MT cortical stream computes coarse depth estimates, but precise directional motion estimates. Overcoming the deficiencies of the form and motion cortical streams in computing precise estimates of form-and-motion-in-depth is predicted to occur via V2-to-MT inter-stream interactions, called *formotion* interactions. These interactions use depth-selective signals from V2 to capture motion signals in MT to lie at the correct depths. In this way, precise form-and-motion-in-depth estimates are achieved in MT, which can, in turn, be used to generate good target tracking estimates.

### This Analysis Clarifies an Otherwise Vexing Issue

Why does the brain bother to create a processing stream through cortical areas V1, MT, and MST to process motion, and a separate processing stream through cortical areas V1, V2, and V4 to process visual form? Indeed, individual cells in V1 already respond to properties of form, such as orientation, and properties of motion, such as direction. Given these shared properties at the earliest cortical stage V1, why could not a single processing stream compute both form and motion? In 1991, Grossberg predicted why this might be so, and in 2006, Ponce, Lomber,

and Born provided data that strongly support this prediction. This prediction was derived from a theoretical analysis of how the form cortical stream computes the *orientation* of form, whereas the motion stream computes the *direction* of motion.

Grossberg noted that the form stream through V1, V2, and V4 creates 3D boundaries and surfaces. In particular, 3D boundaries are computed by matching left and right eye images of visual features with similar *orientation*. The binocular disparity of these similarly oriented features is a key property that is used to compute boundaries whose interactions with surfaces can accurately represent objects in depth. This analysis predicted that the form stream can compute a precise measure of depth, but only a coarse measure of direction. In contrast, the motion stream pools over multiple orientations of an object's boundaries to compute the *direction* in which the object is moving. Pooling over orientations sacrifices the key property that the form stream needs to precisely compute depth. This analysis predicted that the motion stream can compute a precise measure of direction, but only a coarse measure of depth.

These sets of properties (precise depth, coarse direction; coarse depth, precise direction) are computationally *complementary*. Grossberg predicted how an inter-stream interaction from V2 to MT could use the depth-precise boundaries in V2 to select compatible directional motion signals in MT, and thereby overcome these complementary deficiencies to generate a precise representation in MT of moving-form-in-depth. This is what various neurophysiologists, such as Livingstone and Hubel and DeAngelis et al. had earlier reported from their recordings in MT.

### Neurophysiological Support for Form-Motion Complementarity and Formotion Capture

Ponce et al. reported neurophysiological data that are consistent with the prediction that V2 imparts finer disparity sensitivity onto MT: when V2 is reversibly cooled and V2-to-MT signals eliminated, depth selectivity, but not motion selectivity, is greatly impaired in MT. In other words, the predicted precise directional and coarse depth properties were hereby unmasked when V2 inputs were removed. These data do not support the alternative view that fine depth estimates are computed directly in MT.

### Induced Motion and the Role of Form in Conscious Motion Perception

Many psychophysical data support this view of motion capture. Indeed, the V2-to-MT motion selection mechanism clarifies why we tend to perceive motion of visible objects and background features, but not of the intervening empty spaces between them. For example, consider an example of *induced motion* wherein a frame moving to the right caused a stationary dot within the frame to appear to move to the left. Motion signals must propagate throughout the interior of the frame in order to reach and influence the dot. Despite this global propagation, the homogeneous space between the frame and the dot does not seem to move. The 3D FORMOTION model predicts that this occurs because there are no boundaries between the frame and the dot whereby to capture a motion signal. The model proposes that the formotion interaction whereby V2 boundaries select compatible MT motion signals may be necessary, if not sufficient, for a conscious percept of motion to occur.

### Motion-to-Form Feedback and Figure-Ground Separation of Occluded Moving Objects

V2-to-MT motion signals overcome one sort of uncertainty in the cortical computation. Another sort of uncertainty is overcome by using MT-to-V1 feedback signals. These top-down modulatory signals can help to separate boundaries in V1 and V2 where they cross in feature-absent regions. Such feature-absent signals are illustrated by the *chopsticks illusion*; see Figure 5. Suppose that attention or internal noise signals amplify motion signals of one chopstick more than the other via MST–MT interactions. This stronger chopstick can send its enhanced motion signals from MT to V1. The enhanced V1 signals can then use V1-to-V2 figure-ground separation mechanisms to separate the two chopsticks in depth. The form boundary of the attended chopstick will then be strengthened. The FACADE model explains how a stronger form boundary can appear to be nearer than a weaker one. The nearer boundary can then be completed by perceptual grouping mechanisms over the ambiguous region where the two chopsticks cross, much like an illusory contour can be completed. FACADE mechanisms also explain how the intrinsic boundaries of the nearer chopstick can be detached from the farther chopstick, thereby enabling the farther chopstick boundaries to also be completed in depth behind those of the occluding, nearer chopstick. As these boundaries are completed, they are injected back into MT from V2 to capture the corresponding motion direction signals and generate a percept of two separated figures moving in depth, one in front of the other.

**Figure 5** Chopsticks illusion: actual chopsticks motion (clear arrows, top) is equivalent in (a) and (b), with visible and invisible occluders, respectively. Visible occluders result in a coherent vertical motion percept (c, hatched arrow). Invisible occluders result in the percept of two chopsticks sliding in opposite directions (d). Reprinted with permission from Berzhanskaya J, Grossberg S, and Mingolla E (2007) Laminar cortical dynamics of visual form and motion interactions during coherent object motion perception. *Spatial Vision* 20: 337–395.

### Adaptation and Bistable Motion

Another factor that influences motion perception is adaptation. This can be accomplished by a process of transmitter habituation, inactivation, or depression. For example, motion signals at the positions of a static extrinsic terminator can adapt and therefore become weaker through time. Moving intrinsic terminators, on the other hand, generate strong motion signals. The adaptation process hereby clarifies the computation of intrinsic motion signals on a relatively short time scale.

On a longer time scale, bistable motion percepts can occur due to the interaction of cooperative–competitive model mechanisms with habituating mechanisms when multiple moving objects overlap (Figures 1 and 3). For example, percepts of moving plaids or of pairs of random dot patterns can alternate between at least two possible perceptual outcomes. One possible outcome is a transparent motion percept, where two gratings or two dot-filled planes slide one over another in depth. Alternatively, if the directions of motions of the two gratings are compatible, then a percept of a unified plaid pattern may be seen, and no separation in depth occurs. Under prolonged viewing, the same display can perceptually alternate between coherent plaid motion and component motions separated in depth. The combination of 3D boundary and surface processes, augmented by habituating gating and spatial attention, can explain many bistable form and motion percepts. For example, Grossberg and Swaminathan have modeled how these processes may lead to bistable 3D percepts of the Necker cube.

### Shape and Motion Interactions Determine Object Motion Percepts Behind Apertures

Similar mechanisms can explain and simulate percepts of moving object shapes that are more complex than lines or dots. For example, Lorenceau and Alais studied different shapes moving in a circular-parallel motion behind occluders (Figure 6). Observers had to determine the direction of motion, clockwise or counterclockwise. The percent of correct responses depended on the type of shape, and on the visibility of the occluders. In the case of a diamond shape (Figure 6(a)), a single, coherent, circular motion of a partially occluded rectangular frame was easy to perceive across the apertures. In the case of an arrow shape (Figure 6(c)), two objects with parallel sides were seen to generate out-of-phase vertical motion signals in adjacent apertures. Local motion signals were identical in both displays, and only their spatial arrangement differed. Lorenceau and Alais suggested that certain shapes (such as arrows) ‘veto’ motion integration across the display, while others (such as diamond) allow it.

The 3D FORMOTION model explains these data without using a veto process. The model proposes that the motion grouping process uses anisotropic direction-sensitive receptive fields (see Figure 3) that preferentially integrate motion signals within a given direction across gaps produced by the occluders. The explanation of percepts induced by the displays in Figure 4(d)–4(f) follows in a similar way, with the additional factor that the ends of the bars activate intrinsic terminators that can strongly influence the perceived motion direction of the individual bars.

**Figure 6** Lorenceau-Alais displays: visible (a–c) and invisible (d–f) occluder cases. See text for details.

### Rigid and Gelatinous Rotating Ellipses

Motion grouping also helps to explain percepts of rotational motion using the ‘gelatinous ellipses’ display. When ‘thin’ (high aspect ratio) and ‘thick’ (low aspect ratio) ellipses rotate around their centers, percepts of their shapes differ markedly. The thin ellipse is perceived as a rigid rotating form, whereas the thick one is perceived as deforming nonrigidly through time. Here, the differences in 2D geometry result in differences of the spatiotemporal distribution of motion direction signals that are grouped together through time. When these motion signals are consistent with the coherent motion of a single object, then the motion grouping process within the model MT–MST processing stages (Figure 1) generates a percept of a rigid rotation. When the motion field decomposes after grouping into multiple parts, with motion trajectories incompatible with a rigid form, a nonrigid percept is obtained. Nearby ‘satellites’ can convert the nonrigid percept into a rigid one. Weiss and Adelson proposed that such a percept can be explained via a global optimization process. The 3D FORMOTION model shows how motion grouping can provide a biologically more plausible explanation.

Once V2 boundaries capture MT motion signals, what are they used for? One major use is for visually based navigation. For example, Browning, Grossberg, and Mingolla developed the ViSTARS neural model in which motion signals are processed through the cortical areas MT<sup>−</sup> and MSTv to track moving targets, while cortical areas MT<sup>+</sup> and MSTd use motion signals to compute heading from optic flow using computationally complementary interactions. Grossberg and Pilly showed how motion signals through cortical areas MT<sup>−</sup>, MST, and LIP can be used to probabilistically compute decisions about the direction of eye movements in response to moving dot patterns. These latter results will be discussed after the main mechanisms of the 3D FORMOTION model are summarized as a way to unify the discussion and understanding of many experimental data about the psychology and neurobiology of motion perception.

### 3D Formotion Model

The 3D FORMOTION model (Figure 1 and 3) proposes how six types of processes interact together in the brain’s form and motion systems. Because model processing stages are analogous to areas of the primate visual system, they are called by the corresponding anatomical names. (1) V1-to-MT filtering and cooperative–competitive processes begin to resolve the aperture problem by amplifying feature tracking signals and attenuating ambiguous motion signals so that the feature tracking

signals have a chance to overwhelm numerically superior ambiguous motion signals. (2) 3D boundary representations, in which figures are separated from their backgrounds, are formed in the cortical area V2. (3) These depth-selective V2 boundaries select motion signals at the appropriate boundary positions and depths in MT via V2-to-MT signals. (4) A spatially anisotropic motion grouping process propagates across perceptual space via MT–MST feedback to integrate veridical feature tracking signals with ambiguous motion signals and to thereby determine a global object motion percept. This motion capture process solves the aperture problem. (5) MST–MT feedback can convey an attentional priming signal from higher brain areas that can influence the motion capture process, and thereby influence form processing via MT-to-V1 feedback. (6) Motion signals in MT can hereby disambiguate locally incomplete or ambiguous boundary signals in V2 via MT-to-V1-to-V2 signals.

These interactions provide a functional explanation of many neurophysiological data. Table 1 summarizes anatomical connections and neuron properties that occur in the model, alongside experimental references which support those connections or functional properties. Table 1 also lists the model’s key physiological predictions that remain to be tested. As illustrated in Figures 1 and 3, these interactions are naturally understood as part of a *form processing stream* and a *motion processing stream*.

### The Form Processing System

The model’s form processing system comprises six stages that are displayed on the left sides of Figures 1 and 3. Inputs are processed by distinct ON and OFF cell networks whose cells obey membrane, or shunting, equations while they undergo on-center off-surround and off-center on-surround network interactions, respectively, that are similar to those of LGN cells. These cells excite simple cells in cortical area V1 to register boundary orientations in cells that are sensitive to a particular polarity-of-contrast. Then complex and hypercomplex cells pool across simple cells tuned to opposite contrast polarities to detect object boundaries even if their contrast with respect to a background reverses along the perimeter of the object. Then several mechanisms work together to enhance feature tracking signals while downregulating ambiguous motion signals: divisive normalization reduces cell activities where there are multiple ambiguous orientations in a region, end-stopping enhances activity at features like line-ends where feature tracking signals often occur, and spatial sharpening enhances the feature tracking advantage. These cells input to a perceptual grouping circuit in layer 2/3 of V2. Here bipole cells receive signals via long-range horizontal interactions from approximately collinear cells whose orientational preferences lie along, or near, the collinear axis. These cells are indicated

**Table 1** Functional projections and properties of model cell types and predictions

| Connection/functional property                                                            | Selected references                                                                                |

<sup>a</sup>Although Xiao et al. found that some MT neurons have receptive fields that are elongated along the preferred direction of motion, there is no direct evidence that these neurons participate preferentially in motion grouping.

by and-gates the figure-8 shape in **Figure 3**. They act like statistical and-gates that permit grouping only when there is sufficient evidence from pairs or greater numbers of inducers on both sides of the cell body. Grouping completes and sharpens object boundaries. It includes a stage of cross-orientation competition that reinforces boundary signals with greater support from neighboring boundaries while weakening spatially overlapping boundaries of nonpreferred orientations. Boundaries are assigned into different depths, as follows.

### Perceptual Grouping and Figure-Ground Separation of 3D Form

The FACADE model shows how the boundary completion process within the pale stripes of V2 can automatically initiate separation of extrinsic versus intrinsic boundaries in depth without positing separate mechanisms to compute T-junctions. Indeed, one cue for extrinsic versus intrinsic boundaries is occlusion in a 2D image at a T-junction, as illustrated in **Figure 4**, where a moving black bar intersects a stationary gray rectangular occluder. The top of the T belongs to the occluding gray rectangle, while the stem belongs to the occluded black bar. Bipole long-range excitatory horizontal interactions can strengthen the boundary of the gray occluder where it intersects the black bar, while short-range competition (**Figure 3**) weakens, or totally inhibits, the boundary of the black occluded bar where it touches the gray occluder. This *end gap* in the black boundary initiates the process of separating occluding and occluded boundaries.

In other words, perceptual grouping properties are predicted to initiate the separation of figures from their backgrounds, without the use of explicit T-junction operators. This prediction has received support from psychophysical experiments. The figure-ground separation process enables the model to distinguish extrinsic from intrinsic terminators, and to thereby select motion signals at the correct depths.

Qualitative explanations and quantitative computer simulations of 3D figure-ground separation during perception of static images were provided using the laminar cortical circuits of the 3D LAMINART model by Fang and Grossberg, who simulated 3D surface perception in response to dense, sparse, and occluding stereograms. Grossberg and Yazdanbakhsh simulated stable and bistable transparency and 3D neon color spreading. The nonlaminar circuits of the FACADE model were earlier used by Kelly and Grossberg to simulate such percepts as Bregman-Kanizsa figure-ground perception, Kanizsa stratification, and lightness percepts such as the Munker-White, Benary cross, and checkerboard percepts. In 3D FORMOTION analyses of figure-ground separation of moving targets, a complete simulation of all form and motion computations was computationally prohibitive. Instead, to reduce the simulation computational load, Berzhanskaya et al. used the following approximation: As soon as T-junctions were detected by the model dynamical equations, V2 boundaries were algorithmically assigned the depths that a complete figure-ground simulation would have assigned to them. In particular, static occluders were assigned to the near depth (D1 in **Figure 3**) and lines with extrinsic terminators were

assigned to the far depth (D2 in [Figure 3](#)). These V2 boundaries were used to provide both V2-to-MT motion selection signals and V2-to-V1 depth-biasing feedback. While V2-to-V1 feedback is orientation-specific, the V2-to-MT projection sums boundary signals over all orientations, just as motion signals do at MT.

### Motion Induction of Figure-Ground Separation

When form cues are not available to initiate figure-ground separation, motion cues may be able to do so via feedback projections from MT to V1 ([Figures 1](#) and [3](#)). Such a feedback projection has been studied both anatomically and electrophysiologically and it can benefit from attentional biasing within MT/MST. As explained above, this mechanism can help to separate chopsticks in depth (see [Figure 5\(b\)](#)). Focusing spatial attention at one end of a chopstick enhanced that chopstick's direction of motion in MT and MST. Enhanced MT-to-V1 feedback selectively strengthened the boundary signals of the corresponding chopstick in [Figure 5\(b\)](#) enough to trigger its boundary completion across the other chopstick via V1-to-V2 interactions. This operation also initiated figure-ground separation that assigned the now occluded chopstick to a farther depth. Then, by closing the V2-to-MT loop, these two overlapping but depth-separated bars can support depth-selective motions by the chopsticks in opposite directions.

## The Motion Processing System

The model's motion processing stream consists of six stages that represent cell dynamics homologous to LGN, V1, MT, and MST ([Figures 1](#) and [3](#), right).

### Level 1

ON and OFF cell inputs from Retina and LGN, which are lumped into a single processing stage, activate model V1. These inputs are not depth-selective. In response to a 2D picture, this depth-selectivity will come from figure-ground separated V2 boundaries when they select consistent motion signals in MT.

Both ON and OFF cells have a role to play. For example, if a bright chopstick moves to the right on a dark background, ON cells respond to its leading edge, but OFF cells respond to its trailing edge. Likewise, when the chopstick reverses direction and starts to move to the left, its leading edge now activates ON cells and its trailing edge OFF cells. By differentially activating ON and OFF cells in different parts of this motion cycle, these cells have more time to recover from habituation, so that the system remains more sensitive to repetitive motion signals.

### Level 2: Transient cells

The second stage of the motion processing system consists of nondirectional transient cells, inhibitory directional interneurons, and directional transient cells. The nondirectional transient cells respond briefly to a change in the image luminance, irrespective of the direction of movement. Such cells

respond well to moving boundaries and poorly to a static occluder because of the habituation of the process that activates the transient signal. Adaptation is known to occur at several stages in the visual system, including retinal Y cells and cells in V1 and beyond.

The nondirectional transient cells send signals to inhibitory directional interneurons and directional transient cells, and the inhibitory interneurons interact with each other and with the directional transient cells ([Figure 7](#)). The directional inhibitory interneuronal interaction enables the directional transient cells to maintain their directional selectivity at a wide range of speeds. This selectivity is predicted to be due to the inhibitory interneurons, and goes beyond the capabilities of the classical Barlow and Levick model of transient cell activation. The predicted interactions in this model circuit are consistent with retinal data concerning how bipolar cells interact with inhibitory starburst amacrine cells and direction-selective ganglion cells, and how starburst cells interact with each other and with ganglion cells. The possible role of starburst cell inhibitory interneurons in ensuring directional selectivity at a wide range of speeds has not yet been tested.

A directionally selective neuron fires vigorously when a stimulus is moved through its receptive field in one direction (called the preferred direction), while motion in the reverse direction (called the null direction) evokes little response. This type of directional selectivity was first modeled by Barlow and Levick. Mechanisms of direction selectivity include asymmetric inhibition along the preferred cell direction, notably an inhibitory veto of null-direction signals.

As noted above, after the transient cells adapt to a static boundary, then boundary segments that belong to a static occluder – that is, extrinsic terminators – in the chopsticks display with visible occluders ([Figure 5\(a\)](#)) produce weaker signals than those that belong to the continuously moving parts of the chopstick. On the other hand, in the invisible occluder chopsticks display ([Figure 5\(b\)](#)), the horizontal motion signals at the chopstick ends will continually move, hence will be strong, and can thus significantly influence the conscious motion percept.

### Level 3: Short-range filter

A short-range directional filter ([Figure 3](#)) helps to selectively strengthen unambiguous feature tracking signals, relative to ambiguous motion signals. Cells in this filter *accumulate evidence* from directional transient cells of similar directional preference within a spatially anisotropic region that is oriented along the preferred direction of the cell. Short-range filter cells amplify feature tracking signals at unoccluded line endings, object corners, and other scenic features. The short-range spatial filter, followed by competitive selection, eliminates the need to solve the *feature correspondence problem* that various other motion models use, such as Reichardt and Elaborated Reichardt models.

### Level 4: Spatial competition and opponent direction competition

Two kinds of competition further enhance the relative advantage of feature tracking signals. These competing cells are proposed to occur in layer 4B of V1 ([Figure 3](#), bottom-right).

**Figure 7** Schematic diagram of a 1D implementation of the transient cell network showing the first two frames of the motion sequence. Thick circles represent active unidirectional transient cells while thin circles are inactive unidirectional transient cells. Ovals containing arrows represent directionally selective neurons. Unfilled ovals represent active cells, cross-filled ovals are inhibited cells and gray-filled ovals depict inactive cells. Excitatory and inhibitory connections are labeled by '+' and '-' signs, respectively. Reprinted with permission from Grossberg S, Mingolla E, and Viswanathan L (2001) Neural dynamics of motion integration and segmentation within and across apertures. *Vision Research* 41: 2351–2553.

Spatial competition among like-directional cells of the same spatial scale further boosts the amplitude of feature tracking signals relative to those of ambiguous signals. This happens because feature tracking locations are often found at motion discontinuities, and thus get less inhibition than ambiguous motion signals that lie within an object's interior. Opponent-direction competition also occurs at this processing stage, with properties similar to V1 cells that may play this functional role.

Data of Pack et al. support properties of cells at this model stage. In their data, V1 cells exhibit suppression of responses to motion along visible occluders. Suppression occurs in the model due to the adaptation of transient inputs to static occluding boundaries. In addition, V1 cells in the middle of a grating, where ambiguous motion signals occur, respond more weakly than cells at the edge of the grating, where intrinsic terminators occur. Model spatial competition between motion signals emulate this property through its properties of divisive normalization and endstopping. Together these properties amplify directionally unambiguous feature tracking signals at line ends relative to the strength of aperture-ambiguous signals along line interiors, which compete among themselves for normalized activity at their position.

#### Level 5: Long-range filter and formation selection

The long-range directional filter pools together motion signals with the same, or similar, directional preference from moving features with different orientations, contrast polarities, and eyes. These motion signals are carried from model layer 4B of V1 input to model area MT. Its cell targets may be considered

true directional cells which combine evidence from multiple informational sources. These cells have directionally-sensitive properties in the motion stream through MT that are computationally homologous to those of orientationally sensitive complex cells in the form stream through V2. It will be interesting to see if future studies of cortical evolution and development support the idea that these cells share an underlying computational design that is later specialized for motion or form processing.

Area MT also receives a projection from V2. As described above, this V2-to-MT formation projection is predicted to carry depth-specific figure-ground separated boundary signals. These V2 form boundaries selectively assign to different depths the motion signals coming into MT from layer 4B of V1.

Formation selection is proposed to occur via a modulatory on-center, off-surround projection from V2 to layer 4 of MT. For example, in response to the chopsticks display with visible occluders (Figure 5(a)), motion signals which lie along the visible occluder boundaries are selected in the near depth and are suppressed by the off-surround at other locations at that depth. The selected signals will be weak because the bottom-up input from V1 habituates along the selected occluder boundary positions. The V2 boundary signals that correspond to the moving boundaries select strong motion signals at the farther depth. The on-center of the V2-to-MT interaction is modulatory to prevent it from creating motion signals at MT where none are received from V1. This type of circuit is predicted by adaptive resonance theory, or ART, to enable fast learning with self-stabilizing memory, and to focus attention on salient information. In the present case, the V2-to-MT interaction between correlated form and

motion information is predicted to be tuned by learning during perceptual experience.

Boundary-gated signals from layer 4 of MT input to the upper layers of MT (Figure 3, top-right), where they activate a directionally selective, spatially *anisotropic* long-range filter via long-range horizontal connections. The hypothesis that the long-range filter uses an anisotropic filter is consistent with data showing that ~30 % of the cells in MT show a preferred direction of motion that is aligned with the main axis of their receptive fields.

The long-range directional filter cells in layer 2/3 of MT are proposed to play a role in motion grouping that is homologous to the role played by the bipole cells during form grouping within layer 2/3 of the pale stripes of cortical area V2. As noted above, the anisotropic long-range motion filter allows motion signals to be selectively integrated across occluders in a manner that naturally explains the percepts generated by the Lorenceau-Alais displays of Figure 6.

### Long-range apparent motion and target tracking

The long-range directional filter can also help to explain many data about long-range apparent motion, which creates a percept of continuous motion between discrete flashes of light that are separated in space and time. The evolutionary utility of apparent motion may be appreciated by considering an animal running at variable speeds behind forest cover. The forest is an occluder that creates apertures through which fragments of the animal's motion signals are intermittently experienced. The mechanisms of long-range apparent motion enable the brain to group these fragments into a continuous motion percept that facilitates predictive tracking of the animal and its trajectory. Because of the Gaussian shape of the long-range filter, it can interpolate discrete flashes into a continuous trajectory that has many of the properties of long-range apparent motion, notably its ability to speed up as the distance between inducing flashes increases without a change in their delay, or as the delay between the two flashes decreases without a change in their distance. The depth-selective separation of extrinsic versus intrinsic boundaries in V2, followed by V2-to-MT depth-selective motion binding, together help to explain how the forest cover appears closer to an observer than the animal running behind it. In summary, the long-range filter helps to group motion signals across both space and time.

### Level 6: Directional grouping

The first five model stages can amplify feature tracking signals and assign motion signals to the correct depths. However, they do not explain how feature tracking signals propagate across space to select consistent motion directions from ambiguous motion directions, suppress inconsistent motion directions, all the while without distorting their speed estimates. They also cannot explain how motion integration can compute a vector average of ambiguous motion signals across space to determine the perceived motion direction when feature tracking signals are not present at that depth. The model's final stage accomplishes these properties by using a motion grouping network that is interpreted to exist in ventral MST (MSTv), which is known to be important for target tracking. This

motion grouping network is predicted to determine the coherent motion direction of discrete moving objects.

During motion grouping, cells that code the same, or similar, directions in MT send convergent inputs to cells in model MSTv via the motion grouping network. Within MSTv, directional competition at each position determines a winning motion direction. This winning directional cell then feeds back to its source cells in MT. Just as in the case of V2-to-MT signaling, this MSTv-to-MT feedback is defined by a modulatory on-center, off-surround network. It selects activities of MT cells that code the winning direction, while suppressing activities of cells that code other directions. Using this broad feedback kernel, the motion grouping network enables feature tracking signals to select similar directions at nearby ambiguous motion positions, while suppressing other directions there. In other words, motion capture occurs and disambiguates ambiguous motion positions. The use of a modulatory on-center, off-surround top-down circuit from MSTv-to-MT enables bottom-up learning from MT-to-MSTv and top-down learning from MSTv-to-MT to create and self-stabilize directionally selective motion grouping receptive fields during perceptual experience, using general ART properties.

As the grouping process cycles bottom-up and top-down between MT and MSTv, directional motion capture propagates laterally across space: Each cycle of top-down MSTv-to-MT feedback creates a region of cells in MT whose directional preference is consistent with that of the MSTv cells that activated the feedback. Then this newly unambiguous region of directional preference in MT can use the bottom-up MT-to-MSTv filter to select directionally consistent MSTv grouping cells at positions near them, and the cycle continues. In other words, motion capture emerges automatically using the feedback process that enabled stable development of directional tuning to occur. Chey et al. and Grossberg et al. used this process to simulate psychophysical data showing how the aperture problem may be solved via a gradual process of motion capture, and Pack and Born provided supportive neurophysiological data by directly recording from MT cells, as noted above.

### Ubiquitous circuit design for selection, attention, and learning

It is worth emphasizing that both the V2-to-MT and the MSTv-to-MT signals carry out their selection processes using modulatory on-center, off-surround interactions. The V2-to-MT signals select motion signals at the locations and depth of a moving boundary. The MSTv-to-MT signals select motion signals in the direction and depth of a motion grouping. ART predicted that such a modulatory on-center, off-surround network would be used to carry out attentive selection and modulation of adaptive tuning within all brain circuits wherein fast learning and self-stabilizing memory of appropriate features is needed. In the V2-to-MT circuit, a formotion association is learned. In the MST-to-MT circuit, directional grouping cells are learned. Grossberg, and Raizada and Grossberg review behavioral and neurobiological data that support this prediction in several brain systems. The Ponce et al. study supports the V2-to-MT prediction, but does not study how this association may be learned. There do not seem to be any direct neurophysiological tests of the MSTv-to-MT prediction.

## Converting Motion into Action during Perceptual Decision-Making

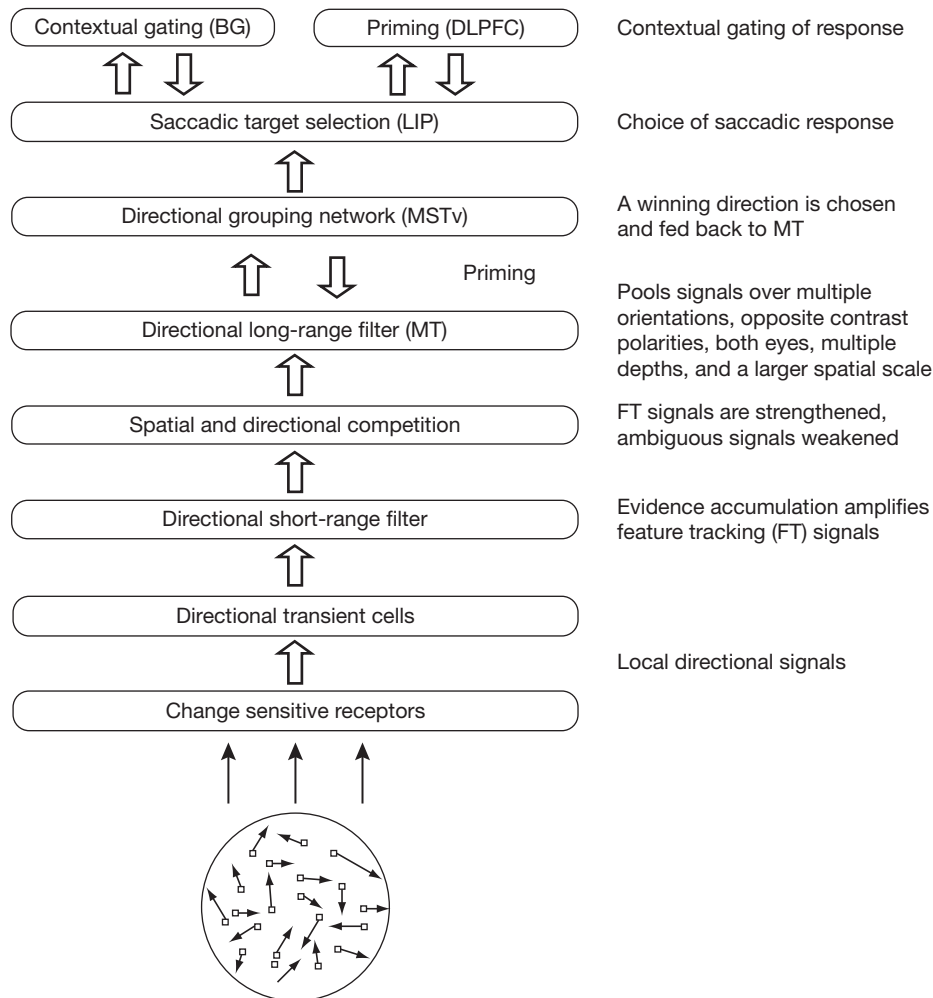

### Motion Capture in Perceptual Decision-Making

The 3D FORMOTION model sheds new light on how the brain may make motion-based movement decisions, in particular saccadic eye movements, in response to probabilistically defined motion stimuli. This example illustrates the general theme that motion may be used to drive a variety of target tracking behaviors.

It is well known that speed and accuracy of perceptual decisions and the movements that they control covary with certainty in the input, and correlate with the rate of evidence accumulation in parietal and frontal cortical neurons. Data concerning such motion-based movement decisions can be explained and quantitatively simulated by preprocessing motion stimuli with the V1–MT–MST mechanisms that are articulated in the 3D FORMOTION model before MST

activates the parietal cortex, indeed LIP, where motion direction is converted into a directional movement command that is gated by the basal ganglia (Figure 8). The model in which these processing stages are implemented is called the MOTion DEcision, or MODE, model because it clarifies challenging data about probabilistically defined motion perception and action.

The MODE model quantitatively simulates dynamic properties of decision-making in response to the types of ambiguous visual motion stimuli that have been studied in LIP neurophysiological recordings by Newsome, Shadlen, and colleagues. The most important circuits of this enhanced model already lie within the 3D FORMOTION model. Since the rate of motion capture in the MT–MST grouping network covaries with the activation rate and amplitude of LIP cells that control a monkey's observable behavior in the experiment. The model hereby clarifies how brain circuits that solve the aperture problem, notably the circuits that realize motion capture, may

**Figure 8** Retina/LGN–V1–MT–MST–LIP–BG model processing stages. See text for details. The random dot motion stimuli are preprocessed by the model retina/LGN and processed by the model cortical V1–MT–MST stream. They contextually transform locally ambiguous motion signals into unambiguous global object motion signals with a rate, amplitude, and direction that covaries with the amount of dot coherence. These spatially distributed global motion signals then feed into model area LIP to generate appropriate directional saccadic eye movement commands, which are gated by the model basal ganglia (BG). Reprinted with permission from Grossberg S and Pilly P (2008) Temporal dynamics of decision-making during motion perception in the visual cortex. *Vision Research* 48: 1345–1373.

control properties of probabilistic decision-making in real time. This is not surprising when one interprets the motion capture process as a resolution of ambiguity that selects the best consensus movement that is compatible with motion data.

### Are the Brain's Decisions Bayesian?

These results are of particular interest because distinguished perceptual and brain scientists, including Newsome and Shadlen, have proposed that perception and decision-making can be described as Bayesian inference, which estimates the optimal interpretation of the stimulus given priors and likelihoods. However, Bayesian concepts do not, in themselves, provide a way to discover the neocortical mechanisms that make decisions. The present model explains data that Bayesian models have heretofore failed to explain, does so without an appeal to Bayesian inference and, unlike other existing models of these data, generates perceptual representations in response to the moving experimental visual stimuli. In particular, the MODE model quantitatively simulates the time course of LIP neuronal dynamics, as well as behavioral accuracy and reaction time properties, during both correct and error trials at different levels of input ambiguity in both fixed duration and reaction time tasks. Model MST computes the global direction of random dot motion stimuli as part of the motion capture process, while model LIP converts a distributed motion representation in MST into a directional movement decision that leads to a saccadic eye movement. MODE hereby trades accuracy against speed, and illustrates how cortical dynamics go beyond Bayesian concepts, while clarifying why probability theory ideas are initially so appealing.

Concerning the appeal of statistical, in particular Bayesian, concepts, it should be noted that the shunting on-center off-surround networks that occur ubiquitously in the brain, and also in the 3D FORMOTION model, tend to normalize the activities across a neural network. The spatially distributed pattern of these normalized activities may be viewed as a type of real-time probability distribution. In addition, any filtering operation, such as the short-range and long-range directional filters, may be interpreted as a prior (namely, the current neural signal) multiplied by a conditional probability or likelihood (namely, the filter connection strength to the target cell). Likewise, a contrast-enhancing operation, such as the LIP recurrent on-center off-surround network that selects a winning direction from filter inputs, may be viewed as maximizing the posterior. These insights have been known in the neural modeling literature for a long time. However, as [Figures 1, 3, and 8](#) illustrate, such local processes do not embody the computational intelligence of an entire neural system that has emerged through evolution to realize particular behavioral competences, such as motion perception and movement decision-making.

### Two Movement Tasks

Newsome, Shadlen, and colleagues studied neural correlates of perceptual decision-making in macaques which were trained to discriminate motion direction. Random dot motion displays, covering a 5° diameter aperture centered at the fixation point, were used to control motion coherence; namely, the fraction of

dots moving nonrandomly in a particular direction from one frame to the next in each of three interleaved sequences. Varying motion coherence provided a quantitative way to control the ambiguity of directional information that a monkey used to make a saccadic eye movement to a peripheral choice target in the perceived motion direction, and thus the task difficulty.

Two kinds of tasks were employed, namely *fixed duration* (FD) and *reaction time* (RT) tasks. In the FD task, monkeys viewed the moving dots for a fixed duration of 1 s, and then made a saccade to the target in the judged direction after a variable delay. In the RT task, monkeys had theoretically unlimited viewing time, and were trained to report their decision as soon as the motion direction was perceived. The RT task allowed measurement of how long it took the monkey to make a decision, which was defined as the time from the onset of the motion until when the monkey initiated a saccade.

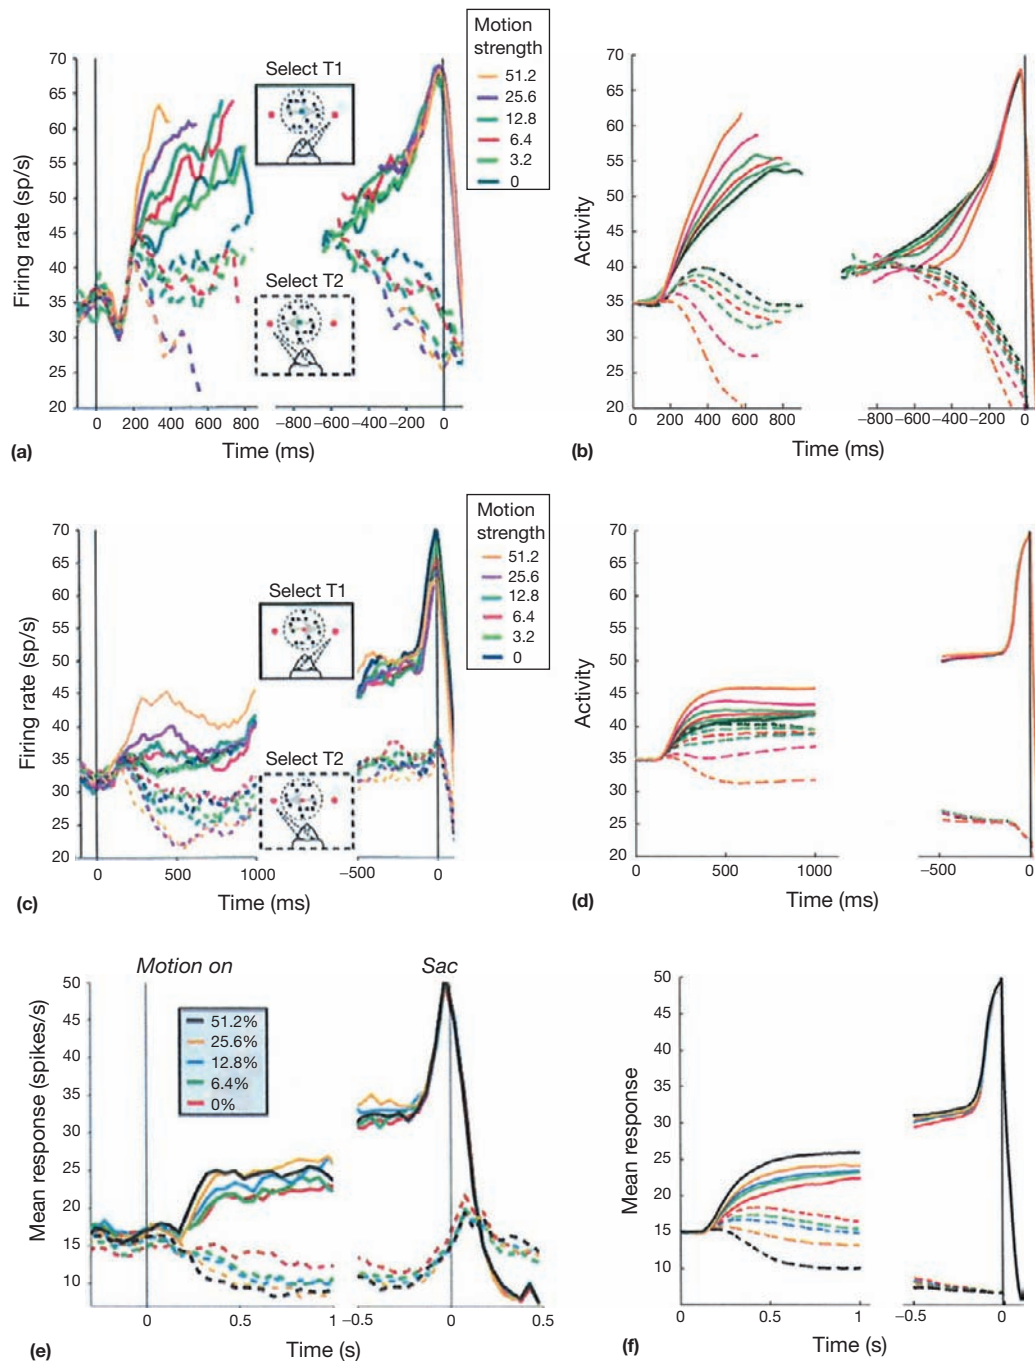

Neurophysiological recordings were done in LIP while the monkeys performed these tasks. The recorded neurons had receptive fields that encompassed just one target, and did not include the circular aperture in which the moving dots were displayed. Also, they were among those that showed sustained activity during the delay period of a memory-guided saccade task. Even though there is no motion stimulus within their classical receptive fields, these neurons still respond with directional-selectivity, probably because of extensive training on the task during which an association was learned. This property has also been observed for neurons in superior colliculus whose movement fields contain just one target.

The recorded LIP neurons show visuomotor responses. On correct trials during the decision-making period, more coherence in the favored direction causes faster LIP cell activation, on average, in both the tasks ([Figure 9](#)), and also higher maximal cell activation in the FD task ([Figure 9\(c\)–9\(f\)](#)). More coherence in the opposite direction causes faster cell inhibition in both the tasks, and also lower minimal cell activation in the FD task.

### Comparing Trackable Features with Coherently Moving Dots

There are many details that need to be carefully discussed to quantitatively explain data from this paradigm. These details should not, however, obscure the main point, which is that a clear mechanistic homolog exists between sparse feature tracking signals and sparse but coherent moving dots.

We have already discussed that, in order to solve the aperture problem, the brain needs to ensure that a sparse set of unambiguous feature tracking motion signals can gradually capture a vastly greater number of ambiguous motion signals to determine the global direction and speed of object motion. In the case of random dot motion discrimination tasks, the signal dots at any coherence level produce unambiguous, though short-lived, motion signals. Thus, individual dots do not experience an aperture problem. Despite this difference, the MODE model shows how the same mechanisms that help resolve the aperture problem can also enable a small number of coherently moving dots to capture the motion directions of a large number of unambiguous, but incoherently moving, dots. Thus, although individual dots do not experience an aperture problem, a sufficient number of randomly moving dots create informational uncertainty that creates a similar

**Figure 9** Temporal dynamics of LIP neuronal responses during the fixed duration (FD) and reaction time (RT) tasks. (a) Average responses of a population of 54 LIP neurons among correct trials during the RT task. The left part of the plot is time-aligned to the motion onset, and includes activity only up to the median RT, and excludes any activity within 100 ms backward from saccade initiation (which corresponds to presaccadic enhancement). The right part of the plot is time-aligned to the saccade initiation, and excludes any activity within 200 ms forward from motion onset (which corresponds to initial transient dip and rise). (b) Model simulations replicate LIP cell recordings during the RT task. In both data and simulations for the RT task, the average responses were smoothed with a 60 ms running mean. (c) Average responses of a population of 38 LIP neurons among correct trials during the 2002 FD task, during both the motion viewing period (1 s) and a part (0.5 s) of the delay period before the saccade is made. (d) Model simulations mimic LIP cell recordings during the 2002 FD task. (e) Average responses of a population of 104 LIP neurons among correct trials during the 2001 FD task, during both the motion viewing period (1 s) and a part (0.5 s) of the delay period before the saccade is made. (f) Model simulations emulate LIP cell recordings during the 2001 FD task. In (a–f), solid and dashed curves correspond to trials in which the monkey correctly chose the right target (T1) and the left target (T2), respectively. Cell dynamics (rate of rise or decline, and response magnitude) reflect the incoming sensory ambiguity (note the different colors; the color code for the various coherence levels is shown in the corresponding data panels), and the perceptual decision (note the two line types). For 0% coherence, even though there is no correct choice per se, the average LIP response rose or declined depending on whether the monkey chose T1 or T2, respectively. Reprinted with permission from Grossberg S and Pilly P (2008) Temporal dynamics of decision-making during motion perception in the visual cortex. *Vision Research* 48: 1345–1373.

computational problem for the visual system to solve. The intuitive idea is that the MT–MST feedback loop needs more time to capture the incoherent motion signals when there are more of them, and cannot achieve as high a level of asymptotic response magnitude when more of them compete with the emerging winning direction. In other words, the effectiveness of the motion capture process depends on input coherence. LIP then converts the distributed motion directional inputs from MST into a directional eye movement command, and thereby enables the monkey to report its decision via a saccade.

### Glossary

**Anosognosia** Refers to the strange clinical phenomena commonly found in association with neglect whereby patients do not appear to be aware of or even deny their neurological and/or neuropsychological impairments (e.g., visual field deficit, motor paralysis, and/or their visual neglect). This striking lack of appropriate awareness appears specific to individual deficits (impairments) and consequences (disabilities) and was first described by Joseph Babinski to denote the loss of recognition for a hemiplegia. Typically seen in 20–30% of hemiplegics after an acute stroke, the underlying mechanisms are not fully understood, but, together with visual neglect, have been associated with poor recovery and suboptimal benefit from rehabilitation.

**Primary sensory deficits** Visual neglect symptoms are typically distinguished from primary sensory deficits such as visual field cuts (hemianopia) which can exist in isolation in terms of lesion location, eye movements, and prognosis. Although eye movement recordings have shown that hemianopic patients employ a series of stepwise saccadic eye movements which often permit them to find and fixate objects initially located in the blind hemifield, given the lesion extent in many patients, it is likely that primary deficits interact with those affecting attentional systems. Consequently, distinguishing the effects of ‘attentional disorders’ is not straightforward in such cases, given that the clinical assessments used to assess both ultimately rely on different assessments of a patient’s ability to report or otherwise respond to specific targets located on the affected side. Since neglect implies a failure in perceptual awareness in the left field, how is it possible for a patient to reliably report stimuli located in the left visual field when responding to visual field testing? Using standard confrontational testing techniques but employing different lateralized positions of gaze, Nadeau and Heilman (1991) reported a patient (without visual neglect) who showed a ‘gaze-dependent hemianopia.’ When patients directed their gaze 30° to the right (such that the left retinotopic field was now in the right hemispace vis-a-vis the midsagittal plane), they showed a marked improvement in movement detection, object naming, shape identification, and color naming over the standard condition with ‘straight ahead’ fixation. The authors concluded that the standard confrontation visual field testing in this case represented more than just a primary visual dysfunction and that the gaze direction effects arose because of the influence of attentional or intentional factors. Using confrontation assessment, Kooistra and Heilman (1989) described a neglect patient with a right thalamic and temporooccipital lesion who demonstrated a left visual field defect, in addition to neglect on standard tasks such as line

cancellation and line bisection. The authors distinguished the effects of neglect and visual field deficit by asking the patient to look to the left or the right while engaged in the visual field assessment. When testing took place with the patient’s eyes directed either straight ahead (i.e., traditional testing) or 30° toward the left, the same patient failed to report stimuli presented in the relative left visual field. However, with eyes directed 30° toward right hemispace, the visual field defect appeared to resolve, suggesting that the patient had visual neglect masquerading as a visual field defect.

**Prism adaptation** The use of prisms as a significant, albeit temporary, reduction in neglect takes advantage of the effect of visuomotor adaptation widely used since the end of the nineteenth century to demonstrate visuomotor short-term plasticity. Short-term exposure to prisms produces a lateral shift of the visual field so visual targets appear at a displaced position. Patients use wedge prisms when making pointing movements to targets placed to the left and right of their body’s midline for around 5 min. Short-term exposure produces a significant reduction in left neglect across a variety of different standard tests (line bisection, cancellation, copying, and reading). Subsequent studies have showed that these clinical benefits extend to numerous neglect-related processes such as straight-ahead pointing, visual exploration toward left hemispace, contralesional somatosensory perception, temporal order judgments, visuo-verbal tasks, wheelchair driving, postural control, and even mental representation. The neural basis for this effect has yet to be formally established, but the cross-sectional observations suggest that even after acquired brain damage, short-term exposure to visuomotor adaptation can stimulate reorganization of the neural representation of space that develops autonomously after removal of the prisms.

**Spatial neglect and conversion disorder** Although conversion disorders, by definition, are not attributed to organic disease, symptoms presenting as cognitive deficits involving amnesia, aphasia, and spatial neglect have been reported. One patient with hysterical conversion showed left spatial /neglect for more than 2 weeks on tests such as line bisection and cancellation tests in addition to presenting with hypoesthesia and weakness of the left arm and leg. Evaluated on line bisection while still experiencing neglect, the fMRI analysis showed selective activation of the posterior parietal cortex found in normals, indicating that brain systems mediating spatial attention were intact and differentially recruited despite the behavioral performance of the patient. The findings from this study (Saj, A., Arzy, S., & Vuilleumier, P. (2009)) suggest that cognitive symptoms such as selective attention may be selectively disconnected from conscious awareness to produce neglect-like behaviors seen in organic cases and may result from inhibitory

processes previously shown to be involved in the production of motor conversion symptoms.

**Spatial working memory** Spatial working memory (SWM) impairments are not uncommon among neglect patients, especially those with parietal damage, and since these correlate significantly with the degree of behavioral asymmetry on cancellation tasks, evidence of an impairment

of (SWM) has been proposed to explain the tendency of some neglect patients to repeatedly explore the same spatial locations on visual search/cancellation tasks. This finding is also in keeping with research that shows target cancellation tasks are more sensitive to neglect when the response required leaves no visible mark, providing greater memorial effort for recalling previously visited locations.

## Introduction: Clinical and Cognitive Relevance

The clinical presentation of patients who ‘ignore’ objects, events, or people on the side of space opposite their brain damage has been described in the medical literature for well over a century (see [Figure 1](#)). Although comparatively neglected prior to the 1970s, research from clinical and cognitive neuropsychology, neurorehabilitation, and cognitive neuroscience has grown significantly in the last 40 years.

Otherwise known as hemispatial neglect or hemi-inattention, visual neglect describes a complex clinical entity that features prominently in most current texts of behavioral neurology and cognitive neuropsychology. Neglect describes a striking and complex clinical phenomenon where patients with acquired brain damage (e.g., cerebrovascular accident (CVA), traumatic brain injury (TBI), and less commonly, brain tumor or neurodegenerative diseases) appear unable to attend to, or respond to, objects and people located on the side opposite their brain damage. Although visual neglect is associated with damage to both hemispheres, *left* neglect after *right* hemisphere damage is more frequent, severe, and long-lasting.

Neglect warrants clinical attention as it occurs in about 25–30% of strokes (3–5 million a year worldwide) and can have a significant impact on health and rehabilitation services. More critically, this predominately lateralized spatial bias is reliably associated with gross impairment of many activities of daily living, spontaneous ipsilesional deviation of head and eyes, slowed recovery in maintaining alertness, nonspatial deficits in attentional capacity, and impaired vigilance. For patients, these impairments have a negative influence on both engagement in rehabilitation and recovery.

**Figure 1** A caricature conveying the sense of florid visual bias involved in neglect and need for exogenous cueing. Reproduced from Cohen R (1993) *The Neuropsychology of Attention*. New York: Plenum.

While it was initially considered a unitary syndrome affecting left-sided space, over the last two decades there has been compelling evidence that neglect results from the interplay of damage to several different cognitive processes where the border between neglected space and nonneglected space is far from absolute. Moreover, the lateralized reference and use of the term ‘left’ requires comment, as it does not necessarily refer to the left of the patient’s midline, but can actually be differentially defined with respect to several different frames of reference. Many symptoms ascribed to the visual or hemineglect syndrome share little in common other than a contralesional gradient of increasing impairment, with a comparatively well-preserved performance on the ipsilesional (right) side of space.

The reasons for this asymmetric pattern (greater left-sided neglect after right brain damage) continue to be the subject of theoretical speculation. In the healthy brain, the left and right hemispheres are assumed to function in mutual competition, with neural activity for each hemisphere driving or modulating spatial attention to the opposite half of space. Normally, these opposing signals are held in balance, ensuring that the person can attend equally well to both sides of space. Damage to the right hemisphere, however, leads to a rightward bias and a left neglect that largely arises from the dominant engagement of the intact left hemisphere. The specialization of the left hemisphere for language has been proposed to explain this presentation laterality – together with the absence of such asymmetries in nonhuman primates. An alternative account is that the right hemisphere is specialized for global processing, while the left is more adapted to focus on local details. Consequently, right hemisphere damage results in more focused attentional bias (e.g., selection preference toward right-sided targets on cancellation tasks) and failure to detect and orient in the wider spatial context.

Neglect is not confined to vision and can affect personal (or body) space, peripersonal space (stimuli within reaching and grasping distance), and extrapersonal space (stimuli within walking distance). Although *lateralized* (left–right) visual neglect has attracted the most interest, comparable phenomena have been observed in nonlateralized space and other dimensions of space (radial and altitudinal neglect). Hence, varieties of neglect have been distinguished on the basis of the regions of space affected, the reference frame, the mode of output as well as the sensory modality.

Although visual neglect has clear and important clinical implications for patient recovery and long-term health care planning, much of the neuroscience interest over the past 30 years stems from the opportunity to examine the neural and cognitive mechanisms that underlie impairments of spatial and nonspatial attentional processes and study of their

behavioral manifestations. Investigations of patients with spatial neglect have contributed in no small way to our understanding of the manifold processes subserving spatial cognition. By considering traditional clinical neurological syndromes such as neglect in terms of damage to known cognitive systems, neuropsychologists have moved beyond mere symptom description and the opportunity to meaningfully link cognitive deficits to their impaired neural processes.

### Clinical Presentation and Functional Consequences

Patients vary enormously in the range and extent of 'neglect' behaviors observed, most of which have a debilitating effect on their everyday life, in particular, their attempts to negotiate wheelchairs or interact with staff. While formal assessments are useful, there is no substitute for simple observation of the patient on the ward or in their home. As a heterogeneous cluster of dissociable deficits, characterized by lateralized spatial bias, most people consider the clinical diagnosis of neglect an 'umbrella term' covering a multifaceted range of attentional, intentional, and representational deficits not directly attributable to primary sensory or motor deficits. Clinically, neglect has been shown to vary as a function of the relative size of lesion, the hemispheric location, time post onset and number and type of assessments used. Although some patients with neglect demonstrate visual field deficits, others with intact visual fields nevertheless show profound neglect on a wide range of tasks. Typical examples include where patients fail to find visual targets presented on the left side of a page, draw only the right half of a remembered image, copy the right half of a picture, and delete and/or compress the numbers on a clock face into the right half of a drawn clock (see Figures 2–4).

Examples of neglect behaviors seen on the ward include (1) failure to notice people approaching from the left; (2) failure to eat food from the left side of the plate; (3) failure to dress on, or groom, the left side; (4) omission of letters, numbers, and/or words on one side of the page when reading; (5) omission of one side of the contents of a picture when verbally describing or drawing; (6) failure to pick up coins or cards on

the affected side; and (7) omission, distortions, and asymmetries in spontaneous drawing and writing. Patients often inadvertently and repeatedly bump into obstacles situated on their left (door frames and chairs) with their wheelchair or while walking and show a tendency to look to right-sided details as soon as a visual scene deploys, as if the left side of space had ceased to exist in any meaningful way. In addition, such patients may ignore their own left limbs or have difficulty reaching toward the left, and fail to respond to auditory stimuli from the left or tactile stimuli presented to the left side. Even more striking, some patients omit information from the left side of an imagined scene – information that they subsequently recall when imagined on the right. In the acute stage, many patients are unaware of their deficits (anosognosia) and can obstinately deny being hemiplegic or neglectful, all of which provides for suboptimal engagement in rehabilitation.

In many patients, reading (neglect dyslexia) and writing (neglect dysgraphia) can be severely compromised by visual neglect. Patients with neglect dyslexia omit the left side of both the text and individual words. When reading single-word errors, this may involve both removal and/or partial substitution for the left sides of words. In the example in Figure 5, both errors are present.

Famous examples /illustrations of neglect seen after stroke (but unrecognized as such) from the nineteenth and twentieth centuries include Charles Dickens and Woodrow Wilson, the American President at the time of WWI. According to McManus, Dickens first recorded neglect episode occurred in 1870 when Dickens noted that "he could read only the halves of the letters of the shop doors that were on his right as he looked."

**Figure 2** Evidence of neglect on a clock drawing task from memory in the acute and postacute stages after right hemisphere stroke. From Robertson IH and Halligan PW (1999) *Spatial Neglect: A Clinical Handbook for Diagnosis and Treatment*. Hove: Psychology Press.

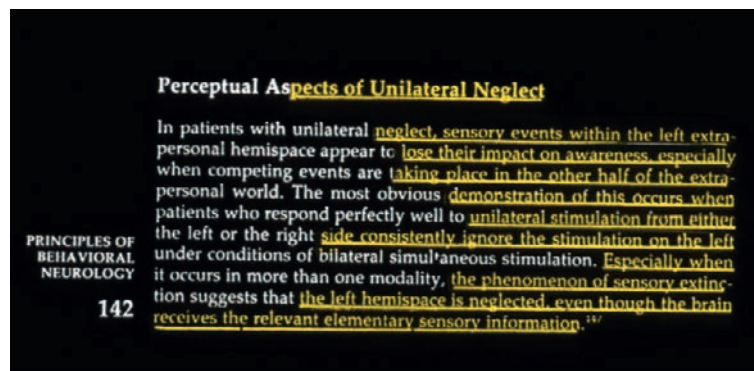

**Figure 3** Long-standing visual neglect involving the left side of the face and body in a patient fully aware of her clinical condition. From Robertson IH and Halligan PW (1999) *Spatial Neglect: A Clinical Handbook for Diagnosis and Treatment*. Hove: Psychology Press.

**Figure 4** Pre- and poststroke sketches from the work of the artist Tom Greenshields. After his stroke and in addition to other visuoconstructive deficits, the artist was unable to attend to the left side of his drawings. From Halligan PW and Marshall JC (1997) *Lancet* 350(9071): 139–140.

**Figure 5** An example of neglect in reading from a neurology textbook describing visual neglect. The (yellow) underlined text is the actual text read by the patient. Reproduced from Mesulam MM (1985) *Principles of Behavioural Neurology*, p. 142. Philadelphia, PA: FA Davis Company.

Dickens apparently noticed his problem most when reading proper names, perhaps because of the presence of contextual cues. After his stroke in 1919, Woodrow Wilson showed many features of visual neglect in association with left-sided weakness. In writing, he often omitted letters or words located on the left side of the page such that his wife had to correct much of his personal correspondence at the time.

Finally, it is worth recalling that several patients take exception to the use of the term neglect to describe their condition. Asked to provide an explanation for her 'visual neglect,' one articulate patient reported by Halligan and Marshall complained that the term 'neglect' was an unfortunate and inaccurate description of her experience. As far as she was concerned, a more accurate description was that left space and its contents did not appear to exist and hence there was nothing to neglect!

Asked to elaborate, the patient said that although she had heard the word 'neglect' mentioned, she could not understand what it meant.

I thought they were saying I was actually neglecting to look to the left. I couldn't move my eyes to the left. It was quite fixed. It was scary. I used to bump into things because I couldn't move my eyes to the left. Because I never used to look to the left at all. I knew the word 'neglect' was a sort of medical term for whatever was wrong but the word bothered me because you only neglect something that is actually there don't you? If it's not there how can you neglect it? It doesn't seem right to me that the word neglect should be used to describe it. I think they thought I was definitely, deliberately not looking to the left. I wasn't really. It was painful looking to the left. ... People think you are not looking ... you are neglecting to look but it's not there. If it's not there you are not neglecting it. I think concentrating is a better word than neglect. It's definitely

concentration. If I am walking anywhere and there's something in my way, if I'm concentrating on what I'm doing I will see it and avoid it. The slightest distraction and I won't see it.

(Halligan and Marshall, 1998)

## Assessment

Assessment and diagnosis of neglect remains important, particularly as it can be helpful in characterizing the types of neglect and predicting functional outcome. Quantifiable assessment of *within subject performance* provides indications of the range, severity, extent of recovery, and nature of presenting neglect, all of which are informative when considering and tailoring individual rehabilitation strategies. While some clinicians have developed tests and assessments that understandably focus more on functional measures by requiring patients to perform tasks, which show potential difficulties in daily life, neglect is typically diagnosed using simple (bedside) tests such as cancellation, line bisection, or copying. For clinical purposes, laterally impaired performance on any one measure, particularly on line bisection, cancellation, or copying, is usually taken as evidence of diagnosis. However, double dissociations between these tests are not uncommon (e.g., patients may omit left-sided targets from a cancellation task while at the same time bisecting lines within normal limits and vice versa), suggesting that the task demands do not overlap or are equally demanding.

Despite content, procedural differences, and double dissociations between many such tasks (e.g., physical and mental line bisection, representational or imaginable neglect, and copying), most tests justify their validity on the basis of demonstrating a predominantly lateralized task performance and by claiming to measure different aspects of the underlying deficit. Patients' asymmetries of performance on *cancellation tasks* can vary from a few left-sided omissions to cancellation of only the rightmost items depending on spatial density, content, and the number of distracters. Some patients repeatedly cancel the same right-sided items, showing a pathological 'revisiting behavior' for objects presented in the supposedly 'normal' sector of space. Patients who compensate for their deficit to some extent, will either as a result of spontaneous recovery or after rehabilitation, cancel out all the elements, but nevertheless keep starting from the right extremity of the sheet, at variance with normal participants, who most often start from the left part of the sheet. *Line bisection* is also a useful tool to discriminate between neglect and visual field defects, such as left homonymous hemianopia, which was once thought to provide an intuitive explanation for neglect. Contrary to this hypothesis, there are patients with left hemianopia but no neglect, which deviate *leftward* on line bisection. The association of left neglect and hemianopia, however, produces large rightward deviations on line bisection. When given relatively short lines to bisect (e.g., 5 cm or less), patients often paradoxically shift the bisection point leftward. The copresence of visual field defects may be a necessary condition for this cross-over effect and other neglect-related behaviors to occur. When copying a drawing, neglect patients often omit left-sided details but more rarely,

some patients actually *increase* the number and spatial extension of left-sided details.

As neglect may be present on some, but not all, tests at the same time, the use of more than one test is recommended. There are many different tests currently available, and from a clinician's perspective, administering multiple types of assessment generally improves sensitivity in revealing the intact as well as the deficits in spatial processing. One well-validated battery used internationally is the behavioral inattention test (BIT) using six 'conventional' standardized bedside paper and pencil tasks and nine more ecologically relevant behavioral subtests developed to simulate some activities of daily living.

The test, which was standardized using 50 normal subjects and 80 stroke patients, has shown itself to have high interrater (0.99), test-retest (0.99), and parallel form reliability (0.91), and is relatively simple to administer and capable of identifying problems that patients encounter in daily life.

## Neuropsychological Insights and Cognitive Mechanisms Implicated

It should be clear from the brief description so far that left neglect is not a unitary, homogeneous entity. Several reliable dissociations of patient performance have been described using different neuropsychological tasks, although it has not always proved possible to find a clear correspondence between behavioral dissociations and lesion localizations given the traditional focus on gray matter lesions and the fact that some dissociations may stem from the patient's own capacity to employ compensatory strategies.

The different mechanisms producing neglect have fostered considerable debate during the last decade. Several independent deficits, presumably interacting with one another, contribute to the range of neglect signs. These include deficits in orienting of spatial attention, in building or maintaining spatial representations, or in programming left-directed hand movements. It is also possible, however, that some deficits have more influence than others in shaping and sustaining patients' behavior. For example, deficits of spatial attention, such as an engagement of attention toward right-sided, nonneglected items as soon as the visual scene unfolds, followed by impaired disengagement from these same items have been considered key component deficits of neglect. Importantly, these deficits seem mainly to concern what are termed exogenous, or stimulus-related, orienting of attention, with relative sparing of endogenous, or voluntary, orienting. Thus, the presence and number of right-sided distracters can perturb patients' performance in a predictable way. Also, there is clear evidence that nonlateralized deficits can contribute crucially to clinical neglect. For example, processing of items presented in central or right-sided locations can be impaired in left neglect. However, it should be remembered that attentional deficits can occur after right brain damage even in the absence of clinical neglect, consistent with the idea that several deficits combine to produce clinically discernible neglect behavior.

## Attention

Attention – the cognitive process of selectively focusing on aspects of our environment while disattending to other things – is

probably one of the most important cognitive processes, given that it pervades all aspects of cognitive life and, when compromised, provides for a wide range of clinical consequences. For many researchers, the motivation for studying patients with neglect stems from the opportunity to study the effects of damage on attention as a way of gaining insights into the often subtle and less obvious ways in which complex attentional systems operate normally. The range of deficits observed stem from the fact that attention is not a single process but rather a set of interacting, albeit relatively autonomous, subprocesses vulnerable to different forms of brain damage with differing patterns of recovery. Because attention cannot be observed directly but is detected by monitoring systematic variation in performance on different attention-demanding tasks, the performance of patients with neglect provides a 'natural' experiment for elucidating the operational functions and constraints under which normal attentional systems operate. Posner's well-established covert attentional-cuing paradigm shows this well (see [Figure 6\(a\)](#) and [6\(b\)](#)).

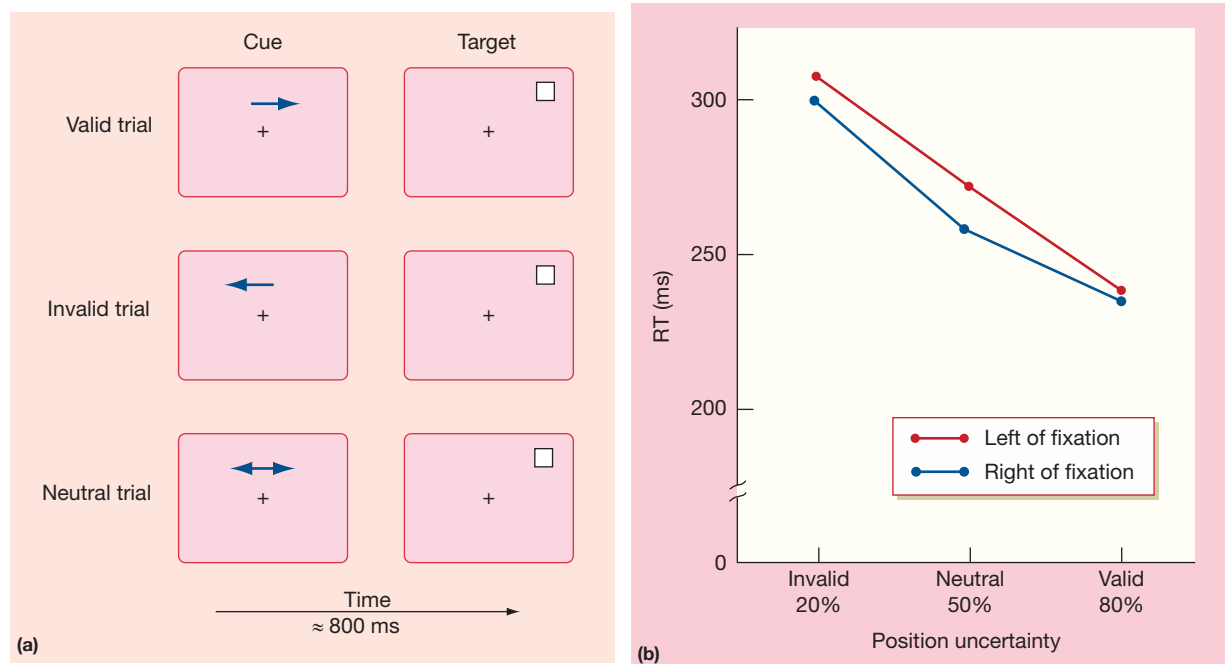

In this classic paradigm, subjects are asked to maintain their gaze at the center of a screen and press a button only when they observe a designated target appearing. Subjects have no information where on the screen this target would be, although on a number of informative trials, they would have received a directional or spatial cue as to the probable location. Attentional cues, when accurate, produced significant reductions in overall reaction time, but when inaccurate, produced significant increases. Given that all other aspects of the task remain constant, the temporal differences are attributed to the movement or allocation of spatial attention. Using this single reaction-time paradigm, Posner and others were able to

distinguish three different mental operations involved in covert orienting of attention: (1) disengaging from the current focus, (2) moving toward the target, and (3) engaging the novel target, which could be, individually or collectively, compromised by neglect. Subsequent research using this simple paradigm with neglect patients has shown that a major feature underlying severe forms of neglect is the severe imbalance in automatic orienting of attention resulting from a rightward bias, particularly evident in bilateral visual stimulation. Owing to this early orientation of attention to the right hemispace, left-sided stimuli are either neglected or attended to after a quantifiable delay, which is an index of the time-consuming reorienting of attention from the right to the left side of space.

### Spatial Frames of References (Object and Space)

The brain appears to code visual inputs with respect to several spatial frames of reference and hence, the terms used to qualify clinical accounts of neglect, such as 'left' or 'hemi,' need to be clarified. The brain uses different frames for attributing up-down and left-right to spatial arrays and can be based on the direction of the viewer's gaze (egocentric) and/or the intrinsic characteristics of an object or its environment (allocentric) (see [Figure 7\(a\)](#) and [7\(b\)](#)):

1. *Egocentric space* (i.e., coding with respect to different viewer-centered frames of reference, including eye-, head-, torso-, shoulder-, arm-, and hand-centered coordinates) can be differentially affected by neglect. The extent to which these different coordinates are truly independent has yet to be established.

**Figure 6** (a) The spatial cuing paradigm of Posner and colleagues. A subject sits in front of a computer screen and fixates on the central cross. An arrow cue indicates to which visual hemifield the subject is to covertly attend. The cue is then followed by a target in either the correctly or the incorrectly cued location. (b) Results of the study by Posner and colleagues, as shown by reaction times (RT) to unexpected, neutral, and expected targets for the right and left visual hemifields. RT for expected locations are significantly faster than those for neutral or unexpected targets.

**Figure 7** In copying a picture of a butterfly positioned (a) horizontal (b) vertically, and again (c) horizontally, the neglect patient reliably omits the left wing in the horizontal conditions where the relevant wing is located to the left of the subject's egocentric mid-sagittal plane. Reproduced from Halligan and Marshall (1996).

**Figure 8** A neglect patient's copy of the top three spatially distinct images managed all the three, but consistently omitted the left side of each image. From Halligan PW, Fink GR, Marshall JC, Vallar G (2003) Spatial cognition: Evidence from visual neglect. *Trends in Cognitive Sciences* 7: 125–133.

2. *Allocentric*: Spatial position can also be coded in object-centered coordinates not dependent on the lateral or relative position of the observer. Clinical studies have reported lateralized deficits that are spatially defined in terms of an object's position relative to another object. Convincing evidence for selective damage to object-based frames of reference can be found in the drawing and copying performance of neglect patients (see Figure 8). Furthermore, object-centered coding that involves the intrinsic order of object parts (e.g., written words have a specified sequence of letters) has also been reported. This form of coding was elegantly demonstrated by Caramazza and Hillis in a left-brain-damaged patient with right-neglect dyslexia. When

**Figure 9** A simple schematic summarizing the three different regions: personal space, peripersonal space, and extrapersonal space. Reproduced from Robertson IH and Halligan PW (1999) *Spatial Neglect: A Clinical Handbook for Diagnosis and Treatment*. Hove: Psychology Press.

reading, her errors were always located on the last letters of the words irrespective of whether the words were presented horizontally, vertically, or even mirror-reversed.

### The Neuropsychological Decomposition of Space

Although psychological space appears to extend seamlessly, evidence from animal and clinical cases involving neglect suggests that it does not appear to be homogeneously represented in the brain. Embodied space can be behaviorally divided into at least three different regions: *personal space*, *peripersonal space*, and *extrapersonal space* (see Figure 9). Patients with right hemispheric brain lesions can demonstrate neglect in any, or all, of these spatial frames of reference. Typical examples of left personal neglect include failure to shave or groom the left side of the face, failure to adjust spectacles on the left side, and failure to notice the position of the left limbs and use them appropriately even when significant motor weakness is not present. By contrast, the ability to use left personal space without difficulty can be seen in the context of neglect of peripersonal space using visual search tasks where targets are located within arm's reach. Double dissociations between personal and peripersonal neglect and between peripersonal and extrapersonal space suggest that distinct neuronal circuits underlie the way the three spaces are represented in the human brain. Although the limits of peripersonal (grasping) space are normally determined by the extended reach of the arms, extending peripersonal space using rigid tools in neglect has shown that enlarged peripersonal space can become remapped as near space.

### Unconscious or Implicit Processing in Neglect

Many students of neuroscience consider neglect to be a classic disorder of visual awareness where awareness is equated with the psychological construct of attention as previously discussed. However, given the remarkable findings from blindsight, where patients show some degree of information processing when tested indirectly, one of the fascinating questions is the level or extent to which covert cognitive processing continues despite overt failure on the part of the patient to consciously report or attend to left-sided space or objects. In this way, studies of visual neglect have made a useful

contribution to the classic debate regarding the processing levels of attentional selection. According to the *late selection* view, preattentive analysis of the whole scene takes place up to and including initial recognition of the object whereas *early selection accounts* argue that only basic perceptual processing takes place preattentively and focal attention is subsequently necessary for object recognition. The key question for neglect research hinges on the cognitive level to which stimuli are preattentively processed.

Studies of visual neglect have shown that dependent on the relevance of the stimuli, preattentive processing up to the level of meaning can take place in the 'neglected' field without conscious awareness. Using cross-field matching and priming experiments, patients with neglect show significantly shorter reaction times to right field stimulus content for congruent rather than noncongruent stimuli despite denying seeing anything in the left visual field. Even on line bisection, patients with severe left neglect show implicit sensitivity to many figural characteristics of the stimulus display, confirming that preattentive visual capacities can influence explicit visuomotor performance. When requested to bisect a line located in the center of a page, most patients with neglect show a displacement of absolute magnitude that is linearly related to line length. This consistent linear performance may be explained in terms of implicit processing of the visual information on the neglected side. Thus, the neglected end of the stimulus line is covertly influencing the patient's performance in deciding the subjective center of the line.

Marshall and Halligan showed evidence of a further type of dissociation between two forms of conscious perceptual awareness – with hierarchical figures on a free vision task. In a series of experiments, they showed that some neglect patients, when

shown hierarchical drawings of shapes or alphabetic letters composed of smaller (local) features or letters in free vision, gave an accurate *verbal* description of both the global and local subfigures despite subsequently (and within seconds) showing neglect when required to cancel the smaller (local) components on the left side of the global figure and despite being able to describe the global figures accurately both before and after cancellation (Figure 10(a)–10(e) left). This 'within subject disconnection' in communication between local and global processing was found even when patients produced an accurate copy of the global figure (Figure 10(c)–right-sided figures) – a circle comprised of localized dots. Requested to cancel the same set of dots comprising the circle just drawn, patients again neglected to mark much of the left circumference of the circle. In such cases, global processing can no longer be used to direct automatic focal attention to spatial locals that require further focal analysis. Without this ability, local attention which is usually biased to the right will always represent too little of the visual world. However, once attention has been focused, the panoramic or global view appears lost to conscious awareness unless exogenously cued. When their focal attention is biased to the right as in the case of left neglect, patients are in a position to observe the absence of left-sided input. Even if selective attention can be voluntarily moved leftward, the necessary guiding framework provided by the global scale is no longer available. Consequently, patients no longer have any reason to continue to explore leftward. In these and other examples where performance within an individual patient appears normal on one aspect and grossly impaired on another involving the same stimulus seconds later, left neglect may be regarded as a partial disconnection of conscious visual awareness where residual processes of

**Figure 10** Dissociation between two forms of conscious perceptual awareness in a patient with left neglect. Reproduced from Marshall and Halligan (1995) *Nature* 373(6514): 521–523.

the impaired right hemisphere cannot be used to constrain the performance of the intact left hemisphere in performing the designated task. Collectively, these findings highlight the danger of equating phenomenological conscious experience with the operation of the perceptual mechanisms involved.

### Representational or Imaginal Neglect

Despite the traditional clinical emphasis on using visual stimuli (e.g., cancellation tasks and copying tasks), neglect can manifest itself in the absence of visual stimuli. When describing known places from memory, some patients omit details situated on the left part of the (mental) scene. In the now classic experiment, Bisiach and Luzzatti asked patients with left-sided visual neglect from Milan to imagine the famous Piazza del Duomo or central square from the vantage point of the cathedral steps in the center of the square. As expected, patients often omitted places or streets to the left side of the square taken from *that imaginal viewpoint*. However, the same patients when asked to imagine they were looking directly at the cathedral, that is, when they were required to change their imaginal viewpoint by 180°, now neglected to mention places on the side of the square previously reported – the ones that now fell to their left from the new imagined point of view. Instead, they recalled places to the right of the new imagined vantage point demonstrating that while they could imagine much of the content on both sides of imagined space, neglect was capable of adversely restricting attention to the respective right side of each imagined representation of the Piazza.

Not all patients with visual neglect show imaginal neglect, perhaps because imagined details have less attention-capturing power than real ones. Imaginal neglect can also occur in the absence of signs of perceptual neglect, either at onset or, perhaps more commonly, as a result of selective compensation for the perceptual aspects of the syndrome. Patients often learn with time (and possibly with the help of people around them) to explore more thoroughly their visual environment. However, compensation may be more difficult to obtain in the more abstract imaginal domain, which is rarely the object of rehabilitation or of more informal reminders to ‘look to your left.’

Neglect patients may also deviate rightward when engaged in the mental bisection of number lines or intervals; for example, when asked for the median number between 11 and 19, they may answer ‘17.’ In this domain as well, visual and imaginal performance can dissociate. Biased performance with mental number lines might be related to concomitant prefrontal damage and spatial working memory impairment. It would be surprising to find that all neglect patients demonstrate such a mental bias, given that people do not always imagine numbers in spatial arrangements, and even when they do, their mental maps are not necessarily oriented along the horizontal direction.

When patients are asked to use a black touch screen to represent the night sky, and to touch the locations occupied by (imaginary) stars, they put significantly more stars to the right of the screen midline, and particularly when the stars remained illuminated after the touch. However, if the screen remained black, the asymmetry was less evident. This confirms the attention-capturing influence of real right-sided visual stimuli on patients’ neglect. But perceptual influences on spatial imagery seem less relevant for casual, task-unrelated stimuli.

When patients are asked to imagine and describe the map of France with eyes open or blindfolded, performance was similar regardless of the condition. During sleep, neglect patients can show suppression of leftward-directed rapid eye movements (REMs), although there are reports of patients with left visual neglect and frequent nystagmoid REMs with alternating leftward slow/rightward fast phases, corresponding to dreams with consistent visual events, such as a train running leftward, but virtually no nystagmoid REMs in the opposite direction. The complex relationships between perception and imagery in general and concerning neglect in particular, are still difficult to predict from the available theoretical models.

### Neural Basis (Lesion Correlates)

Neglect has been long observed to follow damage to a variety of brain regions, including the parietal cortex, frontal cortex, basal ganglia, putamen, caudate, and thalamus. In keeping with the heterogeneous nature of the symptoms, patients with neglect often have relatively large lesions of the right hemisphere, likely to disrupt several functional modules. However, the precise localization and functional disruption of these lesions remain controversial, as patients’ lesions detected by CT or MRI often overlap on the inferior parietal lobule (IPL) at the junction with the temporal lobe. Conflicting evidence, however, also indicates lesions of the middle and rostral parts of superior temporal gyrus (STG), which tends to exclude a role for lesions of the temporoparietal junction. More recent studies suggest that parietal or STG dysfunction may lead to different forms of neglect (respectively, personal/extraperсонаl, or viewer-centered/stimulus centered). However, lesion overlap methods lacking spatial resolution may reflect differences in vascular territories rather than true functional architecture and do not always satisfactorily deal with multiple lesions.

Recent studies show that the previous reliance on structural CT and MRI techniques is now beginning to embrace the findings of new techniques, given the desire to understand neglect in terms of dysfunctional brain networks rather than, as previously, in terms of local damage to specialized gray matter functions.

Transcranial magnetic stimulation (TMS) has been used to transiently disrupt the integrated activity of cortical networks in a relatively noninvasive fashion, which has the advantage of suggesting causal processes rather than depending on the correlative associations used in imaging studies. TMS over the left hemisphere decreases left neglect in right brain-damaged patients. Temporary inactivation of the middle/rostral portions of the STG produces nonlateralized impairments in visual search tasks. In the same study, TMS stimulation of the central sectors of the STG did not modify judgments of the length of horizontal lines (Landmark task), in contrast to inactivation of the posterior parietal cortex, which provoked lateralized effects similar to that shown by patients with neglect on the same task. A more recent study using TMS confirmed that neglect symptoms can rise not only through direct stroke damage to the right parietal cortex, but also through remote excitability changes in the intact *left* parietal cortex not directly damaged by the stroke. These findings provide further support for the influential theory that neglect occurs due to unilateral

stroke disruption of the normal attentional balance of neural activity between the two hemispheres.

Functional MRI has been employed to explore the neural correlates of subacute and recovered neglect. Four weeks after a stroke, when performing a response-timed task to lateralized stimuli, neglect patients showed a decreased activation of structurally intact frontoparietal regions in the right hemisphere (especially the intraparietal sulcus, the superior parietal lobule, and the dorsolateral prefrontal cortex), together with a robust activation of the homologous regions in the left hemisphere. Thirty-nine weeks after lesion onset, recovery of neglect signs was paralleled by the disappearance of the imbalance between the two dorsal frontoparietal attentional networks. Thus, lesions of the right temporoparietal junction may determine a functional imbalance of the superior parietal lobules and the connected prefrontal regions, which are structures important to attentional orienting, with a consequent biased orienting toward right-sided objects.

Temporary electrical inactivation of small brain region (~5 mm) stimuli performed during brain surgery to prevent postoperative deficits have also been informative. One study described the performance of two patients who bisected horizontal lines while undergoing surgical resection of low-grade gliomas. Patients deviated rightward upon inactivation of the supramarginal gyrus (the rostral subdivision of IPL) and the caudal part of the STG; however, bisection performance was accurate when more rostral portions of the STG or the frontal eye field (FEF) were inactivated. The tract of long association fibers in the white matter of this particular patient was mapped in postoperative MRI scans using diffusion tensor MRI tractography (DT-MRI), a new technique capable of tracking white matter fibers (**Figure 11**). The tract whose inactivation had brought about the maximal rightward deviation

**Figure 11** 3D reconstruction of the SLF III (in gold) and SLF II (in blue); top, lateral, and medial views of a glass brain right hemisphere; bottom, frontoparietal connections with their putative cortical projections. AG, angular gyrus; IPS, intraparietal sulcus; SPL, superior parietal lobule; TPJ, temporoparietal junction; FEF, frontal eye field. From Doricchi et al., *Cortex* (2008) vol. 44, pp. 983–995.

corresponded to the likely human homologous of the second branch of the superior longitudinal fasciculus (SLF II). This pathway connects the inferior and the superior parietal lobules, particularly the angular gyrus (BA 39), including the intraparietal sulcus (IPS), to the middle and superior frontal gyri (BA 9, 8, 46, and 6). The observation that functional frontoparietal disconnection dramatically disrupted symmetrical processing of the visual scene is consistent with many findings obtained from animal research.

A recent meta-analysis of previous lesion overlapping studies in human stroke patients demonstrated that the subcortical lesions of neglect patients invariably overlapped at or near the human homologs of the second and third branches of SLF. Disconnection between cortical modules might thus be a general mechanism of neglect. DT-MRI tractography can now be used to explore, in a standardized brain space, the relationships of white matter tracts with the lesions found in stroke patients with standard, anatomical MRI. Thus, for the first time, white matter pathways can be explored in detail in the living human brain, and the focus can shift from the impairment of cortical modules to the dysfunction of cortical networks. A recent study combined principal component analysis on behavioral tests and voxel-based lesion-symptom mapping in 80 stroke patients. Principal component analysis identified three factors, labeled as exploratory/visuomotor, perceptive/visuospatial, and allocentric/object-centered. Voxel-based lesion-symptom mapping indicated distinct brain regions for the three components: the dorsolateral prefrontal cortex for the exploratory/visuomotor component, the IPL for the perceptive/visuospatial component, and deep temporal lobe regions for the allocentric/object-centered component. In patients with severe neglect encompassing several tests, standard lesion overlap analysis disclosed a hot-spot in the hemispheric white matter, in a location consistent with the trajectory of frontoparietal pathways. Thus, components of neglect may result from damage to distinct cortical sites. However, in the most severe cases, neglect results from the disruption of large cortical networks as a consequence of damage to frontoparietal white matter connections.

These results collectively support models of neglect which postulate a dysfunction of large-scale right-hemisphere networks and an involvement of the intact left hemisphere. Parietal components of the network could determine the perceptual salience of extrapersonal objects; frontal components might be implicated in the production of an appropriate response to behaviorally relevant stimuli, in the online retention of spatial information, or in the focusing of attention on salient items through reciprocal connections to more posterior regions. The network approach might prove important for patient diagnosis because a particular form of white matter disconnection might have greater predictive value than the localization of gray matter lesions. The demonstration of anatomically intact but functionally inactivated areas might also open perspectives for treatments (whether pharmacological or rehabilitative), aimed at restoring normal neural activity in these areas.

## Recovery and Rehabilitation

Aside from the fascinating insights that research on neglect has provided for cognitive neuroscience, the reality for many

patients is that neglect is a well-recognized predictor of poor functional outcome. Studies consistently show a strong association with impaired everyday functioning. Commonly associated with left hemiplegia, the presence of left visuospatial neglect renders motor-associated deficit more severe and slows recovery in other functions, including nonspatial attention.

Although recovery occurs in a majority of patients, left visuospatial neglect continues to be severe in some patients and can persist chronically in a small number. A number of studies suggest that some forms of the spontaneous 'recovery' observed reflect compensation rather than reduction in the underlying spatial distortion. Even in some 'recovered' cases, more subtle or challenging assessments (e.g., pointing to the midpoint between two objects or performing a second attentionally demanding task) can reveal spatial distortions – some of which can be clinically apparent when patients are required to operate under more stressful conditions.

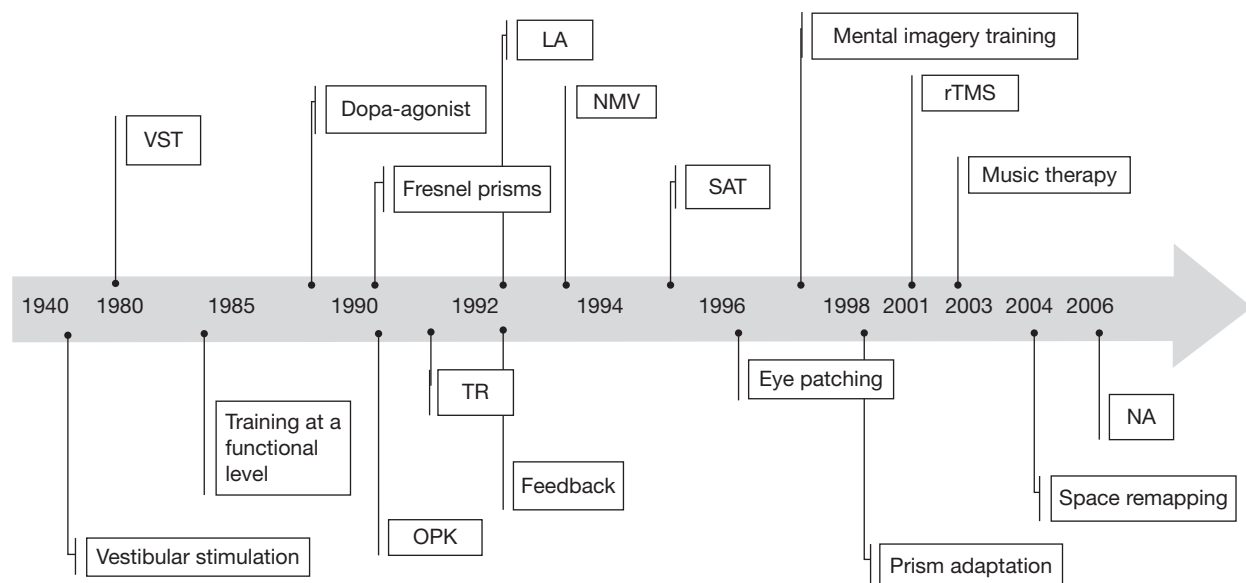

Recent functional imaging studies of patients with neglect suggest that a neurological deficit after a focal brain injury not only reflects local dysfunction at the site of injury but also involves more distributed impairment of connected, structurally intact neural systems. So, after right frontal damage, the resulting spatial attention deficits may be responsible for the abnormal activation in structurally intact dorsal and ventral parietal regions that mediate attentional operations. Consequently, the observed recovery of these attention deficits in the acute stages after stroke may be associated with restoring and rebalancing activity within these crucial regions rather than a restoration of function in the structurally affected areas. Such dysfunctions may be reflected neurally – by deactivation, disconnection, hyperactivity, or interhemispheric imbalance during task processing.

In clinical practice, neglect is typically treated by encouraging the patient to scan and search the environment or the affected body side (see Figure 1). Cueing and scanning training helps some patients on clinical tests, but these do not carry over

into self-care activities. To be effective, 'top down' treatment methods require time and effort on behalf of the staff or carer or depend on the patients becoming aware of their neglect. However, because neglect is often associated with poor insight and arousal, many patients have difficulty in maintaining compensatory search strategies throughout the day. Consequently, treatment methods that do not depend on such 'top-down' processes can be more effective.

Given the debilitating nature of neglect, many different rehabilitation interventions and compensation approaches have been developed to alleviate, reduce, or remediate left visuospatial neglect over the past 60 years (see Figure 12). Most of these are directed at restoring the damage systems involved and/or compensating for the functional consequences and while not all were theoretically inspired, their outcomes have informed theoretical developments. A variety of intervention techniques have been developed in attempts to remediate neglect; these are summarized in Table 1.

Although there are grounds for optimism, particularly in terms of short-term impairment-based effects for some of the interventions, the range and degree of disabilities borne by many patients remain high and the clinical effectiveness for the different methods in terms of long-lasting functional improvement (i.e., improvement of disabilities or handicap) remains unclear. This is not surprising, given the considerable individual response variation to such interventions and given that neglect is often just one of the several impairments. Moreover, few studies directly contrasted outcome with other interventions at a group level – or even examined for possible additive effects of combining treatments. Notwithstanding these caveats, a recent systematic review using comparative and stringent levels of evidence found that visual scanning training (VST), trunk rotation (TR), or repeated neck muscle vibrations (NMV) when associated with an extensive training program, mental imagery training, video feedback training, and

prism adaptation (PA) offered the best indication of return on rehabilitation. In the case of most interventions, further randomized controlled trials (RCTs) are needed to confirm or qualify existing reports. In conclusion, there is evidence at the level of impairment to encourage further RCTs or well-designed single case studies using meaningful activity levels over longer follow-up periods; however, recognizing that neglect is a very heterogeneous condition, developing and evaluating interventions to treat the condition continue to be a clinical priority.

## Conclusion

Neglect continues to be a fascinating and challenging subject, both concerning cognitive mechanisms and its neural anatomy. Despite its clinical importance, it is the implications for understanding attention, consciousness, and perception that continue to attract neuroscience interest. Research on the functional mechanisms appears to be moving from the description of dissociations in patients' performance to the dissection of the possible component deficits and of their modes of interaction. New, high-resolution imaging techniques are providing evidence relevant to the debate on the anatomical bases of

neglect, shifting the focus from the study of cortical modules to large-scale brain networks. A large explanatory gap still separates the functional and the anatomical descriptions of neglect, but this gap is narrowing.

## Visual Perception

L de-Wit and J Wagemans, University of Leuven (K.U. Leuven), Leuven, Belgium

© 2012 Elsevier Inc. All rights reserved.

### Glossary

**Fourier analysis** A tool developed by the French mathematician Jean-Baptiste Joseph Fourier to determine the spatial frequencies and contrasts of the spatial variations in luminance occurring at different spatial scales and orientations in visual images.

**Functional magnetic resonance imaging (fMRI)** A noninvasive imaging technique that is sensitive to changes in the blood flow within the brain. This technique has been used most predominantly in psychology to localize different cognitive functions to different areas of the brain.

**Gabor patch** A local stimulus with a particular luminance profile, described by a Gabor function, which consists of a convolution of a sinusoidal luminance profile and a Gaussian function. Such a stimulus is characterized by a particular contrast, spatial frequency, and orientation, and is considered ideal to stimulate a single neuron in the low-level areas of the visual system.

**Natural scene statistics** The pattern of visual stimulation that reaches the retina in the real world contains certain statistical regularities. There is increasing evidence that the brain is sensitive to these statistical regularities such that it is designed to most efficiently represent visual information in the context of these natural scene statistics.

**Neuropsychological dissociation** When patients suffer brain damage that effects certain cognitive functions but not others, this constitutes a dissociation. Such dissociations can provide a powerful tool for establishing the functional independence of different aspects of cognition.

**Retina** The surface at the back of the eye that contains light-sensitive cells, which convert photons of light into electrical signals that are conveyed to the brain via the optic nerve. The retina does not contain a uniform distribution of light-receptive cells, rather the highest density of these cells is packed onto a central area of the retina called the fovea.

**Retinotopic map** Visual information is repeatedly represented in a spatially meaningful manner in the human visual cortex. These spatial maps do not reflect a one-to-one scaling between the visual angle separating different stimuli, although stimuli that are adjacent to each other on the human retina will, in general, be represented adjacent to each other on these retinotopic maps.

**Transcranial magnetic stimulation (TMS)** A noninvasive technique for transiently disrupting the neural information processing in a small area of the brain, using a strong magnetic field. It has been used as an experimental rather than a correlational technique to study the neural basis of cognitive and perceptual functions, assumed to induce localized and reversible virtual 'lesions.'

**Visual angle** The distance between visual stimuli is commonly measured in terms of the visual angle that separates these stimuli. To illustrate, two stimuli separated by 10 cm at a distance of 57.5 cm from the eye would be 10° of visual angle apart, while the same two stimuli separated by 10 cm would be separated by 5° of visual angle when located 114 cm from the eye.

*Visual perception* is not an immediately intuitive topic of scientific research. Indeed, as far as our intuition is concerned, vision is nothing more than a question of pointing the 'cameras' of our eyes at whatever attracts our attention, 'et voilà': we see. What reaches the human retina, however, is not a picture that can be directly perceived, but a spatial pattern of light that gets transformed into electrical signals via the retina's photoreceptive cells. For the human visual system, this pattern of stimulation at the retina is of little immediate value. In fact, up to a third of the human cerebral cortex is recruited in order to transform this pattern of stimulation on the retina into signals that are useful in guiding human behavior.

The study of visual perception, therefore, is the study of how the brain can transform the pattern of information on the retina into a meaningful perception of the world. Part of the challenge in developing a meaningful representation of the world from the information that reaches the retina reflects the fact that a lot of information about the world is lost, or becomes ambiguous, in the pattern of stimulation on the retina. One of the clearest examples of the ambiguity of information reaching the retina pertains to the problem of depth.

Our perception of the world automatically and effortlessly appears to us in three dimensions. However, information regarding the distance light travels before reaching the human eye is not directly encoded on the retina: a photon of light traveling 1 m or 1 km before it reaches the eye will stimulate the same cell in exactly the same manner. The visual brain, therefore, has to use numerous heuristics and assumptions in order to recover depth from this information.

Furthermore, the pattern of stimulation is not simply ambiguous, but also vast. Of the more than 2 million nerve fibers that carry information from the retina to the visual system, the brain has to rapidly extract the information that can enable it to act most effectively. Part of the means by which the brain attempts to constrain this problem is via attention, that is, the process of selectively enhancing the features of visual information processing that are most visually salient or the most useful in terms of the current task demand.

Although attention is important, there is a much more fundamental step in solving the problem of visual perception. Indeed, the brain cannot allocate visual attention arbitrarily; it can only enhance the processing of visual information along

certain predefined stimulus properties or features such as color, motion, spatial location, and certain forms of 'objecthood' or perceptual grouping. These 'preattentive' features extracted early within the human visual system highlight the first critical step in visual perception: transforming the massive array of information on the retina into an explicit representation of features that can be used to guide behavior.

### Hubel and Wiesel: Giving Vision Research an Explicit Edge

Hence, the most fundamental step in vision research is to understand how the brain rapidly makes explicit the available information that is only implicitly registered on the human retina. Probably one of the clearest demonstrations of this process, and one of the most seminal findings within vision research, comes from a series of studies by Hubel and Wiesel, in which they recorded the types of stimuli that would activate cells at different areas of the cat visual system. Hubel and Wiesel first recorded from cells in the thalamus, where the optic nerve cells terminate along the geniculostriate pathway from the eye to the cortex. They reported that cells in the thalamus fired when a circular dot was presented to the cat's retina at a particular location. After the optic radiation had conveyed the activity in the thalamus to the first area within the cortex (V1 or the primary visual cortex), however, Hubel and Wiesel found that cells no longer responded to simple dots, but to lines or edges. The information required to generate this sensitivity to edges must have been implicitly present at earlier stages of information processing (i.e., the thalamus and, indeed, the retina). However, it is not until this information is processed to the level of the primary visual cortex that basic features such as edges seem to be explicitly represented via the responses of single neurons.

Hubel and Wiesel's work was groundbreaking and inspired generations of vision scientists after them because it demonstrated that it might be possible to study how the visual system can extract features from the mass of information reaching the retina, which could play a vital role in developing a useful model of the external world that could guide behavior. Understanding exactly how early features (like 'edge detectors') might form a meaningful model of the external world is only a starting point, however. Although edges might seem like an intuitively useful starting point in representing the external world, our perception is not simply populated by edges but by meaningful recognizable objects.

One of the most famous attempts to provide a genuine model of how this transformation (from edges to objects) might take place was provided by David Marr. Some of the specifics of Marr's model have turned out to be incorrect over the last few decades (although it should also be seen to Marr's credit that he specified a model to the extent that it could be falsified). Nevertheless, what will persist as Marr's legacy to vision research is a distinction between different levels at which vision (and indeed any biological information processing system) can be analyzed. Rather than detailing the specifics of Marr's model, this article seeks to clarify the nature of human visual perception by analyzing the extraction of edges early in the visual system in terms of Marr's levels of analysis.

### Edges at Marr's Three Levels of Analysis

Marr argued that the problem of vision could be viewed simultaneously at three different levels. The first of these levels is the computational level, pertaining to the purpose of a particular process: What is the function it performs, what is the input it receives, and what is the output it has to compute? The second level refers to the algorithms that achieve a given purpose and the representations in which their outputs are stored, and the final level pertains to how these algorithms are implemented. Taking the implementation of cells representing particular edges in the early visual cortex as an example, it appears that neurons that encode similar properties (such as the orientation of the edge) to some extent cluster together. Given that neurons are connected together by axons that can vary widely in length, it is perfectly plausible that neurons performing similar computations could communicate with each other without clustering together. Understanding why this clustering of neurons with similar response properties occurs is, therefore, an important question for vision research. Indeed, understanding why neurons with similar response properties tend to cluster together could well have implications for the algorithms those neurons are executing and, indeed, the computations they are attempting to achieve. In this sense, these different levels of analysis undoubtedly constrain and influence each other. Moreover, a full understanding of visual perception should span all three levels of analysis. Nevertheless, we feel Marr's framework provides a useful means of breaking down the problem of visual perception, at least for didactic purposes.

#### Edges: Computation Level

We stated earlier that Hubel and Wiesel's work highlighted how edges could be explicitly decoded from the response properties of single neurons in the primary visual cortex. This statement requires some qualification, however, because there is in fact a wealth of evidence to suggest that even when single cells in the primary visual cortex might respond to the presentation of an edge, it does not mean that a perception of an edge is explicitly available to the organism as a whole. One recent source of evidence for this fact has been provided by advances in fMRI analysis techniques in the context of subthreshold visual perception. Using these new techniques, Haynes and Rees have demonstrated that even when the pattern of information in the primary visual cortex is sufficient to decode that an edge of a particular orientation has been presented, it does not mean that that edge will be seen by the participant. Indeed, Haynes and Rees found that they could decode the orientation of a rapidly presented stimulus without the participant ever becoming conscious of that stimulus.

This highlights that, while the primary visual cortex seems to be responsible for making explicit certain forms of information that are only implicit on the retina, it does not mean that those representations will be consciously available to us. This brings us to an important possibility: as far as the computational purpose of human visual system is concerned: seeing or conscious perception might only be part of the picture.

Milner and Goodale have argued exactly this point. More specifically, they have argued that a lot of visual processing does not serve our conscious perception of the world, but

enables us to guide manual actions to visual stimuli. Milner and Goodale's argument for this distinction between vision for perception and vision for action is seen most clearly in their case study of the patient DF. After suffering a rare form of brain damage following carbon monoxide poisoning, this patient showed a very striking dissociation: when presented with a slot at a particular orientation, she could not verbally report the orientation of the edge, but if given a piece of card to post through that slot, she was able to do so with virtually perfect accuracy. Thus, although this patient was not able to consciously report the orientation of a specific edge, she could nevertheless use that information to guide her manual actions. Milner and Goodale contrasted her performance with that of patients suffering from optic ataxia, who show the opposite dissociation: these patients can report the orientation of an edge, but they cannot correctly calibrate manual actions based on the orientation of that slot. By providing additional evidence that the processing of oriented edges is preserved in DF's primary visual cortex, Milner and Goodale have demonstrated that in her brain these edges can only be used for the purpose of guiding manual actions and not for informing conscious perception.

Milner and Goodale mapped these different functions of vision for conscious perception and vision for action to a previously characterized anatomical divide between the dorsal (upward) and ventral (downward) streams that visual information can follow after its entry into the cortex at the primary visual cortex. Ungerleider and Mishkin had already argued that these streams played distinct functional roles, but in contrast to Milner and Goodale's model, they argued that the ventral stream was responsible for identifying what a stimulus was and that the dorsal stream was responsible for representing where a stimulus was (the *what* vs. *where* model). Milner and Goodale argued instead that what and where processing is a property of both streams, but that these properties are extracted for different purposes.

The extent to which dorsal stream areas contribute solely to vision for action (and ventral stream areas to vision for conscious perception) is, however, still unclear. Indeed, this controversy partly reflects the fact that even within Milner and Goodale's model, a strict distinction between the two streams is unlikely: to some extent they must interact such that we can choose to act (using the dorsal stream) upon an object we have recognized as important (via the ventral stream). Indeed, selecting an object for action also seems to be integrally linked to (if not identical to) the allocation of attention (thought to be controlled in part by the dorsal stream) and can, therefore, influence what we see. Thus, understanding when these processes act separately and when they need to interact in the healthy human visual system is an important aim of current vision research. Nevertheless, Milner and Goodale's work highlights that even for a simple property like an edge, vision does not appear to have one ubiquitous function. Rather, the representation of an edge is exploited by different parts of the visual system for very different functions.

### Edges: Algorithm and Representation Level

What Hubel and Wiesel demonstrated was that a particular cell in the primary visual cortex would respond vigorously when

presented with an edge at a certain location. It is intuitive to assume, therefore (and we have, as a simplification, assumed above), that this cell represents a form of 'edge detector.' That is to say, what the firing of this cell represents is an edge. Later work has complicated this interpretation, however, in at least two ways.

The first comes from work that highlights that cells in the early visual cortex might be representing much more complicated features than physical edges. Indeed, von der Heydt and colleagues found neurons in V2 that responded to subjective or illusory contours where no physical edge is present, such as those in the Kanizsa triangle shown in [Figure 1](#). Furthermore, additional work by von der Heydt and colleagues has revealed that some cells in V2 are also sensitive to a property called border-ownership. Border-ownership pertains to the ambiguity of which surface (on either side of an edge) causes (or owns) that edge. Taking the horizontal edge of the upper-left pacman in [Figure 1](#) as an example, the black side can be seen to own the edge (i.e., a black pacman on a white background) or the white side can be seen to own the edge, thus resulting in the subjective perception of a white triangular figure on a black circle. The fact that the response of these neurons is modulated by context and figure-ground organization highlights their functional role in the interpretation of the input, which is not simply the signaling of a black-white luminance transition. A recent neurocomputational model by Kogo and colleagues has clarified this fundamental aspect of 'edge detection' and the role it plays in the context of illusory contours, border-ownership, figure-ground organization, occlusion, and surface filling-in, and highlights how seemingly higher level properties (such as surface and depth perception) play a primary role in the interactions between local edge signals to determine border-ownership.

The second complication comes from the fact that although these cells are sensitive to edges, it does not mean that we can assume they are edge detectors. These cells might reveal

**Figure 1** Kanizsa triangle.

edge-like sensitivities only because they are, in fact, encoding a closely related but distinct representation. Indeed, work following Hubel and Wiesel showed that although a given cell would fire to a particular edge, it would respond even more vigorously if presented with an oriented Gabor patch of a particular spatial frequency. Coupled with behavioral work suggesting that the early vision system might contain a range of spatial frequency channels, this finding was taken to suggest that what was being represented in the primary visual cortex was not an intuitive unit such as an edge but a Fourier transform of the information encoded on the retina. More recently, computational models have been used to argue that the representations within the primary visual cortex represent the most efficient way of encoding, at a small scale, the information reaching the retina, given the nature of natural scene statistics.

In general, this debate highlights that there is a large step between mapping the neural sensitivity of a neuron (or indeed an area of the brain revealed by fMRI) and modeling the actual nature of the representations maintained by that area of the brain.

### Edges: Implementation Level

Whatever the exact nature of the algorithms and representations within the primary visual cortex, these units are sensitive to a number of properties, such as the orientation of the stimulus and the location of stimulus presentation. These orientation and location sensitivities tend to cluster together on the cortex such that neurons sensitive to similar properties are located close to each other. In the case of orientation, for example, neurons with the same orientation preference cluster together into units about the size of a square millimeter, known as orientation columns, with bordering orientation columns being organized into a sort of pin-wheel structure. Why this should be the case is not necessarily clear.

The spatial sensitivity of early primary visual neurons is also clearly organized. In fact, the spatial arrangement of neural sensitivities forms what is called a retinotopic map, such that stimuli that are presented close together are also represented closer together on the cortex. This retinotopic map is by no means a one-to-one correspondence with the spatial pattern of information that reaches the retina. Indeed, like the famous homunculus representing the motor and sensory sensitivities of our physical body, this retinotopic map devotes a larger area of representation to the most critical part of high-acuity vision that is provided by the densely packed receptors of the fovea (an overrepresentation that is referred to as the cortical magnification factor). Perhaps in contrast to orientation sensitivities, it might seem intuitively logical that information should be arranged in a spatially meaningful manner. Such an implementation format is by no means necessary, however. A computer, for example, can store the color values of a given pixel in a bitmap at completely random locations in its memory. Indeed, if a curious engineer was exploring the sensitivities of different memory locations on a computer's hard drive, she would be astonished if she found that the physical locations representing the color values of different pixels maintained the spatial arrangement of those pixels in the image. This different pattern of implementation between human visual systems and computer memory undoubtedly points to a very different

means of computing and representing spatial location. Nevertheless, exactly why different visual properties (orientation or spatial location) cluster together is not truly understood. Importantly, this clustering is far more than a property of the primary visual cortex: throughout the human visual cortex, it appears that neurons that do similar things (e.g., represent color, faces, or motion) seem to cluster together into distinct areas. This pattern of clustering is one of the most prominent features of the manner in which visual representations seem to be implemented in the brain, and leads to a distinctive view of the human visual system as a modular and hierarchical system. Indeed, it also raises some interesting behavioral consequences and computational challenges, which might never have occurred to us as challenges, regarding how the representations in these distinct areas of the brain can combine to underlie the apparent unity of conscious visual experience, as discussed next.

### The Visual Brain as a Modular and Hierarchical System

Earlier in this article, we began to build up a picture of the manner in which the visual brain seems to be divided into functionally distinct subunits, which form part of a modular and hierarchical system. For example, we discussed the primary visual cortex's sensitivity to small edges and how they play a functional role in the coding of figure-ground organization and shape perception. In addition, we saw that the anatomical division between the dorsal and ventral streams has been argued to reflect a distinction between vision for action and vision for conscious perception, respectively. Within the ventral stream, there are, in fact, further functionally distinct areas that could be considered. Distinct functional areas have been suggested for a host of visual properties (shape, color, motion, texture) and object types (faces, body parts, scenes, tools).

Focusing on the coding of shape, a hierarchy of layers have been identified, whereby areas with increasing receptive field sizes (V1, V2, V4) code increasingly larger parts of objects (line segments, angles, corners, junctions, etc.) and eventually converge onto areas within the inferotemporal cortex (IT) in the monkey brain and the lateral occipital complex (LOC) in the human brain, where shapes and objects are coded. In parallel work in macaque monkeys and humans, by combining psychophysics with single-cell recordings and fMRI, Kourtzi et al. have demonstrated that the lower areas contribute to the perceptual grouping of edge fragments into shape percepts and Op de Beeck et al. have demonstrated that the activity in IT and LOC reflects the perceived similarity between shapes.

The apparent unity of our conscious experience would surely never lead us to the intuition that the shape of an object might be processed distinctly from the color or motion of that object. The distinct manner in which different visual features are processed can, however, influence our behavior in extreme circumstances. Anne Treisman, for example, showed that when presented with very brief images of colored shapes, participants will often misattribute the colors with the wrong shape. Furthermore, these illusory conjunctions have also been demonstrated for stimuli presented continuously to a patient with occipital-parietal damage. This patient is correctly able to identify certain motion directions, colors, and shapes but is

unable to correctly report which of these features correspond to the same object.

One might assume that after distributing the processing of different features to different areas of the brain, there would be a further area of the brain in which all these different features are represented together. However, the search for such an integration center within the brain has so far proved unsuccessful. Indeed, the first clues into the modular nature of visual information processing came from studies with patients with strange but specific changes in conscious perception. One patient might lack an ability to perceive color, for instance, or another motion. It seems quite possible, therefore, for the rest of vision to function almost as normal even after losing one module.

Although there is no one specific area of the cerebral cortex that seems to be crucial for visual processing to reach awareness, there is a network of areas associated with the control of attention, and damage to these areas can have a profound influence on conscious vision for all visual properties. For example, when damage to one of these attention control areas occurs on the right side of the brain, a syndrome called neglect is often observed. Neglect patients quite literally neglect and fail to report stimuli appearing in their left visual field. The association between attention control areas and alterations to conscious processing has led to the suggestion that the allocation of attention might be, in some sense, synonymous with the conscious experience of a particular stimulus.

However, a one-to-one association between consciousness and attention is not supported by a host of behavioral, neuropsychological, and fMRI studies. In one early example, Kentridge et al. studied the potential allocation of attention to unseen stimuli in a blindsight patient. Blindsight patients show quite a remarkable dissociation in that they are able to guess certain stimulus attributes, sometimes with a very high accuracy, for stimuli they claim that they cannot see. Kentridge et al. employed a common means of attracting spatial attention and found that when stimuli were cued with some form of flash at the location of a target that was to be discriminated, the patients would still not become conscious of the target, but their guessing rate would improve. This result, like many others of its kind, highlights that, although attention might play an important role in determining the contents of conscious visual perception, the allocation of attention cannot in and of itself be seen as sufficient.

### Interactions in the Visual Hierarchy

The processes that determine what we see, therefore, involve a combination between functional specific areas and more general areas that serve to allocate processing resources. However, the processing of a given stimulus and indeed the allocation of attention to a given stimulus, do not appear to be sufficient for that stimulus to be consciously perceived. What then is required for explicit visual perception to take place? A number of researchers have argued that the answer to this question lies in the extent to which a particular stimulus is 'fed-forward' both within the visual system, and within the brain. If we take visual form (or shape) information as an example, we have already seen that information at early stages of the visual

system, such as orientation sensitivity within the primary visual cortex, is not sufficient to lead to conscious awareness. Furthermore, not only is information in the early areas not sufficient to lead to conscious awareness, activation in higher areas is often more closely related to what people actually see.

One important means of evidencing this fact centers on the study of bistable stimuli. With bistable stimuli, the same sensory input is able to support two different perceptual interpretations. A famous example of this is the Rubin face-vase illusion. A more commonly employed paradigm for studying bistable perception, however, exploits the fact that when different stimuli are presented to each eye, the brain enters into a state of conflict between the two images, called binocular rivalry. In binocular rivalry, the brain is unable to meaningfully combine the information coming from each eye and so continually switches between a percept that is based on what is presented to one eye or the other. In this situation, therefore, although the sensory input remains the same, the brain continues to switch perceptual state. Hence, this paradigm offers a powerful tool to ask which areas of the brain are more closely related to purely sensory processing, and which areas are more associated with our conscious perception of the world. In this respect, both fMRI in humans and single-cell recordings with monkeys have shown something of a progression from early to late areas becoming increasingly related to the reported perceptual state.

Binocular rivalry is, of course, a very peculiar form of perception induced under very unusual sensory conditions. There are, however, other examples suggesting that the later stages of visual processing are more closely related to explicit perception. For instance, Williams et al. have employed recently developed pattern classification approaches to fMRI analysis to show that when participants are performing a difficult discrimination task (in which the participants make many errors), the pattern of activation in higher areas such as the LOC is more directly correlated to the participants' performance than the pattern of activation in early areas such as the primary visual cortex.

Despite the evidence that visual representations become more closely related to perceptual performance in this feed-forward sweep, there is also evidence that the feedback of information might be critical to that information being consciously perceived. This theory has been voiced most explicitly by Victor Lamme, who has argued, on the basis of single-cell recordings, that in order for figure-ground relationships to be perceived these relations have to be fed back to the primary visual cortex. Indeed, although we have emphasized above that perceptual decisions seem to be more closely related to the representations developed in higher areas of the brain, it is becoming increasingly clear that perceptual decisions made at higher levels of processing are fed back to primary visual areas. Thus, in binocular rivalry, although higher areas are more closely related to the perceptual state of the organism, it is not the case that early representations merely reflect the sensory input to the eyes. In fact, fMRI studies and single-cell recordings have demonstrated that some early representations are sensitive to the perceptual state of the organism.

Compelling evidence for feedback comes from work by Scott Murray and colleagues, in which they demonstrated that size constancy scaling effects are evident in the primary

visual system. Size constancy refers to the fact that our perception of size is not simply dictated by the size of stimulation reaching the retina (which changes continuously with viewing distance) but by the brain's interpretation of the stimulation on the retina in the context of the perceived depth. Before the size of a particular stimulus is perceived, therefore, the brain first has to work out the depth of that item, and then scale its size such that objects that are far away are in fact perceived to be larger than objects projecting an identical visual angle on the retina that are perceived to be closer. Rather surprisingly, Scott Murray et al. showed that the representation of size in the retinotopic map of the primary visual cortex did not simply reflect the retinal size of the object, but the scaling induced by two-dimensional depth cues. This suggests that the represented size of a particular stimulus on the primary visual cortex is altered by feedback to reflect the perceived size.

Of course, the critical question is: What is the role of this feedback? Are higher level interpretations merely fed back as a by-product of the higher representation, or does this process play a critical role in determining what we see? Work by Pascual-Leone and Walsh using TMS suggests the latter option may indeed be the case. Pascual-Leone and Walsh exploited the fact that TMS to the motion-sensitive area MT could lead to a perception of motion to ask whether this motion perception would be critically contingent upon feedback to earlier stages of the visual system. Rather strikingly, they found that stimulation to MT would be less likely to lead to a conscious percept if it was followed by TMS to earlier visual areas such as the primary visual cortex. Importantly, the optimal time at which TMS to the primary visual cortex would disrupt the percept following MT stimulation was not simultaneous with the MT stimulation, but fell within a critical time window (about 15–50 ms) after it. The fact that TMS to a lower area influences the ability of TMS at a higher area to lead to awareness implies that activation at the higher area has to be fed back to the lower level before it could lead to a conscious percept.

On the one hand, therefore, it seems that higher level representations seem to correlate more directly with what is consciously perceived; on the other hand, there is increasing evidence not only that the higher level representations are fed back to early areas, but also that this feedback seems to play a critical role in certain circumstances. One model that potentially reconciles these roles for feed-forward and feedback sweeps is provided by Hochstein and Ahissar's reverse hierarchy framework. In this model, they argue that visual perception automatically operates in a feed-forward manner to extract the general gist of a scene, and that our conscious perception is by default based on this 'forest before trees' level of representation. If further details are required, however, then fine discriminations can be achieved by a process of feedback that can extract the details, making up this percept at lower levels of perception.

### Active Vision

Hochstein and Ahissar's reverse hierarchy model very clearly emphasizes the role of internal computations in determining how the visual system extracts the information required to achieve a particular task. Findlay and Gilchrist would

characterize this approach to visual perception as a form of 'passive vision,' which they contrast with the 'active vision' perspective. Active vision starts from the observation that one of the clearest limiting factors in determining what we can perceive is not our ability to computationally analyze sensory input, but the low quality of most representations on the human retina. More specifically, they highlight that only the central area of the retina, known as the fovea, contains a sufficient density of receptors to perform many critical tasks. A key example here is that of reading. Although it might appear to us as if a full page of text is available in front of our eyes, well-controlled tests highlight that we are, in fact, only able to process the text a few degrees of visual angle around the fovea. Findlay and Gilchrist argue that this fundamental constraint in terms of how visual information enters the visual system necessitates the use of eye movements to solve even the most basic of everyday visual tasks.

The active vision perspective holds that while internal processes must obviously play a role, our understanding of vision will be advanced more rapidly if we focus on what they see as the most important means by which humans ensure they can extract the maximal amount of information from any given visual environment: eye movements. An important piece of evidence that motivates the active vision perspective comes from the phenomenon of change and inattention blindness. Change blindness refers to the fact that if an image is changed during an eye movement it can often be very difficult to spot very large-scale changes. The same effect can also be elicited without eye movements if some form of visual transients is added (e.g., the 'mud-splashes' paradigm), so that the transient of the to-be-spotted change does not 'pop-out.' In inattention blindness, the participants' attention is explicitly attracted to a task at certain locations in a visual scene (e.g., counting the number of basket-ball passes) resulting in stimuli at other locations going unseen (even if the unseen stimulus is as bizarre as a man in a gorilla costume). These demonstrations are seen within the active vision perspective as evidence that, although we may feel as if we can 'see' everything in front of us, this feeling is in fact an illusion, and the brain only represents a small amount of the information we receive. Indeed, this argument is often followed by the point that, in the real world, maintaining a representation of everything appearing in front of us is of little value because if we need to access that information we can simply direct the high-acuity fovea of our retina to that location and 200 ms later our visual system will receive all the stimulation it needs to extract the needed information.

Although the structure of the eye and the strategy of sampling the visual environment are undoubtedly critical factors in determining the contents of visual perception, we should avoid throwing the baby of visual representations out with the bathwater of passive vision. An eye-movement strategy, for instance, would clearly be very ineffective if it was not targeted based on the representations extracted from the current fixation. Moreover, in the change blindness paradigm, although changes are not at first consciously detected, it is often the case that there are other aspects of behavior (such as saccade landing location) that are clearly sensitive to the change, suggesting that the details of the scene are represented in the visual system at some level. Indeed, the latter finding accords with Hochstein

and Ahissar's view that the details of visual representations are not immediately accessible for conscious report but that they are nevertheless still represented at some level within the visual system.

## Concluding Comments

We started by noting that, as far as human intuition is concerned, vision is associated with our eyes, and not with our brains. If given the pattern of stimulation on the retina, however, even the most sophisticated computer programs are seriously taxed by the most basic of visual recognition tasks that the human brain performs without conscious effort. We have argued that the foremost function of vision is to make rapidly available, information that is only implicitly registered on the retina. The brain appears to solve this problem by breaking it down into distinct components such that different stimulus dimensions are extracted at different scales and for different functional purposes in different areas of the brain. This division of the process of visual perception results in a very particular modular and hierarchical structure to the human visual system, and explicit conscious vision might be achieved via feed-forward and feedback mechanisms within this hierarchy. Although extracting meaningful information from what we are currently looking at is the foremost function of vision, the limited distribution of information received on the retina means that functional human vision will only be understood by addressing the question of how we use that information to decide where to look next.

### Glossary

**Lifestyle** The integration of decisions in the realms of vocational, personal, and family relationships, and leisure pursuits that result in the attainment of an over-arching purpose or meaning in one's life.

**Vocation** One's life work entailing both paid and unpaid employment that satisfies survival as well as self-esteem, social, and spiritual needs.

**Vocational decision making** A process that not only encompasses making educational, occupational, and employment choices, but also involves making a

commitment and carrying out the actions necessary to implement these choices.

**Vocational development** The implementation of a series of integrated vocational decisions, through the life span, that provide a guiding direction to one's life work.

**Vocational problem solving** A complex set of thought processes involving the acknowledgment of a state of vocational indecision, an analysis of the causes, the formulation of alternative courses of action to achieve a state of decidedness, and the choosing of one of these alternatives.

Vocational choice may be defined in terms of the outcome of a decision-making process involving the consideration of educational, occupational, and employment alternatives at any point in time during the life span with the ultimate aim of attaining a satisfying and meaningful life. An appropriate vocational choice may be considered as one in which there is a high probability that an individual will be able to successfully perform the work and to derive a sense of personal satisfaction. Thus, the decision-making process leading to a choice involves two important aspects: (1) the cognitive and affective processes involved in making a vocational decision at any point in time, and (2) an estimation of the likelihood that a choice will result in occupational success and accomplishment as well as a satisfying and meaningful life. The text that follows examines the act of choosing a vocation from historical, psychological, and social perspectives.

### Overview and Historical Perspectives

Early accounts of the process of choosing a vocation may be traced to the turn of the century when Frank Parsons wrote in his 1909 book *Choosing a Vocation* that there were three key factors in making a career choice: a clear self-understanding, a knowledge of occupations, and the ability to draw relationships between them. He reasoned that if individuals possessed these attributes, not only would they make more effective vocational choices, but that society in turn would be better served by greater efficiency in matching persons to appropriate kinds of work. Since then, this three-dimensional model has provided the fundamental framework for the investigation of how individuals make vocational choices.

Several principal lines of inquiry emanated from this early work of Parsons. One was directed toward helping individuals acquire self-understanding through the development of measures of interests such as the Kuder Preference Record in 1946 and the Strong Vocational Interest Blank (SVIB) in 1943. The original Kuder required individuals, using a pin-punch, to choose the most-liked and least-liked activity from a series of

triads. The results of this interest inventory provided relative estimates of preference in seven areas of interest including science, computational, art, music, literature, social, and persuasive. The SVIB, on the other hand, compared one's likes and dislikes for activities to the likes and dislikes of individuals successfully employed in a variety of occupations. Since the development of these early prototypes, more refined assessments have recently evolved to relate abilities, interests, and values to occupations such as the Kuder Career Planning System, which includes interests, skills, and values assessments, the Strong Interest Inventory, and the Self-Directed Search. This direction of inquiry further led to the development and implementation of a variety of computer and web-based career guidance systems such as CHOICES Planner, DISCOVER, the Focus Career Planning System, and SIGI<sup>3</sup>.

A second line of investigation sought to help individuals to become more knowledgeable about the world of work. Occupational classification systems, traced back to the US Census Bureau's classification system in 1820, were developed to facilitate the storage and retrieval of information about related occupations. Modern classification systems include the North American Industry Classification System (NAICS), O\*NET, and the Standard Occupational Classification System. Computer-assisted career guidance systems typically utilize these classification systems in their databases and are able to link internally the results of the assessment of abilities, interests, and values to occupations.

A third line of inquiry has sought to develop psychological and sociological theories concerning how self-knowledge and occupational knowledge are integrated in the process of making vocational choices. These theoretical approaches may be categorized into three domains. The matching approach sought to identify empirical and rational linkages between measures of personality characteristics and attributes of occupations to derive possible occupational alternatives for further consideration. Cognitive information processing (CIP) is a comprehensive theoretical system that provides a framework for the sequential process of making vocational decisions. And finally, a third domain encompasses important affective,

cognitive, developmental, cultural, social, and spiritual factors that exert an influence on the decision process. These three theoretical domains will be presented in terms of their principle assumptions and propositions, most important concepts, and how the respective theoretical domains may be applied to help individuals make satisfying and meaningful vocational choices.

### Vocational Choice as a Matching Process

Vocational choice as a matching process entails the derivation of empirical and rational estimates of the congruence between measured personality factors and occupational characteristics. The goal of this approach is to provide precise information about one's self or occupations that will assist individuals in identifying appropriate occupational alternatives for further consideration in the vocational decision-making process. A fundamental assumption is that the greater the correspondence between personality characteristics and the requirements of an occupation, the greater the likelihood for attaining successful work performance and satisfaction. Important personality characteristics typically used to make predictions of success include cognitive abilities, scholastic aptitudes, interests, values, and special cognitive or psychomotor abilities. This topic is discussed elsewhere in this encyclopedia. To illustrate this principle of using measures to make the best estimates of matches between persons and occupational environments, three types of matching approaches are described, trait-factor, the Holland's RIASEC Theory, and computer-assisted career guidance systems.

#### Trait-Factor Theory

According to Robert Lent, "trait-factor models have contributed greatly to the understanding of career behaviors and to career counseling by highlighting relatively stable features of persons and environments that, if appropriately matched, are likely to lead to satisfying and satisfactory choices." From the standpoint of trait-factor theory, personality may be considered as comprising a set of theoretical constructs or dimensions that exist along a continuum from low to high. Important personality dimensions in vocational choice relate to cognitive abilities, interests, values, and cognitive and psychomotor skills. An awareness of the extent to which certain dimensions are possessed allows individuals the opportunity not only to compare the strengths of their personality characteristics relative to others, but also relative to members of norm groups as well. Such information facilitates the acquisition of self-knowledge, one of the cornerstones in the Parson model. It also provides more precise information with which to estimate the degree of match between individual characteristics and the requirements of an occupation.

A trait may be defined as an enduring or persisting personality characteristic that provides a means by which individuals can be distinguished from one another, and is manifested consistently across a wide range of circumstances or situations. A factor is considered the operational form for measuring the existence of a trait such as an intercorrelated set of test items comprising a scale on an aptitude test or an interest inventory.

Further, while traits were at one time assumed to be enduring neurologically based structures, many psychologists now believe that traits are highly influenced by learning and that they are task or situation specific. Nevertheless, while the nature–nurture aspects of traits are still unresolved, the kinds of human traits that play an important role in making vocational choices – such as interests, aptitudes, abilities, and values – do appear to be relatively stable over time.

There are several key assumptions or propositions in relating trait–factor theory to vocational choice. One is that each individual possesses a unique and stable pattern of traits that can be measured empirically. Second, for each occupation, there is a unique pattern of traits required of individuals to perform the critical duties and tasks of an occupation successfully. Third, the closer the match between a person's traits and the trait requirements of an occupation, the greater the likelihood of successful job performance and personal satisfaction. Thus, given these assumptions, if measures of traits could be developed with sufficient validity and reliability, individuals could use such information about their abilities, interests, and values to formulate appropriate occupational alternatives and to make more informed vocational choices. Measures such as the Kuder Career Planning System, the Strong Interest Inventory, the General Aptitude Test Battery, and card sorts can assist individuals in acquiring accurate appraisals of important job-related traits. A matching approach to vocational decision-making process typically involves a knowledgeable professional or other human services staff members who assists individuals in identifying possible career alternatives, locating relevant occupational information, and in formulating a plan for an occupational search strategy. In some instances, individuals may receive assistance in locating and obtaining appropriate training or job opportunities. Though some individuals in the field of vocational psychology have suggested that matching approaches are no longer viable in today's uncertain and changing global economy, and research results have been modest in their predictions, these approaches continue to play a significant role in vocational counseling interventions and practice. John Holland's work, one of the most widely researched and applied examples of matching theories, is discussed in the next section.

#### John Holland

The Holland typological theory relates personality characteristics to occupations on the basis of the old adage, "birds of a feather flock together." He extended the work of the trait and factor theorists by drawing empirical (in addition to logical) relationships between personality traits and selected occupations of which over 1300 are listed in the Occupations Finder that accompanies the Self-Directed Search. The principal theoretical presupposition undergirding Holland's work is that when individuals are classified on the basis of measured traits as belonging to a given occupational category, they can be linked to many occupational alternatives within that category. The empirical matching process enables individuals to quickly identify themselves as belonging to an occupational subgroup and to develop an array of corresponding occupational alternatives for consideration. There are several key assumptions on which Holland's theory is based:

- Most individuals can be placed into one of the six personality types: Realistic, Investigative, Artistic, Social, Enterprising, or Conventional (RIASEC). The relationship among these six personality types is portrayed in the form of hexagon (see [Figure 1](#)) in which adjacent occupational groups on the hexagon have more in common in terms of personality characteristics than groups that are opposite one another.
- There are six occupational environments corresponding to the six personality types. According to Holland, people tend to surround themselves with others like themselves and hence create environments that reflect the type they are. Thus, R-type personalities are more congruent with R-type environments than with S-type environments.
- An individual's behavior is determined by the interaction between one's personality and the environment. Thus, career phenomena such as vocational choice, career development, job satisfaction, and career advancement is influenced by the extent to which there is a match between personality characteristics and occupational environments.
- The degree of differentiation affects the strength of the match between person and the occupational environment. Differentiation refers to the extent to which one or two interests are clearly different from the others. When an individual with a high degree of differentiation is in an environment congruent with the dominant code (S, for example) and less like others (e.g., R, C, or I), the greater the likelihood of satisfaction in that environment.

The six personality types and environments portrayed in [Figure 1](#) may be described as follows:

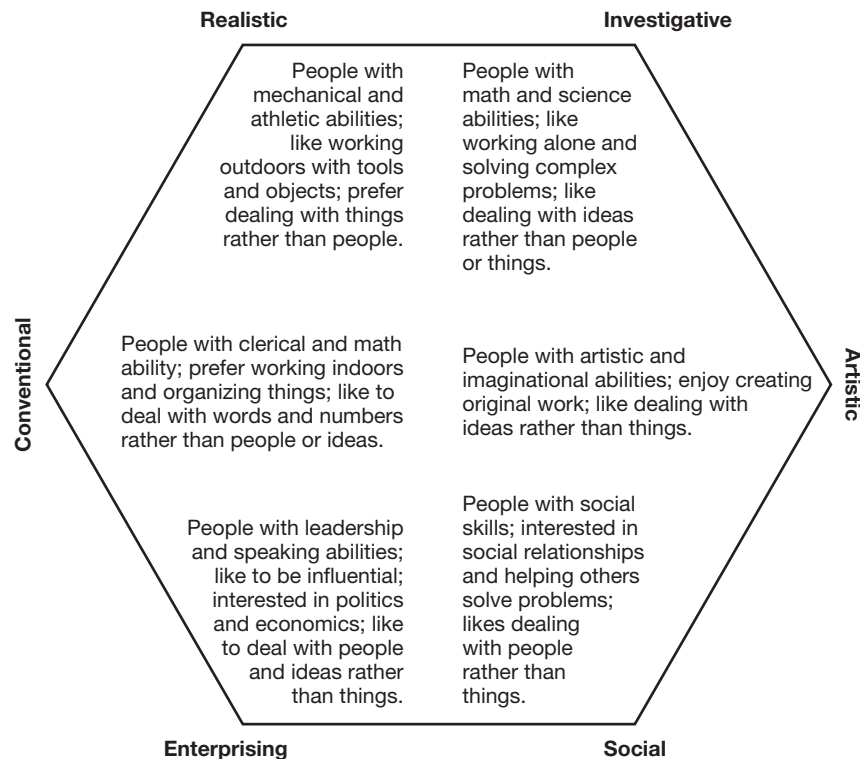

Realistic (R) personalities enjoy working with their hands, tool, machines, and they possess mechanical and athletic abilities, whereas corresponding R-type environments require manual, technical, and mechanical competencies, interaction with machines, tools, and objects, and encompass occupations such as automobile mechanic, surveyor, farmer, or electrician.

Investigative (I) people enjoy scholarly and intellectual activities and have mathematical and scientific interests, while the investigative environment demands systematic observation of physical, biological, or cultural phenomena as in biologist, chemist, medical technologist, or anthropologist.

Artistic (A) persons prefer ambiguous, free, unsystematic activities that lead to the creation of art forms or products, whereas this environment may be portrayed as unstructured and encouraging individuals to perceive the world in complex, unconventional and flexible ways as in writer, musician, artist, interior decorator, and stage director.

Social (S) personalities like to help and understand others and prefer activities that entail informing, training, curing, developing, or enlightening people, while the social environment demands manipulation or the development of others to achieve social goals as in teacher, psychologist, social worker, or the clergy.

Enterprising (E) individuals prefer activities that entail persuading others to attain organizational or economic goals and possess leadership and speaking abilities, while the corresponding environment demands the manipulation of others to attain certain economic or organizational goals as in salesperson, buyer, manager, sports promoter, and television producer.

**Figure 1** RIASEC hexagonal model. Reproduced with special permission of the publisher, Psychological Assessment Resources, Inc., from *Making Vocational Choices*, 3rd ed., Copyright 1973, 1985, 1992, 1997 by Psychological Assessment Resources, Inc. All rights reserved.

Finally, Conventional (C) people prefer activities involving the systematizing and manipulation of data, the operating of data processing equipment, and word processing machines, while the conventional environment requires the manipulation and systematizing of information as in court reporter, financial analyst, title examiner, or tax accountant.

Holland's typological theory has been operationalized through the development of the Self-Directed Search (SDS), a measure that helps individuals determine their three highest personality codes (e.g., SAE or RIE), and the Occupations Finder, a resource that helps individuals locate occupations consistent with their three-point code. The three-point codes of many occupations were derived empirically from having job incumbents take the SDS, while the three-point codes of other occupations were derived from expert consensus and job analysis. Holland and Gottfredson's *Dictionary of Holland Occupational Code* provided an even greater level of analysis for more than 12 000 occupations.

The compelling nature of Holland's theory lies in its parsimony as a theory, the ease of administration and scoring of the SDS, and the high degree of efficiency in locating potential matching occupations listed in the Occupations Finder. The predictive validity of the three-point code in terms of training performance and job performance and satisfaction varies considerably across the codes and occupations. Therefore, in vocational choice, the primary use of the SDS and the Occupations Finder should be to assist individuals in expanding their horizons of possible occupational alternatives to consider for further exploration. Following the identification of plausible occupations, individuals can obtain further occupational or educational information that would facilitate the narrowing of options and ultimately arriving at a selection of a vocational choice.

### Computer-Assisted Career Guidance (CACG) Systems

CACG systems continue to serve as a valuable resource for facilitating matching approaches to vocational choice. CACG systems provide an online interactive instructional medium that allows individuals an opportunity to assess some combination of interests, abilities, and values, to conduct a search for potential occupational alternatives, and to gain access to built-in career libraries of educational and occupational information. Some CACG systems may also include modules on such topics as career decision-making strategies, developing action-plans to implement a choice, the assessment of needs, an orientation to world-of-work information, financial aid, assistance in coping with constraints that impede vocational choice, and strategies for career decision making. Examples of some of the more prominent comprehensive CACG systems are annotated as follows to provide a representation of the technological capabilities and features of these systems:

DISCOVER, developed by the American College Testing (ACT) Program, includes a series of assessments that cover career-relevant interests, abilities, and job values. The assessment results are designed to help individuals explore career options that are a good match for them. DISCOVER incorporates ACT's Work-of-Work Map to organize occupations into six clusters, parallel to Holland's Hexagon, which further assists users in matching self-knowledge to options that fit

them best. DISCOVER is based on a comprehensive, developmental guidance process which can help users identify their strengths and needs, make good career decisions, and build a plan based on their personal profiles. The system offers current databases of occupations, college majors, schools and training institutions, financial aid/scholarships, and military options. Users can also learn how to develop good job-seeking skills through effective resumes, cover letters, job applications, and interviewing skills.

SIGI<sup>3</sup> (formerly known as SIGIPLUS) is the third generation of a CACG system that was originally developed by the Educational Testing Service, and is currently managed by Valpar International Corporation. Valpar describes the system as follows: SIGI<sup>3</sup> integrates self-assessment with in-depth and up-to-date career information that is easy to use and provides students and adults with a realistic view of the best educational and career options for their future success. The program introduces users to a decision-making paradigm, allows them to compare jobs using a grid format, offers guidelines for coping with career transitions, taking the next steps to implement career goals, and provides strategies for securing jobs in the area of one's vocational choice.

FOCUS-2, developed by Career Dimensions, Inc., is an online, interactive career and education planning system that combines self-assessment, career exploration, and decision making into one comprehensive program. According to the developer's website, FOCUS-2 helps individuals connect their interests, personality, values, and skills assessment results to identify areas of study and plan their education and career paths. FOCUS-2 includes information on more than 1200 occupations and allows users to compile their results in an online portfolio.

Even though CACG systems possess vast capabilities for the efficient storage and rapid retrieval of information, and contain information about a wide range of occupations and educational institutions, they are generally not recommended as stand-alone instruments to facilitate the making of vocational choices. The research literature suggests that even though individuals seeking career assistance express a strong liking for their experience with these systems, clients still prefer to use them as a helpful adjunct to the career counseling process with a professionally trained career counselor or other appropriately trained human services staff member. Further, the psychometric qualities of the embedded interest and related assessments, as well as the predictive validity of suggested occupations in terms of success in training programs or job satisfaction, are not widely documented with regard to evidence-based practice.

### Vocational Choice as a Decision-Making Process

We now turn from vocational choice as a matching process, which emphasizes the development of measures and technology to increase the precision and capabilities of the person-occupation matching process, to the decision making which focuses on the actual thought processes that individuals might employ in making a vocational choice. The cognitive information processing approach, which builds on earlier vocational decision-making models, is presented to represent this domain of approaches to vocational choice.

### Cognitive Information Processing

Initially, Peterson et al., in their book *Career Development and Services: A Cognitive Approach*, and recently, Sampson et al., in their book *Career Counseling and Services: A Cognitive Information Processing Approach*, introduced from the field of cognitive psychology a comprehensive perspective on vocational choice and career development. The cognitive information processing (CIP) paradigm was initially formulated in works of Newell and Simon in their book *Human Problem Solving* and from other cognitive scientists in the late 1970s. CIP concerns the thought and memory processes related to a career problem, as well as a cognitive strategy in the form of an orderly prescribed sequence of stages to resolve it. Further, in applying CIP theory to the practice of vocational counseling and guidance, the emphasis shifts from helping individuals to make an appropriate choice at a given point in time, to the acquisition of knowledge and cognitive skills to solve vocational problems and to making vocational decisions over time. Therefore, the aim of this approach is to help people become skillful vocational problem solvers and decision makers.

### Assumptions

Some of the key assumptions on which the application of CIP to vocational choice is based include:

- Making vocational choices is a problem-solving activity. A vocational problem is defined as a gap between an extant state of indecision and a desired state of decidedness with respect to career and life goals. Vocational problem solving is defined in terms of an information transformation process in which a series of thought processes are used to arrive at a course of action to remove the gap. Thus, vocational problem solving involves the transformation of information through the recognition of a gap (problem definition), an analysis of its causes, the formulation of alternative courses of action, and the selection of one of the alternatives that represents the most optimal solution. Career problems are exceedingly complex involving an ambiguous cue function, the optimization of solution alternatives, and the lack of certainty that the anticipated outcomes of the choice process will remove the gap.
- The capabilities of vocational problem solvers depend on the availability of cognitive operations as well as knowledge. An analogy can be made to the functions of the computer. Data files represent occupational knowledge and self-knowledge stored in long-term memory, while the programs are cognitive algorithms, also stored in long-term memory, which are used to transform the data into new, and more useful and meaningful forms of information. In this way, relationships between self-knowledge and occupational knowledge are formulated through a series of problem-solving and decision-making algorithms.
- Vocational development involves continual growth and change in knowledge structures. Self-knowledge and occupational knowledge consist of sets of organized memory structures called schemata (singular schema) that evolve over the lifespan. Since both the occupational world and individuals are ever changing, the need to develop and integrate these domains never ceases.
- The aim of vocational counseling and guidance is to facilitate the development of information processing skills. From a CIP perspective, vocational counseling involves providing the conditions of learning that enhance the acquisition of self- and occupational knowledge, and the development of cognitive problem-solving and decision-making skills that are necessary to cope with the inevitable occurrence of gaps between indecision and decidedness that arise in the course of a lifetime.

### Structural attributes of CIP

In order for individuals to become independent and responsible vocational problem solvers and decision makers, certain information processing capabilities must undergo continual development throughout the life span. From an adaptation of the works of Robert Sternberg, these capabilities may be envisioned as forming a pyramid of information processing domains with three hierarchically arranged domains. Two knowledge domains, self-knowledge and occupational knowledge, lie at the base of the pyramid with the decision skills domain placed above it, and the executive processing domain at the apex (see Figure 2).

Information from the respective knowledge domain is combined using the information processing skills of the decision skills domain. These skills, referred to as generic information processing skills, are configured in the form of a recursive cycle (i.e., the CASVE cycle), and they are presented in Figure 3.

They are used as a heuristic in the career decision-making process as follows:

1. Communication (C). Information is received which signals that a problem exists. One then queries oneself and the environment to formulate the gap (or discontinuity) that is the problem. It also entails getting 'in touch' with all components of the problem space including thoughts, feelings, and related life circumstances.
2. Analysis (A). The causes of the problem are identified and the relationships among problem components are placed in a conceptual framework or mental model.
3. Synthesis (S). Possible courses of action are formulated through the creation of possibilities (synthesis elaboration) and the subsequent narrowing (synthesis crystallization) to a manageable set of viable alternatives.

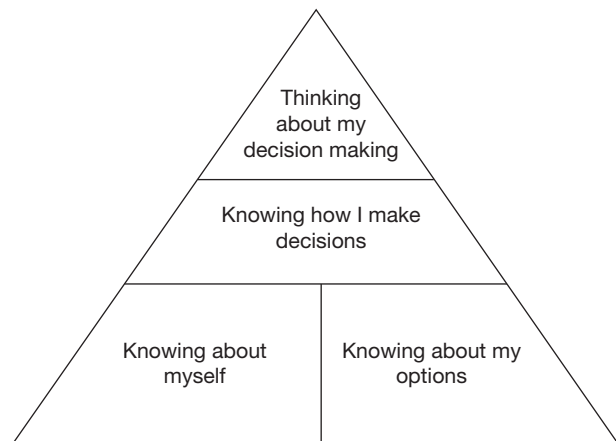

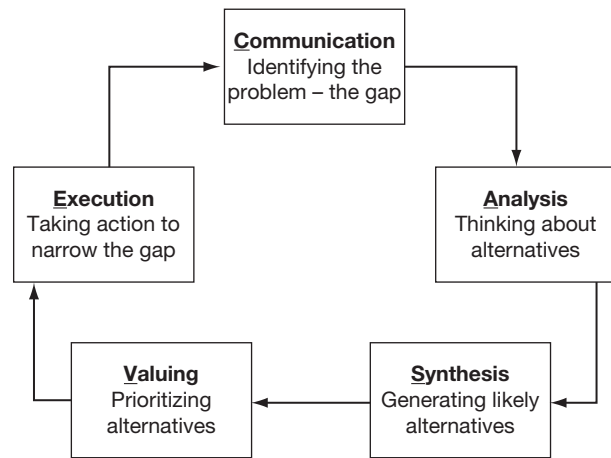

Figure 2 Pyramid of information processing.

**Figure 3** CASVE cycle.

4. **Valuing (V).** Each course of action is evaluated and prioritized according to its likelihood of its success in removing the gap and its probable impact on self, significant others, cultural group, community, and society. Through this process a first choice for a course of action emerges and the vocational problem is solved.
5. **Execution (E).** An action plan is formulated to implement the choice, which becomes a goal for the client. A series of milestones are laid out in the form of means–ends relationship that will lead step by step to the attainment of the goal. Thus, a vocational decision is made when individuals move deliberately toward a goal, such as selecting a course of study, choosing an occupation, or seeking employment in a chosen field.
6. Upon executing the plan, there is a return to the communication phase to evaluate whether the decision successfully removed the gap. If so, the individual moves on to solve succeeding problems that arise from the implementation of the solution. If not, one recycles through the CASVE cycle with new information about the problem, one's self, and occupations identified from the initial passing through the CASVE cycle.

There is yet a set of higher order of cognitive functions that guide and regulate the lower order functions in the pyramid, the executive processing domain. This domain comprises meta-cognitions that (1) control the selection and sequencing of cognitive strategies to achieve a goal, and (2) monitor the execution of a given problem-solving strategy to determine if the goal is being reached. A third vital component of this domain consists of the beliefs, assumptions, and awareness of one's self as a vocational problem solver that are necessary to effectively carry out the lower order functions of the pyramid. Dysfunctional beliefs or invalid assumptions pertaining to any facet of the respective domains will inhibit progress through the CASVE cycle and the development of career problem-solving and decision-making skills. A measure such as the Career Thoughts Inventory can be used to assess the impact of dysfunctional thinking on all components of the information processing pyramid.

A career counseling environment emphasizing self-directed exploration can be developed along the lines of the paradigm to assist individuals in progressing through the respective phases

of the vocational decision process. Self-instructional modules can be made available to assist individuals in progressing through the phases of the CASVE cycle. A comprehensive career resource center (both physical and virtual) that includes occupational information, computer-assisted career guidance (CACG) systems, and related materials, can help individuals clarify interests, abilities, and values, and formulate possible career options once they reach the synthesis phase of the decision cycle. Career advisors and counselors provide assistance in defining and analyzing the career problem, diagnosing one's capabilities as a vocational problem solver, designing individualized learning plans (ILPs) to master components of the pyramid, and achieving mastery of the paradigm so that clients use their presenting problem as an instance in becoming more proficient vocational decision makers. Further discussion on this topic is discussed elsewhere in this encyclopedia.

### Self as an Integrating Factor in Vocational Choice

Self theorists allude to higher-order cognitive processes that transcend such activities as the formulation and consideration of occupational alternatives or the making of specific vocational choices. Psychological constructs such as self-concept and self-efficacy not only provide an integrating force that bears directly on the consideration of occupational alternatives in the making of a vocational choice at any point in time, but they also span successive vocational decisions over the lifespan and give one's work and life continuity and meaning. When individuals possess positive self-concepts or a high degree of self-efficacy, vocational decisions are made as a matter of course in moving through the life span. However, the process of vocational decision making often becomes excruciatingly difficult in the presence of a negative or fragmented self-concept or when one's self-efficacy is low. Theories that emphasize the constructs of self-concept and self-efficacy are presented below to illuminate this important aspect of vocational choice.

### Self-Concept

Over his long career, Donald Super developed one of the most comprehensive theories of vocational choice. However, for purposes of this article, only the components of his theory concerning the role of self-concept are described, which incidentally constitute a major part of his writings. Some of the key propositions of his theory concerning the development of the self-concept include:

- Career development is essentially a process of developing and implementing one's self-concept, or in later writings, self-concept systems. A self-concept is the product of the integration of inherited aptitudes, physical makeup, the opportunity to play various roles, and the extent to which these roles are reinforced by peers, parents, and superiors.
- While the self-concept begins to stabilize in late adolescence, it continues to evolve throughout the life span as a result of life's experiences and making choices.
- The degree of satisfaction people attain from work is in proportion to the degree to which they are able to implement their self-concepts.

In Super's theory, the implementation of self-concepts was thought of as a matching process in which individuals related their perceptions of attributes of themselves to their perceptions of attributes of occupations. This matching process maybe static, focusing on a single vocational choice, or it can be developmental, relating a series of vocational choices to a common integrated theme. The implementation of the self-concept in making career decisions over time enhances the evolution of one's identity. Further, as one's identity develops and becomes clearer and attains a more stable and complex structure, one's self-concept becomes more positive as well.

One of the implications of self-concept theory for vocational choice is that occupational alternatives are viewed with respect to the degree to which one's self-concept varies from positive to negative, or to the extent to which it is developed in terms of its structural complexity. Negative self-concepts often restrict the formation of viable options. For example, individuals may use an interest inventory or a CACG system to generate a list of plausible options, but because of a negative self-concept, they may inappropriately reject many of them.

An immature or undifferentiated self-concept will often result in the inability to discriminate among interests such that either almost all occupations generated by an interest inventory or a CACG system may seem plausible on one hand, or very few seem plausible on the other. Undifferentiated self-concepts may also result in computers producing long, nearly randomly generated lists of occupations without focus. Finally, undifferentiated self-concepts may foster a lack of consistency among vocational choices over time. Thus, when there is no consistent self-referent to guide lower-order decision-making processes, wide-ranging and frequent changes in educational or career aspirations are a common outcome.

Another common occurrence in the vocational choice process is that even if an individual arrives at a first choice of an occupation, a person with a negative self-concept will tend to disconfirm the choice because it is perceived to be unattainable, thus fostering a state of chronic indecision. In the presence of a negative self-concept, group counseling interventions have been found to be effective, such as a job club, where individuals may express their fears and doubts while obtaining social support in the formation and exploration of career alternatives.

In recent years, Savickas has extended Donald Super's theory with regard to a role of self-concept in the implementation of vocational choice, by describing the process as one of career construction. According to Savickas, "careers do not unfold, they are constructed as individuals make choices that express their self-concepts and substantiate their goals in the social reality of work role." Client's vocational choices unfold as they impose their unique meaning on their vocational behavior and occupational experiences. Savickas suggests that the career construction perspective is not designed to replace choice theories that focus on person-environment fit, but rather it helps to integrate diverse segments, and improve career counseling practice. Individual's views about their ability to construct and implement their career goals is closely tied to the notion of self-efficacy which is described in the section that follows.

## Self-Efficacy

Bandura defined self-efficacy expectations as people's judgments of their capabilities to organize and execute actions necessary to attain specific kinds of performances. These expectations influence whether a course of action will be initiated, the amount of effort invested in the action, persistence in attaining the desired level of performance, the amount and kinds of cognitive processing, and the affective reactions when confronted with obstacles. Self-efficacy is viewed as a dynamic aspect of the self-system that is primarily domain specific and interacts with other persons in the immediate environment. The principal proposition of the theory is that accurate and strong self-efficacy expectations are vital to the initiation and maintenance of any goal-directed behavior. Bandura speculated that self-efficacy beliefs pertaining to a task may be shaped or modified by (1) perception of past performance, (2) modeling the behavior of others (3) verbal support or persuasion, and (4) emotional or psychological arousal experienced in the conduct of the task.

Hackett and Betz extended self-efficacy theory into the area of career development proposing that self-efficacy influences career decisions, achievements, and occupational adjustment. Self-efficacy beliefs have been found to be related to other career phenomena including the range of perceived options, educational attainment and persistence, career indecision, work performance, overcoming barriers imposed by gender and race, and the effects of job loss. Additionally, Hackett and Betz have found that self-efficacy is related to the extent to which females pursue traditionally male-dominated academic subjects and occupations. Following their initial work, numerous studies has been conducted that shed light on how self-efficacy beliefs develop, how they are maintained, or how they can be altered through education or therapeutic intervention. Further discussion on this topic is discussed elsewhere in this encyclopedia.

## Social Psychological Perspectives on Vocational Choice

From this theoretical viewpoint, vocational choice is seen as a process heavily influenced by the interaction with important individuals in one's social context. Social cognitive career theory (SCCT), advanced by Lent, Brown, and Hackett, is selected as one of the representatives of this domain of vocational choice theory because it speaks of the influence of background and social factors as well as self-efficacy on the vocational choice and implementation process. Krumboltz' social learning theory, on the other hand, describes how vocational choice is shaped through social learning processes. Finally, Gottfredson's theory of circumscription and compromise provides a developmental perspective on vocational choice.

## Social Cognitive Career Theory

Lent, Brown, and Hackett extended the construct of self-efficacy to formulate a comprehensive path model of career choice and occupational attainment, social cognitive career theory (SCCT), in which self-efficacy is a key component.

SCCT emphasizes the importance of background and social context influences on self-efficacy and a resulting vocational choice. In this model, one's self-efficacy is derived initially from the interactions among an individual's background characteristics, such as gender, race/ethnicity, disability/health status, personality predispositions, and contextual affordances. These background factors lead into cumulative life learning experiences, which in turn shape both self-efficacy and outcome expectations of the vocational choice process. From here, self-efficacy and outcome expectations influence the development of interests, which in turn form the basis of choice goals, which lead to choice actions, which result in educational and occupational performance, attainments, and satisfaction. Contextual influences on the choice process in the present, such as economic, parental, peer, teacher, and sibling support, may exert an impact on one's choice of goals and actions. SCCT provides counselors with a rich perspective of contextual factors and processes from which to view their clients as they engage the vocational choice process.

### Social Learning Theory

From the standpoint of social learning theory advanced by John Krumboltz, the social environment provides the context for learned behavior. Since vocational choice can be ultimately thought of as an instance of learned behavior, it can be understood from the behavioral paradigm. According to proponents of social learning theory, there are three principal types of learning: instrumental learning or operant conditioning, in which the probability of a response is altered by the frequency, recency, and intensity of events contingent upon the response; associative or classical conditioning, in which the learning is the result of the pairing of a significant event with a neutral event and the latter acquiring the power to invoke the same response as the initial significant event; and modeling, in which a behavior is acquired by observing and copying others and then being reinforced for the mimicked behavior. Krumboltz applied these principles of social learning to the realm of vocational choice. Some of the important factors that influence vocational choice and career decision making include:

#### *Genetic endowment and special abilities*

Personality characteristics such as race, gender, and physical abilities or disabilities, as well as partially determined genetically determined talents such as intellectual, musical, artistic, and kinesthetic may delimit career options open to individuals.

#### *Environmental conditions and events*

These are factors that are out of control of the individual, which may either enhance or constrain the array of career options open to individuals for consideration. Examples of such factors include the availability of jobs or educational opportunities, job entry criteria, salaries, labor laws and policies, family expenses and resources, and community resources.

#### *Learning experiences*

Every individual possesses a unique repertoire of learned responses through the interaction between one's inherited characteristics and the environment. Instrumental learning, those responses reinforced through contingencies such as grades

earned in school; associative learning, responses acquired through paired conditioning, such as attitudes toward an occupation held by someone admired or disliked, and modeling, a form of associative learning, are additional factors that influence the attractiveness of potential career options.

#### *Task approach skills*

These learned skills interpret the environment in relation to self-knowledge and world knowledge and make predictions about future events. Such skills include perceptual and cognitive processes (such as symbolic rehearsal), attention and memory, mental sets, and work habits.

#### *Self-observational generalizations*

These comprise the learned elements of self-knowledge and are general conclusions about ourselves resulting from self-observations in a variety of situations. These generalizations can be subdivided into three domains: task efficacy, the evaluation of our performances compared to others; interests, the conclusions of whether we like or dislike certain kinds of experiences; and values, generalizations about the desirability of certain behaviors.

#### *World-view generalizations*

These generalizations are conclusions, derived from instrumental and associative learning, about the social and physical environment we have experienced. Also included in world-view generalizations are the stereotypes and impressions of occupations and the occupational world.

Krumboltz' application of social learning theory to vocational choice calls our attention to the many factors in one's life history and in the environment that influence the consideration of career options and our career decisions over the lifespan. Further, while both social cognitive career theory and social learning theory are perhaps more explanatory than predictive, they nevertheless demonstrate how vocational choices throughout the life span are influenced by one's social context in the past and in the present.

### Gottfredson's Theory of Circumscription and Compromise

Linda Gottfredson's theory offers developmental and sociological perspectives of vocational choice by describing processes leading to the formulation of occupational aspirations in childhood and adolescence. Her theory addresses a fundamental question, 'Why do children seem to re-create the social inequalities of their elders long before they themselves experience barriers to pursuing their dreams?' In her theory, the processes of circumscription and compromise are enacted through four stages of child and adolescent development. The outcome of the developmental sequence is the identification of career aspirations in late adolescence that are not only preferred and acceptable, but represent an attempt to find one's niche in a broader social order.

Early in development, children begin to distinguish among occupations in the world of work according to the dimensions of masculinity versus femininity, prestige, and field of work. Individuals then arrive at an assessment of compatibility or suitability of a variety of occupations through the

consideration of factors such as perceived gender appropriateness, prestige, and the extent to which an occupation fulfills one's preferences and needs. Through the compatibility assessment, a 'zone of acceptable occupational alternatives' or 'social space' is created with a variety of occupations representing individual conclusions as to their occupational fit in society. Gottfredson contends that children may not invest a great deal of effort in career exploration and arrive at an array of suitable occupational alternatives that are merely 'good enough' or 'not too bad,' but may not be their 'best choices.' Further, individuals may become indecisive when the array of options within their zone of acceptable alternatives is undesirable.

The process of *circumscription* involves the elimination of unacceptable options that are in conflict with the self-concept. Children begin eliminating occupational alternatives as soon as they are able to perceive essential differences among people and lives. The circumscription process is guided by five principles: (1) the capacity to understand and organize complex information about themselves and the world; (2) the belief that occupational aspirations enhance one's self-concept; (3) the ability to discriminate among people regarding key variables of gender and prestige and to integrate these distinctions into their self-concept; (4) the elimination of options is influenced by the growing complexity and clarity of the self-concept; and (5) the process is gradual and transitions from one stage of development to the next are not immediately obvious. These principles are enacted through four stages of development, described as follows.

#### **Stage 1: orientation to size and power (ages 3–5, preschool)**

This stage reflects the onset of object constancy in cognitive development in which children are able to classify people in terms such as big and powerful versus little and weak, and they are able to perceive size differences between themselves and adults. They are also able to recognize occupations as adult roles and that they too will one day become working adults.

#### **Stage 2: orientation to sex roles (ages 6–8, elementary school)**

At this stage, children become aware of male and female sex roles and interpret sex role stereotypes as behavioral imperatives. Their occupational aspirations (e.g., such as firefighter, truck driver, or doctor for boys, and nurses or teachers for girls) reflect gender appropriateness. During this stage, children develop their 'tolerable-sextypic' boundary condition in forming the zone of acceptable occupational alternatives. One must be mindful that culture can influence children's sex-typing of occupations.

#### **Stage 3: orientation to social valuation (ages 9–13, middle school)**

Here, children become more aware of social class by age 9 and prestige by age 13. Occupations that do not meet with the approval of their social reference group are eliminated from further consideration. Moreover, occupations not in line with their perceived ability level to attain them are also discounted. Thus, the considerations of social class and ability form the 'tolerable level' lower-level boundary condition in the zone of acceptable alternatives such that occupations that are perceived below this level are eliminated. Children also establish an

upper boundary condition, the 'tolerable-effort level,' which reflects the maximum effort they are willing to exert and the risk of failure they are willing to accept in pursuing an occupation. Occupations exceeding the tolerable-effort boundary are also excluded from the zone of acceptable alternatives. While circumscription reduces the cognitive load in considering an array of occupations, it can also lead to the foreclosing of potentially socially and financially rewarding aspirations.

#### **Stage 4: orientation to the internal, unique self (ages 14 and beyond, high school and beyond)**

At this stage, adolescents are better able to engage in abstract thought, and they become more introspective and self-aware. They tend to explore occupations that are congruent with their emerging sense of self and can engage in the consideration of interests, abilities, and values. They are also able to discriminate between idealistic aspirations and realistic aspirations as modulated by accessibility. Further, adolescents shift from the process of eliminating occupations from the zone of acceptable alternatives by embracing options that are most preferred and acceptable. Here, the process of *compromise* is introduced in which adolescents may be required to choose among minimally acceptable alternatives as preferred options are eliminated from consideration due to reality factors such as accessibility, required abilities, and social and financial resources.

The particularly noteworthy contribution of Gottfredson's theory to vocational choice lies in describing how and when career aspirations are formulated, evaluated, and either included or dismissed from an array of viable career alternatives during childhood and adolescence. At this stage of development, individuals should be encouraged by parents, teachers, counselors, and people important to youth to engage in effortful cognitive processing in career exploration and to not dismiss occupations because of misperceived barriers. Somewhat unfortunately, there has not been a great deal of research on Gottfredson's theory and the research that has been reported is modest in its support of her propositions. Nevertheless, her theory takes an important place in the vocational choice literature by addressing developmental and social aspects in the formulation of career aspirations that eventually lead to life-determining vocational choices.

### **Special Considerations**

Race, gender, ethnicity, age, family background, socioeconomic status, and physical disabilities all may be considered as contextual 'background factors' that bear on the vocational choice process and outcome. All of these factors can actively influence such career phenomena as stereotyping, academic self-confidence, fear of success or failure, levels of career aspiration, mastery strivings, career commitment, risk-taking attitudes, work motivation, and opportunities for employment and advancement in the work place. Such factors also influence the development of one's personality structure that forms the basis of identity, knowledge structures of the world of work, meanings that are derived from work, the ways life and career problems are framed, the thought processes used to derive career options and evaluate their prospects, and one's view of personal success.

Differences among individuals in background factors such as race, gender, ethnicity, age, disability, and socio-economic status, and their effects on vocational choice can perhaps be understood from the standpoint of culture. From a vocational development perspective, culture is defined as a system of beliefs, values, customs, and institutions shared and transmitted by members of a particular society, from which people derive meaning from their work, love, and leisure activities. Further discussion on this topic is discussed elsewhere in this encyclopedia. Thus, each factor may be thought of as contributing to forming a basis for belonging to a certain subculture of society, each sharing its unique values, beliefs, and vocational orientations. The following assumptions regarding cultural differences may be applied to how these background factors influence vocational choice:

1. Culture is a determinant of meaning. Each subgroup possesses its own meanings regarding the nature of work itself, the relation of work to family and leisure, and the relative importance of intrinsic and extrinsic motivational factors.
2. Culture as determinant of communication. Misunderstandings between members of different cultures occur not because people use different vocabularies or languages to describe the same constructs, but because common words are used with different semantic meanings and because different cognitive reasoning processes are used to arrive at truth. Thus, the pragmatic aspects of human communication influence not only internal thought processes involved in making individual choices, but also interactions within and between members of different subgroups. As our society moves toward a more pluralistic work force, the pragmatics of human communication will play an increasingly important role in maintaining productive work groups.
3. Cultural relativity. Even though there are differences among cultural subgroups, no subgroup is objectively superior to another. Further, we come to know our own subgroup through the formation of contrasts between one's own and others. Thus, instead of differences serving as a basis for dividing people and forming barriers to access and opportunity, differences should become vehicles to higher understandings of ourselves, our groups, our work, and our society.

Differences among individuals, as determined by membership in subgroups or cultures, introduce important factors in shaping one's identity, and therefore how vocational choices are made and integrated over the lifespan.

## Summary

Vocational choice, as a field of inquiry in psychology, has received the attention of theorists and researchers for more than a century and has been driven by a very practical issue, namely, how can individuals secure meaningful and satisfying work in which they can become productive members of pluralistic and free society? The theoretical approaches vary in terms of descriptive, explanatory, predictive, and heuristic emphases. For example, the trait and factor theories emphasize prediction and applications in the use of technology, decision theories function as process heuristics, while self theories and

social psychological theories are descriptive and explanatory. All approaches are useful and provide essential perspectives for practitioners of the science of vocational psychology and the craft of vocational counseling. As Sampson suggests, we can avoid the unnecessary divorce between varying approaches to vocational choice and integrate the best of each perspective in order to meet the needs of clients across varied settings. Some of the emerging issues in the field of vocational choice include the expanding of a theoretical and research base on the influences of gender, culture, ethnicity, and physical disabilities on vocational decision-making, job satisfaction, and job performance. Moreover, the role of mental health in vocational choice, the optimal use of technology, and ascertaining how knowledge structures, cognitive skills, and attitudes can be developed through education, guidance, and counseling interventions are additional important avenues of research in the twenty-first century. Blustein has suggested the need to focus on a 'psychology of working' that broadens our perspective to include groups of individuals whose volition of choice has been restricted or nonexistent. Expectations are that the field will continue to evolve as the ability to make vocational choices becomes an increasingly important survival skill in a rapidly changing society – a society wrought by powerful international forces moving us toward greater pluralism in the labor force, a peacetime market economy leading to increased global interdependence, an expanding and aging population, and an ever greater use of technology in the production of goods and services.

War is the father of all and the king of all; and some he has made gods and some humans, some bond and some free.

Heraclitus of Ephesus, c.500 BC

Warfare is only an invention – not a biological necessity

Margaret Mead, 1940

Across the social and behavioral sciences, there are not many topics as important to the functioning of human societies and as surrounded by controversy as warfare. In this article, an attempt to synthesize research on warfare from anthropology and psychology and also history and sociology to a lesser extent has been made to address four basic questions:

1. Is the propensity to make war innate to human nature?
2. What is the role of warfare in the evolution of human societies?
3. How is warfare collectively represented in the psyche or mentality of people?
4. What is the relationship between warfare and individual and collective psychological functioning today?

## The Anthropology and Archeology of Warfare: Is the Propensity to Make War Innate?

To begin with, it is important to situate this debate in the context of the prevailing wisdom of archeologists and cultural anthropologists working on warfare. As exemplified by the opening quotation by Margaret Mead, they would mostly adopt the position that warfare is mainly a recent phenomenon, dating back to the last 10 000 years or so since the development of complex hunter-gatherer and/or agricultural societies, and likely much later in many regions of the world. In the last two decades or so, however, there has been significant movement against this orthodoxy, with an increasing weight of evidence arguing that use of collective violence among simple hunter-gatherer societies, while on a small scale typically not identified with the term 'warfare,' nevertheless bears many characteristics similar to warfare in more complex societies with larger populations.

Twenty years ago, there were few references to turn to on the subject of prehistoric warfare beyond Robert Carneiro or Andrew Vayda. Apart from Carneiro's conviction that warfare drove cultural evolution as successful leaders built chiefdoms, then states, and Vayda's detailed discussion of how Maori wars were fought, the archeology of warfare was not well developed. That has changed dramatically after Lawrence Keeley's 1996 book *War before Civilization* collected the available evidence and argued that anthropologists and archeologists had pacified the human past by downplaying the evidence of prehistoric and traditional warfare. Keeley further argued that in cases

where war was undeniable, there has been a strong tendency to classify it as a mere ritual and differentiate it from warfare in complex societies. Numerous archeologists have taken on this 'call to arms' and produced a robust alternative reading of warfare at the dawn of human society.

Consequently, a majority of archeologists who study prehistoric chiefdoms or states now give at least some countenance to warfare as an important factor in their structure and evolution. But for a variety of reasons, and despite much evidence to the contrary, the small-scale societies of foragers (especially the most mobile hunter-gatherers) are considered by many, if not most anthropologists, as inherently peaceful with low levels of violence or warfare. This is a glaring omission because it is central to a key unanswered question regarding warfare: when and why it originated. Some have argued that it is in our genes; others have argued that its roots are in social competition inherent in even small populations; and still others have argued that war did not arise until dependence on agriculture led to greater resource accumulation that allowed increased competition between groups directed by leaders. Thus far, there has been no firm resolution to this issue, but there is significant intellectual activity brewing.

## Hawks and Doves

Keith Otterbein is an influential cultural anthropologist who has produced a colorful dichotomy of two species of scholars with views on this subject of war. Hawks believe that war has always been with us since before the first recognizable hominids. Doves believe that warfare is fairly recent, and is mainly associated with the spread of more complex societies such as large chiefdoms, early states, and especially, colonial empires.

It is really not too hard to stretch the Hawks-Doves scheme to make it congruent with one of the oldest debates in Western social science as exemplified by Hobbes and Rousseau. In *Leviathan*, Thomas Hobbes stated his famous case that life for our ancestors was 'nasty, brutish and short.' Jean-Jacques Rousseau championed the other side that humans were not very nasty or brutish at all until civilization came along and ruined everything. This is a high-profile debate that has attracted the interest of many scholars of many disciplines and has significant investment on both sides.

The most notable hawk among physical anthropologists is Richard Wrangham of Harvard University. Apart from his scholarly writings, he hit a lot of nerves with the popular book he coauthored with Dale Peterson, *Demonic Males: Apes and the Origins of Human Violence*. He has been on television frequently, gives popular lectures, and takes an awful lot of flak from Doves. His view is that the documented group violence exhibited by chimpanzees is an accurate glimpse of the distant hominid past as well. His argument is that humans are

adapted for violence, and in particular that it is male humans who are selected for coalition-based fighting:

That chimpanzees and humans kill members of neighboring groups of their own species is . . . a startling exception to the normal rule for animals. Add our close genetic relationship to these apes and we faced the possibility that intergroup aggression in our two species has a common origin. This idea of a common origin is made more haunting by the clues that suggest modern chimpanzees are not merely fellow time-travelers and evolutionary relatives but surprisingly excellent models of our direct ancestors. It suggests that chimpanzee-like violence preceded and paved the way for human war, making modern humans the dazed survivors of a continuous, 5-million habit of lethal aggression.

Though, as Smith pointed out, both Freud and Einstein thought that the war was innate to humans, this is obviously a controversial position. Many objectors do so explicitly on the argument that it would mean that war is likely to always be with us and nearly impossible to avoid, an emotional rather than logical point, that could for example be countered by our peaceful ape near-relations, the bonobo. Hence, Wrangham and Peterson's position could be considered speculative. Many scholars shy away from any suggestion that humans, and especially males, are biologically driven to be violent. However, new research reveals evidence of the biological bases of human behavior with regularity. Hence, we should not reject this position out of hand just because it would lead to the conclusion that war in the future may be difficult to avoid given biological tendencies in our species. But there is also a need to carefully consider the discourses used to promulgate such findings, because in this area, description can easily veer into prescriptions for political elites and mass media.

The best known archeological hawk is Lawrence Keeley. His book arguably caused a paradigm shift in archeology. A second prominent archeological hawk would be Steven LeBlanc, also of Harvard University. He, like Wrangham, also teamed up with a popular writer to produce the hawkish, *Constant Battles: The Myth of the Peaceful, Noble Savage*, whose title proclaims its content. Hawks of a variety of disciplines rely heavily on Wrangham, Keeley, and LeBlanc to argue that war has been around for a long time.

*War in Human Civilization*, a recent book by Azar Gat, is a good example of a multidisciplinary approach in which military history plays a dominant role. The author looked over the available evolutionary, archeological, and ethnographic evidence and concludes that violent aggression has been with us for at least 2 million years (the origin of the genus *Homo*) and that it is primarily caused by resource scarcity. He also points out that violence and war have many proximate causes such as prestige, revenge, sorcery, use of narcotics, and so on, but underlying it all is the ultimate issue of competition for resources. Even the simplest hunter-gatherer societies, he argues, have high rates of mortality from violent conflict resulting from competition for reproductive success and territory.

A second recent popular hawkish work is *The Most Dangerous Animal: Human Nature and the Origins of War* by the philosopher David Livingstone Smith. He accepts the evolutionary view of innate aggression in humans and also agrees that the ultimate cause of this is competition for reproductive success and resources. He thinks that humans are naturally aggressive, xenophobic, and nepotistic. But he also thinks that humans

are evolved to dread killing, and are inherently self-deceptive and that this conflict must be understood to solve 'the puzzle of war':

The track record of our species shows, beyond a shadow of a doubt, that we are extremely dangerous animals, and the balance of evidence suggests that our taste for killing is not some sort of cultural artifact but was bred into us over millions of years by natural and sexual selection. But we have also seen that there is something in human nature that recoils from killing and pulls us in the opposite direction. These contrary dispositions exist side by side within us, and any explanation of war must honor the tension between them. It is incorrect to claim, without qualification, that we are killer apes, but to say that we are essentially peaceable is every bit as misguided. We are *ambivalent* about killing, and it is impossible to understand the relationship between war and human nature without taking this into consideration. (Smith 2007, p. 161)

An influential and ardent dove is the cultural anthropologist Douglas P. Fry, whose book *The Human Potential for Peace: An Anthropological Challenge to Assumptions about War and Violence* is aimed at the general reader to counter popular hawks like Wrangham and Keeley. He accepts that warfare is very common indeed over the past 4000–6000 years and in both agricultural and complex hunter-gatherer societies. But he argues that foragers are characterized by low levels of violent conflict between groups, though he acknowledges high rates of homicide and medium levels of feuding. He is adamant that feuding between kin groups should not be conflated with warfare, which he sees as being conflict between communities. He reanalyzes previous cross-cultural studies of warfare and concludes that most hunter-gatherer societies were peaceful with essentially zero warfare. His book attempts to show that "nomadic foragers, living a weakly partitioned or unpartitioned social world, perceive homicides and lesser disputes in terms of individual grievances, not as occasions for making war, group against group." Key here are definitional issues: whereas hawks view violence in forager societies as proto-warfare because group-size is necessarily small, doves view this as a fundamentally different form of violence because of alternative organizational and ideological/interpretive features.

The most well-known cultural anthropologist on the dove side would be R. Brian Ferguson of Rutgers University. One of the few anthropologists to work extensively on warfare in the 1980s, his most polemic work thus far is his contention that much tribal warfare can be attributed to changes wrought by European encroachment in the last few centuries. This has been a fairly persistent strand of scholarship, where warfare is blamed on the encroachment of modernity rather than inherent to the indigenous society.

Jonathan Haas might be held up as a dove archeologist. He argues that the archeological record of the Southwest shows that warfare was common only after climatic changes and population increase in the last thousand years. This is perhaps a view shared by the majority of current anthropologists: that warfare is a cultural phenomenon dependent on social organizational features interacting with environmental scarcity. They hold that warfare is an instrumental and adapted rather than inherent feature of human society.

While it is obvious that drawing conclusions in this area is fraught with controversy, there are some major points worth commenting on. First, Rousseau's idea of a noble, peaceful

savage separate and distinct from the corrupted and violent human beings recorded in history today cannot be sustained by the available evidence. Second, environmental factors like population density and resource availability, and social factors like norms and meanings play important roles in the prevalence and organization of murderous violence. Murderous violence, whether it is labeled as interpersonal and treated as a different phenomenon from warfare, or whether it is considered as a form of proto-warfare adapted to low infrastructure conditions in forager societies, appears to be part of the human condition. The key is how big a part, how much it varies, and the relationship of this variation to the evolution of human societies over time.

### What is the Role of Warfare in the Evolution of Human Societies?

While there is a fairly long history of the anthropology of warfare and conflict, the most influential thinkers in cultural anthropology in recent times are Raymond Kelly and Keith Otterbein. Neither can be placed squarely in the camps of hawks or doves, their views are more subtle, but they tilt toward the view that warfare is a cultural formation triggered by environmental circumstances.

Kelly recently published *Warless Societies and the Origin of War*, in which he presented “a general model for the initial evolution of war that is grounded in the comparative analysis of ethnographic data and then to apply this to the interpretation of pertinent data in the archaeological record” (p. ix). He used case studies from the limited set of ethnographically identified ‘peaceful’ or ‘warless’ societies, as well as those from societies with frequent incidence of warfare in order to identify key differences or thresholds in sociocultural context. It was this change in context, according to Kelly, that pushed societies toward warfare in the human past. He believes that warfare was rare until the development of fairly complex segmented societies where group members perceive the killing of one of their own as an attack on the entire group. Kelly views the ‘calculus of social substitutability’ as key to the transformation of violence into an instrument of the social group. Since he classifies human societies during the Upper Paleolithic (~35 000 years ago) as unsegmented societies, he concludes that warfare was rare until later in human history.

Otterbein has published on the anthropology of warfare for several decades, but his latest book, *How War Began* (2004), claims that both sides are right to an extent. His argument is that the hawks are correct that our early hominid history was competitive and warlike. He thinks this was largely because of competition over hunting game, and helped our species to expand at the expense of Neanderthals and other Archaic *Homo sapiens*, and indeed throughout the world. In contrast to Kelly, Otterbein thinks that the origin of agriculture led to millennia of peace – that is, that farmers do not fight. War then arose a second time AFTER the development of expansionistic complex chiefdoms and states. He utterly denies a role for warfare in the origin of complex social groups; it was solely a *result*, not a *cause* for the origin of the chiefdom or state.

This is a controversial position because, as Allen and Arkush have noted, war can be the cause or the consequence of the

evolution of complex societies. Otterbein ignores arguments made by Mesoamerican archeologists that warfare was a key factor in the origin of the Zapotec chiefdom and state in Mexico’s Oaxaca Valley. He similarly dismisses data from the Old World and South America. In sum, Kelly and Otterbein provide some important ideas and hypotheses regarding the origin of war, but they have not treated all evidence equally. Where they often seem weakest is when they stray from ethnographic data and speculate about the more distant forager past.

### Unilineal and Multilineal Theories of Cultural and Societal Evolution

It is likely that unilineal theories about warfare and human society as articulated by Kelly and Otterbein will never quite satisfy, because the role that warfare plays in the evolution of even simple societies depends on its interaction with other fundamental factors, including population density and resource scarcity, available technology, ideology/meaning, social organization, and economics. The contingent nature of the interplay of these factors becomes even more complex if we move beyond forager societies to the role that warfare plays in cultural evolution across a broad range of human societies. It is fair to say that in some periods, as in the age of colonial empires or at the dawn of the European nation-state, warfare was considerably more central to cultural evolution than during other periods.

In recent years, unilineal or ‘grand’ theories of cultural evolution have been challenged and to a significant extent undermined by multilineal theories in anthropology and sociology. Within the multilineal theories that have arisen to account for the diverse evolutionary trajectories that have actually been observed and documented over time and space, warfare is accorded a central role as *one* of the causal factors that drives cultural and societal change, but it is not accorded hegemony as *THE ONE* as suggested by the opening quotation by Heraclitus. There is a deepening understanding of society as a dynamical system, where causal change can come from a number of independent factors, and feedback between them can significantly alter the character of the impact of these causal factors on one another and on the society at hand. A cause can look like an effect at a particular moment in time in a particular society and vice versa. There is a need to look at the evidence broadly, through time, and as reflected in myriad case studies.

The materialist approach taken by Johnson and Earle is to analyze warfare, and particularly the costs, benefits, and opportunities of warfare in the framework of a political economy. In their model, intensification is the primary engine of sociocultural evolution: it is population growth and technological development that are the drivers of social change; at the initial stages of the evolution of cultural complexity, a political economy emerges in response to the material needs of subsistence-oriented families. The decisions made by these networks of families, often under the direction of their most influential members, to manage the challenges of intensification like problems of procuring food, or the risks of raiding and warfare, or inefficiencies or deficiencies in resources or resource usage, determine societal features like social stratification and political and economic formations.

War in this model is motivated by resource competition, and is in effect characterized as an instrumental activity that can become profitable when populations reach particular densities and resources/technologies are sufficiently rich to warrant the use of violence to monopolize/defend or to attack/co-opt the surpluses derived from them. The very purpose and definition of warfare changes with intensification: in simple societies with low population densities, collective violence is often aimed at driving away other people, whereas in more complex societies with higher population densities the conquest and incorporation of other groups within one's own collective becomes the objective and definition of collective violence. With increasing complexity comes increasingly sophisticated political and economic formations like bureaucracies, armies, noble families, banks, etc. that again change the political and ecological landscape on which warfare acts as a cause and an effect of cultural evolution. The level of abstraction in this model is necessarily high, but even so not all researchers would agree that intensification can serve as the motor for sociocultural evolution across the broad range of human societies over time.

A more definitively multilineal model of sociocultural evolution is Mann's *Sources of Social Power*. In this magisterial work, societies are conceived as four types of organized power networks: ideological, economic, military, and political. Each form of power is sourced in different aspects of the human condition. Ideology is our propensity for meaning-making, where monopolizing social norms and rituals are a route to power. Economic power "derives from the satisfaction of subsistence needs through the social organization of the extraction, transformation, distribution, and consumption of the objects of nature." Political power "derives from the usefulness of centralized, institutionalized, territorialized regulation of many aspects of social relations." Finally, central to this article, military power derives "from the necessity of organized physical defense and its usefulness for aggression." Each one of these is conceptualized as an autonomous power base capable of causing sociocultural change, and offering different potentials for constructing societies.

Mann describes military organization as concentrated-coercive, whether in war or in peace. Concentration of force is key to the power of military means to change society, through such wrenching events as regime changes or conquest. According to Mann, military forms of organization are much better suited to concentrated tasks like defeating or terrorizing an enemy, building fortifications, or controlling transport channels than dispersed tasks like bringing in harvests or making sure there are plenty of supplies of livestock. Military power has an extensive reach far beyond its ability to exert control. Raiders like the Mongols or Vikings were able to terrorize and extract surplus from other populations but not control them because their military means far exceeded their political, ideological, and economic power. In Mann's model, war is a powerful driver of sociocultural evolution, but without concurrent political, ideological, and economic power it cannot consolidate enduring societal formations.

The interaction between politics, ideology, and war can be illustrated with some quick examples. In the age of empires, military force was able to impose a top-down system

of control to extract tribute and high-level obeisance, but the daily lives of ordinary people were often unaffected by who ruled over them. More enduring empires like the Qin and Han dynasties in China used ideological and political innovations like a shared script and sophisticated bureaucracy to consolidate the changes wrought by war; the Spanish empire brought in Catholicism as a consolidator of its conquest of the New World. In a subsequent era, Tilly argues that war made the nation-state in Europe, and the nation-state thrived on war. War opens doors to societal change, but other sources of power are required to consolidate those changes.

### How is Warfare Collectively Represented in the Psyche or Mentality of Peoples?

Popular representations of history are simpler. They appear to position wars as the most important events in world history. Liu et al. used open-ended nominations of the most important events in world history by more than 2000 university students to find that World War II was considered as the most important event in world history among 23 of the 24 societies surveyed. Overall, between 30% and 58% of events (45% on average) nominated across cultures concerned warfare and collective violence. Hence, in free response formats among educated young people, warfare (together with politics) constituted the key events in the collective remembering of history. They are the makers and breakers of society according to these lay accounts. Advances in technology and commerce were far less salient in free recall.

This hegemony of politics and war in free recall of important events and leaders suggests that lay people share a view of history as a product of violence. However, in studies based on closed-ended ratings, war- and politics-related events were less privileged. The salience of WWII was to a large extent confirmed as this war was considered as more important than former or more recent wars or revolutions. Yet, in general, war- and politics-related events were not perceived as more important than socioeconomic trends like the Industrial Revolution. Moreover, agreement with statements which describe the content of history as being related to wars and politics was lower than the agreement with the idea of history as being related to socioeconomic progress and technological development. Even if wars are more vivid in free recall, social-structural factors are recognized as important and prevail in more reflexive thinking about history.

Studies focused on a single country reveal the centrality of warfare in the collective remembering of the history of a nation: the birth of a nation is often accompanied by collective violence, and frequently this violence is commemorated as part of the narrative of the birth of a nation as in the Fourth of July celebrations in the United States; recent instances of collective violence like 9/11 are also privileged.

In this context of nationalities in conflict, wars are depicted as necessary and just and even religion is used to justify war ('In God We Trust' was a slogan used by both sides in WWI). An analysis of official documents in nineteenth- and twentieth-century Europe (mainly focused on Germany and France)

found the following common features of representations of past wars: 'Our' shameful past war episodes are concealed; 'our' heroes, martyrs, and epic battles are acknowledged and remembered; our internal conflicts and crimes are forgotten. Recalling past persecutions and martyrs imposes the duty of fidelity and justifies revenge against evildoers. References to others as victims, civilians killed, and suffering are concealed. In fact, aggression against enemies is a manner to repay injuries suffered by the nation or nation's ancestors. War becomes a legitimate form of honoring the memory of ancestors and victims. Unacceptable elements of the actual behavior of 'our' soldiers (cruelty, rape, cowardly) tend to be omitted from formal and informal representations of the war and collective memories. This idealized propaganda image of a 'good' soldier, a combination of patriotism and manliness, loyalty to the collective, and professional skill, was shared by combatants to an extent. Most soldiers remember war as a negative but normalized experience – more positive in the case of victorious armies, like the Red Army, and more negative in the case of defeated armies, like the German Army. Even in the case of defeated nations, like Germany and Japan after WWII, people share and remember their own suffering, but conceal, silence, or ignore other people's suffering.

### What is the Relationship Between Warfare and Individual and Collective Psychological Functioning Today?

We close this article with a consideration of the impact of warfare on contemporary psychological functioning. Put simply, recent available evidence suggests that normal soldiers in battle commit atrocities. For instance, Browning describes how a group of German 'Ordinary Men' become mass murderers in Poland during WWII, from shooting innocent men, women, and children to clearing out the ghettos of Jews and ensuring they boarded trains to concentration camps. During WWII, American, British, and Canadian troops killed German POWs and wounded soldiers, used soldiers belonging to the German Wehrmacht or Waffen SS as human shields, and forced them to walk through minefields. In Vietnam, American soldiers treated the civilian population as targets to be killed, terrorized, and sexually abused. Few of the veterans interviewed regarded killing civilians as wrong. During WWII, the behavior of the Soviet soldier on German territory included widespread rape and looting.

However, at the same time, millions of men and women in the armed forces of even the world wars never saw combat and only a small percentage actually killed the enemy. Studies suggest that only a minority fight and that human beings resist killing members of their own species. Based on his postcombat interviews, Marshall concluded that only 15–20% of the individual riflemen in World War II fired their weapons at an exposed enemy soldier. The great majority of individual combatants throughout history appear to have been unable or unwilling to kill, even if their training was successful in increasing rates of participation (at the price of increasing rates of posttraumatic stress disorders among soldiers).

Given the horror of war, we review psychological explanations of participation in combat, and particularly participation in war crimes, killing of noncombatants, genocide, and the systematic rape of women.

- (1) *Selection*: The classical explanation that psychopaths are recruited as soldiers and a fringe minority of 2–3% perform most war crimes does not receive widespread support. Ninety percent of European armies in WWI and WWII were composed of nonvolunteers. The best killers in armies are men whose outward personalities were modest and sensible. Documented cases of German mass murderers have included not just Nazi fanatics but ordinary middle-aged men of working-class background who were neither specially trained nor volunteers. Most were old enough to have grown up before the rise of Fascism, and knew perfectly well the moral norms of German society before the Nazis.
- (2) *Brutalization by war*: Evidence for the idea that in war men are traumatized by having to kill others, and then permanently brutalized by the experience as an explanation for wartime atrocities is also inconclusive. The battle stress of the soldiers or psychological stress caused by the bloody battles and atrocities has been used to explain the rape of German women by Red Army. However, this idea of war leading to brutalization through combat doesn't explain Reserve Battalion 101 under the Nazis since they didn't experience action before participating in genocide. Moreover, evidence suggests that fear of dying, not fear of killing, is the most debilitating emotion for soldiers, inducing high levels of trauma. Most veterans seem to have been able to distinguish clearly between the act of killing on the battlefield – even casual atrocities against enemy wounded or prisoners – and killing in civil society. As a result, they seldom seemed brutalized by combat, particularly if they were on the winning side. Bourke suggests that the most hardened battlefield killer was able to adjust to civilian life with little evidence of trauma.
- (3) *Ideology of just war and indoctrination*: Racial stereotypes or images of the enemy as subhuman, primitive, childlike, and animalistic play a significant role in wartime and warfare and its collective remembering. In WWII, some Americans thought of the Japanese as monkeys and Japanese thought of the Americans as large apes. On the Eastern Front, Germans thought of fighting against subhuman Slavic bolsheviks. The dehumanization of the enemy makes possible a war of extermination and the devastation of civilian populations – in fact, war on the Eastern Front and in Asia provoked higher casualties than in the West front in WWII.
- (4) *Following orders and obedience to authority*: Ordinary people will more than likely follow orders, even those they might personally question, when they perceive these orders as originating from a legitimate authority. Milgram's experiments produced findings that mirrored historical facts. Direct proximity to the horror of the killing significantly increased the number of men who would no longer comply with orders. Distance from victims facilitates compliance, as when with the division of labor and removal of

the killing process to concentration camps the men felt scarcely any responsibility at all for their actions, just as in his experiments on destructive obedience. Desensitization and routinization of killing explain how men slowly escalated their participation in killing. Veterans attest to the difficulty of killing face to face for the first time, but the act of killing escalates willingness to do violence. Studies show that once a person complies with a small request (e.g., hitting unarmed prisoners or civilians), he will be more likely to comply with a more substantial request which is related to the original request (e.g., firing on these people and participating in war crimes). The idea is that the initial commitment on the small request will change one's self-image, therefore giving reasons for agreeing with the subsequent, larger request. Slow escalation of hurting others is a slippery slope in which each act of aggression becomes a reason for more aggression. Similar processes may occur during war.

- (5) *Conformity*: One of the classical explanations of the ability of the German Army to keep fighting despite terrible losses was ingroup cohesion and conformity. Soldiers fight for their buddies and to survive. In the case of wartime mass murders, Browning concludes that if a member of this group refused to kill, he was refusing his share of an unpleasant collective obligation. In the case of Germany in WWII, Soviet soldiers who refused to take part in rapes were treated at best with suspicion, and at worst could be shot by their drunken comrades. A few Vietnam veterans who could not take part in atrocities later confessed to feelings of inadequacy, of letting down their comrades. Even if war is a negative experience, there are also positive facets, like pleasures of comradeship and the glimpses of extraordinary courage.

Taken together, racial stereotypes and indoctrination, obedience to authority, escalating commitment, peer pressure, and group dynamics when placed in a coherent group setting explain why soldiers commit war crimes or engage in destructive obedience, even if they find these actions morally reprehensible.

## Conclusion

War may not be the father of all things, but across cultures it is imagined by lay people and theorized by experts as one of the key drivers of history and as a maker of nations. There may not be definitive evidence as to whether the propensity to make war is innate, but there are strong intimations that recourse to collective violence is as old as human society itself. Warfare interacts with other fundamental drivers of societal evolution like economics, technology, politics, and ideology as a vehicle of concentrated force, making it much more effective as an agent of culture change in some eras than others. No simple psychological explanation like selection or brutalization explains willingness to kill in war or commit war crimes, but rather a complex of societal and psychological factors, like the propensity to glorify and sanitize warfare, ideologies legitimizing war and dehumanizing the enemy, negative stereotypes, a willingness to obey commands especially of a graduated

nature, conformity and the desire for comradeship, combine to create a pressure cooker for societies and the individuals within them that make war a frighteningly powerful and unfortunately prevalent element of human experience.

### Glossary

**Alzheimer's disease** A type of age-related dementia in which word-retrieval problems are a prominent symptom.

**Aphasia** Language impairment due to brain damage; aphasia can impact language production, resulting in difficulty initiating speech and fragmented phrases, and language comprehension, resulting in difficulty understanding language.

**Connectionist models** Models of memory and language systems in which pieces of information are represented by nodes that are connected to one another in a network through which activation is transmitted.

**Mental lexicon** Within memory, the stored representations of the meaning, sounds, and syntax of all known words.

**Phonology** Individual sound units are called phonemes, and the set of phonemes that together form a word are described as the word's phonology.

**Semantics** Aspects of the meaning of a word.

**Slips of the tongue** Word-retrieval errors in which an incorrect word or phoneme is produced or a word or phoneme is mispronounced.

**Tip-of-the-tongue (TOT) states** Frustrating failures of word retrieval in which a word's meaning is accessed but its sounds are not retrieved. Sometimes partial phonological information is available to speakers having TOTs.

**Word retrieval** The process of accessing a known word from memory to express a specific linguistic concept. Also called lexical retrieval.

Word retrieval, also called lexical retrieval, refers to the cognitive process by which we identify, access, and produce an individual word in order to express an idea or concept during communication. Lexical retrieval often occurs as a subcomponent of production of larger units of language, such as sentences. It is an important and interesting cognitive skill, one which people use thousands of times per day with a great deal of success. When errors in lexical retrieval do occur, they tend to be of predictable types, and these regular patterns of errors have been very influential in understanding the processes underlying accurate lexical retrieval. This article presents major models of lexical retrieval, discusses some types of errors that are committed by all people during word retrieval, and reviews findings from some populations for whom word retrieval is different or especially problematic.

### The Mental Lexicon

Words are stored in a system called the mental lexicon, which contains information about the meaning, grammatical structure, and sounds that comprise each word that an individual knows. For most adults, the mental lexicon contains tens of thousands of words. During normal conversation, people produce two to three words per second, indicating that lexical retrieval is a very frequently used skill. However, researchers have found that we make speech errors only once or twice out of every one thousand words spoken, highlighting the general effectiveness of our word-retrieval system. While word-retrieval processes are critical to both spoken and written language, this article will focus on lexical retrieval during spoken language production.

The mental lexicon enables us to combine pieces of information to make complete and coherent thoughts, utterances, or written ideas. There are different types of information stored

in association with each word in the mental lexicon. The first type of information is the precise concept associated with any given word, better known as the *semantics* of the word. When an idea comes to mind that a speaker wants to express, an array of words that fit that concept are identified from the known vocabulary. The speaker must determine what type of word is needed, including the word's specific connotation and its grammatical class (i.e., noun vs. verb). At this point, the precise term to be retrieved from the mental lexicon, sometimes called the *lemma* or *lexical node*, has been specified and selected. It is generally agreed that following specification of the exact term to be retrieved, speakers commence retrieval of the word's *phonology*, or the sounds that comprise the word. In other words, virtually every model of word retrieval has separate representations for the semantics of a word and for its phonology. The word-retrieval process is successfully accomplished only if selection of a word from the lexicon matches the desired concept, and then the phonology of that word is correctly retrieved and produced. As indicated previously, these processes occur very quickly, and lexical retrieval is generally very accurate as well as efficient.

### Models of Word Retrieval

There are several models that detail very specifically how the word-retrieval process happens during everyday speech. *Connectionist models* are a popular framework in which to explain lexical retrieval. They are called connectionist because they propose a network of connections between different systems in the mental lexicon. Specifically, these models stipulate that activation spreads between semantic and phonological systems to allow access to information, and that when all the necessary information has been activated, word retrieval is complete. In several connectionist models, the representations

**Figure 1** An example of representations of the semantic and phonological systems in an interactive activation model.

of pieces of information that constitute a word are called *nodes* (see [Figure 1](#)). Frequently, models of word retrieval capture the explanation of how nodes in the mental lexicon are accessed by discussing two separable stages. In the first stage, selection of word units occurs. The second stage involves retrieval of phonological forms that map onto the desired term.

Words (and the lexical nodes which represent them) are usually described as one type of information within the *semantic system*. The nodes in this system represent information about concepts that correspond to specific words (see [Figure 1](#) for examples). In English, as in many other languages, it is possible for many words to be associated with one concept. For example, the concept of being tired can be expressed with various words that are nearly synonymous with *tired*, including *sleepy*, *exhausted*, *drained*, or *beat*. Additionally, multiple concepts, including lexical items for differing parts of speech, can be associated with one word. For example, *beat* can be used different ways in sentences such as *I am beat after such a long day*, *He beat the drum*, *It beats me why she did that*, or *This song has a strong beat*. Each of these concepts is represented by a unique lexical node, even if there are synonyms or multiple meanings for that lexical item.

As thoughts occur to a speaker, nodes representing semantic information are accessed. This is the least understood aspect of lexical retrieval: Why people have thoughts, and how they are translated into linguistic form, are questions for which the field of psycholinguistics has no current satisfactory answer. However, once a linguistic plan is conceptualized, there is general agreement that activation of nodes within the semantic system will spread to nodes for specific lexical entries. Not only should the content of the node accurately represent the desired concept, but also the node must be from the correct grammatical class. In the previous example about beating the drum, *beat* is used as a verb, but in the example about the song, *beat* is used as a noun (see also [Figure 1](#)). The lexical node from the correct syntactic category that receives the most activation will be selected for further processing.

Another system contains the rules of the language regarding how the sounds of a word are structured, including the number and types of syllables in a word, as well as how many and which sounds it contains. This is referred to as a *lemma* or *lexical node* (see [Figure 1](#)). Once the information about the concept and structure of a word is selected, the activation from nodes in this system spreads into the phonological system.

The nodes in the *phonological system* contain information about the specific sounds of a word (in [Figure 1](#), the examples are individual phonemes, although syllable nodes and phoneme feature nodes are also sometimes included in this system). For accurate production, the correct word for a given concept must receive the most activation and be selected, and the correct phonology for that word must be activated.

The process of producing words that correspond to thoughts is described as top-down, which means that higher levels of the network are accessed first. Specifically, the semantic system is the first to be activated. This activation then spreads down to lexical nodes in the network, and finally down to nodes in the phonological system that ultimately indicate what sounds to produce. Speaking, writing, and unspoken linguistic thought are all potential output from this production process. Most models describe connections as bidirectional, allowing the spread of activation both top-down and bottom-up across lexical systems. Thus, comprehension processes (e.g., reading and listening) are bottom-up, input processes that rely on the same connections. When an individual encounters sounds (or spellings) that make up a word, they engage bottom-up processing to activate the meaning of the words they have heard or read.

## Factors Influencing Word Retrieval

Several factors have been determined to influence how quickly and efficiently the word-retrieval process occurs. The first variable thought to affect the strength of the connections, and thus the amount of activation transmitted between systems, is how frequently a particular piece of information is accessed. Words or sounds that are used more often are accessed at a faster rate and with fewer errors than items that are not used often. For example, the word *piano* is more readily available for retrieval than the word *dulcimer*; both are instruments, but most people use the term *piano* more often than *dulcimer*. The age at which a word is first learned and used, or the age of acquisition, can also influence retrieval processes. This is probably partly due to the fact that high-frequency or common words tend to be among the first words that children learn, and then those items are used more often across one's lifespan. Additionally, how recently a word has been produced or encountered will also impact its accessibility. This benefit of recent processing

can occur even without awareness of having seen or heard a word, so that nodes that have been used recently can facilitate word retrieval without the speaker's knowledge. Relatedly, verbs appear to be less susceptible to retrieval failures than nouns, perhaps because verbs have higher average frequencies than nouns. Grammatical class may play an important role in word retrieval and should be further explored.

A word's *neighborhood*, or the set of words in an individual's mental lexicon that are phonologically similar to that word, can also influence retrieval ability. For example, when considering the target word *dog*, members of its phonological neighborhood include *fog*, *log*, *dot*, and *dock*. Neighborhood structures have been conceptualized in two ways. The first is referred to as neighborhood density, which is determined by the number of words that are phonologically related to a given target word. The second factor that has been examined is neighborhood frequency, which involves how often the phonologically similar words (i.e., the neighbors) occur in the language. It has been proposed that similar-sounding words may compete with one another, a process referred to as blocking. According to this idea, a target with a dense neighborhood composed of frequently used words will have a greater amount of competition during selection, which should slow the process of retrieving and producing a given target word. Other theories suggest that having many similar-sounding, frequently used words will strengthen connections to a target word's phonological components. Under this approach, words would benefit from these neighbors during the retrieval process. Recent experiments have shown a facilitative effect of large, dense neighborhoods, such that target words with greater neighborhood density and frequency are produced more quickly and with fewer errors than words that have few phonological neighbors.

Another factor that influences the facility of word retrieval is *gesturing*. During normal conversation, individuals frequently use gestures in addition to vocalized speech in order to convey a concept. Gesturing is believed to help the word-retrieval process and eventual production because it increases the activation of the information contained in the mental lexicon. The benefits of gesturing may be greater for some individuals than for others. For example, people with lower verbal abilities may rely on gesturing to supplement speech more than those with higher verbal abilities. On the other hand, it may be that increased verbal ability results from increased production of gestures. Some research has shown that differences between groups of participants with varying verbal abilities may be reduced if the groups are made to gesture equally often. One possibility is that using gestures enhances the capacity for processing by maintaining task-relevant information in working memory.

Research has shown that prohibiting gesturing during word retrieval can increase failures. Participants instructed to keep their hands still have evidenced greater rates of tip-of-the-tongue states (TOTs) and decreased correct responding. This may indicate a direct benefit of gesturing on word-retrieval processes. Alternatively, it may merely demonstrate that holding still is difficult for people, in effect requiring them to divide their attention between the word-retrieval task and the instructions to not gesture. Regardless of this potential criticism, the bulk of research indicates a facilitative role for gesturing in word retrieval.

## Problems in Word Retrieval

Given the amount of information contained in the mental lexicon, and the complexity of the system, it is surprising that lexical retrieval is generally error free. However, problems do occur and can be quite frustrating. Research on errors in word retrieval is vital to understanding the underlying language system and how it functions correctly. Exceptions to the general rule of accuracy allow a better understanding of the processes involved in successful lexical retrieval, as well as when and why they sometimes fail.

### Tip-of-the-Tongue States

The most extreme form of word-retrieval error is a complete failure, or a temporary inability to produce a well-known word, which is referred to as a TOT experience. It is important to note that TOTs are different from not knowing a piece of information and that TOTs reflect inaccessibility of the desired term. In other words, the individual knows the information but simply cannot retrieve it at the moment. TOTs can be extremely frustrating, and when the target word for which a person has been searching is ultimately retrieved (i.e., when the TOT is resolved), it comes as a tremendous relief to the speaker.

TOTs were initially described by William James in the late nineteenth century, and they occur in virtually every known language, but the first systematic study of TOTs was conducted fewer than 50 years ago. The TOT phenomenon has been explored using both diary studies and experimental methods. Participants in diary-based research report their naturally occurring TOTs on specific forms, which they fill out over the course of several weeks. Participants in these studies indicate having TOTs one to four times per week, with rates increasing throughout adulthood. Researchers have also utilized laboratory manipulations to study TOTs under more controlled circumstances. When TOT states are examined in experiments, researchers are able to probe the participants for more information about their TOT experiences, as well as to manipulate aspects of the context in which retrieval is attempted. Both naturalistic observations and laboratory experiments provide useful information about the failures, and researchers have been able to gain a fairly comprehensive understanding of the process of TOTs and word retrieval by using a combination of methods.

Among studies that have experimentally induced TOTs, most have used definitions of commonly known, but infrequently produced words (e.g., *nepotism*; *sextant*), as these are the types of lexical items most likely to yield TOTs. Other studies have shown pictures of famous individuals to induce TOT states for their names, an effective choice because proper names appear particularly likely to elicit TOT responses. Across these different types of stimuli, certain characteristics have been consistently found in participants' TOT states. For example, individuals in a TOT state often report a strong sense that they know the word, despite the inability to produce it at the moment. Ratings of feeling-of-knowing, or how imminent they believe retrieval to be, are related to the likelihood of subsequent recognition of the target word. Participants report that the TOT target is a word they have successfully produced

on previous occasions, and they are frequently able to provide some partial information about the target they are searching for, including its initial or final letters or phonemes, the gender of the desired term (in gendered languages, e.g., Italian), and the number of syllables and syllabic stress pattern of the target word. TOT states are sometimes accompanied by other words that come to mind repeatedly. The speaker knows that these persistent alternates are not the target word they seek, but cannot stop the words from entering consciousness. These alternate words may share similar sounds, meaning, and grammatical class with the target word, and often induce the subjective feeling that they are blocking retrieval of the desired term. Some early TOT research showed that phonologically similar words can act as competitors to block retrieval, but these studies have been widely criticized (e.g., target words in some experiments were not counterbalanced across conditions, limiting the conclusions that can be drawn). At present, there is a paucity of experimental evidence for the notion of blocking as a cause of TOT states.

As an alternative to blocking, connectionist models of lexical retrieval (as described earlier) postulate that TOTs occur when connections between nodes are too weak to transmit sufficient activation to all of a word's phonological nodes. Under these models, failure to transmit adequate activation to every phonological node of a word means that the speaker will be unable to produce the target word. When a subset of the phonological nodes for the target are activated, individuals are able to provide these pieces of partial information about the target word (e.g., initial phoneme; number of syllables). However, if no phonological nodes receive sufficient activation, no partial information can be reported.

TOTs are believed to be resolved when connections are strengthened and phonological nodes receive adequate activation. Encounters with other words that share phonology with the target word strengthen connections to and from all connected nodes, which can increase the activation of the target word's phonology and result in successful retrieval. This mechanism appears to play a critical role in spontaneous resolutions (i.e., when the target word 'pops' into mind while retrieval is no longer actively being attempted). It has recently been shown that in order for a phonologically related word (or *prime*) to facilitate TOT resolution, the prime must be from a grammatical class different from that of the target word. If it is from the same class, the prime receives the most activation, and resolution of the TOT is delayed until its activation has subsided. For example, if an individual has a TOT for *trellis*, which is a noun, encountering another noun, such as *trend*, as a phonological prime will delay resolution. On the other hand, having a phonological prime from a different grammatical class, such as the verb *tremble*, is helpful in resolving the TOT.

### Slips of the Tongue

Another type of word-retrieval error is a *speech error* or *slip of the tongue*. Unlike TOTs, these are not complete failures, because a word is retrieved and produced. Rather, slips of the tongue involve production of an incorrect word or sound, or a mispronunciation of an intended word. Naturally occurring speech errors are notoriously difficult to code because the speaker's intent is not always clear; so, as with TOTs, laboratory

methods have been developed for inducing slips of the tongue. Together, laboratory and naturalistic sources of speech error data have indicated that there are two major subclasses of slips of the tongue: *contextual errors* (which are influenced by other elements in the intended utterance; see many examples below), and *noncontextual errors* (which are influenced by information outside the components of the intended speech, such as irrelevant thoughts or nearby conversations).

Speech errors can involve entire words, or phonological components within words. Word-level errors can be of several subtypes, including: substitutions of words in the utterance, additions of unintended words, deletions of intended words, and shifts in the order of intended words. More specifically, exchanges are a type of substitution error that involve swapping the planned position of two intended words (e.g., producing *the table is on the napkin* instead of *the napkin is on the table*). Perseverations are another type of substitution in which a previously produced word is repeated (e.g., producing *the glass is in the glass* instead of *the glass is in the sink*). Anticipations occur when a word that is planned for a later part of the utterance is produced earlier than intended (e.g., producing *my yard is near the yard* instead of *my dog is near the yard*). Another type of word-level error is an addition, which occurs when information that is relevant, but unintended, is added to speech (e.g., producing *the old cat is aging* instead of *the cat is aging*). A deletion is the omission of an intended word (e.g., producing *my house was nice* instead of *my previous house was nice*). A blend is an utterance that combines two planned words into a single utterance (e.g., producing *I am totally responsible for this error* instead of *totally* or *solely*, either of which would be appropriate). For word-level slips, the lexical items that change places or intrude are usually from the same grammatical class and are also frequently phonologically similar to one another.

The types of errors that occur at the phonological level are similar to word-level errors. For example, phonological-level exchanges are when incorrect sounds are substituted for intended portions of a word (e.g., producing *flaid plannel* for the intended *plaid flannel*). When this type of exchange results in real words (e.g., producing *flea of my cat* instead of *key of my flat*), the error is called a Spoonerism (named after a man famous for making such errors). Anticipations and perseverations occur at the phonological level, but the duplication consists of phonemes within the word, rather than whole words (as in word-level errors). Elisions are omissions of one or more sounds in an intended word (e.g., producing *back cat* instead of *black cat*). Interestingly, phonological-level slips evidence a lexical bias, meaning they tend to create real words (e.g., misproducing *bed barn* for *red barn*, as opposed to misproducing *red ram*). Probably, errors that form real words are less likely to be noticed and corrected prior to their production. Phonological speech errors also demonstrate a positional constraint, such that word beginnings replace other word beginnings and word endings replace other word endings, rather than beginnings replacing endings or vice versa.

When applying the findings on speech errors to theory development, researchers have determined that word-level and phonological-level anticipation errors indicate that planning precedes production but is not completed before production begins. When individuals are able to correctly

produce portions of the word (e.g., its initial and final sound), this reveals weakened connections among some, but not all, of the phonological components. Together, the data on TOTs and slips of the tongue suggest that semantic and phonological systems really are separable.

## Word Retrieval in Specific Populations

Studying groups of people for whom lexical retrieval is different, is undergoing change, or is problematic has improved understanding about word retrieval in general. Specifically, research has explored the development of lexical retrieval processes in children and in bilinguals, as well as changes that occur in older adulthood. Problems in word retrieval are evidenced in individuals suffering from age-related dementias (such as Alzheimer's disease (AD)) and some types of aphasia. In this section, we consider word retrieval in these specific populations.

### Childhood

Children represent a special population because word-retrieval processes begin to develop during childhood. At around 18 months of age, children typically begin to demonstrate a tremendous growth in their ability to name objects. Researchers studying development suggest that during this time period, children exhibit significant progress in acquiring semantic and conceptual information. Some linguists assert that there is an advantage for acquiring nouns, including concrete nouns and proper names, over other types of words, such as verbs. According to this hypothesis, nouns are acquired more easily due to the transparent nature of their relationship to the world. Research has confirmed that children learn new nouns more quickly than new verbs, and nouns are produced more often than verbs by young children learning to speak. It has also been shown that among nouns, words for more unique concepts (e.g., animate objects) are most easily learned.

Interestingly, during this early stage of language acquisition, there is a noticeable increase in word-retrieval errors. It is often difficult to study word-retrieval failures per se in children because to suffer a true retrieval failure, the word must be correctly and completely known to the child. Researchers have found that children's errors in word retrieval frequently involve incorrect extensions and applications of knowledge they have about certain words to new words that appear to share some relevant characteristics. There are also instances where a child does know the correct word and has previously been successful in production, yet he or she retrieves and produces an incorrect word. Additionally, children demonstrate increased use of fillers and empty words in speech, as well as longer pauses, and increased word substitutions and word repetitions. These difficulties seem to indicate inaccessibility of target words.

Children have shown an increased susceptibility to word-retrieval errors during a period of rapid growth in the rate of acquisition for new words. It is suggested that this reflects weak connections for representations of these newly acquired words. During the time of intensive acquisition of new words, there may be an increased amount of competition among lexical

items. This increased vulnerability (due to infrequent use and/or to greater competition) leads children to have a large number of word-retrieval errors. As children repeatedly use words over time, the transmission of activation is increased and the rate of errors declines.

Word retrieval is recognized as an important component of language processing and cognitive development, but there remain relatively few studies of children's experiences with word retrieval. It has been suggested that models of adult retrieval may not adequately address the children's experiences during this very important developmental phase. Therefore, theoretical development may be necessary to provide a greater understanding of children's word-retrieval processes.

### Bilinguals

A speaker's complete fluency in a second language is another important variable in understanding the process of word retrieval. The role of bilingualism in lexical retrieval should vary depending on the speaker's degree of fluency in each language, his or her degree of use of each language, and the age at which each language was acquired. Typically, adults who are true bilinguals learned both languages during childhood, and we focus here on this population, as opposed to people who have learned a second language to a lesser extent or later in life. When a bilingual individual speaks in one language, lexical representations for the same concepts might also be activated in the language they are not using. If they are, their activation could result in word retrieval in the incorrect language or might lead to other types of errors. The notion that representations of both languages may be active at the same time during speech production is referred to as *parallel activation*. If there is parallel activation, bilingual speakers must have a way to determine which language to use in the current situation.

Studies of word-retrieval errors involving both languages have provided evidence for parallel activation. In research testing semantic interference effects in monolinguals, participants see a picture (e.g., of a car) that appears with a semantically related distractor word (e.g., *train*) typed on or near the picture. Other participants see the same picture along with a word that is semantically unrelated to the picture (e.g., *fruit*). Monolinguals are slower to name the picture when the distractor word is semantically related than when it is unrelated. The bilingual version of this paradigm entails having participants name the pictures in one language while seeing distractor items in their other language. Many studies report semantic interference effects, indicating that activation of semantic and lexical information in one language spreads to the other language.

Other research had bilingual participants name target pictures in one language while they were presented with a phoneme. Their task was to indicate whether that phoneme was included in the name of the target. The phoneme was never present in the target word in the response language, so the correct response was that the phoneme was not present. However, on some trials the phoneme was part of the other-language translation of the target. Participants had more difficulty rejecting the phoneme when it was present in the second-language translation of the target word, again indicating that both languages must be activated during the task.

Another line of research involves speech errors of bilinguals. There are two relevant types of errors: when a word from one language is produced when the speaker is actually intending to use the other language and when the intended word and its translation in the other language are blended together. The fact that these types of slips occur seems to indicate that both languages are (at least sometimes) activated at the same time, which can lead to errors in the retrieval and production of the target word.

A recent review detailed criticisms of these findings related to parallel activation and determined that results to date are inconclusive. There exist reasonable alternative explanations for all of the findings just described, and there are methodological limitations to the research. Some of the weaknesses of research on word retrieval in bilinguals can be resolved if the notion of competition is removed from models of lexical retrieval. Taken together, the preponderance of evidence regarding lexical retrieval in bilingual speakers supports interactive connectionist models of word retrieval.

### Older Adulthood

Research has shown that many cognitive processes change with age. However, verbal abilities have been shown to be relatively preserved in healthy aging. Word retrieval is one aspect of language where this is not the case: older adults' word retrieval is slower and less accurate than young adults'. For example, it takes older adults more time to produce names for pictures or definitions of an object, and they produce more pauses and hesitations in their speech, presumably reflecting problems retrieving desired words. They report more TOTs than young adults in both diary and experimental studies, and they produce more speech errors (particularly of specific types) than young adults. They generate more ambiguous references (e.g., using *he* instead of producing a specific man's name) than young adults do in conversation. These difficulties with word retrieval suggest declines in the access of phonological information. The ability to formulate concepts to express seems to remain intact with age; yet older adults show an inability to map these concepts onto the necessary phonological forms for production.

One class of theories explains the retrieval deficits of older adults by positing general slowing of cognitive processes with increasing age. The theories propose a slower speed of cognitive functions regardless of the task at hand, and have been supported by findings that older adults perform more slowly than young adults on many cognitive tasks. However, these theories cannot account for asymmetric effects of aging on language. That is, while deficits occur in the output processes of language production, input operations (i.e., language comprehension processes) appear to remain relatively intact.

Connectionist models (described earlier) can better account for asymmetrical effects of aging across different cognitive processes. As explained, these theories detail connections between networks of the language system, and the strength of these connections determines how much activation spreads across systems, and therefore, what information is retrieved. According to these theories, aging is an additional, separate variable thought to weaken connections among nodes. Because the production of language (an output process)

utilizes top-down processing, it is more vulnerable to reduced spread of activation into the phonological system of the network. This is because each phonological node must receive activation from only one connection before becoming accessible. On the other hand, information in the semantic system receives converging activation from all associated pieces of information, which compensates for any particular connection being weakened. In other words, when phonological information is provided to an individual during the perception and comprehension of language (i.e., input process), there are small or no effects of aging, as opposed to substantial age-related deficits found on production tasks. Connectionist models predict this asymmetry for aging effects, which has been confirmed by empirical evidence.

Many studies have examined age differences in the TOT experience. Older adults have more TOTs than young adults, partly because with increasing age, there is potential that the target word has not been produced for a longer period of time. It has also been suggested that older adults have more TOTs because they know more words and have to 'filter' through all of them to retrieve the correct word; however, evidence indicates that this is not the case. Older adults frequently describe their TOTs as a complete void of phonological information, still accompanied by a sense of imminent retrieval and frustration. They access relatively little partial information about the target word, and have fewer persistent alternate words come to mind than do young adults. In some experiments, TOT resolution rates have been shown to be similar for young and older adults, and priming of TOT resolutions has been shown to be similarly effective for young and older adults.

One particular aspect of retrieval that is unduly affected by aging is the ability to retrieve proper names. Names of individuals are especially difficult to retrieve in comparison to other information, such as the person's profession, and the age difference in TOTs for known names is much larger than for known occupations. According to connectionist models, this is because there are fewer connections between information about an individual's name than between information about his or her profession. Deficits in the transmission of activation to these pieces of information are even greater in older adults than in younger adults, resulting in more name retrieval failures and slowed production for older compared to young adults.

### Age-Related Dementia

Alzheimer's disease (AD) is one example of dementia whose prevalence increases with age. A diagnosis of AD can be confirmed only during autopsy, where it is determined by finding cellular changes in the brain. The beginning phases of this disease frequently look like typical age-related changes, such as forgetfulness. As more indications of cognitive decline begin to surface, a neurologist can do behavioral and cognitive assessments to determine if an individual is likely experiencing AD. The course and duration of the disease is quite variable, but individuals show some declines in cognitive functioning, including memory deficits, declines in fluid intelligence, and changes in temperament and behavior.

During the early stages of the disease, the individual with AD may begin to show some pronounced difficulty in naming

objects or people. They usually struggle more than healthy older adults do with the production of low-frequency words or complex sentences, and unlike healthy older adults, language comprehension may also be compromised. As the disease progresses, the individual may begin to show more severe deficits in comprehension and his or her speech may become more fragmented. The processing of semantic and lexical information is especially affected by AD, despite being unaffected in healthy older adults, and severe word retrieval deficits are a hallmark of AD and other age-related dementias.

## Aphasia

Aphasias are language disorders resulting from damage to particular areas of the brain. There are many varieties of aphasia, each linked with different types of language deficits. The location of brain damage predicts which specific functions will be affected. For most people, the areas of the brain associated with language are on the left side. Damage to these areas may be caused by stroke or traumatic brain injury, in which case there is an acute onset of symptoms. Alternatively, aphasia may develop over time, such as in the case of a brain tumor.

There are two main categories of aphasia. The first is nonfluent, or expressive, aphasia, of which Broca's aphasia is a well-known type. Individuals experiencing nonfluent aphasia are typically able to understand the speech of others, though they may struggle with particularly fast speech or symbolic language. During the production of language, they often speak with short, fragmented phrases, and they appear to expend a great deal of effort to retrieve and produce words. Speech of these aphasics is usually comprehensible, with the omission of only function words (e.g., articles such as *a* or prepositions such as *to*).

The other main class of aphasia is fluent, or receptive, aphasia, with the best-known type being Wernicke's aphasia. In this type of aphasia, the individual typically struggles with understanding the speech of others, as well as understanding their own speech production. For example, persons with receptive aphasia may produce long sentences that are difficult to understand, frequently adding unnecessary words, substituting incorrect words, producing words in the incorrect order, or producing things which are not words. Even though they produce a great deal of speech, their word-retrieval processes are not functioning correctly.

One benefit to studying these language disorders, as with studying speech errors in healthy speakers, is that it improves our understanding of language systems. The different types of aphasias (i.e., receptive vs. expressive) imply that the connections between meaning and sound may be damaged in one direction but not the other. Additionally, studies examining the retrieval errors that occur in different types of aphasias have often supported interactive activation models of lexical

retrieval. Various interventions, such as increased gesturing or provision of a semantic context, are being explored as treatments for retrieval problems in patients with a variety of aphasic disorders.

## Conclusion

In this article, we have described the processes involved in lexical retrieval, or the ability to produce individual words. We discussed major theories of lexical representation and production, and described some of the factors known to influence the accuracy and efficiency of word retrieval. We also discussed two major classes of word-retrieval errors: TOT states and slips of the tongue. Finally, we described word-retrieval processes in various populations, such as bilinguals, older adults, and people with aphasia. There remain many questions to be answered by future research. For example, further development of theories of successful word retrieval, perhaps incorporating underlying neurological mechanisms, is warranted. Also, research should continue to address the retrieval of words from various grammatical classes (not just nouns), and should expand current knowledge about word-retrieval processes in bilingual speakers and in children. These and many other questions remain under investigation by word-retrieval researchers worldwide.

### Glossary

**Attitudes** A state of mind or feeling about objects, people, or events often expressed as a like or dislike.

**Commitment** The degree to which an individual identifies with and is involved in a particular activity or organization.

**Efficiency** Acting in such a way as to use a minimum of time, money, or unnecessary effort, and the ratio of effective output to the input required to achieve it.

**Effort** The use of energy to do something; exertion.

**Goals** End results toward which human activity is directed.

**Motivation** Effort expended to perform work.

**Paradigm shift** Situations when an individual, team, or organization tackles a problem with radically innovative solutions rather than taking a step-by-step approach.

**Persistence** Directed effort over time.

**Satisfaction** Contentment derived from a relationship or a level of living or working.

**Stress** The body's reaction to a demand, or a physical or an emotional situation that causes imbalance.

**Work** Physical or mental effort expended to produce or accomplish something.

Work efficiency and motivation emerged as concerns of managers and researchers in the twentieth century and continues through the twenty-first century. From its beginning in the United States with the assembly-line efficiency studies of Frederick Taylor, this area of study has grown into a sophisticated science applicable to all organizations. His work is updated with new applications such as the Japanese-influenced 5S Concept discussed in this essay. The interest in the topic has emerged because of the recognition that successful organizations need people who are motivated and efficient, challenged but not overly stressed. As the pace of change accelerates, paradigm shifts are taking place. There is not always time for a step-by-step approach to increase productivity. Less clutter, physical and mental, may be part of the solution. How to increase motivation and efficiency in workers are on-going issues throughout the world. It would be difficult to find a recent research journal or book on industrial psychology, organizational behavior, family relations, or management that does not address these issues.

### Introduction

There are two levels to this discussion: societal and individual. Society is rapidly changing as evidenced by technological innovation and adoption affecting time management and worker availability and shifting demographics. Globally, the Internet, text messaging, and cell phones have revolutionized communication and impacted lives beyond measure. In the United States, the number of households has increased significantly but the number of people per household has decreased significantly (Goldsmith, 2010). It is predicted that the 2010 census will reveal that the most prevalent household type will be a married couple without children followed by a single person household. This demographic pattern is also seen in other developed nations. So what has happened in the work and family discussion of impacts on work efficiency and motivation is a switch from using the term 'work-family balance' to more usage of 'personal-professional life balance' as evidenced

in this international journal article title 'Sacrificing personal or professional life? A gender perspective on the accounts of retail managers' (Broadbridge, 2009).

A unified treatment of work efficiency and motivation must explore the phenomenon of human behavior at the individual level. Each individual is unique, and placed in similar situations all people do not act alike. However, certain fundamental consistencies that underlie behavior can be identified, measured, and predicted. This predictability allows for the systematic study of human behavior. The aspects of behavior to be discussed in this article are work efficiency and motivation.

### The Nature of Efficiency

Many practical problems are associated with how efficient workers are. The overall productivity (output) of an organization is linked to the way workers perform. How to encourage efficiency and maintain high-quality performance in workers are problems for everyone from line foremen to company presidents. This problem permeates all organizations, large or small, for profit or nonprofit. Since the 1940s, the emphasis shifted from increasing efficiency to increasing effectiveness as a means for boosting productivity. For example, a department store is considered effective when it successfully meets the needs of its shoppers. It is efficient when it can do this and still keep costs low. Thus, a store is most effective when it attains its sales or market share goals in a productive and efficient manner. The emphasis is not purely on making the most number of sales in record time, but on making sure that the sales are well handled, to encourage repeat business, and good 'word of mouth.' The concept of effectiveness implies a concern for the long haul as well as for short-term gains. The roots of efficiency studies that eventually led to the more global concept of effectiveness can be traced to the early 1900s when Frederick Taylor proposed scientific management principles designed to maximize production efficiency. The goal of these principles was to eliminate wasted time and motion in

repetitious work, especially assembly-line work. By carefully studying the most efficient ways jobs could be performed and implementing changes to increase efficiency, he was able to achieve productivity improvements from 200 to 300%. Naturally, Taylor became the favorite of managers, but drew criticism from some workers who felt his methods depersonalized production. Because of his contributions, Taylor is often called the father of management or the father of time and motion studies.

Eventually, his methods were criticized more because many previously creative, personally satisfying jobs became routinized and boring leading to increased absenteeism, and in some cases disruptive and even destructive behavior by employees. In highly routinized jobs, workers can begin to feel like 'cogs in a wheel' rather than as intelligent, skilled human beings. Managers who are aware of this problem try to resolve the creativity/efficiency conflict through a variety of ways. Most typically, jobs are redesigned to make them less routine and more meaningful. For example, encouraging team work stimulates workers' interest in their jobs and increases productivity. Rotating tasks are another means to keep work interesting. Ultimately, organizations need to develop a strategy and a structure that address the needs of its workers as well as its clientele. By the 1940s and 1950s, concern for the plight of the individual worker became the subject of many management and industrial psychology studies. During these decades, worker motivation became increasingly recognized as a contributor to productivity.

In the 1970s inflexible work hours and health effects from stress overload became topics considered by many to be primarily women's issues, but as time passed it was clear that the either-or of work and personal/family life was an issue for both men and women (Broadbridge, 2009). Stress can be internal (arising from personal thoughts, worry) or external such as the sudden appearance of a belligerent boss (Goldsmith, 2007). There is an emerging literature on the emotions in the workplace and the transactional approach to the stress process. Closely allied to the subjects of stress, efficiency, and effectiveness is the concept of motivation to be discussed next.

## **The Nature of Motivation**

Motivation comes in many forms and should be addressed within the over-arching economic climate. The word motivation was originally derived from the Latin word 'movere,' meaning 'to move.' In management theory and practice, motivation refers to movement and also direction, vigor, persistence, creativity, and sustained energy. To increase worker motivation, employers can choose from several methods. Some of these are enriching job skills through workshops, on-the-job training, travel and international assignments, sabbaticals, workplace seminars, courses, job rotation, and other forms of job/skill enrichment or by providing promotions, bonuses, or raises. Complications arise from the fact that what motivates one worker might not motivate another. The skilled manager tries to match the person with the most appropriate type of motivation. Keeping job skills up-to-date and providing a stimulating workplace are two ways that usually ensure a continual reservoir of highly trained, motivated employees.

Regarding the economy, with the downturn in recent years many organizations had to let go of workers and furlough the

ones remaining. Furloughs can mean working for several days or weeks a year without pay or in some cases, not having to come into work but not being paid (this might be during nationally recognized holidays or on days selected by the employer or the employee with approval of the manager). Firings, reduced hiring, overloads, and furloughs affect worker morale, on the other hand, it motivates many employees to work harder, happy to have a job during hard times. In many industries during the economic downturn, services to customers improved and employee retention was not a problem, motivation took a back seat to survival.

The previously mentioned methods to motivate employees are all extrinsic. In other words, they describe ways employers or managers (outside sources) can motivate workers. Another form of motivation is intrinsic. In intrinsic motivation, the effort, comes from within the worker. The concept of intrinsic and extrinsic motivation provides many puzzles for human behaviorists. Origin is one. Some individuals need very little external push to work harder while others seem to need a lot. Are the differences caused by genetics? By childhood experiences? By early work experiences? Another puzzle is how to stimulate intrinsic motivation. Studies on intrinsic motivation date back to the 1920s, but the concept became more widely known in the 1950s. Intrinsic motivation implies enjoyment in an action, a feeling of being totally immersed by an activity. Far more is known about extrinsic than about intrinsic motivation. It is generally agreed that to increase productivity, organizations need to tap both intrinsic and extrinsic motivation. Since motivation appears to be affected by both personal and situational factors which interact with one another, managers need to address both sets of factors. Many previous studies on motivation have centered on three main concerns: (1) what motivates or energizes human behavior, (2) how this behavior can be stimulated and sustained, and (3) what organizations can do to initiate, direct, and channel motivation. The rest of the article addresses these concerns.

## **Central Issues in Efficiency and Motivation**

One specific efficiency issue, efficiency versus effectiveness, has already been discussed. Generally, organizations today stress effectiveness. Also the problems inherent in overemphasizing efficiency and routinization and underemphasizing creativity and individualism in jobs have been mentioned in the Frederick Taylor discussion. A more central issue germane to both efficiency and motivation is how to stimulate and reward people who work hard.

## **Influences**

Why is it that some workers can be depended on to work hard while others cannot? There are many influences on worker efficiency and motivation. The most basic ones are personality, heredity or history, environment, and situations. Personality, the qualities, traits, and personal characteristics of a person, appears to be a result of both heredity and environment. The way it is enacted depends on the situation in which people find themselves.

Probably the best known theory of motivation was developed by psychologist Abraham Maslow. He hypothesized that each individual has a series of needs ranging from lower order needs to higher order needs. He called this series a hierarchy of needs. The lower order needs include physiological needs (i.e., thirst, hunger, shelter) and safety (i.e., security, safety from danger). The higher order needs include love (i.e., affection, acceptance), esteem (i.e., respect, admiration, status), and self-actualization (i.e., the development of full potential, fulfillment). According to Maslow, physiological needs have first priority and must be partially met before a person can fulfill higher order needs. All people seek to fulfill their needs, but each individual fulfills them in a different way.

Given this hierarchy, an organization that wants to motivate an employee should try to assess where that person is on the hierarchy and focus on satisfying that level of needs before proceeding to the next level. For example, during a recession or a period of down-sizing, the emphasis should be on safety needs (level two). During high growth times, the emphasis may shift to esteem or self-actualization (levels four and five).

Motivation can be envisioned as a process that originates with unsatisfied needs. Unsatisfied needs lead to tension which in turn stimulates drive and search behavior. The process ends when needs are satisfied and tension is reduced.

An individual as well as an organization can seek to influence the motivation process. Ideally, individual needs should be compatible and consistent with organizational needs. Unfortunately, it is not unusual for these needs to not match and to prove counterproductive. For example, a worker may be seeking solutions to problems which no longer hold importance for his or her manager. Communication and a shared vision are the keys to creating the right fit between individual effort and organizational output.

By the 1960s a philosophical shift was taking place in the field of organizational behavior. The human factor became an even more important subject of study than it had been previously. Jobs were no longer looked at as strictly technical, but as sociotechnical systems. This approach took into consideration the individual's response to their job as well as to the actual mechanics of the job. Technical tasks were viewed within the greater context of the work culture and environment. The narrowly defined concept of scientific management, that is, efficiency first and foremost, gave way to a much broader definition of management and all its permutations.

For example, in 1960 Douglas McGregor suggested in his book *The Human Side of Enterprise* that the manager's view of the nature of human beings is biased toward two main groupings of behavior assumptions which he labeled Theory X and Theory Y. Theory X assumes that the lower order needs identified by Maslow dominate the individual so that under Theory X, the assumptions held by managers are:

1. Employees inherently dislike work and will avoid it if they can.
2. Since employees dislike work, they must be coerced, controlled, directed, or threatened with punishment to put forth adequate effort toward the achievement of organizational objectives.
3. Employees will try to avoid responsibilities and seek security and direction whenever possible.

The assumptions underlying Theory Y are:

1. Employees view work as being as natural as rest or play.
2. Employees will exercise self-direction and self-control if they are committed to organizational objectives.
3. Employees are committed to objectives that are related to the rewards associated with their achievement.
4. Employees under normal conditions seek responsibility.
5. Most employees will exercise a relatively high degree of imagination, ingenuity, and creativity.
6. Under the conditions of modern life, most employees' intellectual potentialities are only partially utilized.

McGregor thought that Theory Y assumptions were more valid than Theory X. He believed that most people would thrive on opportunities for growth, challenging jobs, good interpersonal relations, and responsibility.

Motivation took on a more complicated formula with the introduction of the motivation-hygiene theory of psychologist Frederick Herzberg. He asserted that intrinsic factors such as achievement, recognition, responsibility, and growth were related to job satisfaction whereas extrinsic factors were more associated with dissatisfaction. A person's attitudes, therefore, have a great deal to do with that person's satisfaction and job success.

Just as with Taylor, the theories of McGregor and Herzberg have their detractors. For example, Herzberg's theory is criticized for emphasizing satisfaction over productivity and McGregor's for being too simplistic. However, all three theorists along with Maslow have had an enormous impact on the way organizations manage workers and design jobs. There are a number of newer theories that fall into the following categories: (1) needs, (2) goal-setting, (3) reinforcement, (4) equity, (5) expectancy, and (6) stress and fatigue. Due to space limitations not all can be sufficiently addressed in this article. What they have in common is that they try to explain and predict motivation, and many build on the works previously cited.

The field of psychology has always had a strong influence on the theories, research, and applications in organizational behavior. As an example, the roots of needs theory can be traced to Maslow's hierarchy of needs and those of reinforcement theory to the work of Harvard psychologist B. F. Skinner. Since Skinner found that rewards are most effective when they immediately follow the desired response, his research influenced when and how managers rewarded positive work behaviors.

Probably of the six theory categories listed, the one most relevant to the subject of motivation is expectancy theory. According to this theory, a person's motivation is a function of (1) matching effort to performance expectancies, (2) matching performance to outcome expectancies, and (3) the perception of attractiveness of outcomes. Satisfaction is conceived as a result of performance rather than a cause of it.

### Job Attitudes and Performance

Attitudes are thoughts or feelings (positive or negative) about objects, people, or events. For instance, people like or dislike opera. They also like or dislike certain aspects of their work. People have thousands of attitudes, but for the purposes of this article the focus will be on job attitudes, specifically, job satisfaction, involvement, and commitment.

Job satisfaction refers to the general attitude people have about their jobs. There are many measures of work satisfaction. Most attempt to determine whether workers are challenged in their work, feel adequately compensated, rewarded, and comfortable in their work environment including the physical facilities and interpersonal relationships. Job involvement has to do with how strongly people identify with and really care about the work they do. Commitment refers to how much the person identifies with the overall organization. Research indicates that high job involvement and commitment result in lower absenteeism and job turnover. Job satisfaction, involvement, and commitment are all subject to change, but usually people strive to maintain a consistency or balance in their attitudes and behaviors. This is consistent with McGregor's Theory Y discussed earlier; most people want to do well at their work.

In regard to performance, individuals are motivated if they can see that their performance is appreciated, noted, and rewarded. They need to know what the organization's performance expectations are and what the outcomes of their individual performance will be. Unclear objectives and a lack of consistency or confidence in the organization to define and recognize good performance will decrease worker motivation, and productivity may suffer.

A new managerial organizing principle for workplaces which has been found to improve performance is called the 5S concept. The name comes from a list of five Japanese words which when loosely translated into English become five words beginning with the letter 'S':

- *Sort*: Order items and activities (prioritize)
- *Straighten*: Arrange
- *Shine*: On task completion, clean and restore
- *Standardize*: Consistent methods will increase order, save time
- *Sustain*: Afterwards, maintain, reduce waste, evaluate

An example of the 5S concept in practice is when a hospital was reconfigured and stethoscopes were put in drawers marked 'stethoscope' rather than placing them on desk tops or hooks. Afterward every doctor and nurse knew where to find them, sounds simple, but it saved time (and perhaps lives) and lessened clutter. Efficiency experts are brought in to factories and multistory office buildings to make them more consistent and systematic using the 5S concept. This works particularly well in shared work spaces such as production lines and in the media with 24-h news where no one 'owns' a desk.

### Diversity in the Workplace

In the 1990s, a concern emerged about how well past motivational and efficiency theories fit the changing composition of the workforce. The growing number of women, minorities, and older workers in the labor force led organizations to reassess previously held notions about workers and their motivations. Appropriate changes in reward systems have begun to be implemented. As one example of a policy responsive to changes in the work force, the popularity and pervasiveness of flextime (flexible hours of work arrival and departure) can be partially traced to the growing number of working parents who are trying to balance work and family responsibilities.

By 2010, white non-Hispanics in the United States will constitute 54% of the population under the age of 18. In the ten largest cities, no ethnic or racial group will have a clear majority. The urban work force will become increasingly diverse.

The recognition of diversity in the workplace has brought to question the notion that an organization has a uniform culture to which all employees subscribe. Typically in organizations there is a dominant culture and several subcultures. A subculture is a set of values and attitudes held by a minority of the organization's members. Subcultures may fall along the lines of specializations, interests, or in a variety of other ways. Subcultures can weaken and undermine an organization, but more likely they will ascribe to and support the values of the dominant organization culture while seeking to maintain their own identity.

Respecting diversity and working with it rather than against it will be the key to the continued success of organizations. In order to remain competitive, employers are making an effort to recognize, recruit, and manage an older and more culturally and racially diverse work force. While practical applications are moving ahead, research on workplace diversity in relation to motivation and efficiency is in its infancy.

### Motivational Techniques

The concept of goal motivation is used to explain how direction, effort, and duration/persistence affect goal-setting. Goals direct action and behavior. It has been established that higher goals produce higher performance. If goals are set too low they are not motivating enough. Conversely, goals set unreasonably high can be frustrating. Thus, finding the right level of goals is a management problem. The words 'duration' and 'persistence' refer to directed effort over time, a relentless, driving behavior. Goal commitment implies a determination to continue goal-seeking. Research indicates that self confidence and previous success at achieving goals positively affect a person's future goal commitment and achievement.

Technique refers to the systematic procedure for accomplishing a task. Motivational techniques, therefore, are procedures that stimulate a person to accomplish a work task. Goal-setting is one technique for motivating workers.

### Goal-Setting

In 1968, Edwin Locke published a paper that is considered to be the seminal work on goal-setting theory. He wrote that people strive to attain goals in order to satisfy their emotions and desires. Although goal-setting is an important motivational stimulus, the concepts of needs and values are also fundamental concepts of work motivation according to Locke.

More recently, researchers and theorists have concluded that goals direct and focus attention onto certain task requirements, away from conflicting or alternative actions. Thus, goals direct behavior and provide a framework for a strategy of performance. Sometimes intentions and goals are used interchangeably, but they are different in that intentions may be theoretical (a person plans or intends to do something) whereas the word goal implies action. In the terms 'goal attainment' and 'goal achievement,' an end result is assumed.

Before goals can be achieved, they need to be set. Research on goal-setting falls into the following categories: (1) specific versus general, (2) difficult versus easy, (3) owned or shared versus imposed, and (4) timely feedback and progress toward goals. The results of the research indicate that specific, challenging, and owned or shared goals are preferred. The degree of persistence applied to goal pursuance is closely linked to ultimate achievement. And in the end, timely and appropriate feedback is preferable to no feedback. Workers want to know the results of their efforts.

Organizations put a great deal of energy into setting goals and motivating workers to achieve organizational goals. At the same time, workers have personal goals they are trying to achieve. Two examples of worker goals are the opportunity to learn more and move ahead. Organizations try to match worker's needs with organizational needs-enhancing work satisfaction and output for both.

In the 1980s, American business embraced a Japanese business practice called total quality management (TQM). One of the techniques in TQM relevant to goal-setting is the widespread use of quality circles (QCs). In QCs, a group of employees regularly meets to identify and solve work-related problems.

Their focus is on increasing productivity and meeting department and organizational goals. Improvements are suggested. A group leader reports the proposed improvements to higher management. Steering committees sort through the suggestions and implement the ones they consider viable. With QCs it was thought that everyone benefits from the increased communication between the various levels of the organization and the cooperative spirit generated by teamwork.

By the 1990s, some drawbacks to QCs and TQM were uncovered. This form of management involves many meetings and a lot of paperwork that is time consuming. Some of this time was taken away from the basic organizational functions of serving customers and producing goods. Consequently, TQM and QCs are being reassessed. Research continues to try to determine in what situations, settings, and organizations QCs and TQM are most effective.

### Reward Systems in Organizations

A review of the literature reveals the importance of rewards in the relationship between motivation, satisfaction, and work performance. Lyman Porter and Edward Lawler developers of the Porter Lawler motivation model recommend that organizations make sure that their reward policies are closely linked to performance. This is suggested because the individual worker's job satisfaction is derived from the difference between the amount of rewards he or she receives and the amount he or she expects to receive. Job satisfaction represents an attitude, positive or negative, rather than a behavior. Zellars et al. (2004) point out the relationships among attributes such as emotions and problem solving to coping with what goes on in organizations.

Equity is an important part of job satisfaction. Employees want pre motion and pay systems that they perceive as just, equitable, and fair. Individuals who perceive reward decisions as unambiguous and consistent with their expectations will likely report satisfaction with their job.

Closely linked to the concepts of intrinsic and extrinsic motivation discussed earlier are the concepts of intrinsic and extrinsic rewards. The pleasure or value a person derives from the content of work itself makes it intrinsically rewarding. Rewards received from the work environment, the organization, are extrinsic. A company-paid car is an extrinsic reward, whereas the feelings of personal satisfaction from a job well done are intrinsic. Intrinsic rewards may stem from greater job freedom and discretion, more interesting work, opportunities for personal growth, and more participation in decision making. There are dozens of extrinsic rewards ranging from assigned parking spaces to profit sharing. To be most effective, rewards should be individualized to meet each person's needs. One employee might value a flexible lunch hour so he can swim every day in the nearby university pool while another employee may put more value on a paneled office with a large desk. Rewards can be used by organizations to recognize an employee's past achievements or to direct him or her toward certain future achievements.

### Concluding Remarks on Efficiency and Motivation

Observing and commenting on human behavior is a fundamental and enduring subject for the novice as well as the professional. This article explored how organizations try to direct employee behavior toward higher productivity. The theories discussed in the article reveal that there is not one, singular all-purpose way to motivate workers or to make an organization more efficient. Generally it is agreed that satisfied, motivated workers are more productive than dissatisfied, bored workers. Organizations try to identify, recognize, and reward productive workers. Research reveals that rewards should be consistently and fairly distributed. The ultimate organizational behavior goal is a happy/productive/consistent worker-not one alternating between despair and elation. Rewards should not produce ups and downs, but a secure feeling that efforts are noted and rewarded, if not immediately, then soon.

Since its beginnings in assembly-line management, the concept of efficiency has given way to a broader view of productivity encompassing effectiveness and worker satisfaction. The effective organization sets goals and keeps in mind the different levels of job needs of its workers. Organizations in the future will make fuller use of the skills, diversity, and motivational potential of their human resources and more effectively integrate ever-changing technology to their advantage.
