Glossary

Avoidance Cognitive, behavioral, or motivational activity that is performed in order to prevent or escape from unpleasant emotion and anxiety associated with the trauma.

Flashbacks One of the reexperiencing symptoms of PTSD that include very vivid images, or visual pictures of some aspect of the trauma that suddenly pop into the mind, as if the trauma is occurring again.

Hyperarousal Physical or emotional tension produced by the fight-or-flight response; a common symptom of PTSD.

Hypervigilance Increased physical arousal, responsiveness to stimuli, and searching of the environment for threats; a common symptom of PTSD.

Posttraumatic stress disorder A chronic psychiatric disorder that results from a traumatic experience and is characterized by intrusive thoughts about the trauma, avoidance of stimuli associated with the trauma, and increased autonomic activity, all of which interfere with normal functioning.

Trauma An event that involves actual or threatened death or serious injury, or a threat to the physical integrity of self or others, such as a natural disaster, sexual or physical assault, being threatened with a weapon or violence, childhood abuse, military combat, exposure to a war zone, imprisonment, torture, or diagnosis with a life-threatening illness.

General Description

As its name implies, posttraumatic stress disorder (PTSD) is unique among the mental disorders in that it is a reaction to a clear precipitating event – a traumatic experience. Although it is to be expected that people will experience distress after a serious trauma, individuals with PTSD continue to be bothered by the traumatic event long after it has passed. They often are distressed at or avoid thoughts or situations that remind them of the trauma. Features of PTSD include prominent symptoms of fear, anxiety, avoidance, and arousal, which are consistent with its classification as an anxiety disorder. However, it also includes depressive symptoms, numbing of feelings, and flashbacks.

Diagnostic and Statistical Manual (DSM) Conceptions

Before the modern conceptualization of PTSD, the syndrome was known by several other names that reflected the hypothesized etiology at the time. For example, during World War I ‘shell shock’ or ‘combat/battle fatigue’ were terms applied to soldiers suffering from symptoms consistent with modern PTSD. During World War II, ‘war neurosis’ or ‘traumatic neurosis’ was more common. Although PTSD first appeared in the *Diagnostic and Statistical Manual for Mental Disorders*, 3rd edn., earlier editions of the Diagnostic and Statistical Manual (DSM) noted disorders triggered by traumatic stressors. A category of gross stress reaction was recognized in the DSM-I, although it was conceptualized as a phasic response limited to combat. This disorder was eliminated in the DSM-II and instead appeared as a combat stress reaction under stress reactions. Once the high occurrence of postcombat syndrome in Vietnam veterans was exposed, related responses to other traumas (e.g., assault, rape, natural disaster) were recognized and a more inclusive disorder called PTSD was termed and classified as an anxiety disorder in the DSM-III.

PTSD symptoms are classified in the DSM-IV into the following three domains: reexperiencing, avoidance and numbing, and hyperarousal. PTSD symptoms typically begin within 3 months after the trauma, and specifiers are used to label onset and duration of these symptoms. When symptoms of PTSD last less than 3 months posttrauma, the disorder is specified as ‘acute,’ whereas symptoms that last 3 months or more posttrauma are ‘chronic.’ Finally, a less frequent presentation of PTSD, ‘delayed onset,’ occurs when symptoms begin at least 6 months or more following the traumatic event.

PTSD Criteria

PTSD consists of affective, cognitive, and behavioral symptoms that some individuals develop in reaction to a traumatic event and that are associated with distress and impairment in functioning. Criteria related to the traumatic event and resultant symptoms are required together to make a PTSD diagnosis.

A person may develop a posttraumatic stress reaction as a result of experiencing, witnessing, or having been confronted with a trauma. For the traumatic event to support a PTSD diagnosis, it must involve ‘actual or threatened death or serious injury, or a threat to the physical integrity of self or others’ (Criterion A1). Examples of events that would meet Criterion A1 include, but are not limited to, a serious accident, a natural disaster, sexual or physical assault, being threatened with a weapon or violence, childhood abuse, military combat, exposure to a war zone, imprisonment, torture, or diagnosis with a life-threatening illness. This definition contrasts with the previous conceptualization of a traumatic stressor in the DSM-III-R as a rare event ‘outside the range of usual human experience.’ It is now estimated that exposure to lifetime trauma may be as high as 81.7%. However, exposure to a traumatic event is a necessary but not sufficient condition for a PTSD diagnosis. In fact, the vast majority of persons exposed to trauma will not go on to develop clinical traumatic

stress reaction. Persistent psychological distress after a trauma may relate to how a person reacted at the time of the trauma. DSM criteria take this into account by requiring that the individual responded to the trauma with 'intense fear, helplessness, or horror' (Criterion A2).

The DSM-IV symptoms for PTSD include the following three clusters: reexperiencing, avoidance and numbing, and hyperarousal (see Table 1). First, individuals must have at least one symptom of reexperiencing, such as intrusive memories, nightmares, flashbacks, or reactivity to traumatic reminders. Second, individuals diagnosed with PTSD must display three or more symptoms of avoidance and/or numbing, such as avoidance of trauma-related thoughts or situations,

Table 1 DSM IV-TR diagnostic criteria for 309.81 PTSD

- A. The person has been exposed to a traumatic event in which both of the following have been present:
 1. The person experienced, witnessed, or was confronted with an event or events that involved actual or threatened death or serious injury, or a threat to the physical integrity of self or others
 2. The person's response involved intense fear, helplessness, or horror. Note: In children, it may be expressed instead by disorganized or agitated behavior
- B. The traumatic event is persistently reexperienced in one (or more) of the following ways:
 1. Recurrent and intrusive distressing recollections of the event, including images, thoughts, or perceptions. Note: In young children, repetitive play may occur in which themes or aspects of the trauma are expressed
 2. Recurrent distressing dreams of the event. Note: In children, there may be frightening dreams without recognizable content
 3. Acting or feeling as if the traumatic event were recurring (includes a sense of reliving the experience, illusions, hallucinations, and dissociative flashback episodes, including those that occur upon awakening or when intoxicated). Note: In young children, trauma-specific reenactment may occur
 4. Intense psychological distress at exposure to internal or external cues that symbolize or resemble an aspect of the traumatic event
 5. Physiologic reactivity upon exposure to internal or external cues that symbolize or resemble an aspect of the traumatic event
- C. Persistent avoidance of stimuli associated with the trauma and numbing of general responsiveness (not present before the trauma), as indicated by three (or more) of the following:
 1. Efforts to avoid thoughts, feelings, or conversations associated with the trauma
 2. Efforts to avoid activities, places, or people that arouse recollections of the trauma
 3. Inability to recall an important aspect of the trauma
 4. Markedly diminished interest or participation in significant activities
 5. Feeling of detachment or estrangement from others
 6. Restricted range of affect (e.g., unable to have loving feelings)
 7. Sense of foreshortened future (e.g., does not expect to have a career, marriage, children, or a normal life span)
- D. Persistent symptoms of increasing arousal (not present before the trauma), indicated by at least two (or more) of the following:
 1. Difficulty falling or staying asleep
 2. Irritability or outbursts of anger
 3. Difficulty concentrating
 4. Hypervigilance
 5. Exaggerated startle response

anhedonia, interpersonal detachment from others, or emotional numbing. Lastly, a PTSD diagnosis requires the presence of two or more hyperarousal symptoms, such as insomnia, hypervigilance, or heightened startle response.

Duration is another element of the PTSD diagnosis. Although distress is a normative reaction following a traumatic event, most people do not go on to develop a clinical stress reaction. For example, in a study of rape victims, 94% of the sample met criteria for PTSD immediately after the trauma (mean = 12.64 days postassault). However, this number decreased to 65%, 47%, 42%, and 30% at 1, 3, 9, and 12 months postassault, respectively (see Figure 1).

Given the natural recovery trajectory of many traumatized individuals, a diagnosis of PTSD requires that the disturbance is present for greater than 1 month. PTSD is specified as chronic if the symptoms persist longer than 3 months. People who develop significant posttraumatic stress symptoms typically experience them starting soon after the traumatic event. However, in rare cases in which symptoms arise 6 months or more after the traumatic event, the DSM specifies this as PTSD 'with delayed onset.' Similar to other mental disorders, a PTSD diagnosis requires symptoms to cause significant distress or impairment in functioning.

A limitation of the 1-month duration criterion for PTSD in the DSM-IV is that it excludes those victims of trauma who immediately exhibit significant symptoms that may demand clinical attention. Acute stress disorder (ASD) was introduced to fill a diagnostic gap for those individuals experiencing high distress in this acute phase after a trauma. In this case, the diagnosis of ASD can be applied if symptoms emerge within the month after the trauma and last for at least 2 days. A second goal of the ASD diagnosis was to predict who would eventually develop PTSD after a trauma.

The International Classification of Diseases (ICD) is the international standard classification system created by the World Health Organization (WHO). It is currently available in the 10th edition (ICD-10). Like the DSM-IV, the ICD-10 requires a history of trauma exposure along with the three symptom clusters (reexperiencing, avoidance, and hyperarousal). However, there are also several differences in diagnostic criteria between the two systems. First, the ICD-10 does not require the subjective stressor criterion (the person's response involved intense fear, helplessness, or horror). The ICD-10 requires only one symptom of avoidance and does not include numbing. The ICD system also specifies that symptoms onset must be within 6 months of the stressor. Finally, the ICD-10 does not require functional impairment.

Figure 1 Percent with PTSD symptoms by months since trauma.

Prevalence

As described earlier, a majority of individuals show natural recovery after a trauma. However, many trauma survivors fail to recover and experience persistent symptoms of PTSD. The first National Comorbidity Survey (NCS) found trauma exposure rates of 60–70% and lifetime rates of PTSD in the United States of 10.4% and 5%, for women and men respectively. Although the subsequent NCS replication (NCS-R) yielded a higher rate of trauma exposure (82%), likely due to the less restrictive definition of a trauma, estimated lifetime prevalence of PTSD was similar at 6.8%. Twelve-month prevalence for PTSD was estimated at 3.5%. Epidemiological studies with European samples have reported variable lifetime prevalence rates of PTSD. For example, whereas one study of six European countries estimated prevalence at 1.9%, a large-scale study in Sweden estimated prevalence at 5.6%. Thus, PTSD prevalence may be somewhat specific to nations or regions.

Various demographic factors affect risk for PTSD. As suggested by the numbers above, females are nearly twice as likely to meet criteria for PTSD as compared to males. This sex difference does not appear to be due to overall rate of trauma exposure or type of trauma, but may be due to a greater risk of developing PTSD following assaultive violence. Although some studies have reported higher rates of PTSD among ethnic minorities, these differences did not persist after controlling for sociodemographic variables, such as SES and residential area. Moreover, NCS-R data revealed no significant differences in lifetime prevalence of PTSD across different ethnic groups. Finally, several studies have reported that higher risks of trauma exposure and PTSD are associated with younger age.

Morbidity

Individuals with PTSD have an increased likelihood of past or current psychiatric disorders, with lifetime comorbidity rates of ~80%. Mood and anxiety disorders commonly co-occur with PTSD. For example, in the initial NCS, nearly 50% of participants who reported lifetime PTSD also reported a history of depression. In a separate study, 32% of women with current PTSD met criteria for major depression compared to only 4% of women without PTSD. Elevated rates of alcohol and drug use disorders have also been observed among individuals with PTSD.

PTSD also has been linked with poorer general physical health as well as negative health behaviors. Substantial research indicates that it is associated with disturbances in cardiovascular, gastrointestinal, neuroendocrine, and immune functioning. Based on the most recent national epidemiological study of psychiatric disorders, both trauma and PTSD predicted increased risk for a number of chronic medical diseases, including chronic pain conditions and heart disease. Individuals with PTSD also are more likely to be past or current smokers. Negative health behaviors, such as smoking, and dysregulation of the hypothalamic–pituitary–adrenal (HPA) axis could partly explain the relation between PTSD and physical health. Furthermore, biological studies suggest that hypersecretion of cortisol in PTSD may be associated with age-related memory impairments.

Finally, PTSD results in significant functional impairment and has a large economic impact. It can have deleterious effects on interpersonal functioning. Galvoski and Lyons (2004) reviewed the negative impact that combat-related PTSD has with respect to relationship distress and dissolution and parenting abilities. Economic burden includes greater medical costs, higher rates of unemployment, and lost wages. PTSD has been associated with up to 4000 dollars more in medical costs, even after controlling for other factors. It is also negatively related to employment among veterans, with PTSD associated with more than 3 times greater probability of unemployment in some samples. Even working veterans with a lifetime diagnosis of PTSD had significantly reduced earnings. Similarly, in a large-scale population study, PTSD diagnosis predicted greater work days lost, even after controlling for age, sex, and comorbidity.

Etiology

PTSD is unique among the anxiety disorders because a precipitating event is part of the diagnostic criteria. However, the specific reason for the persistence of symptoms in PTSD remains largely unknown. There are several theories that attempt to explain the development and maintenance of PTSD symptoms. Most empirically supported treatments are based on some variant of learning theory. First, learning theory (e.g., Mowrer's two-factor theory) proposes that initial symptoms develop due to classical conditioning (pairing of the trauma cues with a fear reaction) whereas the persistence of symptoms over time is due to operant conditioning (avoidance is reinforced through reduction of fear). Second, emotional processing theory holds that PTSD emerges due to the development of a fear network in memory that elicits escape and avoidance behavior. Mental fear structures include stimulus, responses, and meaning elements. Any information associated with the trauma is likely to activate the fear structure. The fear structure in people with PTSD is thought to include a particularly large number of stimulus elements; therefore, it is easily accessed. Attempts to avoid this activation result in the avoidance symptoms of PTSD. Third, social-cognitive theories focus on the content of cognitions within a social context. There is supporting research evidence for all three theoretical approaches.

Treatment

Currently, cognitive behavioral therapy (CBT) is the treatment of choice for chronic PTSD. CBT is not a single technique but rather a broad approach that includes a range of techniques. The goals of CBT are to reduce the intensity and frequency of distressing negative emotional reactions, modify erroneous cognitions, and promote functioning. CBT programs for PTSD include variants of exposure therapy, stress inoculation training (SIT), and cognitive therapy (CT). Each of these programs has been administered by itself or in combination with one another. A fourth treatment for PTSD that has received empirical support is eye movement desensitization and reprocessing (EMDR), a treatment that utilizes elements of exposure and cognitive restructuring but with the addition of therapist-directed rapid eye movements or other

bilateral stimuli. Two recent innovations in the treatment of PTSD are the application of imagery rehearsal therapy to PTSD-related nightmares and the use of technology, such as virtual reality technology and delivery of therapy via the Internet. As the research on these more recent treatments is relatively limited, they will not be discussed further in this article.

Exposure Therapy

As described previously, PTSD is characterized by the reexperiencing of the traumatic event and attempts to ward off the intrusive symptoms or avoid the trauma reminders, even when such trigger stimuli are not inherently dangerous. Given these two broad categories of feared stimuli (the traumatic memories and triggers that are reminders of the trauma), the core components of exposure programs for the disorder are (1) imaginal exposure, which involves revisiting the traumatic memory, repeatedly recounting it aloud, and processing the revisiting experience; and (2) in vivo exposure, which involves repeated confrontation with trauma-related situations and objects that evoke excessive anxiety but are not inherently dangerous. The goal of this treatment is to promote processing of the trauma memory and to reduce distress and avoidance elicited by the trauma reminders. Additionally, individuals with pronounced symptoms of emotional numbing and depression are encouraged to engage in pleasurable activities even if these activities do not elicit fear or anxiety but instead have dropped out of the person's repertoire due to loss of interest. The rationale for this latter component is similar to the use of behavioral activation strategies in the treatment of depression.

Exposure therapy programs that have been evaluated in RCT differ in the type of exposure techniques used, how they are implemented, and what other nonexposure techniques are utilized. For example, some researchers have relied exclusively on imaginal exposure, whereas others have relied exclusively on in vivo exposure. By contrast, the prolonged exposure (PE) program developed by Foa and colleagues and a similar program developed by Marks and colleagues utilized both imaginal and in vivo techniques. Exposure therapy programs also differ in the extent to which exposure techniques are the primary focus in therapy, such as the programs developed by Foa and colleagues and Marks and colleagues, or are substantially supplemented with other CBT techniques such as stress inoculation and CT procedures, such as the CBT program developed by Blanchard, Hickling, and colleagues. In some CBT programs, such as Resick's cognitive processing therapy program (discussed in greater detail later) and the Blanchard and Hickling program just mentioned, exposure to the trauma memory is implemented through narrative writing exercises.

Stress Inoculation Training

Veronen and Kilpatrick (1983) adopted Meichenbaum's (1974) SIT approach for the treatment of PTSD symptoms in female rape victims. As applied to PTSD, SIT includes education about trauma-related symptoms plus anxiety management techniques such as controlled breathing and relaxation training, cognitive restructuring, guided (task-enhancing) self-dialogue, assertiveness training, role playing, covert modeling, and thought stopping. Once the various techniques have been introduced, the

therapist and patient work together to select and implement the techniques in a flexible manner to address patient's current concerns or specific symptoms. As with exposure therapy, SIT programs vary from one another, with the most notable difference being that some programs include an exposure component whereas others do not. Although interest in the study of SIT for PTSD has diminished in recent years, one innovative use of SIT has been to target anger among veterans with chronic PTSD and significant anger problems.

Cognitive Therapy

CT for PTSD is derived from Beck's model of treatment for depression and its extension to anxiety, wherein the goal of therapy is to help patients identify trauma-related dysfunctional beliefs that influence emotional and behavioral responses to a situation. Once identified, patients are taught to evaluate the thoughts in a logical, evidence-based manner. Information that supports or refutes the belief is examined as are alternative ways of interpreting the problematic situation. The therapist helps patients to weigh the evidence and consider alternative interpretations before deciding whether the belief accurately reflects reality, and if not, to replace or modify it. CT programs differ in the length and number of sessions. Moreover, some CT programs include an exposure component, such as Resick's cognitive processing therapy and the CT program based on Ehlers and Clark's cognitive theory of PTSD, whereas other CT programs do not.

Eye Movement Desensitization and Reprogramming

In EMDR, the therapist asks the patient to generate images, thoughts, and feelings about the trauma, to evaluate their aversive qualities, and to make alternative cognitive appraisals of the trauma or their behavior during it. As the patient initially focuses on the distressing images and thoughts, and later focuses on the alternative cognition, the therapist elicits rapid, lateral alternating eye movements by instructing the patient to visually track the therapist's finger as it is moved back and forth across the patient's visual field. Originally, Shapiro regarded these eye movements as essential to the processing of the traumatic memory, but the importance of the eye movements has not gained empirical support. Some EMDR programs have replaced the eye movement components with other procedures (e.g., patient alternating finger tapping from the right to the left hand), claiming equivalent mechanisms underlying these various procedures; however, dismantling studies have not demonstrated that these movements affect symptom reduction, and well-designed treatment outcome research studies have found no advantage of EMDR over exposure therapy alone.

Efficacy/Effectiveness of Treatments

According to consensus panels such as the Institute of Medicine (IOM), the National Institute of Clinical Excellence (NICE), American Psychiatric Association, and International Society for Traumatic Stress Studies, the treatment of choice for chronic PTSD is exposure therapy or some other form of CBT. The IOM of the National Academies (2008) reviewed 53 psychotherapy and 37 pharmacotherapy RCTs in the treatment of PTSD and concluded that the evidence was sufficient to

conclude the efficacy of exposure therapies in treating patients with PTSD. However, they found that the evidence was inadequate to reach a conclusion regarding the efficacy of EMDR, cognitive restructuring, coping skills training, other therapies, and psychotherapies administered in a group format. The IOM committee also concluded that the evidence was inadequate to determine the efficacy of pharmacotherapy for PTSD. Similarly, the ISTSS guidelines stated that CBT (imaginal and in vivo exposure), CT, SIT, or CPT is recommended as first-line treatment for chronic PTSD. The [NICE \(2005\)](#) guidelines were similar, stating that drug treatments for PTSD should not be used as routine first-line treatment in preference to trauma-focused psychological therapy.

Overall, the data suggest that the various forms of CBT are effective in treating chronic PTSD with no major differences in outcome between treatments; however, exposure-based treatments have the largest amount of support to date.

Summary

The experience of a traumatic event in one's life appears to have become the rule rather than the exception. Studies show that as many as 80% of people report experiencing a traumatic event in their lifetime. After a trauma, most people report posttraumatic symptoms including reexperiencing, avoidance, and hyperarousal. However, these symptoms largely dissipate over the period of ~1 year. For a significant minority, these symptoms may persist and become chronic without some form of treatment. Thus, PTSD is seen as a failure of the natural recovery process. The evidence to date from all sources (consensus panel recommendations, meta-analyses, and RCTs) suggests that cognitive-behavioral interventions should be considered the treatments of choice for PTSD. Specific recommendations vary depending on the amount of time between the index trauma and the point of intervention. Immediately following a traumatic event, psychological debriefing of all exposed individuals is contraindicated. Rather, a watch-and-wait strategy is preferred. Most trauma survivors experience PTSD symptoms that improve with the passage of time. For those individuals in whom intervention is indicated prior to meeting criteria for chronic PTSD, brief CBT (B-CBT) should be considered. CBT should be considered the standard of care for patients with chronic PTSD. The CBT programs with the largest evidence base to date are the exposure-based treatments. Thus, the major thrust of evidence-based practice should be focused on connecting trauma survivors with CBT practitioners if they continue to experience PTSD symptoms after a period of 3 months.

Preference Judgments (Individuals)

E R Igou, F van Dongen, and W A P van Tilburg, University of Limerick, Co. Limerick, Ireland

© 2012 Elsevier Inc. All rights reserved.

Glossary

Choice Act of deciding between alternatives by preferring one alternative over other alternatives.

Emotion Object-related affective state; relatively acute, intense, and momentary; grounded in arousal and cognitive appraisals.

Mood Affective state without specific object, relatively low in intensity and enduring.

Preference Difference in overall value associated with objects or alternatives; reflected in relative differences in ratings, rankings, or choice preferences between alternatives.

Preference reversal Change of preference as a function of the presentation of objects or alternatives.

Rational choice Norm that people prefer choice alternatives that maximize utility.

Subjective experience General term that includes a wide spectrum of different experiential phenomena such as mood, emotions, and processing fluency; can serve as heuristic, prime, can interact with other information, and can influence processing strategies.

Utility In decision-making, subjective evaluation of objective values.

Introduction

When do we prefer something over something else? Preference judgments are based on comparisons between objects. The term 'object' refers here to any kind of category that preferences are about (e.g., people, materials, ideas). The most straightforward indicators of preferences are choices between two alternatives. For example, a person may choose to drink a cup of café latte rather than a cup of cappuccino, indicating a preference for café latte over cappuccino. Besides choices, preferences can be reflected in relative evaluations of objects; café latte may be evaluated more positively than cappuccino. If people do not care about a comparison of objects, for example, when they do not drink caffeinated beverages, they are unlikely to prefer one object to another. Objects may be evaluated differently, for example, regarding the amount of milk that beverages contain, yet this evaluation may not constitute a preference. Only if a set of objects are relevant to the self, can we speak of preferences. Despite this specification, the preference concept is broad and preferences are omnipresent in many implicit and explicit judgments and in actions and decisions in everyday life.

Preferences are relative because they may change with the set of objects that is considered, that is, a preference for an object may not occur with the addition of a different object. In addition, perceptions of the overall value or suitability of objects may change, leading to different preferences. That is, the underlying value may vary between people, over time, or between contexts. Many of the potential variations of preferences indicate that preferences are inherently subjective in nature. Objective outcomes of alternatives cannot be equated with subjectively perceived outcomes (*utilities*). In a mathematical sense, negative values and positive values are equally important and both increase in a linear fashion; however, decision-making research has demonstrated that negative values loom larger than positive values, and that the relationship between objective and subjective values is curvilinear: convex for negative values and concave for positive values (see value function of prospect theory). Similarly, objective probabilities of outcomes are unequal to subjective probabilities. Subjective

probabilities are overestimated when likelihoods are generally small, they are underestimated when likelihoods are moderate, and outcomes are perceived as certain when likelihoods are very high (see probability function of prospect theory).

Psychological research has greatly contributed to the understanding of preference judgments. Besides considering the objective situation (e.g., decision problem, task), it is central to examine how people's preferences are affected by their interpretations of particular situations. To shed light on these interpretations, it matters, for example, which information is salient in the situation (e.g., how a problem is presented), how information is encoded and classified, whether a person processes the information automatically or deliberately, how a person is motivated, and how a person is affected by moods, emotions, and other subjective experiences. Explanations of psychological processes that affect preference judgments and decision-making have evolved based on comparing normative (i.e., rational) models of behavior to actual behavior. First, we will give a brief summary of some classic findings, and then we will consider some of the research that has evolved more recently.

How Rational Are Preference Judgments?

Historically important for research on preference judgments and decision-making is John von Neumann and Oskar Morgenstern's Expected Utility Theory. According to this normative theory, the maximization of control (probability of an outcome \times utility of an outcome) reflects rational behavior. Note that other concepts of rationality are possible (e.g., reasoned, nonemotional, logical); however, we will use this particular definition because it was central for the development of research on preferences. In order for behavior to qualify as 'rational,' it has to be consistent with a set of axioms. Unfortunately, human behavior, neither in everyday life nor in the lab, seems to live up to these ideals; in fact, preference judgments often violate these axioms of rationality. The Allais Paradox, the Ellsberg Paradox, preference reversals, and risky

choice-framing effects are important examples of such violations. These phenomena have in common that preferences vary as a function of ‘irrelevant’ changes in the way situations are presented.

Allais Paradox and Ellsberg Paradox

Maurice Allais described a situation that demonstrates how human preferences are incompatible with one of the rationality axioms. The cancellation axiom states that preferences between two options should depend only on the difference between these options – not on a common factor. Allais gave the following example:

Situation 1: Would you prefer Alternative A or Alternative B?

Alternative A: Certain win of 100 mio.

Alternative B: 10% chance of winning 500 mio.
89% chance of winning 100 mio.
1% chance of winning nothing.

Situation 2: Would you prefer Alternative C or Alternative D?

Alternative C: 11% chance of winning 100 mio.
89% chance of winning nothing.

Alternative D: 10% chance of winning 500 mio.
90% chance of winning nothing.

Most people would prefer Alternative A to Alternative B, demonstrating a preference for the *certain* alternative although the expected value (probability \times value) is much higher for Alternative B. To be more specific, Alternative B has a higher expected value of 39 million than Alternative A; yet, people usually prefer Alternative A. Note that Alternative D has a 39 million higher expected value than Alternative C. Now most people would prefer the alternative with the higher expected value. They do so because the amount that could be won is much larger in Alternative D and the probability of winning this amount is only a little less than the probability in Alternative C. We can conclude that even though the objective differences (in expected value) between the alternatives are identical in each situation, preferences for the alternatives vary. To illustrate how these preferences violate the cancellation axiom, consider a lottery with 100 balls in an urn (see also [Baron, 2008](#)).

	Ball numbers		
	1	2–11	12–100 = 100 balls
<i>Situation 1</i>			
Alternative A:	100 mio	100 mio	100 mio
Alternative B:	0 mio	500 mio	100 mio
<i>Situation 2</i>			
Alternative C:	100 mio	100 mio	0 mio
Alternative D:	0 mio	500 mio	0 mio

A person makes a choice between one of two alternatives. Then a ball is drawn, which determines the payoff. The first column (Ball 1) is identical in Situations 1 and 2, and the second column (Balls 2–11) is also identical in both situations,

thus not providing any basis for a change in preferences. The third column (Balls 12–100), however, is not identical between the two situations. Here, the difference between Situations 1 and 2 is a constant (100 million), that is, the alternatives in Situation 1 consist of identical higher payoffs than the alternatives in Situation 2. Strikingly, this difference *between* the situations leads to different preferences *within* each situation. As according to the cancellation axiom the constant must not influence preferences in each situation, we can conclude that people’s preferences violate this axiom.

A similarly famous problem is known as the *Ellsberg Paradox*, introduced by Daniel Ellsberg, and like the *Allais Paradox*, it demonstrates a violation of the cancellation axiom. Imagine an urn that contains 30 red balls and a total of 60 black and yellow balls, the ratio of the black and yellow balls being unknown. One ball would be drawn at random from the urn, and its color would determine the payoff (\$0 vs. \$100). People are then asked to choose between alternatives: betting on color red (Alternative A) versus betting on color black (Alternative B).

<i>Situation 1</i>	Number of balls		
	30	60	
	Red	Black	Yellow
Alternative A:	\$100	\$0	\$0
Alternative B:	\$0	\$100	\$0

In Situation 1, people usually prefer Alternative A to Alternative B. There is no evidence suggesting that Alternative A would be objectively better than Alternative B. People know that 30 of 90 balls are red, but the number of black (yellow) balls can be somewhere between 0 and 60. The preference for Alternative A thus allows people to *avoid uncertainty*. Now consider Situation 2, where people would either bet on a red or yellow ball (Alternative C) or they would bet on a black or yellow ball (Alternative D).

<i>Situation 2</i>	Number of balls		
	30	60	
	Red	Black	Yellow
Alternative C:	\$100	\$0	\$100
Alternative D:	\$0	\$100	\$100

In Situation 2, people usually prefer Alternative D to Alternative C. Again, people prefer the alternative with the *least uncertainty*. The crucial difference between these two urn situations is the addition of \$100 for the yellow ball. However, between the alternatives in both situations, the yellow ball is always worth the same: either \$0 (Situation 1) or \$100 (Situation 2). Switching preferences between alternatives from one to the other situation thus violates the cancellation axiom. Below, we will examine two violations of a different axiom.

Preference Reversals

According to the invariance axiom, a preference between alternatives must not change as a function of the mere presentation when the objective characteristics of the alternatives remain unchanged. Recall that preferences can be measured in very different ways; for example, they can be measured as choices between objects or as independent evaluations of objects. Interestingly, research demonstrates that this variation between these formats affects people’s preferences. For example,

Sarah Lichtenstein and Paul Slovic demonstrated that people frequently change their preferences as a function of whether they choose between gambles (choices) or whether they indicate prices for which they were willing to sell each gamble (bids). In their study, gambles included a probability with which an outcome would materialize (e.g., a 33% chance of winning \$16 with a 67% chance of losing \$2; a 99% chance of winning \$4 with a 1% chance of losing \$1). When making choices between gambles, people usually focus on the probabilities, but when they make bids, they usually focus on pay-offs. Specifically, people prefer high-payoff gambles (e.g., 33% chance to win \$16 with 67% chance to lose \$2) over high-probability gambles (e.g., 99% chance to win \$4 with 1% chance to lose \$1) when selling them separately, but they prefer high-probability gambles over high-payoff gambles when they make choices between these gambles.

Framing Effect

The risky choice-framing effect is another important phenomenon that demonstrates the violation of the invariance axiom. Amos Tversky and Daniel Kahneman demonstrated the framing effect with the – now classic – *Asian disease* scenario:

Imagine that the United States is preparing for the outbreak of an unusual Asian disease, which is expected to kill 600 people. Two alternative programs to combat the disease have been proposed. Assume that the exact scientific estimates of the consequences of the programs are as follows:

In the gain frame condition, participants read:

If Program A is adopted, 200 people will be saved.
If Program B is adopted, there is 1/3 probability that 600 people will be saved, and 2/3 probability that no people will be saved.
Which of the two programs would you favor?

In the loss frame condition, participants read:

If Program A is adopted, 400 people will die.
If Program B is adopted, there is 1/3 probability that nobody will die, and 2/3 probability that 600 people will die.
Which of the two programs would you favor?

In both decision frame conditions (gain vs. loss), participants had a choice between a secure alternative and a risky alternative, each having the same expected value (probability \times value). In the gain frame condition, the majority of participants preferred the secure alternative to the risky alternative. In the loss frame condition, the majority of participants preferred the risky alternative to the secure alternative. This framing effect is typically explained with prospect theory's value function, which describes the deviations of subjective values (utilities) from objective values (see section 'Introduction'). The framing of the decision scenario shifts the reference point either upward or downward, so that people interpret the original values as either negative (resulting from an upward shift) or positive (resulting from a downward shift). Preferences as a function of decision frames thus reflect the difference in subjective values that people assign to the secure and the risky alternatives based on the characteristics of the value function for gains (concave) or for losses (convex). In the example, a gain of 200 has a higher subjective

value than 1/3 of 600, and a loss of 2/3 of 600 has a higher subjective value (i.e., is less negative) than a sure loss of 400. Much research has investigated cognitive and motivational variables that moderate the framing effect. Would people not 'see' the similarities between the alternatives if they thought in-depth about the problem? There is no straightforward answer to this question, but it can be concluded that in-depth processing alone does not help to overcome the impact of decision frames – in fact, some research findings suggest that deep processing increases framing effects.

These classic examples demonstrate how people's preferences are influenced by changes in the presentation format of the task, and how these variations conflict with axioms of rational behavior. This research inspired other researchers who examined more closely the particular processes that underlie preference judgments. Interesting research questions emerged, regarding the impact of particular subjective experiences, personality factors, and processing styles on preference judgments.

How Do Subjective Experiences Influence Preferences?

The term subjective experience refers to a wide spectrum of different experiential phenomena such as processing fluency, mood, and emotions. They can serve as a heuristic or a prime, they can interact with other information, and they can influence the processing strategies that people use.

Processing Fluency

According to Tversky and Kahneman's *availability heuristic*, the ease with which information is retrieved from memory affects people's judgments. Schwarz and colleagues further refined this research by demonstrating that the subjective experience of *ease of retrieval* influences judgments independent of the amount of retrieved information about an object. This type of processing fluency effect has been shown for a large variety of judgments, including political judgments and product preferences. The ease-of-retrieval heuristics focus on subjective experiences of recalling information from memory; another type of fluency effect focuses on *perceptual fluency*, that is, the fluency with which incoming information is encoded. It has been shown that perceptual fluency increases evaluations of objects that are encoded, which seems to parallel the widely documented effects of repeated exposure (mere exposure) of objects. Interestingly, it has been demonstrated that perceptual fluency increases positive (but not negative) affect, which in turn can influence preference judgment.

Moods

A mood state is an affective state that does not require a specific object, and it has a relatively low intensity and long duration. Due to this low intensity, mood has a 'background character,' which causes it to influence people without their awareness.

Mood-congruency effects

When people are in a positive (vs. negative) mood, their evaluation of an object is likely to be more positive (vs. negative). These mood-congruency effects can be explained in different

ways. Mood may function as *prime* by increasing the accessibility of mood-congruent thoughts. That is, positive (vs. negative) mood leads to positive (vs. negative) thoughts about objects, which in turn affects judgments of the objects. Alternatively, mood states can serve as *information*. That is, people may misattribute their mood state to the object in question when making judgments or decisions, as if the object caused the positive or negative response in them. This 'How do I feel about it?' heuristic is especially likely to occur when the judgment target is complex (e.g., life satisfaction), when the judgment is made under time pressure, and when mood is not attributed to target-irrelevant causes. Research suggests that both processing styles contribute to mood-congruency effects, but that the priming process accounts for the effects when processing effort is high and that the heuristic process accounts for the effects when processing effort is low. No matter which underlying process accounts for mood-congruency effects; note that they are common phenomena, often reflected in preference judgments and decisions in the lab and in everyday life.

Mood and processing strategies

Much research suggests that positive mood enhances the use of general knowledge structures (e.g., schemata, heuristics) and global information processing, whereas negative mood enhances the processing of more detailed, specific information. These results are consistent with recent versions of the mood as information approach. Positive mood signals a benign environment, in which the use of general knowledge structures is adaptive. However, as negative mood signals a problematic environment, it is more adaptive to consider the specifics of the situation. Given that processing strategies influence which information people focus or rely on when forming preference judgments (e.g., heuristic cue, quality of arguments), it is essential to recognize these mood effects on processing strategies.

Mood as goal versus mood as resource

A number of studies suggest that people manage their moods such that they process information that preserves positive mood and repairs negative mood. As a consequence of this hedonic principle, people are drawn to information that is positive in nature and avoid information that is negative. Further, people are reluctant to elaborate on unfamiliar information because this information could affect their mood state negatively. However, mood seems to have different effects in self-evaluative situations (e.g., receiving feedback). Negative information about the self is often unpleasant, but self-improvement depends largely on receiving such information. That is, negative self-relevant information often poses a self-control dilemma between the long-term learning benefits and short-term affective costs of processing this information. Research suggests that in these situations, positive mood facilitates preferences for the negative self-relevant information, thus serving long-term learning goals rather than hedonic mood management goals.

Risks and benefits

Especially in risky situations, mood affects people's preferences as it influences whether people focus on *risks* or *benefits*.

In general, positive mood increases perceived benefits and decreases perceived risks, especially under time pressure. Therefore, people in a positive mood are more likely to prefer risky options to safe options. Furthermore, according to the 'risk-as-feelings hypothesis,' affective responses to risky situations sometimes have a bigger impact on preferences than on cognitive evaluations.

Emotions

Compared to moods, emotions are more intense and relatively momentary. Furthermore, emotions are object-focused, as they reflect one's feelings about something or someone. They can differ, for example, in their valence (positive vs. negative) and in their activation/arousal level (low vs. high; the circumplex model of affect). For example, anger and sadness are both negative emotions, but anger has a higher arousal than sadness. Additionally, emotions can be distinguished by their expressions (e.g., facial expressions), physiology, action tendencies, actions, motivational goals, thoughts, and feelings.

Positive and negative emotions

Experienced emotions with the same valence can affect preferences differently, that is, effects of emotions depend greatly on the specific characteristics of the emotions even if they have the same valence. For example, the broaden-and-build theory makes specific predictions for different positive emotions: joy induces a preference to play, interest induces a preference to explore, and contentment induces a preference to savor and integrate. Similarly, there are also differences among negative emotions. For example, sad people prefer pleasurable stimuli, whereas anxious people become more attentive to information.

In addition to the influence of experienced emotions, *expected emotions* (i.e., predictions about the emotional consequences of future events) influence preferences as well. Expected positive emotions induce a preference for decisions that are expected to maximize happiness. Furthermore, according to 'regret theory,' if people expect the possibility of experiencing regret in the future, then they prefer less-risky options (i.e., risk aversion). For example, a person may fear to leave a partner in exchange for a very attractive alternative, especially when the alternative is unsure of committing to a relationship. There is a bulk of research on the influence of expected negative emotions on morality. According to the social intuitionist approach, moral emotions (e.g., disgust, shame, anger, contempt, embarrassment) can function as moral intuitions as they guide judgments of 'right' and 'wrong.' If someone expects the experience of a moral emotion (e.g., one expects to feel guilty if one does not help a friend in need), then this emotion promotes the preference for moral behavior (e.g., helping a friend in need).

Emotion activation levels

As described above, emotions with a different valence can have different effects on preferences. For example, anxiety leads to higher risk aversion and excitement leads to more risk seeking. In addition to valence, the arousal level (i.e., the degree of activation) can also influence preferences. The degree of activation may determine preference by leading people to develop stronger preferences for stimuli that are congruent with their respective level of activation. For example, sad people have a

higher preference for a quieter advertised resort, whereas angry people prefer a more actively framed resort. It can be concluded that both the valence and arousal of specific emotions have an influence on preferences, but it is also the combination of both that needs to be considered.

How Do Personality Factors Affect Preferences?

The extent to which objects or alternatives are preferred is partially dependent on psychological dispositions and personality factors, that is, variations in preferences between people. Such chronic tendencies may affect the value associated with option features, the motivations that underlie preferences, and the way in which information is processed. Many dispositional factors have been identified that affect preferences, some of which are briefly highlighted below.

Generally, people are more risk averse than risk seeking; however, the *extent* to which people are risk averse and risk seeking varies across individuals. For example, *sensation seekers* are typically more risk seeking and less risk averse. Furthermore, people may be risk seekers for risks holding a pleasant form of stimulation (e.g., gambling), independent of whether people are generally risk averse in the context of achieving instrumental outcomes. In addition, people differ in the extent to which affect and sensations associated with a product impact their preferences, reflecting a hedonic consumption style. Research on people's chronic *regulatory focus* makes an important distinction regarding the tendency to which people are motivated to prevent pain (a prevention focus) and to approach pleasure (a promotion focus). As a consequence of the different regulatory orientations, people high on prevention focus tend to prefer safe and stable options, whereas people high on promotion focus prefer alternatives that imply change. For example, having a promotion focus may make a person more inclined to try out different coffees whereas a prevention focus would make him stick to his favorite café latte.

People differ in the extent to which they have a *rational processing style* and also in the extent to which they have an *experiential processing style*, with the former being associated with less nonoptimal decisions and the latter leading to greater reliance on heuristics in making decisions. The rational processing style is related to another common distinction, namely the *need for cognition*. It corresponds to people's chronic tendency to enjoy and subsequently engage in effortful information processing. People high in need for cognition have been found to be less susceptible to decision-making biases and their attitudes are more resistant to change.

How Do Deliberation and (Un)Conscious Thought Affect Preferences?

Will more deliberation contribute to preferences that in turn serve the maximization of utility (i.e., rational behavior)? Dual-process theories assume that preferences and decisions are influenced by either one set of processes or another set of processes. One system is based on automatic, unconscious, and relatively effortless processes, whereas the other system is based on deliberate, conscious, and effortful processes.

Traditionally, deviations from rationality have been attributed to the first system, whereas the second system seemed to facilitate more rational preference judgments and behavior. Recent research, however, suggests that it is less straightforward. Many findings suggest that more deliberate thought can *reduce* the quality of preference judgments and choices, and unconscious thought often leads to better preference judgments and choices. A typical example is the situation when someone is selecting an apartment after having seen several alternatives. The research findings suggest that unconscious thoughts (e.g., when being distracted) regarding the characteristics of apartments lead to better decisions than conscious deliberations of the pros and cons. Taken together, it seems essential to consider additional variables (e.g., task characteristics) in order to conclude which of these processes are beneficial in particular situations.

How Well Do People Predict Their Preferences?

If people were able to predict future preferences, then such predictions would help to maximize experienced utility. However, it seems that predicting future preferences is generally not easy. For example, research by Daniel Kahneman and Jackie Snell suggests that people have little insight into the change of their tastes. That is, predictions of future tastes and actual preferences seem to be uncorrelated. One reason for this low correlation is based on people's belief that their taste changes more frequently than it actually does. The imprecision of predicting one's preferences is in part based on people's lack of insights into the psychological processes that underlie preferences, the limited insight into future affective states, and the temporal distance of future events as psychological distance to events changes our perceptions of these events. That is, people's understanding of their preferences is generally limited; in addition, it is difficult for people to account for the differences between momentary preferences and future preferences. However, understanding the processes that change preferences may provide tools that increase the precision of these forecasts.

How Are Preferences Assessed?

The concept of preferences has been widely used in the domains of economics, economic psychology, decision-making, and social psychology. Consequently, a variety of different implicit and explicit assessments of preferences have been used, each with certain benefits. Three common types of explicit preference measurements are *choice*, *ranking*, and *rating*.

The Oxford Dictionary defines *choice* as the act of choosing between two or more possibilities, and its scientific investigation involves the psychological processes involved in this selection. Choice measures are used when researchers wish to know what option is ultimately preferred, and is broadly adopted across the domains of decision-making research. For example, a person may ultimately choose a café latte rather than a cappuccino, indicating her preference for café latte over cappuccino. Famous uses of choice measures include the *Asian disease problem* and *preference reversal* scenarios. Choice measurements result in dichotomous (nominal) variables and can

hence be analyzed using nonparametric tests such as the *chi-square test* where frequency of choices is compared across groups, using a *binominal test* where choice frequencies are compared to a base level usually derived from a normative prediction, *logistic regression analysis* in which a dichotomous choice is predicted by a single or variety of variables, or *latent class analysis* in which the change of dichotomous category membership can be modeled. Benefits of choices as proxy of preferences include that choices can reveal distinct preferences even when options seem objectively interchangeable and choices are intuitively close to real decision processes in everyday life.

A *rank* reflects the relative position in a hierarchy; with respect to preferences, ranking involves the organization of several options according to hierarchically ordered preferences. *Ranking* preferences may be used when the relative preferences of the options are of key interest, as is often the case in marketing or political psychology. For example, a person may rank café latte as most preferable, followed by cappuccino and then espresso. Because rank measurements result in ordinal variables, common analyses may involve *rank-biserial correlation* in which the association between ranked categories with some interval or ratio level variable is evaluated, *multinomial logistic regression* in which category membership is estimated as function of predictor variables, or *latent class analysis* in which the change of dichotomous category membership can be modeled. Benefits of ranking measures are that direct information is attained concerning the *relative* preferences for each of the options.

Assessing preferences by means of *rating* – a classification based on a comparative assessment of quality, standard, or performance – involves asking people to rate each of the available options according to one or more evaluative dimensions, for example, using Likert-like scales. For example, on a scale from 1 (*very low*) to 7 (*very high*), a person may rate café latte as 6 and cappuccino as 5, indicating that she likes cappuccino less than café latte. Scale ratings are among the most common measurements of preferences in specific and attitudes in general across the domains of the quantitative social sciences. Preference ratings are typically analyzed separately for each rated option or based on computed relative differences between options. Rating measurements are commonly treated as interval variables and common analysis of ratings hence includes *Pearson correlation* in which the association between two ratings is evaluated, *analysis of variance* in which ratings are compared across groups, the *paired-sample t-test* in which different ratings of the same person are compared to each other, *linear regression analysis* in which ratings are predicted by one or several other variables, *structural equation modeling* in which complex relations between the variables are evaluated, or *hierarchical models* in which the ratings embedded in a hierarchical sample structure are evaluated. Benefits of preference ratings are that the measure captures a relatively high amount of information for each option and allows for further computation of relative preferences, preference ranking, and the use of advanced statistical methods with relative ease.

In recent years, psychological research has developed a variety of *implicit* attitude measures. Some of these measures are comparative measures, indicating relative preferences for one object over another object. Perhaps the most common test of implicit preferences or attitudes is the *implicit association test* in which a categorization task is used in order to evaluate the

relative preferences of one object compared to another object. Very briefly stated, people are requested to categorize an object, and response reaction times are compared across trials when the object was presented together with a concept representing either extreme of an evaluative attribute dimension (e.g., the word ‘pleasant’ and the word ‘unpleasant’). Due to prior categorization tasks, the attribute elicits a consistent categorization decision or an inconsistent categorization decision. Relative reaction time differences are subsequently assumed to partially represent implicit evaluative judgments. Results of implicit measures often involve preferences indicated by reaction times expressing the speed of associating a target with an attribute (e.g., positive vs. negative attributes). Implicit measures hold the benefit that they may capture information that is often not assessed by explicit measures, but interpretation of the cognitive underlying processes can be complex.

Summary

Preference judgments are omnipresent, constantly affecting human behavior. Preferences vary over time, between situations, and between people. Research on preference judgments is largely examined in basic and applied psychological research and in economic research. Preferences can be assessed by using very different indicators: choices, rankings, ratings, and implicit preferences. Historically important is research suggesting that variations of preference judgments are incompatible with axioms of rationality because it initiated research questions on the psychological processes that can explain these discrepancies. The presentation of tasks and decision problems, as well as cognitive, affective, and motivational factors, influences how preferences are set and how they affect human behavior. In essence, the investigation of preference judgments relates to the core investigations of human thought and behavior, and a deeper understanding of the sources and consequences of preference judgments may contribute to increases in utilities of human action and subjective well-being.

Prejudice, Discrimination, and Stereotypes (Racial Bias)

D M Marx and S J Ko, San Diego State University, San Diego, CA, USA

© 2012 Elsevier Inc. All rights reserved.

Glossary

Between-category stereotyping A perspective on stereotyping, which assumes that all group-relevant stereotypes can be applied equally to all group members.

Discrimination The unfair or unjustified treatment of others based on their group membership.

Implicit racial bias A negative evaluation of racial groups that we carry without awareness or conscious thought.

Prejudice A generally negative evaluation of a group and its members.

Racial bias A negative evaluation of racial groups.

Racism Discrimination or prejudice based on a person's race.

Stereotypes Beliefs or overgeneralizations about the characteristics of a group and its members. Stereotypes can be either positive or negative.

Within-category stereotyping A perspective on stereotyping that recognizes that not all group members are equivalent; thus, group-consistent and inconsistent stereotypes can equally apply to group members.

Overview

The term 'stereotype' first came into use during the late 1700s to refer to a printing process, in which metal plates were used to create reproductions of images and prints. It was not until the early 1920s that the term became common parlance when journalist Walter Lippmann likened stereotypes to 'pictures in the head,' or mental reproductions of reality. From there, the term evolved into its current usage – overgeneralizations about social groups. The term prejudice, on the other hand, was not widely used in the research literature until the early 1930s when Katz and Braly linked the negative aspect of stereotypes to prejudice. In the ensuing years, researchers and lay public alike have frequently used the term stereotype erroneously to represent prejudice. It is therefore important to understand the distinction between these terms. Stereotypes refer to both positive and negative beliefs or overgeneralizations about the attributes of a group and its members. For instance, stereotypes about Blacks include both negative (aggressive) and positive (athletic) attributes. Prejudice represents solely the negative aspect of stereotypes. In this case, the association of Blacks with aggressiveness would be considered prejudice. Prejudice is also captured by the negative emotional reactions one feels toward a group, such as fear toward Blacks, in the absence of any concrete beliefs or thoughts about that group.

Early conceptions of stereotypes and prejudice were that they are rigid. More modern conceptions allow for more fluidity, in that they may ebb and flow as the information about a social group is encountered. For instance, one may harbor strong prejudices about a group that may fade as tensions with that group lessen or as the number of positive encounters with that group increases. Moreover, situational influences may also alter the expression or endorsement of a stereotype. That is, the presence of less stereotypic, or even counter-stereotypic, individuals may call to mind a different set of stereotypes than does the presence of more stereotypic individuals. Hence, exposure to these counter-stereotypic individuals will, over time, weaken the stereotype, particularly if exposure occurs across multiple situations with multiple individuals. Stereotypes are not fundamentally bad or even wrong in many cases; they are part

of a normal cognitive process that helps preserve scarce cognitive resources. They are part of the act of categorizing the world around us. It is how an individual acts upon those stereotypes that makes them 'wrong.'

Although prejudice, stereotyping, and discrimination often go hand in hand, there is also the possibility to have one without the others. For instance, knowing the stereotypes about a group is one thing, but to endorse or 'feel' those stereotypes is another thing. Moreover, to act upon those stereotypes in a discriminatory manner takes the knowledge and negativity we feel toward a group even further. Of course, the action is driven by the stereotype or prejudice directed toward that group; hence, discrimination generally does not occur without prejudice, but stereotypes and prejudice can occur in the absence of discriminatory behavior. In this sense, then, discriminatory behavior may separate the racists from those who simply know the stereotypes, but do not necessarily endorse the stereotypes. This defines the distinction between personal and cultural stereotypes, which is one of the primary foci of modern-day research on stereotyping and prejudice. These processes may also work at an unconscious or implicit level such that the individual may be unaware of acting in a discriminatory manner or applying stereotypes when judging others. In fact, the current conception of stereotypes, prejudice, and discrimination is that they are partly automatic and partly controlled and that how one responds to them is due to triggers in the social situation and to the beliefs and knowledge one has about the social group in question.

A Brief History of Research on Stereotypes, Prejudice, and Discrimination

The focus on prejudice as a distinct research area first emerged in the early 1900s and was based upon prevailing race theories that attempted to prove White superiority over other racial groups. These efforts resulted in the rather simplistic assertion that Whites were superior intellectually, and that prejudice was a natural response to inferior races. This perspective changed in the 1930s and 1940s with progress in civil rights and growing

concerns about anti-Semitism resulting from the disbelief surrounding the Holocaust and the atrocities committed by Nazi Germany. Indeed, the events of World War II sparked the development of theories focused on demonstrating that a certain type of person harbors these prejudicial beliefs. In other words, prejudice was inextricably linked to the individual. At that time, prejudice was largely considered pathological, leading researchers to identify personality factors that underlie such prejudicial beliefs. Adorno's conception of an authoritarian personality was borne of these pursuits. The authoritarian personality was considered to be emblematic of rigid thinking and strict obedience to authority and adherence to social rules and hierarchies.

Although the notion of an authoritarian personality has fallen out of research favor, vestiges of this personality-based theory of prejudice still remain in more current work, such as work on social dominance orientation (SDO) and system justification theory (SJT). For instance, SDO holds that people who view the social world hierarchically are more likely than others to hold prejudices toward low-status groups. This is especially true of people who want their own group to dominate and be superior to other groups. Many studies on SDO have linked it to anti-Black and anti-Arab prejudice, sexism, nationalism, opposition to gay rights, and other attitudes concerning social hierarchies. Similar to SDO is the theory of system justification, which proposes that people not only want to hold favorable attitudes about their group but they also want to hold favorable attitudes about the general social order and their group's place in it. A consequence of SJT is that the existing social order is preferred, and that modifications to this order are criticized and not encouraged, particularly by those higher in the social hierarchy. Interestingly, research on system justification has shown somewhat surprisingly that those lower in the social hierarchy often support, to some degree, the existing hierarchy, often at the cost to themselves and their group.

The 1950s through early 1980s saw a cognitive revolution in which the dominant perspective was that stereotypes are cognitive-saving devices – they were considered mental shortcuts used to make quick judgments or evaluations of social groups. To this end, researchers began looking 'inside the head' rather than relying on behaviors or responses that could be open to social desirability concerns or other forms of biased responding. This approach thus used procedures that inferred what a person was thinking rather than directly asking about a person's thoughts (we provide details of the more popular procedures below). Dominant theories of stereotyping and prejudice quickly followed suit. And by the late 1980s, researchers such as Patricia Devine proposed that there is an unconscious or automatic aspect of the stereotyping process that is based on a person's cultural knowledge (as opposed to their personal beliefs) about a particular social group. What then differentiated those who were biased or not was the overt or explicit expression of these beliefs. Accordingly, current research on stereotyping and prejudice has been focused on the dissociation between one's implicit beliefs and the explicit expression of these beliefs. The issue, however, is how then can we tell whether a person's response is due to cultural knowledge or personal beliefs, particularly if the response is made at the implicit level where such cultural knowledge is so

ingrained that it is automatic. In other words, if we know that overt expressions of prejudice are taboo in modern society and we know that implicit expressions are prone to cultural knowledge, then how can we know what a person's true beliefs are about racial groups? To date, no clear, universally accepted answer has been found.

New Perspectives and Current Trends for Research on Prejudice and Stereotypes

Traditional theories in stereotyping have proposed that stereotyping is a purely category-based phenomenon. For example, all females are caring and all males are analytical. In other words, people's perceptions of social groups or categories are so homogenous that a member of a given category is, in essence, perceived as the same as any other member of that category. Researchers more recently have branched out to explore how subtle variations in physical cues that occur between individuals within a category also impact stereotyping. For example, Emily and Aly are female; however, their voices vary in the degree to which they sound feminine within their gender category: Emily's voice is the most feminine while Aly's voice is the least feminine. This variation in within-category 'vocal femininity' itself elicits different gender stereotypic inferences such that speakers with more feminine-sounding voices are more strongly associated with female than male stereotypes just as speakers with less feminine-sounding voices are more strongly associated with male than female stereotypes, regardless of the speaker's gender. Within-category cue-based, as compared to the more traditional between-category-based, biases may better capture the modern state of stereotyping and prejudice.

Over the past half-century or so, strong proscriptive norms have evolved that discourage overt category-based stereotyping and prejudice. On the surface, this seemed effective as numerous studies reported significant reductions in overt expressions of prejudiced attitudes. However, it was soon discovered that more subtle measures focusing on implicit or automatic evaluations and beliefs suggested no discernable reduction in stereotyping and prejudice. In other words, modern-day biased attitudes are just better hidden and/or reflect a more nuanced perception of groups and their members. What makes within-category cue-based stereotyping distinct from other similar subtle measures is the fact that it does not have to rely on perceivers being unaware of the true purpose of the task. People are usually unaware of its effects but even when perceivers are explicitly told that the cues can bias their judgments, they are unable to control their impact. This is because, unlike category-based judgments, which are easier to control because they are a matter of curbing dichotomous decisions (e.g., male vs. female, Black vs. White), within-category cue-based judgments rely on the more fine-grained variation in physical cues. For example, there are many acoustic cues that constitute vocal femininity such as pitch, resonance, variability in pitch, and intensity just to name a few. Moreover, the experience of within-category variation in vocal femininity comes not only from the variation in one of these myriad of cues but also the variation in the constellation of all of these cues. Consequently, curbing within-category cue-based stereotyping would

require monitoring the influence coming from the variation in all of these cues at once, which as one can imagine is probably not feasible.

Within-category cue-based stereotyping has some surprising real-world implications. In modern-day criminal sentencing for instance, there no longer seems to be a relationship between racial category (i.e., Black vs. White) of offenders and sentence length as was the case in the past. However, both Blacks and Whites, within their respective racial category, vary in the extent to which they have Afrocentric cues and this within-category variation in Afrocentric cues strongly impacts sentence length. Specifically, the stronger the within-category Afrocentric cues of the offender, the longer the offender's sentence, regardless of the offender's racial category. This finding seems to hint at a process that involves the relationship between category and within-category cue-based stereotyping. Both category and within-category cues are capable of affecting stereotypic inferences but the former effect seems to be easier to control than the latter. Given societal pressures over the years to curb category-based stereotyping and prejudice, people may have become well practiced at suppressing such biases. Ironically, suppressing category-based biases seems to lead perceivers to rely more on within-category cues as a basis for biased perceptions or even discriminatory behavior. Moreover, researchers have shown that the more perceivers suppress using category, the more they use within-category variation in cues as a basis for biased judgments. In sum, norms that censor people from acknowledging any differences between social categories for the purposes of reducing biased judgments may ironically defeat the purpose because it may make people more susceptible to biases based on cues that are related to a given category, but vary more subtly within the category.

The Effects of Prejudice and Stereotypes on the Self

Gordon Allport wrote in the *Nature of Prejudice* that "one's reputation, whether false or true, cannot be hammered, hammered, hammered, into one's head without doing something to one's character" (p. 142). It is perhaps fair to say that most researchers assume that Allport is talking about beliefs about a person's character that may have an adverse influence on the person's well-being and behavior. This assertion is based on Merton's concept of a *self-fulfilling prophecy* in the sense that what Allport may have had in mind was a process by which the target of prejudice internalizes the negative views of his or her group through the 'hammering' exposure of these negative beliefs and then 'self-fulfills' those internalized beliefs as one would self-fulfill any type of expectancy.

Although this view might be a quite reasonable interpretation of how stereotypes and prejudice can affect a person, it may not be the complete story. Indeed, another possible way in which the negative perceptions of a person's group might come to affect their behavior and psychology is based on situational influences. Aside from whatever effects negative stereotypes may have through its internalization as a self-expectancy, it may also have effects that stem directly from it posing an acute situational pressure on a person's life and psyche. For example, Allport writes that the mere prospect of being seen and treated stereotypically may cause a state of "obsessive

concern" in a person about how he or she will be perceived. For that matter, a Black person, as Allport writes, cannot "enter a store, restaurant, movie, hotel, amusement park, school, train, plane, or boat, to say nothing of a white person's home, without wondering uneasily whether he will suffer insult and humiliation" (p. 140). This leads to a state of uncertainty whereby members of any negatively stereotyped group struggle with the uncertainty of whether other's beliefs about them is due to their race or to them personally. This notion is captured by the theory of attributional ambiguity proposed by Crocker and Major and the theory of stereotype threat proposed by Steele and his colleagues. We now turn to a description of these two self-related theories of stereotypes and prejudice.

Attributional Ambiguity

In many cases, it is clear when members of certain racial groups are treated in a discriminatory or prejudicial manner, but in other cases there may be significant uncertainty about the cause of one's treatment. To be sure, everyone at one time or another feels some amount of uncertainty about how he or she is treated, but this uncertainty may be particularly pernicious for members of stigmatized racial groups, because of how their group is viewed by society. In this case, negative outcomes may be attributionally ambiguous because such outcomes could just as easily be due to poor performance, lack of ability, or other shortcomings as it could be due to the discrimination or prejudice directed toward them as a function of their racial group membership. Hence, when in such an ambiguous situation, members of devalued racial groups (e.g., Blacks) can choose to attribute negative feedback to prejudice and discrimination, thus preserving their self-esteem, something that members of other racial groups (e.g., Whites) are unable to do. The downside of this approach is that members of devalued racial groups may also lose out on the potential benefit of the feedback to improve the self.

Stereotype Threat

In 1995, Claude Steele and Joshua Aronson proposed that the awareness of culturally held stereotypes about one's group may have a profoundly negative effect on how one behaves. This notion of stereotype threat has become one of the most widely applied explanations for the academic disadvantage of many social groups, in particular Blacks in most realms of higher education and women in math-related fields. According to the theory, the concern about confirming or being judged in terms of the negative stereotype (belief in the stereotype's validity is not necessary) usurps cognitive resources and drains emotional reserves for those individuals targeted by the negative stereotypes. Hence, it is the situation and the cues in that situation which 'tell' the perceiver how members of his or her group will be judged and thus poses a burden that undermines their performance. An interesting and critical piece of this theory is that it is the very individuals who care the most, in that they have the skills, desires, and motivation to succeed, who are the ones most afflicted by stereotype threat. Another troubling downstream effect is that repeated experiences with stereotype threat may lead to misidentification with the

academic domain. In this case, the constant threat in the air surrounds targeted group members because they are too burdensome to bear and thus pushes them out of the domain as a way to minimize and/or avoid such threats. Stereotype threat is not unique to academics, as it can apply to any group to which negative ability-based stereotypes apply, making it a powerful explanation for the many group-based differences that exist in society today.

Methods to Study Prejudice and Stereotypes

Historically, the study of prejudice and stereotypes was done at the explicit level, often using self-report or survey-type measures. In this case, respondents were simply asked to indicate how they felt or what they thought about certain social groups. The most common self-report method up until two decades ago was the adjective checklist, first used in the early 1930s. In this method, participants were given a list of trait adjectives and asked to indicate how typical each adjective is of a particular group (e.g., Blacks). The stereotypes of each group were then defined by the set of adjectives most commonly assigned to that group.

This method has served as the model for the majority of stereotype studies conducted until more recently when issues surrounding social desirability concerns led researchers away from such explicit self-report measures. To be sure, social desirability may have been a concern from the start, but only somewhat recently have researchers attempted to minimize or take into account this concern when devising methods to examine stereotypes and prejudice. Nevertheless, it could be argued that the adjective checklist served researchers well in the past because the then social climate was one where endorsement of stereotype groups was more widely accepted. Consequently, participants may have been more willing to express and endorse prejudice and discriminatory behavior toward members of out-groups. It should be noted, however, that the endorsements of the traits usually matched those often portrayed via popular media, raising the issue of whether these endorsements truly reflected an individual's personal beliefs or simply his or her knowledge of cultural stereotypes. The past two decades have seen a rise in popularity among implicit measures of stereotypes and prejudice. The assumption is that implicit measures are capable of assessing a person's true beliefs because they are believed to capture stereotypes or prejudice occurring at a more automatic and uncontrollable level. The rise in interest and use of implicit techniques has largely been commensurate with the advance in technology of the desktop computers. With this advancement, researchers had a powerful way to study those cognitive processes that were once hidden from view. Below, we describe some of the more popular methods for examining stereotypes and prejudice, such as the lexical decision task (LDT), the implicit association task (IAT), and the more general associative type tasks, such as word-fragment completions.

Lexical Decision Tasks

The basic procedure for an LDT is for respondents to be primed with a stimulus (words or pictures usually below conscious

recognition) and then presented with a mixture of letter strings that form a word or a nonword. The respondent's task is to indicate, as fast as possible, usually with a button press, whether the letter string is a word or not. The prime is anything that represents the category of interest. Some examples are a common Black name or even the category label – Black. A selection of the presented words would be stereotypic of the category (e.g., aggressive, athletic). The idea is that the stronger the respondents' stereotypic beliefs about a category, the faster they will respond to a stereotype as compared to other words and nonwords. For instance, when subliminally primed with the category label 'Black,' respondents who hold strong stereotypic beliefs may show faster response to the word 'violent' than to the word 'intelligent' or to nonword letter strings 'thrud.' The logic behind this is that the category label activates knowledge structures that then guide the subsequent lexical decision. Furthermore, if the responses are faster to negative (e.g., violent), relative to positive stereotypic words (e.g., athletic), then it is inferred that respondents are prejudiced toward that category.

Implicit Association Test

The IAT is arguably the most popular technique to measure implicit bias. At the most basic level, the IAT assesses the strength of an association between a target concept and an attribute dimension by measuring the speed at which respondents can press one of the two response keys that have been assigned dual meanings. For example, consider a race IAT. The respondent's task is first to categorize stimuli (e.g., words or pictures) representative of a particular racial group (i.e., Black or White) by pressing one of two response keys. Here, the response keys would be labeled Black or White. Next, the respondent would categorize stimuli that are considered stereotypic or counter-stereotypic (i.e., violent or intelligent) of the racial group in question. Here, the response keys would be labeled 'good' or 'bad.' After this training phase, both types of stimuli pairings are presented at the top corners of the computer screen while a stereotypic word is presented in the center. The respondent's task is to determine, by pressing a predetermined response key, which of the two stimuli pairings (e.g., Black/bad or White/good) is consistent with the presented stereotypic word (e.g., violent). According to the logic of the IAT, faster response should occur when the stimuli pairings are consistent (e.g., Black/bad) with the stereotypic word (violent), compared to when it is inconsistent (e.g., Black/good) because violent is both bad and stereotypic of Blacks. Racial bias is assessed by subtracting the mean response time for the consistent pairings from the inconsistent pairings. A positive value (i.e., faster response times to the consistent, relative to the inconsistent pairings) would indicate bias toward the racial group in question.

It should be noted that the IAT is not without controversy. For instance, many critics of the IAT argue that it does not measure personal beliefs but rather measures knowledge of the cultural stereotypes and hence is prone to the same concerns that plague more explicit measures of racial bias. Also, no clear relationship between a respondent's IAT score and his or her prejudicial or discriminatory behavior toward the racial group in question has been found, calling into question the IAT's predictive power.

The Bona Fide Pipeline

This task was developed in response to the concerns that many of the measures used to assess racial bias did so by priming the stereotype rather than merely the racial group; it was unclear if responses were driven by personal or cultural stereotypes. To get around this issue, the bona fide pipeline (BFP) used faces to activate the race and then measured responses to trait adjectives that were presented immediately after the face prime. The logic of this task is that if respondents are prejudiced toward the racial group reflected by the face, then they should show speeded responses to negative trait adjectives and slower responses to the positive trait adjectives after face primes are reflective of the racial group in question. Thus, by using faces instead of stereotypic traits, it should be possible to demonstrate that faster response was due to personal stereotypes about the racial group, since stereotype content is not confounded with activation of the racial group.

First-Person Shooter

This task is a first-person shooter videogame that presents a series of young men set against realistic backgrounds, who are either armed or unarmed. This task is thus used to investigate whether decisions to 'shoot' a potentially hostile (i.e., armed) target are influenced by that target's race. Participants are instructed to shoot any target who is armed and not to shoot any target who is unarmed. Half of the targets are Black, and half are White. The basic finding is that participants shoot an armed target more quickly and more often when that target is Black, rather than White. Furthermore, participants decide not to shoot an unarmed target more quickly and more often when the target is White, rather than Black. In essence, participants appear to process stereotype-consistent targets (armed Blacks and unarmed Whites) more easily than counter-stereotypic targets (unarmed Blacks and armed Whites). Evidence of racial bias is assessed via the speed of responding as well as by response errors. A variation of this task is the weapon misidentification procedure in which respondents are asked to indicate as quickly as possible whether an object flashed immediately after a Black or White face prime is a weapon or a tool. Racial bias is again assessed via the speed of responding as well as by response errors.

Word-Fragment Completions

Although this task does not rely on speeded responses to assess racial bias, it is nevertheless implicit in the sense that respondents may not be aware of how their responses reflect their bias. For instance, respondents who are in an experimental setting where they have just been exposed to Black and White faces and then are asked, in a second unrelated task, to complete word fragments may be unaware that completing the word fragment, U N, with G U N instead of S U N or F U N, could be used as an indication that they associate Blacks with violence. Again, based on how a person responds – completing word fragments with more stereotypic words, or with more *negative* stereotypic words – researchers can infer a person's level of racial bias.

Reducing Prejudice

Alongside the work dedicated to understanding the experiences of being a target of prejudice and discrimination, there is a large body of work focusing on ways to reduce these adverse effects of stereotypes on one's thoughts, feelings, and behavior. In this section, we deal with some of the more prominent approaches to reducing prejudice and discrimination.

Contact Hypothesis

This method for reducing prejudice is predicated on the notion that racial bias occurs because the different races did not have adequate contact to break down the misconceptions about each other. Essentially, it is an attempt to eliminate the 'fear of the unknown.' Interestingly, this approach was borne approximately at the time that the civil rights movement in America was occurring. Hence, it reinforced the notion that eliminating the separate but equal policy would also tear down racial barriers. Although an attractive hypothesis, merely increasing contact between races did not reduce racial bias. If anything, it reinforced racial biases because the contact was often forced, overly formal, unsanctioned, etc. All was not lost, however, because there were many instances when contact did lead to racial harmony, provided that the contact occurred under certain crucial conditions. These conditions are described below.

Opportunities for contact

When contact is more accessible and varied, when people get to meet many people from the other group in a variety of settings, then this can breed understanding and reduce bias. Thus, frequency and variety of contact reduces conflict especially when the contact is made in many different settings.

Equal status

In general, if the contact occurs between individuals of equal status, regardless of whether they are of high or low status within their group, the contact can reduce racial bias. Of course, it also depends on whether the status is context-dependent. It is not about relative status but whether in that situation the individuals are of equal status.

Casual versus intimate contact

Less structured, less formal, and more intimate contact is shown to be better at reducing racial bias. Intimate contact is defined as one where individuals have more opportunities for self-disclosure, to have a chance to get to know the other person. This intimacy creates bonds and promotes reciprocity in sharing, and by doing so racial bias is diminished.

Institutional support

When the contact is supported or endorsed by a respected institution, contact is more effective. Similar to institutional support is the notion that endorsement from a legitimate authority will also be effective.

Cooperative and competitive factors

This of course relates to one of the more basic of factors that leads to reduction in racial bias via contact. Working together builds mutual trust and respect provided that the cooperative

behaviors lead to a successful outcome (see below about jigsaw classroom). Competition, on the other hand, fuels differences and a goal-oriented style in which the other person is viewed as an 'enemy'; thus, the contact will breed racial bias rather than reduce it.

Personality factors

Depending on one's personality (see the description of the authoritarian personality described above), contact may be more or less effective. For instance, if one is insecure then contact will cause one to lose a scapegoat, a victim to blame when things go wrong. Thus, contact will not lessen a person's racial bias no matter how cooperative, intimate, and equal the contact is. Indeed, this aspect of the contact hypothesis fits well with the conception of an authoritarian personality as it too allows for a form of rigid categorical thinking as one of the underlying forces behind a person's prejudice.

Jigsaw Classroom

One of the most successful methods for reducing racial bias is the jigsaw classroom technique. The jigsaw classroom is a cooperative learning strategy akin to a jigsaw puzzle in that each student plays a critical part for the completion and comprehension of the final product. If each student's part is essential, then by extension each student is essential. Note that just as in the contact hypothesis, the cooperative behaviors need to lead to a successful final outcome, otherwise finger-pointing and scapegoating may occur.

Let us use an example to illustrate the basic idea of the jigsaw puzzle method. Say a jigsaw group is assigned to work on a project about conservation and the environment. Aly is responsible for researching the different ways to recycle, Chris is responsible for researching water conservation, Emily is responsible for researching ways to limit air pollution, Brad is responsible for researching alternative energy, and Meghan is responsible for researching the impact of global warming. The situation is specifically structured so that the only access any student has to the other pieces of the project is by listening closely to each student's report. Thus, if Aly does not like Meghan, or if she thinks Chris is a nerd and mocks him, she will not do well on the assignments. Hence, by relying on the students in the jigsaw group, all students begin to view the other group members as valuable, important, and critical to the group's success, which then translates into general positive perception of the students and their respective social group.

Personal Experience of Discrimination

This is an interactive and experiential approach to prejudice reduction, in which typically nonstereotyped individuals are exposed to prejudice and discrimination. The point is that these individuals experience the very same unpleasant treatment that members of negatively stereotyped groups undergo everyday. And through this experience, they should become more empathetic and understanding of the problems faced by the stereotyped groups. The most well-known example of this approach is depicted in the 1970s film, *The Eye of the Storm*. This film details Jane Elliot's

exercise in which students were treated differently based on the color of their eyes. For one day, the brown-eyed children ruled the classroom and on the next day the blue-eyed children had their turn. The ensuing prejudice and discrimination based on eye color highlighted just how quickly we can turn on each other when provided with a clear social hierarchy in which we find ourselves on top (similar exercises have been used in sensitivity training for public officials such as police officers or prison guards).

Multicultural Ideology

Rather than ignoring differences and promoting what is often called a color-blind ideology (also known as egalitarianism), a multicultural ideology recognizes and embraces the differences between groups. The color-blind ideology is best represented by the notion that America is a melting pot, in which all racial differences are melted into one America. The multicultural ideology is best represented by the notion that America is a salad bowl, in which all racial differences are mixed together. The basic logic underlying the notion of multiculturalism is that it promotes the respect of others and embraces the differences between groups as a way to enhance group harmony. While the color-blind ideology shares the basic tenet of group respect, its downside is that it ignores the differences between groups and these differences may be an important aspect of how one sees himself or herself.

This article is a revision of the previous edition article by Margaret L Moline, volume 3, pp. 587–599, © 1994, Elsevier Inc.

Glossary

Anxiety sensitivity The tendency to focus on and catastrophize about the meaning of physical sensations that is linked to increased premenstrual distress and the development of panic disorder.

Biopsychosocial perspective A theoretical model that includes physical, psychological, and cultural factors in the development of diseases and disorders.

Cognitive-behavior therapy A psychotherapy approach that focuses on identifying and challenging negative thinking and schemas in psychological disorders.

Late luteal phase Refers to the 5–7 days prior to the onset of menstrual bleeding (menses).

Menstrual reactivity hypothesis A dual vulnerability model including psychological, social, and physical explanations for premenstrual exacerbation of symptoms.

Panicogenic task Refers to the administration of substances that increase the symptoms (e.g., intense fear, increase in sympathetic nervous system symptoms) associated with a panic attack.

Rumination The tendency to focus on the experience and causes of thoughts, feelings, and sensations associated with dysphoric mood that may lead to increases in depression and anxiety.

Social construction perspectives A model that focuses on social processes that influence the discourse surrounding psychological diagnoses.

In Western and non-Western cultures, fluctuations in menstrual symptoms have been noted for over 2500 years. Since its introduction to the medical nomenclature in the 1930s, the topic of premenstrual syndrome (PMS) has consistently elicited controversy, and differences in methodologies and small sample sizes have led to inconsistent findings. Research on PMS relied heavily on retrospective reports, which are problematic due to bias and overestimation of symptoms. Furthermore, definitions of PMS have not been consistent in the past, and generalization across studies is limited. However, PMS is an important topic of study, particularly when considering prevalence rates, impact, and societal views relating to PMS. The recent focus on using more standardized criteria for PMS has added greatly to the research literature, and the state of contemporary PMS research represents significant advances in our understanding of this condition.

Symptoms, Epidemiology, and Classification

Symptoms of PMS

In general terms, PMS refers to a variety of emotional, physical, and behavioral symptoms that occur after ovulation during the late luteal phase (days 21–28 of the menstrual cycle) and end with the onset of menstrual bleeding (day 1). Although over a hundred symptoms have been associated with the premenstrual phase, the following listed symptoms are the most commonly reported. Emotional symptoms may include anxiety, depression, anger, irritability, and mood swings. Physical symptoms can include breast tenderness, water retention, headache, fatigue, acne, joint pain, and gastrointestinal distress. Behavioral symptoms typically include appetite change, sleep disturbance, crying, social withdrawal, agitation, forgetfulness, and poor concentration.

Epidemiology

Approximately 80% of reproductive age women may report some of these premenstrual symptoms, and most of these symptoms occur at a mild level that does not interfere with daily functioning. Approximately 25% of women may experience PMS, which occurs when symptoms are experienced at a moderate-to-severe level and daily functioning becomes impaired. The International Classification of Diseases (ICD-10) categorizes PMS as premenstrual tension syndrome. More severe symptoms with significant impairment occur in ~2–9% of women and lead to a diagnosis of premenstrual dysphoric disorder (PMDD). Approximately 50% of women may seek medical treatment for their PMS symptoms. Although PMS can be diagnosed in menstruating women of any age who have ovulatory cycles, it is typically diagnosed in women in their thirties and forties.

To be diagnosed with PMS, symptoms must be cyclical and not represent the exacerbation of another disorder. Women who suffer from the following psychological disorders may also experience premenstrual exacerbation of their symptoms: depression, bulimia, binge eating disorder, and panic disorder. Also, women with the following health conditions may experience an increase in symptoms or severity: epilepsy, fibromyalgia, asthma, multiple sclerosis, rheumatoid arthritis, and migraines. Women with PMS are more likely to report excessive menstrual flow, abdominal pain, and bleeding during other phases of the menstrual cycle. Current smoking and passive smoke exposure are associated with anxiety, cravings, water retention, breast pain, back pain, and headache in PMS. Increased alcohol consumption and less physical activity are related to more severe premenstrual symptoms. Increased consumption of caffeine is also linked to more severe premenstrual symptoms.

Classification Issues

Unfortunately, there is a continuing lack of consensus regarding definitions, assessment, and treatment of PMS. However, current diagnostic criteria indicate that in order to qualify for a diagnosis of PMS, symptoms must meet the following criteria: occur in the 5 days prior to menstrual bleeding onset and increase by at least 30% from other times in the menstrual cycle, cease by day 4 of menstrual bleeding, and symptoms must remit during the remainder of the menstrual cycle. More strict criteria require that both physical and emotional symptoms must be present during the 5 days before menses. Another issue to consider is the consistency of PMS symptoms over time. In this regard, prospective, daily recording of symptoms for two consecutive menstrual cycles is considered necessary to establish symptom patterns and the symptoms must be distressing as well as cause impairment in normal, daily functioning.

Biopsychosocial Perspective of PMS

The most current view of PMS derives from a biopsychosocial perspective. A biopsychosocial approach posits that biological factors, psychological factors, and social factors interact to play a significant role in human functioning. Although the menstrual cycle *itself* is not considered a disease or illness, the biopsychosocial perspective can be used as a model to better understand the vast array of conditions that may affect a woman's menstrual experience. Menstruation is a normal and integral biological process for women. However, psychological factors may also play a role in the report, interpretation, and experience of menstrual symptoms. Indeed, research suggests that symptom severity is quite variable and may be more related to psychological factors than biological ones. Social factors, such as age, racial/cultural diversity, and religion, may also play a role. Health care and mental health care providers, thus, need to consider the interaction of these factors in PMS in order to provide the best assessment and treatment for patients. In this article, PMS and PMDD are presented from a biopsychosocial perspective.

Biological Aspects of PMS

Current research indicates that ovulation and ovulation-related processes play a central role in the development of premenstrual symptoms. Support for this model comes from research findings that PMS symptoms disappear when ovulation does not occur. Although the exact mechanisms are not clear, reproductive hormones are thought to play a significant role in symptom fluctuation across the menstrual cycle. During the late luteal phase, progesterone metabolites typically decrease and estradiol levels increase. Interestingly, however, reproductive hormone levels in women diagnosed with PMS tend to fall in the normal range. At present, there are no hypotheses concerning what would account for sensitivity in some women to normal changes in hormone levels.

Progesterone and estrogen are also hypothesized to modulate neurotransmitters (e.g., serotonin, GABA, dopamine, norepinephrine) that are typically associated with changes in

mood and behavior. Decreased levels of serotonin are linked to sleep disruption, appetite change, fatigue, and depressed mood which are associated with PMS. Research has found that women with PMS have lower levels of serotonin during the last 10 days of the menstrual cycle. One hypothesis is that serotonin deficiency could enhance sensitivity to progesterone changes. Support for serotonin as a contributory factor in PMS is bolstered by the efficacy of selective serotonin reuptake inhibitors (SSRIs) in the alleviation of some PMS symptoms. However, it is not known why some women would be more sensitive to these changes. Allopregnanolone, a metabolite of progesterone, has also been linked to PMS. However, low and high levels of it have been found in women with PMS.

Genetic contributions have also been examined in women with PMS. For example, if a woman's mother had PMS, her chances of having PMS were ~70%. If one monozygotic twin had PMS, the other twin had a 90% chance of having PMS. Thus, the role of genetics in PMS deserves more study. Cyclic changes in stress hormone levels (e.g., adrenocorticotrophic hormone, cortisol) have also been found in some women with PMS. This type of research represents an emerging area of interest that needs more study.

Another promising area of interest relates to cyclic changes in the immune system. During the premenstrual phase, cell-mediated immunity is suppressed. This cyclic change is thought to have evolutionary adaptation for the developing embryo. However, there has been no research conducted to test this interesting model of PMS and no hypothesis about why some women would experience symptoms and others don't.

Other potential biological causes of PMS posited are differences in prolactin and aldosterone levels (i.e., hormones that affect fluid balance), thyroid imbalances, glucose metabolism, and insulin imbalances. However, there is no confirming evidence for causality for these hormones in the development and maintenance of PMS symptoms. Potential nutritional differences (e.g., vitamin B₆, calcium, magnesium, caffeine) have also been mentioned as possible contributions to PMS symptoms. Again, there is no evidence to support these nutritional causes when women with PMS are compared to controls. In addition, there is no explanation of why some women might be more affected by these biological changes during the menstrual cycle than others. Given the lack of support for purely biological causes of PMS, researchers have also investigated the role that psychological factors or trait variables may play in PMS experience.

Psychological Aspects of PMS

For women with PMS, quality of life may be significantly impacted. Women with PMS may experience impairment in social relations, personal relationships, hobbies, and household activities. PMS may also result in work disruption, decreased productivity, and increased use of health care. Women with PMS report more daily stress, life stress, perceived stress, and physiological stress than controls. Similarly, women with PMS report experiencing more traumatic events than controls. However, these findings are correlational and do not imply causation.

There are several psychological disorders that are comorbid with PMS. In fact, ~50% of women with PMS report a history

of anxiety or mood disorders. Given that women with PMS often respond to a panicogenic task similar to women with panic disorder, it has been suggested that PMS and panic disorder may share a similar pathophysiological mechanism.

According to the menstrual reactivity hypothesis, some women report more severe premenstrual symptoms based on an array of influences: accurate symptom reporting, biases that relate to past premenstrual experience, cultural attitudes and beliefs, and a predisposition to focus on internal bodily sensations and catastrophize about their meaning. This model has been used to explain premenstrual distress differences between women varying in levels of anxiety as well as to women with asthma. In this dual vulnerability model, some women may experience physiological sensations or symptoms and then mood symptoms may develop in response to those symptoms. As yet, this model has not been tested in PMS.

Sociocultural Factors in PMS

In any discussion of PMS, the potential for the medicalization of the menstrual cycle needs to be addressed. It is clear that the menstrual cycle *itself* should not be considered a problem, disease, or illness that needs to be solved or treated. However, it is also clear that some women will experience moderate-to-severe premenstrual symptoms that may impair their normal functioning. Does receiving a diagnosis of PMS perpetuate a myth that women are emotionally unstable and captives to raging hormones? Does this diagnosis reinforce traditional beliefs about femininity? For these reasons, sociocultural factors are particularly important to consider.

There are inconsistent findings regarding the effect of education, employment, and marital status on PMS prevalence. One study found that work-related stress was a significant predictor of premenstrual symptom severity. Another study found that younger age, high levels of stress, and less education were positively associated with emotional symptoms of PMS. As women age, anxiety, mood changes, and back pain associated with PMS decrease. Women with low BMI tend to report less premenstrual symptoms (possibly due to lower levels of estrogen). Relatedly, women who are obese are three times more likely to suffer from PMS. Preliminary research also suggests that Caucasian women, smokers, and younger women are more at risk for PMS. Clearly, more research on age and weight as they relate to PMS experience is needed.

Although PMS is thought to be found worldwide, culture plays a role in the reporting of symptoms. In one large survey, women of Asian descent reported fewer premenstrual symptoms than Caucasian, African American, and Hispanic women. Anxiety and mood changes were reported less by African American and Japanese women. There are, however, too few studies to be able to definitively say that race and culture may play a significant role in PMS experience.

Assessment and Treatment of PMS

Assessment

Assessment of PMS requires daily monitoring of symptoms for two consecutive menstrual cycles. Given that women may vary in the types of symptoms they experience, symptoms from

the emotional, behavioral, and physical realms should be included. Women should be able to indicate the severity of the symptoms as well as the level of impairment of the daily symptoms in all life domains. In addition, other medical conditions that have similar symptom presentations, such as menopause, hyperthyroidism, hypothyroidism, and polycystic ovary syndrome, should be ruled out.

Recent assessment measures have led to more consistencies in how premenstrual symptoms are measured. For example, the premenstrual symptoms screening tool (PSST), a short survey of 14 items, maps onto current diagnostic criteria for PMDD, and can also be used to screen for PMS symptoms. The daily record of severity of problems (DRSP), a prospective monitoring tool, is completed daily for two consecutive menstrual cycles to obtain a diagnosis of PMS or PMDD. The premenstrual symptoms impact survey (PMSIS), a brief survey of six items, can discriminate between women with clinically significant PMS and controls. With the continued use of such measures in larger samples, study results will be more reliable and generalizable to other populations.

Treatment

Typically, women who seek treatment for their PMS symptoms are prescribed medication. Although there is no support for the progesterone deficiency model of PMS, progesterone-based therapies are commonly prescribed. SSRIs (e.g., fluoxetine, sertraline, paroxetine) are also frequently used throughout the menstrual cycle or just during the premenstrual phase (e.g., luteal phase dosing) with demonstrated efficacy compared to placebo. SSRIs may help reduce depression, anxiety, irritability, and fatigue associated with PMS. However, the long-term efficacy of using SSRIs has not been demonstrated for PMS and ~40% of women with PMS do not have reduction in symptoms.

Another treatment involves the suppression of ovulation and/or menstruation (e.g., GnRH analogs, Danazol, transdermal estradiol patches). However, the long-term use of such medications may include bone loss, menopausal symptoms (e.g., hot flashes, irritability), and cardiac difficulties. Oral contraceptives (OCs) may also be used to suppress ovulation. Research has shown that continuous use of OCs may result in reductions of headaches, fatigue, and water retention.

Dietary changes are often suggested for women with PMS such as reducing salt intake, chocolate, caffeine, nicotine, and alcohol. Eating frequent meals high in complex carbohydrates may help reduce binges and cravings. Intake of vitamin B₆, calcium, magnesium, and vitamin E is also recommended. Moderate aerobic exercise may also help manage PMS symptoms. Stress management techniques may also be helpful in reducing stress associated with work, school, and relationships. Nonsteroidal anti-inflammatory drugs (NSAIDs) may help some women with PMS in reducing muscle tension and headaches. Yoga, acupuncture, relaxation, and social support are also recommended but have no empirical support or controlled trials.

Compared to a wait-list control group, women with PMS who received cognitive-behavioral therapy (CBT) reported a reduction in the negative effects of symptoms and these results were maintained over time. However, the majority of CBT for

PMS studies were not controlled trials and CBT has not demonstrated greater efficacy compared to SSRIs. More research is necessary to determine the mechanisms and which women with PMS might benefit from this type of treatment.

PMDD Diagnosis, Epidemiology, and Quality of Life Impact

Diagnosis of PMDD

Premenstrual dysphoric disorder (PMDD) is a severe form of premenstrual distress characterized by significant increases in physical and affective symptoms during the premenstrual phase of the menstrual cycle. These symptoms are serious enough to cause clinically significant distress and interfere with functioning (e.g., in work, school, home, daily activities, and/or social relationships). Symptoms of PMDD include depressed mood, anxiety, anger/irritability, mood swings, loss of interest, difficulty in concentrating, lack of energy, appetite changes or cravings, sleep disturbance, feeling overwhelmed or out of control, and physical symptoms (e.g., bloating, breast tenderness, weight gain). In women with PMDD, these symptoms are present during the premenstrual phase, improve within the first few days of the onset of menstruation, and remit during the remainder of the menstrual cycle. In other words, PMDD is characterized by dramatic emotional, physical, and behavioral changes that occur cyclically and are restricted to the premenstrual phase. Thus, PMDD is a separate diagnostic entity, rather than a premenstrual exacerbation of another disorder, such as depression.

Epidemiology

PMDD is estimated to impact ~2–9% of women in the United States. Similar prevalence rates have been found in several European, African, and Asian countries. However, no research has examined potential differences between racial and ethnic groups in the United States in terms of prevalence rates, symptom expression, or correlates.

Regarding onset of PMDD, symptoms typically emerge during the mid- to late twenties and follow a chronic course if left untreated. In women with PMDD, symptoms tend to worsen over time but discontinue during interruptions of the ovulatory cycle (i.e., menopause, pregnancy, and ovariectomy). Lifetime comorbidity rates for PMDD are high (30–70%), particularly with other mood disorders. PMDD may put women at risk for later depression, including perimenopausal and postpartum depression. Conversely, mood or anxiety disorders may put women at risk for later development of PMDD.

Quality of Life Impact

Women with PMDD experience significant impairment in quality of life. PMDD is associated with decreased social and parental functioning, as well as occupational performance. Some women with PMDD also report cognitive difficulties (e.g., attention, concentration), although research findings in this area are mixed. PMDD is also related to health-related quality of life impairment in both physical and mental health

domains. Women with PMDD report health-related quality of life burden comparable to individuals with other chronic physical (e.g., arthritis) and mental (e.g., depression) disorders. Although individuals with PMDD are most impaired during the premenstrual phase, they are more impaired in several areas of functioning during other menstrual cycle phases compared to women not diagnosed with PMDD. Overall, it is clear that PMDD has a major impact on the lives of women diagnosed with this disorder.

Biopsychosocial Perspective of PMDD

Biological Aspects

Most research on the etiology of PMDD has focused on biological explanations. However, research on biological models for PMDD has produced mixed findings. The majority of research has investigated the potential role of gonadal hormones. Support comes from evidence that symptoms are not present during interruptions of the ovarian cycle, and research suggesting that oral contraceptives may be an effective treatment. Symptoms may be related to the declining levels of ovarian steroid hormones during the premenstrual phase of the menstrual cycle. Estrogen and progesterone are elevated during the luteal phase, and then drop dramatically in the late luteal (premenstrual) phase. Estrogen is linked to mood through its influence on the serotonin system. Fluctuations in estrogen may also impact the secretion of corticotrophin releasing hormone (CRH), of which decreased levels have been associated with depression. There is some initial research suggesting that women with PMDD may have higher levels of estrogen during the follicular phase, and that PMDD symptoms may vary as levels of estrogen change. However, research has not confirmed relationships between estrogen levels and PMDD, and research does not support a relationship between progesterone levels and PMDD.

Hormone imbalance, rather than fluctuations, may be related to PMDD. For example, a hormonal ratio imbalance between estrogen and progesterone has been implicated. In particular, when estrogen levels are high in relation to progesterone, this may be related to PMDD. In addition, it has been suggested that the pattern of secretion of hormones in women with PMDD may be abnormal. However, some studies have found that levels of ovarian hormones are normal in women with PMDD, and studies have not found differences in hormone levels in women with PMDD compared to controls. Thus, evidence regarding the role of hormones in PMDD is mixed at best.

Neurotransmitters have also been studied relating to the etiology of PMDD. Decreased levels of GABA have been associated with depression and anxiety; therefore, it has been suggested that women with PMDD may have low levels of GABA during the premenstrual phase. Serotonin has also been studied in relation to PMDD, due to its links with other mood disorders. Endogenous opiate withdrawal during the premenstrual phase may be associated with fatigue, depression, and pain sensitivity. However, research on the role of neurotransmitters in PMDD has produced inconsistent findings, and many studies lack a comparison control group. At present, there is no confirmed relationship between neurotransmitter deficiencies and PMDD.

In sum, biological explanations for PMDD have produced mixed findings. However, given that symptoms coincide with physiological changes, it is important to continue to research these factors. Research that investigates biological factors in relation to psychological and social factors may be particularly valuable in understanding this complex disorder. It is likely that PMDD is multiply determined by a combination of biological, behavioral, and cognitive factors such that attempts to assign primacy to any one of them could be misguided. In other syndromes such as panic disorder, it is now clear that unfamiliar bodily sensations stemming from normal physiological variations can be misinterpreted in ways that amplify the original concern needlessly. A similar formulation has been applied to some chronic pain syndromes. The development of negative expectations, together with the operation of conditioning processes, can create a feedback pattern that escalates manageable discomfort into seemingly unendurable distress. In the context of panic disorder, that formulation has proven to be extremely helpful in clarifying etiology and focusing effective treatment regimens that have been demonstrated to have substantial empirical support.

Psychological Aspects of PMDD

Limited research has investigated psychological factors that may play a role in the development of PMDD. Psychoanalytic explanations have focused on the 'meaning' of the symptoms for PMDD. For example, premenstrual symptoms could be interpreted as repressed hostility toward males, who are more favored in society. Another view suggests that premenstrual mood symptoms are caused by a woman's grief over failure to conceive. These explanations are refuted by the pattern of symptom onset and remittance in PMDD, since symptoms actually decrease at the onset of menstruation.

The state of the empirical literature on psychological factors related to the etiology of PMDD is severely lacking at present. However, as research has demonstrated in PMS, the role of beliefs, expectations, and interpretations of symptoms may be influential in PMDD (e.g., menstrual reactivity hypothesis). Research on psychological factors involved in PMS has resulted in two important findings that may shed light on our understanding of PMDD: (1) Women with PMS may respond to emotional changes in a manner that is maladaptive (e.g., rumination, self-blame), and (2) Women with PMS may focus inward on physiological sensations and view these as catastrophic, thus increasing these symptoms (e.g., anxiety sensitivity). Therefore, it is possible that the manner in which women with PMDD respond to their symptoms is related to increased distress during the premenstrual phase. That is, biological changes alone do not account for PMDD per se, but rather women's responses to physiological and emotional changes that result from the menstrual cycle may be related to the experience of PMDD. Given that research on biological factors involved in the etiology of PMDD has yielded mixed findings, incorporating psychological and social factors is likely to provide a more complete explanation of this disorder.

Another line of research has examined potential shared etiologies between PMDD and other psychological disorders. Although PMDD involves symptoms of depression, it also shares similarities with anxiety disorders. Interestingly, irritability and

anxiety are actually reported more often in women with PMDD than sadness or loss of interest. Research in this area has resulted in criticism of the classification of PMDD as a mood disorder. For example, women with PMDD respond more strongly to panicogenic challenges than women with depression, and women with PMDD and panic disorder seem to share underlying etiological factors, such as anxiety sensitivity. Given these findings, it has been suggested that PMDD is particularly similar to panic disorder. Furthermore, there are high rates of comorbidity between PMDD and other psychological disorders, such as anxiety and depression. It is possible that shared vulnerabilities exist between PMDD and these other diagnoses that may make women more susceptible to developing comorbid disorders.

Sociocultural Factors in PMDD

Social constructionist perspectives contend that diagnostic categories emerge out of social processes. As such, psychological disorders are social, not natural, categories. In other words, the etiology of PMDD lies with society rather than individuals. Within this framework, feminist critics have raised concerns over the diagnosis of PMDD. In particular, a diagnosis such as PMDD may serve to subjugate women. Labels such as PMS and PMDD may reinforce women's lower class standing. Furthermore, this classification system can be seen as medicalizing women's sexuality. Labeling women's premenstrual symptoms as a disorder may validate the ideas that there is something 'wrong' with women's bodies, and thus underemphasize social and cultural influences on attitudes and beliefs about menstruation. For example, what girls are taught about menstruation and societal views tend to reinforce is that menstruation is painful, debilitating, and something to be embarrassed about, rather than emphasizing that menstruation is healthy and natural. These views may lead to negative attitudes toward menstruation, which could in turn contribute to premenstrual distress. For example, the menstrual reactivity hypothesis suggests that women may respond to cultural stereotypes regarding the menstrual cycle in addition to actual symptoms. Social constructionist and feminist critics have also pointed out the large financial stake in the PMDD diagnosis, particularly through pharmaceutical sales.

Assessment and Treatment of PMDD

Assessment of PMDD

PMDD is currently listed in the *Diagnostic and Statistical Manual of Mental Disorders* (APA [DSM-IV-TR], 2000) in the appendix as a set of criteria provided for further study. PMDD is diagnosed as a Mood Disorder Not Otherwise Specified. There has been debate over the classification of PMDD, including the number of symptoms required for diagnosis, as well as the location of PMDD in the manual. The state of the classification of PMDD for the updated version of the diagnostic manual (DSM-V) is unknown at present.

According to current diagnostic criteria, PMDD involves five moderate-to-severe symptoms, of which at least one is primarily affective in nature (i.e., depression, anxiety, irritability, loss of interest). Of the ten symptoms listed, only one

involves physical symptoms (e.g., bloating, aches). Symptoms must also cause significant interference in work, school, or social activities/relationships. Additionally, symptoms must not be premenstrual exacerbation of another disorder.

Diagnosis of PMDD is made using prospective ratings of symptoms for two consecutive menstrual cycles. This is typically done using a daily rating form (e.g., DRSP) on which women report the severity of each symptom. Prospective rating is particularly important considering the presence of a significant recall bias for premenstrual symptoms. Many women who retrospectively report meeting PMDD criteria do not meet criteria after rating symptoms prospectively, and retrospective and prospective ratings often do not correlate with each other. The requirement of prospective ratings for two menstrual cycles has been criticized in terms of its practicality. However, it is often possible to make a provisional diagnosis prior to obtaining prospective ratings of symptoms, for example by using a screening tool (e.g., PSST).

It is particularly important to consider differential diagnoses when assessing for PMDD. For example, women with mood or anxiety disorders may experience premenstrual exacerbation of these disorders, which can present similar to PMDD in the absence of prospective ratings. Similarly, mood or anxiety disorder onset could occur during the premenstrual phase but not follow a cyclical pattern, highlighting the importance of rating two consecutive cycles. Additionally, women with menstrual-cycle-related symptoms (e.g., cramps) that occur during the menstrual phase, after the onset of bleeding, could report increased symptoms on premenstrual screening tools, despite the fact that these symptoms do not occur premenstrually.

Treatment of PMDD

In general, treatment of PMDD is similar to that of PMS. Pharmacological treatments for PMDD include psychotropic medications, such as SSRIs and anxiolytics, both of which have demonstrated some success in treating PMDD. Interestingly, some studies show that SSRIs may be effective even when taken only during the premenstrual phase. Oral contraceptives (i.e., birth control pills) have also been used in the treatment of PMDD; however, empirical studies on the success of this intervention have produced mixed findings. Research suggests that oral contraceptives may be most beneficial for physical symptoms compared to the affective symptoms of PMDD. Type of oral contraceptive may also be important. Thus, more research on pharmacological treatments for PMDD is warranted.

Research on psychological treatment for PMDD has demonstrated some promising results. In particular, CBT interventions for PMDD indicate that this may be a potentially beneficial treatment for PMDD. However, research in this area is lacking and more studies are necessary to establish empirical support for the treatment of PMDD with CBT.

Conclusions

Since the 1990s, considerable research has been conducted on women's premenstrual experience. Stricter diagnostic criteria

have been proposed for PMS and PMDD. However, there is still no agreed-upon etiology for the two conditions. Most researchers agree that any causal model of PMS/PMDD must be multifactorial, considering biological, psychological, and sociological factors from multidisciplinary fields. More is known about treatment options, even though this research is plagued by small samples and uncontrolled trials. It is important that researchers continue to tease apart premenstrual exacerbation of existing conditions from primary PMS/PMDD.

Glossary

Encephalization quotient The ratio of an individual's or species' brain to its body weight; humans have the largest EQ among the primates, followed by other apes and then the monkeys. Capuchin monkeys are unusual among monkeys in also possessing a large EQ.

Hominoids The phylogenetic term for the great ape species, including humans, chimpanzees, bonobos, gorillas, and orangutans. The great apes show a marked increase in the encephalization quotient as compared to other primates, except the capuchin monkey.

New World monkeys Five families of primates from Central and South America, including Callitrichidae (marmosets and tamarins), Cebidae (capuchins and squirrel monkeys), Aotidae (owl monkeys), Pitheciidae (titis, sakis, and uakaris), and Atelidae (spider monkeys). These monkeys are typically arboreal and of smaller body size than the Old World monkeys. The New World monkeys and Hominoids shared a common ancestor ~40–50 Ma.

Nonhuman primates Any primate except humans, including prosimians, New World monkeys, Old World monkeys, and apes.

Old World monkeys Two subfamilies of primates from Asia and Africa, including Cercopithecinae (mainly African) and Colobinae (mostly Asian). These monkeys are very diverse; some are arboreal while some are solely terrestrial and range in body size from medium to large. The Old World monkeys and Hominoids shared a common ancestor ~20–25 Ma.

Physical cognition The cognitive skills used to survive in one's physical environment, including foraging skills, defense mechanisms, learning, and problem solving.

Social cognition The cognitive skills used for interacting with others, both opponents and collaborators. These skills include such things as defending one's group, navigating the dominance hierarchy, cooperating, and finding a mate.

Introduction

Cognition is the process by which a species learns, remembers, and solves problems with flexible behavior that may change depending on the situation, motivation level, and environmental pressures. Cognition in nonhuman primates is adaptive because it increases efficiency. Behavioral responses can go beyond trial-and-error learning and use problem solving and reasoning based on input from the environment, past experiences, and knowledge of the social environment. Nonhuman primate (hereafter primate) cognition is important to the understanding of the evolution of human minds, as well as a better understanding of the underlying cognitive mechanisms of primate behavior.

Humans are a primate and a member of the great apes, with chimpanzees and bonobos (to whom we are the most closely related), gorillas, and orangutans. We are next most closely related to the Old World monkeys (common ancestor ~25 Ma), followed by the New World monkeys (common ancestor ~40 Ma) and the prosimians (lorises, lemurs, and tarsiers; common ancestor ~80 Ma). While all primate species are interesting in their own right, those phylogenetically closest to humans are often studied based on the assumption that they are a better comparison to human behavior and cognition.

Cognition is commonly divided into physical and social cognition, both of which are important to individuals' success. Physical cognition addresses the skills used by primates to survive in their physical environment, including foraging skills, defense mechanisms, learning, memory, and problem solving. Social cognition is equally important to survival, as most

primates are highly social, interacting with many other individuals on a regular basis. Social cognition provides skills for interacting with others, both opponents and collaborators, in situations ranging from defending one's group to finding a mate. We first focus on physical cognition, including object manipulation and tool use, features and categorization, numerosity, delay of gratification, memory, and metacognition. Next, we turn to social cognition, including social intelligence, cooperation, decision-making, social learning, communication, deception, and theory of mind.

Physical Cognition

Physical cognition is how an organism understands and manipulates its physical world. Much of this takes place in the context of foraging. The ability to locate, obtain, and manipulate food is at the forefront of survival for all species. Primates also attend to other nonfood objects they encounter in their environment.

Object Manipulation and Tool Use

Object manipulation skills likely evolved in the context of foraging, in particular, extracting and processing food. Tool use opens up further adaptive possibilities by allowing the animal to change their environmental niche. Some tool using species, including (but not limited to) primates, seem to understand the interaction of the tool with the environment; they use tools flexibly, modify tools, and even manufacture tools in novel situations.

Ecological constraints strongly influence the degree of object manipulation. For instance, species showing more interest in object manipulation tend to consume a wider diet and use more flexible foraging techniques. Among primates, prosimians are the least exploratory of objects, possibly due to their restricted diet in comparison with the other primate orders. Monkeys show a more pronounced tendency to manipulate objects in their environments, including such behaviors as seriation, or arranging objects in a series or order. Great apes also excel at object manipulation and can even do fairly precise manipulations such as stacking objects. Human children are the most exploratory and manipulative primate species. In a study comparing juvenile bonobos and human children, the children engaged in more bimanual manipulation and tertiary relating and combining of objects, and could switch attention between objects more quickly and efficiently. In all of these cases, object manipulation and tool use clearly interact.

Tool use incorporates the use of objects in relation to each other and moves beyond simple object exploration. The use of tools demonstrates the ability to recognize the affordances of objects, rather than just their physical features. Tool use requires flexibility and complexity as well as mental representations. Flexibility and complexity are shown by using two or more tools in a sequence, such as when chimpanzees use one tool to open a beehive and another tool to extract honey. 'Metatools,' or using a tool to make another tool, are another form of flexibility and complexity. This may include chimpanzees using a support stone to level an anvil before nut cracking with a hammer stone. Mental representations are shown when a specific tool is chosen for a certain situation without overt trial-and-error and when an individual can adapt a normal pattern of tool use readily in a new circumstance. Both of these cases of mental representation show the use of insight or foresight.

Only some species appear to use tools habitually, including some monkeys (e.g., capuchins) and great apes. These species can make and use tools flexibly and may be relying on some form of mental representations. In captivity, some monkeys use tools even if they are not known to do so in the wild. This could be due to lack of data from the field or ecological constraints, in which they only develop tool use if it is necessary for their habitat. Primates are not the only tool using species. Many corvids spontaneously make or modify tools, rivaling primates in their skill. There is also some evidence of elephants and dolphins using tools.

Tools also provide information about how individuals understand causal relations. The classic observation was made by Kohler in 1925 after working with the chimpanzee Sarah. She showed insight learning in several contexts by fashioning a tool with no previous experience or exposure (e.g., fitting two sticks together to make one long stick or piling up boxes to climb to acquire a banana). Monkeys too appear to be able to understand simple causal relations, particularly in the context of the structure of social interactions (e.g., using vocalizations to interpret events outside their immediate visual field). However, monkeys have repeatedly failed more complex causal tasks, such as the trap tube task, which apes can solve, indicating that apes may understand causal relations better than monkeys.

Features and Categorization

Identifying objects and categorizing types of objects allows individuals to organize and simplify their worlds. These abilities are often tested with discrimination learning experiments, such as learning sets and delayed response tasks. Primates have demonstrated the ability to remember stimuli, categorize objects and phenomena, and learn general rules to use in novel situations. In a classic experiment by Harlow, monkeys learned to choose a correct (rewarded) choice in fewer trials as they gained experience. He argued that this transfer of learning across problems suggested some kind of conceptual mediation, thus speeding the process of learning in subsequent trials. Categorization also extends to social stimuli. In their natural environment, primates classify food items or other things, such as individuals as opponents, kin, or potential mates.

Primates are also able to conceptualize. For instance, primates can place objects into categories based on shared physical features, that is, identifying all triangles as similar, which has been described as the ability to conceptualize based on characteristics in common. In another example, match-to-sample tasks indicate that individuals can match two items utilizing a relational concept more advanced than stimulus-response learning. Several species of primates are able to generalize their knowledge of relational sameness and difference to novel stimuli. In addition, chimpanzees appear capable of using relations-between-relations to solve analogy problems. Although abstract discrimination skills are present in many species, primates typically generalize more rapidly and more widely than other species, indicating a selective premium on this type of conceptual learning, despite a similar predisposition to attend perceptually to physical features of the environment.

Finally, primates may also classify items based on an understanding of natural concepts that are more ecologically relevant. Classification has been extensively studied in a laboratory setting; a typical paradigm requires individuals to sort objects into groups based on shared characteristics. These classifications are not based on any shared physical features, but rather on the things that objects afford. Object sorting is a more difficult form of categorization because it requires both the comparison of objects and the manipulation of the objects according to previously made judgments. Chimpanzees show this ability to classify objects based on their functionality rather than physical similarities when they sort objects into superordinate categories, such as foods and tools, using symbols. Several primate species have been found to be capable of sorting objects based on various qualities, including color and kind, and most do so with little to no training. In fact, language-trained apes are able to sort objects more efficiently than 1- and 2-year-old human children and equivalently to 3- and 4-year olds.

Numerosity

Primates are very adept at quantity discriminations. They make use of these to complete everyday tasks such as foraging (e.g., estimating the quantity of food items available) and social interactions (e.g., estimating the number of potential mates or opponents). Such abilities do not necessarily require a concept of numerosity; they could be based purely on perceptual mechanisms. However, a purely perceptive mechanism cannot explain experimental results in which quantitative assessments

are made when sets are spatially segregated or presented sequentially. For instance, primates can discriminate quantities when they are presented item-by-item, or when they see the items as they accumulate. Apes can also discriminate when food presentation differs spatially or temporally. These types of judgments seem to require an analogical system, rather than a perceptual estimation mechanism.

In experimental studies, primates are very proficient at choosing a group with more items from among several options (cardinality). Apes also appear to use ordinality, which refers to understanding the sequence of these labels or numbers. One chimpanzee, Ai, trained in numerical computer tasks showed evidence of using planning, executing, and monitoring phases when ordering numerals, much like humans.

Primates may also use transitivity, or the ability to recognize a sequentially ordered relationship. The ability to make transitive inferences may be crucial for animals living socially because it allows them to make judgments based on social ranking without having to learn each possible dyadic relationship individually. Humans, monkeys, and pigeons all perform well on serial-order tasks. However, humans and monkeys form mental representations that are well-organized into an associative chain while pigeons rely on discrimination cues. Nonetheless, sociality is clearly critical; in a study comparing highly social pinyon jays and relatively nonsocial western scrub-jays, pinyon jays learned to follow and assess relationships more quickly and accurately than western scrub-jays, indicating that there is more at work than phylogenetic distance from the primates. These studies support the social complexity hypothesis, which states that animals living in highly social groups should display more advanced cognitive skills in the domain of group living.

Delay of Gratification and Planning

Delay of gratification is the ability to wait for a better outcome, and is important in planning and foresight of goal-directed behavior. Such self-control may be particularly useful in primate foraging decisions, as individuals who understand the benefit of postponing a behavior instead of acting on it immediately may reap better rewards in the future. Although delay of gratification exists in nonprimate species such as dolphins, primates appear to be better at inhibition, possibly because of their higher encephalization quotient.

Two typical methods of assessment are the smaller-sooner/larger-later paradigm and the accumulation paradigm. The smaller-sooner/larger-later paradigm assesses an individual's ability to inhibit the impulse to take a smaller but sooner reward and instead wait for the larger but later pay off. The accumulation paradigm examines the individual's ability to inhibit reaching for rewards in order to allow them to accumulate. Studies employing these methods find a relationship among self-control, ecology, and life history. For instance, primates who live in fission–fusion groups show greater inhibitory skills than those in more cohesive primate social groups. This is possibly because social complexity seen in the fission–fusion societies supports higher cognitive abilities, such as inhibition, which is beneficial in a fluid social environment. Feeding ecology also plays a role. Among callitrichids, gum eating marmosets delay longer for food rewards than insectivorous tamarins. This differential ability likely evolved

because marmosets must wait a period of time for the gum to exudate from trees, while tamarins must act quickly and impulsively to catch their insect prey.

The ability to delay gratification may function to increase planning. Apes engage in spontaneous planning behaviors, such as caching, or even manufacturing, tools for use at a later date. This indicates mental foresight of upcoming events. Primates may also use planning in their social interactions with conspecifics. For instance, chimpanzees gather stones to throw at human observers, and other chimpanzees have been described as planning an attack on another individual at night while the caretakers were gone. Finally, while the mechanisms for delaying gratification are largely unknown, primates use many techniques that humans do to increase their ability to wait. For instance, chimpanzees practice self-distraction with objects available in the environment, which allows them to wait for longer periods of time.

Memory

The ability to remember certain elements of the environment and information from one's social group is an important part of a primate's world. We will further discuss memory among social groups later (see section 'Social Cognition'); for now we focus on how memory serves primates in their physical environment.

Primates, like many other animals, must remember the locations of what they are seeking (e.g., the location of ripe food, water, or sleeping sites) and understand where they are in relation to other sites. Primate social groups may cover an extensive range throughout their day and must remember their environment in order to efficiently move throughout their territory and utilize its resources. Some primates travel up to 10 km a day and make use of cognitive mapping skills, or the ability to create and remember a mental representation of the spatial environment, in order to successfully manipulate their environment. Optimal foraging theory suggests animals make use of least effortful routes when foraging, minimizing effort while maximizing gains. Apes, Old World monkeys, and New World monkeys have been shown to use cognitive mapping while foraging both in experimental lab studies and in the wild.

Primates also show the ability to remember different entities within the laboratory. Chimpanzees can recall Arabic numbers in a memory task with an equal or greater success rate than novice undergraduate students. Monkeys can remember serial lists across various sensory domains, including photographs and auditory lists, and when items vary. Monkeys also appear to be able to access their memories to judge their own knowledge. In laboratory studies, monkeys avoid memory tests when their knowledge is lacking and they act spontaneously when they have the knowledge that is needed.

The goal-directed behavior seen in primate spatial movement is not only suggestive of cognitive mapping, but also episodic memory. Episodic memory is the ability to recall specific events in an individual's lifetime. It has been suggested that episodic memory is a uniquely human trait and nonhuman animals do not possess the capability of traveling back in time to a specific event. Experimentally, it is not possible to assess whether primates experience feelings of 'pastness' as is

described in human accounts of episodic memory; so instead, nonhuman animal studies investigate 'episodic-like' memory, or the individual's ability to recall what, where, and when information. There is evidence for these episodic-like memories in apes and monkeys, but also in mice and scrub jays, indicating a fairly widespread ability. However, other species' episodic memory may differ from our own; for instance, in some tasks the time frame is relatively short (10 s).

Metacognition

Metacognition is the ability to monitor and adaptively control one's cognitive processing or thinking about thinking. Self-awareness of one's memory serves the function of allowing individuals to avoid situations where they lack knowledge which is needed. Although research in this area in nonhuman species is relatively new, it is clear that species beyond humans are also aware of what they do and do not know.

In a typical metacognition task, subjects are given a series of increasingly difficult discriminations but can indicate that they do not know. Old World monkeys reliably perform very well, choosing the uncertain response more often when the discriminations are more difficult. All great ape species demonstrate metacognition in a task in which they tried to collect necessary information that was missing before solving a task, such as seeking out the location of food in a tube by looking into the tube before making a decision.

New World monkeys have not performed well in most metacognition tasks. However, some capuchin monkeys recently demonstrate the capacity to opt out of a memory test based on past performance suggesting they are also able to make judgments on their knowledge. Nonetheless, the monkeys do not appear to be able to monitor the detailed contents of their short-term memory as well as Old World monkeys and apes. Although additional research is needed both within the primates and in other taxonomic groups, it appears that there are taxonomic differences which are consistent with other cognitive differences between the primates.

Social Cognition

Primates are good psychologists in their own right. Because most species are highly social, they must be able to interpret and predict others' behavior to maximize their own fitness. They must be able to recognize individuals and their relationships to oneself, recognize others' relationships, make judgments based on their knowledge, and use past experiences to predict the future. In order to do this, they appear to use mental representation of social knowledge and the properties of social relationships beyond simple associations.

There are several hypotheses for the evolution of advanced social cognition. First, it may be that the social pressures themselves drove the evolution of social cognition. The Social Intelligence hypothesis suggests the evolution of intelligence in primate species is a direct result of group living; intelligence has evolved in response to social living and the complexities that arise with it. The related Machiavellian Intelligence hypothesis argues that the brainpower needed to outmaneuver one's group mates motivated the advanced cognition seen in

primates. In this case, cognition is argued to have arisen through individuals' need to cooperate, deceive, and manipulate. Ecological pressures may also have shaped primate intelligence, in tandem with social pressures. Most apes, including humans and some monkeys, live in dispersed social groups or fission-fusion societies (e.g., spider monkeys, baboons, and chimpanzees); this system is socially demanding and is argued to have selected for even more advanced cognition in these species.

Cooperation

Many species cooperate on a regular basis, including with unrelated individuals, or even with individuals of other species. There is clearly adaptive value to cooperation, although the reasons for the evolution of this behavior, and its attendant proximate mechanisms, are still the topic of much debate. In general, cooperation is believed to evolve in the context of indirect fitness (e.g., kin selection), mutual encounters in which there is no risk of defection (e.g., it is in each individuals' benefit to cooperate in each interaction), and in reciprocal interactions. Although all of these situations increase fitness, this latter is the most difficult to explain as there are incentives for individuals to not cooperate, or defect. Cooperation is widely present in ape and monkey species, occurring in foraging contexts (e.g., cooperative hunting) and social contexts, such as the coalitions and alliances used for group defense, dominance, and mating. Several factors seem to play a role in whether or not cooperation occurs. These include whether the cooperative opportunity is intuitive, the level of social tolerance among the interactors, and the structure of the payoffs.

Although it has been argued that reciprocal altruism rarely, if ever, occurs in nonhuman animals because it would require too many cognitive mechanisms, such as individual recognition and memory, many primates meet these criteria. Moreover, reciprocity and interchange (the exchange of different commodities) have been demonstrated in numerous situations in several species of primates. This is true in apes and monkeys, although there is variation between different species. In the field and in observational studies, reciprocity is common in grooming and food sharing, as well as interchanges among grooming, support, food, and mating. Most interactions occur over fairly long-time scales, making this behavior somewhat difficult to study experimentally. This issue of time scales as well as the fact that partner choice (the ability to choose one's partner) appears to be a critical component of reciprocity, may explain why contingent reciprocity has been so difficult to elicit in the lab.

Finally, not all instances of reciprocity need be cognitively complex. Although reciprocity may involve tit-for-tat and calculation, Brosnan and de Waal propose three types of reciprocity which vary on the requirement for calculation. At its simplest, cooperation may be symmetry-based, with reciprocity emerging based on individuals' relationships. At the next level, attitudinal reciprocity, behavior is contingent but not based on explicit calculation; instead individuals who receive favors feel a positive effect, which leads them to return the favor (or reciprocate). Finally, calculated reciprocity is both contingent and, as the name implies, calculated. Although much cooperation research, particularly among the primates,

focuses on the cognition required for cooperation to function, it is clear from studies of other species that quite complex cooperation can exist with little-to-no cognition, as, for instance, among the castes of eusocial species or among cleaner fish mutualisms.

Decision-Making

Primates make myriad decisions on a day-to-day basis. They must decide, for instance, how to allocate their time, where to forage, and which foods to consume, and which partners to seek out and which to avoid. All of these decisions require individuals to evaluate costs and benefits, but many may also require them to explicitly include risk or relative payoff in their decision calculus. Below we discuss two of the better studied situations in which decision-making requires these additional considerations, inequity and 'irrational' decision-making.

Although it has been known for years that humans dislike situations of inequity, only recently has this been demonstrated for other species. This behavior is closely linked to contrast effects, or violation of expectation, but in this case, the expectation is based on what a conspecific received, rather than one's individual experience. In studies comparing how individuals respond when they receive a less good outcome than that of a conspecific, both capuchin monkeys and chimpanzees often refuse foods they typically like if a partner receives better food. This response occurs only in the context of a task of some sort and is limited to differences in outcome; differences in the effort required to achieve an outcome do not lead to these negative responses. This response is also affected by an individual's sex, rank, and relationship to their social partners. Inequity is hypothesized to be a mechanism which functions to support cooperation by allowing individuals to identify partners who are not sharing the outcomes.

Of course, on the surface, turning down an outcome because it is less than a partner's seems irrational, or counter to one's immediate interests. Other behaviors, such as loss aversion and the endowment effect also meet this criterion, leading to a surge in research on irrational decision-making and cognitive biases in primates. For instance, several species of apes and monkeys show an endowment effect, or a tendency to value what is in their possession more than they valued the same item prior to ownership. Primates' interest in increasing their outcomes interacts with risk, likely causing them to value what they have (a certain outcome) over what they could obtain (a risky one). This response occurs for foods, but not for nonfoods, indicating that the evolutionary salience of the item affects decision-making. This may explain some of the variation in the effect in human studies. Supporting this, capuchin monkeys also show loss aversion, a tendency to avoid gambles framed as losses, but not those framed as gains. In these decision-making situations, studying other species may help us better understand how these responses evolved in all primates, including humans.

Social Learning

Primates learn a great deal of information from others. Learning from conspecifics allows individuals to obtain information quickly, without potentially costly trial-and-error.

This may include learning basic information, such as the relevance of a specific location or stimulus (local or stimulus enhancement) or more detailed information, including procedures (copying) and goals (emulation). At its most basic, social learning exists among all of the primates, including prosimians, as well as many nonprimate species. The most complex form of social learning is argued to be imitation, in which individuals learn others' goals and the procedures used to reach these goals. In fact, comparative studies indicate that humans do more imitation than other species (who rely on emulation or less cognitively complex mechanisms). Humans appear to have been selected to imitate exactly, perhaps due to our proportionally greater reliance on socially transmitted information.

Social learning may also lead to more advanced phenomena, such as culture and teaching. There is little evidence for teaching among species other than humans; the mechanism for social acquisition among other species seems to be primarily up to the learner, rather than the model. However, there is evidence for social traditions or cultures in primates, including both monkeys and apes. There are now studies on several species, including nonprimates, showing evidence for behaviors which differ between groups, and cannot be explained by genetic or environmental factors. This leads to the assumption that the behavior must be transmitted socially. For instance, different chimpanzee populations have their own methodology for ant fishing, and some crack nuts while other groups, with the same opportunities for nuts and the availability of potential tools, do not. More recent studies implicate mechanisms such as conformity and prestige in affecting social transmission in primates, as they do in humans.

Communication

Communication is an integral part of daily life in socially grouped primates; it is used to convey information and to influence others' behavior. Primates communicate about many things, from the location of food and the presence of predators to an individual's emotional state and intentions. Communication occurs through several modalities, and different modalities can be used in combination (e.g., vocal and nonvocal communication). Nonvocal communication involves transmission of information through gestures, body posture, or facial expressions. One of the major facilitators of nonvocal communication in primates is the face, which provides information on age, sex, individual identity, underlying emotions, and impending behavior. Recent studies on face perception indicate similar perceptual processes in nonhuman primates and humans, suggesting perceptual mechanisms in facial recognition are preserved throughout the primate lineage.

While faces may be particularly expressive, much communication also takes place through gestures. Some have even argued that gestural communication was the first means of communication in our early human ancestors. Extensive gestural communication seems to be limited to apes and humans, suggesting a shift toward a more flexible and intentional form of communication in the Hominoidea lineage. Gestures are predominately produced together with another form of communication, either facial expressions or vocalizations. This multimodal communication is beneficial because individuals gain greater flexibility, more amplification, and greater

complexity in signal output. Multimodal communication in which gestures are produced along with vocalizations is also seen in human children, and seems to precede language development.

Finally, much primate communication is vocal. There are three primary views on the evolution of vocal communication. The first of these is the classical ethological view that vocalizations evolved because they could change a listener's behavior by acting on the salience of acoustic events and the listener's capacity for affective learning. A second view is that signals act as representations of objects or external events, rather than conveying a signaler's motivational state. This view was prompted by Cheney and Seyfarth's work which indicated, among other things, referential alarm calls in vervet monkeys. Finally, the affect-induction view is that nonlinguistic vocal communication influences the behavior of others through changing their affective state. In this case, calls are not always associated with particular contexts and may not have a meaning-based interpretation. Unlike the previous two theories, this theory puts the focus on the listener's affective state, rather than the vocalizer's. Thus far, all of these theories have at least some support.

There is extensive debate over the presence of language or language-like skills in other species. As discussed previously, the gestural origins of language theory suggests that gestures were the starting point for human language. It is also suggested that language emerged from referential vocal signaling in primates. At the most basic level, language evolution may go even further back than the primates. Recent evidence using looking-time tasks indicates that other species, including birds and primates, can understand basic grammar-like structures. However, humans are unique with respect to language. Historical attempts to teach language to other species, including nonprimates, indicate that while they can learn to communicate using symbols or sign language and achieve quite impressive outcomes, including vocabularies of hundreds of words and syntax comprehension, their language never reaches the degree of proficiency seen in humans.

Deception

Deception allows individuals to manipulate another's behavior for their own gain. In tactical or functional deception, an individual produces a signal outside of its typical context in order to affect listeners' behavior. While deception is meant to change others' behavior, it is not clear if the signaler intends to create false thoughts or beliefs in others. Deception is, by definition, rare if it is to be effective, making it rather difficult to study experimentally. Nonetheless, good evidence exists for at least functional deception in primates.

Deception can be passive or active. In passive deception, an animal refrains from a particular behavior so others will not detect their presence or actions, for example, hiding facial expressions or erections, or withholding food calls. Although such behavior is 'passive,' it may indicate that the animals have awareness that they can manipulate their communicative displays. On the other hand, individuals may also actively mislead or provide false information to others. False alarm calls are a common form of active misleading. Cheney and Seyfarth report a vervet monkey giving an alarm call in the middle of an

intergroup encounter (but in the absence of a predator) that stopped the dispute when the combatants fled. Capuchin subordinates use alarm calls to distract more dominant individuals during competitive situations, reducing some of the costs associated with competition for food in the wild. Although these forms of deception function to manipulate others' behavior, there is no evidence that the intention is to manipulate their psychological states.

Finally, there is some evidence for counterdeception, or individuals taking active countermeasures against a conspecific's deceptive act. For instance, others may learn to avoid the calls of deceptive callers in food or aggressive contexts. In an experimental study involving chimpanzees, one chimpanzee in a group knew the location of hidden food and soon learned to keep the food's location a secret to avoid having it stolen by her ignorant partner. The ignorant chimpanzee then began to follow the knowledgeable chimpanzee, ignoring her attempts at misleading, indicating that he anticipated her attempts at deception. In other experimental procedures, chimpanzees have learned to withhold information – and even provide false information – to competitive human experimenters who do not provide food to the subject in experimental tasks.

Theory of Mind

Theory of mind is the ability to reason about the mental states of both the self and others. The attribution of mental states allows one to know about other's beliefs, emotions, and intentions. Individuals capable of attribution have a competitive advantage because they can predict future behavior, generalize their knowledge, recognize ignorance in others and choose to reveal or withhold information. In a primate's world, the better social strategist, who used their knowledge to their own and their kin's benefit, would have the advantage. Whether or not primates actually know about the psychological states of others is heavily debated.

A basic prerequisite for theory of mind is self-awareness, or viewing the self as a social agent. There is a distinction between conscious self-awareness and self-recognition. Self-awareness is being aware of one's own state of mind and using this to predict and explain one's own and others' behavior. Self-recognition is distinguishing self from others but does not imply any awareness of doing so. Initial research focused on self-recognition. First developed by Gallup, the mirror self-recognition (MSR) test gauges self-recognition in young children and primates. The individual in question receives a painted mark on his/her forehead and then is shown a mirror. If they recognize themselves, they should show behavior directed at the mark, such as touching it, when exposed to the mirror. Critically, they must also act differently than when a 'sham' mark that they cannot see has been placed on their head, to rule out the possibility that tactile, olfactory, or other cues are at work. These studies have demonstrated that chimpanzees and other apes recognize themselves in the mirror, as do elephants and dolphins. Monkeys do not show evidence of self-recognition; however, they can use mirrors to solve problems and they do not treat their mirror image in the same way as they treat a stranger.

Initial attempts to test for further abilities were negative. A series of studies were run to test whether chimpanzees would

recognize when a human was and was not able to help them in a task (e.g., would they be able to understand the experimenter's view of the world). These studies presented chimpanzees with two containers, one of which contained a hidden food item, and allowed them to choose between experimenters to obtain the food for them. One of the experimenters was in a position to know where the food was, while the other was not (e.g., their face was covered, their eyes were averted, or they were facing backwards). Chimpanzees consistently failed to discriminate between the experimenters.

On the other hand, others have found evidence that nonhuman primates, especially chimpanzees, go beyond behavioral rules and understand others' goals and possibly intentions, thus possessing aspects of theory of mind. First, these initial studies have been run in situations which do not rely on the chimpanzee expecting the human to collaborate, to very different results. For instance, when chimpanzees are trying to steal food, they fail to do so more often when the experimenter is able to see them versus unable to see them. Moreover, when the experimenters back is turned, chimpanzees reliably choose options which do not alert the experimenter (e.g., a door which does not squeak), indicating an understanding that nonvisual cues may also alert a competitor. Moreover, additional studies demonstrate that chimpanzees, like human children, understand others' intentions by reacting to a goal rather than the actual behavior of the human experimenter. For instance, chimpanzees will help an experimenter reach an out of reach object, and both chimpanzees and orangutans react differently to a loss of food when it appears to be intentional versus accidental.

No monkey has been shown to succeed in any of these theory of mind related tasks. Although monkeys seem to have a sense of self within their social group, they do not impute motives to others, cannot imitate, do not actively teach, show no evidence for self-awareness (they do not pass mirror tests) and do not appear to reflect upon their own knowledge. On the other hand, they can deceive each other, although functional deception may not require an understanding of others' minds (see section 'Deception'). However, apes possess elements of a theory of mind; they appear to know others have beliefs and they can alter those beliefs, understand others' goals and motives (can imitate), deceive, understand others' knowledge and lack thereof, but cannot attribute false beliefs, and do not engage in active pedagogy. Thus, humans' full theory of mind appears to be an extreme along a continuum, rather than a uniquely human trait.

Conclusion

The study of primate behavior is vital to our understanding of the evolution of cognitive mechanisms. Primates must adapt to both their physical and social worlds and do so flexibly by employing cognition. In order to thrive in their physical

environment, primates must be able to successfully manipulate their resources, which can include problem solving and planning. They must also successfully coexist in social groups and maintain relations with conspecifics. By delving into the minds of our close evolutionary cousins, we learn not only how they navigate in their own world, but how we evolved to navigate in ours.

Problem Solving

R E Mayer, University of California, Santa Barbara, CA, USA

© 2012 Elsevier Inc. All rights reserved.

Glossary

Computer simulation Programming a computer to solve a problem like a human.

Heuristics General strategies for problem solving.

Insight The act of mentally restructuring a problem.

Means-ends analysis A problem-solving heuristic based on setting subgoals.

Problem Any situation in which a problem solver has a goal but does not know how to accomplish it.

Problem representation A phase in problem solving in which the problem solver constructs a mental representation of the problem.

Problem solving Cognitive activity directed at achieving a goal when there is no obvious solution method.

Problem solution A phase in problem solving in which the problem solver devises, carries out, and monitors a plan.

Problem space A description of the given state, goal state, and all possible intervening states.

What Is a Problem?

Definition

A *problem* exists when a problem solver has a goal but does not know how to accomplish it. A somewhat more precise way to express this definition is to say that a problem occurs when a situation is in the given state, the problem solver wants the situation to be in the goal state, and there is no obvious way of changing from the given state to the goal state. As you can see, a problem consists of a given state (i.e., a description of the current situation), a goal state (i.e., a description of the desired situation), a set of operators (i.e., rules for moving from one state to another), and obstacles preventing a smooth transition from the given to the goal state.

The Gestalt psychologist, Karl [Duncker \(1945: 1\)](#) defined a problem in the following way: "A problem arises when a living creature has a goal but does not know how this goal is to be reached." Although Duncker's definition is still valid, it must be updated to include the possibility of problem solving by machines, and so the term *problem solver* can refer to both living creatures and machines. This definition is broad enough to include a physician who seeks to make a diagnosis of a patient's ailment such as a defect in a specific valve in the heart (i.e., goal state) on the basis of patient information including test results and the patient's description of chest pains (i.e., given state). This is a problem because, at least initially, there is no obvious path from the given state to the goal state.

Types of Problems

An important distinction – based on the clarity of the problem statement – can be made between well-defined problems and ill-defined problems. A *well-defined problem* has a clear given state, a clear goal state, and a clear set of allowable operators. For example, finding the value of x in an algebraic equation such as $2x + 5 = 8$ is a well-defined problem because the given state is the equation, the goal state is a value for $x = \underline{\hspace{1cm}}$, and the operators are defined by the rules of algebra and arithmetic. In contrast, an *ill-defined problem* has a poorly specified given state, goal state, and/or operators. For example, choosing an

appropriate education for a career path or determining how to end an economic recession are ill-defined problems because the goal and allowable operators are not clearly specified. Most problems encountered in school are well-defined problems, whereas most crucial problems in everyday life are ill-defined.

Another important distinction – based on the knowledge of the problem solver – can be made between routine and non-routine problems. *Routine problems* are identical or very similar to problems that the problem solver already knows how to solve, and therefore require what [Wertheimer \(1959\)](#) called *reproductive thinking* – reproducing responses that have been produced previously. For example, a routine problem for most high school students is " $5 + 5 = \underline{\hspace{1cm}}$ " or "The headquarters of the United Nations is located in the city of ." In the strictest sense, routine problems do not conform to the definition of problem, since they do not include an obstacle between the given and goal states. In contrast, *nonroutine problems* are different from any problems that the problem solver already knows how to solve and therefore require what [Wertheimer \(1959\)](#) called *productive thinking* – creating a novel solution. Examples for most high school students include writing a computer program to compute the mean and standard deviation of a sample, or working out why Spanish explorers waited several centuries before colonizing California. In school, students often work on routine problems called *exercises*; however, most important problems in everyday life are nonroutine.

A third distinction can be made between problems requiring convergent and divergent thinking. *Convergent thinking problems* have a single correct answer that can be determined by applying a procedure or retrieving a fact from memory. Examples include arithmetic computation problems and answering factual questions. *Divergent thinking problems* have many possible answers, and so the problem solver's job is to create as many solutions as possible ([Guilford, 1967](#)). Classic examples include uses problems, such as "List all the possible uses of a brick," and consequences problems, such as "List all the consequences of humans having six rather than five fingers." Creativity can be measured in terms of the originality and usefulness of the answers, and divergent thinking skills, which underlie creativity, are taught in courses on

creative thinking (Sternberg, 1999). Although divergent thinking is the hallmark of creativity, most school-based problems mainly require convergent thinking.

What Is Problem Solving?

Problem solving is directed cognitive processing aimed at finding a way to achieve a goal when the problem solver does not know an obvious solution method. Mayer and colleagues (Mayer, 1992; Mayer and Wittrock, 2006) summarized four major elements in a definition of problem solving: (a) problem solving is *cognitive* because it occurs internally within the problem solver's cognitive system, (b) problem solving is a *process* because it involves manipulating or performing operations on the problem solver's cognitive representations, (c) problem solving is *directed* because the problem solver is attempting to achieve some goal, and (d) problem solving is *personal* because problem solvers enter the situation with different prior knowledge.

In short, problem solving occurs when a problem solver engages in cognitive activity aimed at overcoming a problem. Duncker (1945: 1) noted that "when one cannot go from the given situation to the desired situation simply by action, then there has to recourse to thinking" and "such thinking has the task of devising some action which may mediate between the existing and desired situations." Similarly, Polya (1981: ix) defined problem solving as "finding a way out of a difficulty, a way around an obstacle." In developing computer simulations of problem solving, Newell and Simon (1972) defined problem solving as a search for a path between the given and goal states of a problem.

This definition of problem solving includes a wide variety of cognitive activities such as in a physician who is given information about a patient and must make a medical diagnosis, a potential renter who must choose between various housing options, a chess player who must generate the next move in a game, a student trying to solve a homework problem in physics, or a scientist who wishes to test a theory about climate change. Each case requires problem solving because the problem solvers seek to generate useful and original solutions when they are confronted with problems they have never seen before.

What is the relation between problem solving and other high-level cognitive processes such as thinking and reasoning? Thinking can be broken down into two types – directed and nondirected thinking. Problem solving is a common and pervasive type of thinking, namely, *directed thinking* in which the thinker engages in cognitive processing aimed at achieving some goal. In contrast, in *nondirected thinking* the thinker engages in cognitive processing that is not aimed at achieving some goal, such as daydreaming or the abnormal thinking of autistic or schizophrenic people. In general, the terms *problem solving* and *thinking* can be used interchangeably, with the recognition that nondirected thinking is excluded.

Reasoning can be viewed as a type of problem solving that is required in deductive reasoning tasks and inductive reasoning tasks. In *deductive reasoning*, the problem solver is given premises and must apply the rules of logic to derive a

conclusion. For example, if you know "all four-sided polygons are quadrilaterals" and "all squares are four-sided polygons," you may logically conclude, "all squares are quadrilaterals." In *inductive reasoning*, the problem solver is given a series of instances or events or examples and must infer a rule. For example, after learning the Spanish words *la casa*, *el libro*, *la escuela*, *el perro*, *la muchacha*, and *el muchacho*, you may conclude that the article *la* goes with words ending in *a* and the article *el* goes with words ending in *o*, a grammatical rule that is not without exceptions in Spanish.

Finally, creative thinking occurs when a problem solver generates ideas and critical thinking occurs when a problem solver evaluates them. Two important criteria in creative and critical thinking are that the ideas must be original and useful.

What Are the Cognitive Processes in Problem Solving?

Problem solving can be divided into two major phases: problem representation and problem solution. *Problem representation* involves building a mental representation of the problem, and includes the cognitive process of *representing* (i.e., building a *situation model*, that is, a mental representation of the situation described in the problem). *Problem solution* involves devising and carrying out a plan for solving the problem, and includes the cognitive processes of *planning* (i.e., devising a plan), *executing* (i.e., carrying out the plan), and *monitoring* (i.e., tracking the effectiveness of the plan).

The cognitive processes involved in problem representation and problem solution may interact, rather than occur in linear order. For example, a student may be given the following word problem: "Sarah has three marbles. David has two more marbles than Sarah. How many marbles does David have?" In representing the problem, the student must translate each sentence into an internal mental representation, such as "Sarah's marbles = 3" and "David's marbles = Sarah's marbles + 2," and mentally integrate them into a situation model, such as a spatial representation consisting of a bar for Sarah's marbles (3 units high), a bar on top of it for the difference between Sarah's and David's marbles (2 units high), and a bar next to these for David's marbles (indicating that Sarah's marbles and the difference set of marbles are subsets of David's marbles). This situation model is presented in Figure 1. Planning involves determining the operations to be performed, such as determining that 3 and 2 must be added together. Executing involves carrying out the operation(s), such as computing that 5 is the sum of 3 and 2. Monitoring involves detecting when a plan is not working, a step was not executed correctly, or an answer is questionable. Although school instruction tends to emphasize execution of basic skills, students' major difficulties are in learning how to represent problems, devise plans, and monitor problem-solving processes.

Figure 1 A situation model for the marble problem.

What Kinds of Knowledge Are Required for Problem Solving?

Several types of knowledge are required for successful problem solving: facts, concepts, procedures, strategies, and beliefs (Anderson et al., 2001; Mayer, 2008). *Facts* are elements of a factual knowledge about the world, such as, “There are 1000 milliliters in a liter.” *Concepts* are principles or models (which are elements of conceptual knowledge) such as, “In the number 567, 6 refers to the number of tens,” or categories or schemas (which are elements of schematic knowledge), such as knowing that “What is the probability of flipping a fair coin three times and getting heads all three times?” is a joint probability problem. *Procedures* are step-by-step processes, such as knowledge of the procedure for long division used for 252 divided by 12. *Strategies* are general methods for problem solving, such as knowing how to break a problem into smaller parts. *Beliefs* are thoughts about one’s cognitive processing, such as believing, “I am good at solving statistics problems.” Facts and concepts are useful in the process of representing; procedures are useful for the process of executing; and strategies and beliefs are useful for planning and monitoring. Although school instruction may tend to emphasize facts and procedures, all five kinds of knowledge are needed to support problem solving.

What Are the Approaches to the Study of Problem Solving?

The history of scientific research on problem solving, which is barely hundred years old, has been influenced by three distinct approaches – associationism, Gestalt, and information processing. The associationist approach views thinking as a chain of mental associations, in which one idea is associated with another and so on. The associationist approach motivated the earliest research on problem solving starting around 1900, including Thorndike’s studies of how cats and dogs learn to get out of a puzzle box that has a trap door so they can eat food that is nearby. According to Thorndike’s (1911) theory, the problem solver possesses a set of responses associated with any problem situation based on past experience. When the problem solver is confronted with a problem situation, the problem solver tries the strongest response associated with the situation; if it works, the association is strengthened and if it does not work, the association is weakened. Although associationist theories are useful in describing problem solving in familiar situations, their value in explaining creative problem solving has been criticized.

The Gestalt approach, which developed in the 1920s through the 1940s, viewed problem solving as mentally restructuring the problem, that is, seeing the problem in a new way. The act of restructuring a problem is called insight and often involves overcoming previous experience that blocks new ways of seeing the problem. For example, Kohler observed an ape in a cage with crates on the floor and bananas attached overhead and out of reach. To solve the problem of getting bananas that are out of reach, the ape had to view the crates as a potential staircase rather than as containers; this insight allowed the ape to restructure the problem by using the crates to reduce the distance from the bananas. The Gestalt approach

emphasizes the creation of a novel solution, but the theory has been criticized for lack of precision.

The information processing revolution, which began in the 1950s and 1960s, offers another approach to problem solving. In the information processing approach, thinking is a series of mental operations (or computations) that are applied to knowledge representations in the problem solver’s working memory. For example, Newell and Simon (1972) produced computer simulations of human problem solving, that is, they programmed computers to solve problems in the same way as humans. Successful problem solving required both domain-specific knowledge and general strategies for how to solve problems. Problem solvers must build a problem space – a representation of the given state, goal state, and all possible intervening states – and must use a strategy such as means-ends analysis to find a path through the problem space. In means-ends analysis, the problem solver works on one goal at a time by continually asking, “What do I want?” and “What can I do to get what I want?” The information processing approach, with its emphasis on thinking as making mental computations, is precise; however, it has been criticized for its lack of attention to practical problem solving in realistic social contexts.

More recent directions include a focus on how people solve problems in realistic social situations, which has been called situated cognition (Robbins and Aydede, 2009) and a focus on the brain activity involved in problem solving, which is a subfield of cognitive neuroscience (Anderson, 2007).

What Are Some Enduring Issues in Problem Solving?

Rigidity in Thinking

A major obstacle to effective problem solving is rigidity in thinking. For example, in some problem-solving situations the problem solver must use an object in a new way, such as using a brick as a doorknob or using a pencil as a bookmark. When a problem solver can only conceive of using an object in its most common function, then the problem cannot be solved. Duncker (1945) used the term *functional fixedness* to refer to a situation in which a problem solver cannot think of using an object in a new function that is required to solve the problem. Another example of rigidity occurs when a problem solver uses a well-learned procedure on a problem for which the procedure is inappropriate. For example, if a student solved a long series of arithmetic story problems that all contain the word ‘more’ and require adding the numbers together, the student may incorrectly carry out this same addition procedure for a new problem that actually requires subtracting the numbers from one another. Luchins (1942) used the term *einstellung* (or problem-solving set) to refer to this phenomenon. A goal of instruction in problem solving is to help students avoid rigid thinking.

Problem-Solving Transfer

Transfer is the effect of prior learning on new learning. When the new learning task is a problem to solve, we can use the term *problem-solving transfer* to refer to the effect of prior learning on solving a new problem (Mayer and Wittrock, 2006). *Positive transfer* occurs when previous learning helps you on a new task, whereas *negative transfer* occurs when previous learning hurts

you on a new task. For example, if you have learned arithmetic, it should be easier for you to solve an arithmetic word problem – which would indicate positive transfer. If you learned to drive on the right side of the road in the United States, you may experience negative transfer in trying to learn to drive on the left side of the road in Australia.

How does transfer work? This has been a central research question in psychology and education since Thorndike's (Thorndike and Woodworth, 1901; Thorndike, 1931) pioneering work in the early 1900s, and has generated three alternative explanations: general transfer, specific transfer, and mixed transfer. *General transfer* is the idea that learning task A can help you on task B, even if A and B have nothing specifically in common. For example, the *doctrine of formal discipline* (which is a classic theory of general transfer) posited that learning certain school subjects, such as Latin and geometry, would improve students' minds in general and thereby help them on unrelated tasks in the future. The doctrine of formal discipline was used to justify the establishment of Latin schools, in which the curriculum consisted of learning Latin, Greek, geometry, and similar subjects. In one of the first experiments in the field of educational psychology, Thorndike (Thorndike and Woodworth, 1901; Thorndike, 1931) was able to show that students who learned Latin did not perform any better in learning bookkeeping than did students who had not learned Latin. Subsequent research (Singley and Anderson, 1989) also found little support for the idea of general transfer.

In contrast, *specific transfer* is the idea that learning task A will help you in task B only to the degree that A and B have identical elements in common. Thus, learning Latin may help you learn Spanish because some of the verb conjugations are similar and many of the words are similar. The theory of specific transfer is problematic for educators because it suggests that students need to learn every specific piece of knowledge they will ever need.

Mixed transfer is a compromise between general and specific transfer that involves specific transfer of a general principle, that is, mixed transfer occurs when a learner abstracts a general principle from learning A and is able to apply it to solving a new problem B. The transfer is specific because both A and B can be solved by the same general principle but what is being transferred is a general principle rather than specific behaviors. For example, if students learn to make sense out of text passages by producing summaries, this general method can be transferred to the task of making sense out of a new text passage. Research on teaching cognitive strategies shows that students can benefit from learning general strategies such as summarizing in reading comprehension (Pressley and Woloshyn, 1995; Mayer, 2008).

Promoting positive transfer is a fundamental goal of education, that is, educators seek to help students learn in ways so that they will be able to use what they have learned to solve new problems. Mayer and Wittrock (2006) have described seven ways to promote problem-solving transfer: load-reducing methods, such as helping students build automaticity in basic skills; structure-based methods, such as using concrete models; schema-based methods, such as using advance organizers or pretraining; generative methods, such as encouraging learners to engage in elaboration or self-explanation; guided discovery methods, such as providing hints as someone

solves a problems; modeling methods, such as providing worked examples; and teaching thinking skills, such as training people to use effective methods and strategies.

The Distinction Between Productive and Reproductive Thinking

Why is it that some people invent clever solutions when confronted with a problem, whereas other do not? The Gestalt psychologist, Max Wertheimer (1959) attempted to answer this question by distinguishing between two kinds of thinking mentioned above, namely productive thinking and reproductive thinking. *Productive thinking* involves producing a novel solution when confronted with a problem whereas *reproductive thinking* occurs when problem solvers use solution procedures that they already know as a result of solving previous problems.

For example, Wertheimer (1959) described two ways of learning how to find the area of a parallelogram – learning by rote and learning by understanding. In learning by rote (or *rote learning*), the student is taught to measure the height, measure the base, and then multiply height times base, as shown in the top of Figure 2. According to Wertheimer, students who learn by rote perform well on retention tests, such as finding the area of similar parallelograms, and poorly on transfer problems, such as finding the area of an unusually shaped parallelogram. In contrast, students who learn by understanding (or by *meaningful learning*) are encouraged to discover that the parallelogram can be converted into a rectangle by cutting the triangle off one end and moving it to the other end, as shown in the bottom of Figure 2. Students who learn by understanding are expected to perform well on both retention and transfer tests. Thus, rote learning leads to reproductive thinking (as measured by retention tests) whereas meaningful learning leads to productive thinking (as measured by transfer tests).

The Nature of Insight

Insight is the cognitive process by which a problem solver suddenly moves from a state of not knowing how to solve a problem to a state of knowing how to solve a problem (Mayer, 1995). Insight plays a crucial role in creative thinking

Learning by rote

Learning by understanding

Figure 2 Two methods of teaching how to find the area of a parallelogram.

(Sternberg, 1999), in which a problem solver invents novel solutions to a problem. How does insight work? The Gestalt psychologists and others have offered five somewhat interrelated explanations (Mayer, 1995): insight as completing a schema, insight as sudden visual reorganization, insight as reformulation of a problem, insight as removing mental blocks, and insight as finding a problem analog. Selz, working in the early 1900s in the Netherlands, produced psychology's first explanation of insight as completing a schema (Frijda and de Groot, 1982). For example, when given a problem such as "What is a coordinate of baseball?" a problem solver may say, "Let's see. Baseball is a sport. Another sport is football, so football is the answer." In this case, the problem solver is not following a chain of associations, but rather is trying to build a cognitive structure that has a superset ('sport') linked to two subsets that are coordinates ('baseball' and one more); so, coming up with an answer amounts to completing a schema. The idea that meaningful learning requires active construction by the learner is the fundamental theme of many current theories of learning (Bransford et al., 1999).

Kohler, also working in the early 1900s, provided evidence that insight is a process of sudden visual reorganization in which the problem solver literally sees how all the parts of the problem fit together (Kohler, 1925). For example, when an ape was put in an area that had stackable crates on the floor and bananas hanging overhead out of reach, the ape looked around and then in an apparent flash of insight, suddenly stacked the crates to form a sort of ladder leading to the bananas. This approach is consistent with current interest in using computer-assisted visualizations and concrete representations to help people understand how various systems work.

Dunker (1945) described insight as a reformulation of the problem, particularly a restatement of the givens or the goal in a new way. For example, in the tumor problem, you are asked to free a person of an inoperable stomach tumor by using "rays which destroy organic tissue at sufficient intensity" (p. 1). In order to solve the problem, the problem solver must restate the goal as, "lower the intensity of the rays as they pass through the healthy tissue," which leads to the solution of having many weak rays all converge on the tumor. This approach is consistent with the current idea that the most difficult aspect of problem solving is mentally representing the problem in a productive way.

Dunker (1945) also described insight as a process of removing mental blocks, that is, of being able to use an object in way that is different from its conventional use. For example, in the candle problem, the problem solver is given a box containing candles, a box containing tacks, and a box containing matches, and is asked to mount a lighted candle on a wall. The solution – involving using a box as the base, which is tacked into the wall – is much more difficult if the objects are in the boxes rather than next to them. According to Duncker, presenting the objects in the boxes creates *functional fixedness* – the tendency to be able to conceive of only one use of an object even though a problem solution requires using an object in a new way. Removing mental blocks is a key focus of current programs aimed at teaching thinking skills.

Finally, Wertheimer (1959) offered a fifth explanation of insight – finding a problem analog – in which the problem solver abstracts a general principle from one problem and

applies it to a new one. Thinking by analogy is still an important theme in cognitive science, and is the basis for more current views of problem-solving transfer (Holyoak, 2005).

A sixth explanation – insight as nothing new – holds that solving insight problems is no different from solving other problems (Weisberg and Suls, 1973), although Metcalfe and Wiebe (1987) have shown that problem solvers use qualitatively different thinking processes for insight problems and routine problems.

Problem Space and Search Processes

Information-processing theories of problem solving focus on constructing a problem space and finding a path through the problem space (Newell and Simon, 1972; Novick and Bassok, 2005). A problem space consists of a representation of the initial state, goal state, and all intervening states. For example, the problem space for solving the equation, $2X - 5 = X$, has this equation as the initial state, and $X = \underline{\quad}$ as the goal state. Two of the intervening states, directly after the initial state are $2X = X + 5$ and $2X - X - 5 = 0$, which were created by applying legal operators such as add 5 to both sides or subtract X from both sides. Similarly, other states are created by applying operators to these states, and so on.

Once a problem is represented as a problem space, the problem solver's task is to search for a path from the initial state to the goal state. *Means-ends analysis* is a search strategy in which the problem solver works on one goal at a time; if that goal cannot be achieved directly, the problem solver sets a new goal of removing barriers, and so on. This search strategy is commonly used in computer simulations of problem solving and is consistent with the way that beginners solve problems.

Problem Solving in Realistic Situations

Although classic research focused mainly on solving artificial puzzles or formal syllogisms, cognitive science research on problem solving and reasoning has been shifting toward realistic situations including everyday problem solving, expert problem solving, and problem solving in subject areas (Ericsson et al., 2006; Holyoak and Morrison, 2005).

Research on everyday thinking shows that people rarely use school-taught methods to solve problems encountered outside of school (Lave, 1988; Nunes et al., 1993). For example, to determine the best buy in a supermarket – such as 90 cents for a 10 ounce can of peanuts or 45 cents for a 4 ounce can – the school-taught procedure is to compute the unit cost of each item (i.e., 9 cents vs. 11.25 cents, respectively). However, Lave (1988) found that people almost never used the school-taught procedure; instead, they invented arithmetic procedures suited to the situation, such as the ratio strategy in which the problem solver notes that the larger one is a better buy because it costs twice as much and gives you more than twice as many ounces.

Research on expert problem solving compares differences in how novices and experts solve problems in domains such as physics, medical diagnosis, computer programming, and the game of chess. For example, when Larkin (1983) asked experts and novices to think aloud as they solved physics problems, she found that experts were more likely to focus on underlying physics concepts (such as forces and weights) whereas novices focused on surface characteristics (such as pulleys and ropes).

Figure 3 The given and goal state in the Tower of Hanoi problem.

Similarly, when [Chi et al. \(1981\)](#) asked experts and novices to sort physics problems into groups, experts sorted problems based on their underlying physics principle (such as conservation of energy), whereas novices sorted the problems based on their surface characteristics (such as inclined planes and springs). Results of expert–novice studies suggest that experts represent and solve problems differently from novices, and so instruction can focus on helping novices think more like experts.

Another example of problem solving in realistic situations involves theories of situated cognition, which posit that problems should not be seen as abstractions but rather are always linked to the concrete setting in which they arise ([Kirsh, 2009](#)). According to the situated cognition view, the same problem is solved in different ways depending on how it is framed – that is, on the context in which it is encountered.

Past and Future Research Trends

Traditionally, research on problem solving has focused on how people solve artificial puzzles and games in controlled laboratory situations. For example, in the Tower of Hanoi problem, the problem solver is given three pegs and three disks as shown in the top of [Figure 3](#), and the problem solver's task is to move the three disks to the third peg as shown in the bottom of [Figure 3](#). However, the problem solver is allowed to move only the top disk on any peg and may never place a larger disk on top of a smaller disk.

In contrast, recent research has focused on problem solving in more realistic settings. Research on expertise examines differences between expert and novice problem solvers in professions such as medicine, physics, and computer programming. Research on situated cognition examines how people solve problems that occur naturally at work, at home, or at the market. Research on analogical reasoning examines how people use previous problems to solve new problems. Research on intelligence seeks to understand individual differences in problem-solving performance. Research on teaching of thinking strategies focuses on how to help people become more effective problem solvers. Finally, research on the cognitive neuroscience of problem solving examines where in the brain various problem-solving processes take place.

Glossary

Attachment The biologically based bond between a child and its caregiver that ensures the safety, survival, and emotional well-being of the child.

Countertransference The unconscious reactions of the therapist to the patient stemming both from earlier situations in the life of the therapist and from feelings induced by the behavior of the patient.

Mentalization The capacity to be aware of the existence of the mind in oneself and others combined with the recognition that one's own perceptions and those of others are highly subjective, that is, influenced by feelings, thoughts, and life experiences.

Psychodynamic Used interchangeably with psychoanalytic, this term refers to a way of thinking about feelings, thoughts, and behavior that involves unconscious factors, developmental influences, and multiple determinants.

Resistance The unconscious activation of the patient's defenses in the context of psychotherapy or psychoanalysis in order to oppose the therapist's efforts to help.

Self-object A term from self-psychology that refers to the experience of another person as an aspect of the self that is missing or needed.

Transference The patient's emotional experiences and fantasies about the therapist based on experiences with significant figures in the patient's past but influenced by the real characteristics of the therapist.

Modern psychodynamic theory had its origins in the thinking of Sigmund Freud at the end of the nineteenth century and during the first four decades of the twentieth century. The original model that Freud used to explain hysterical symptoms and other psychopathological phenomena was based on intrapsychic conflict. Hence *psychodynamic* originally connoted interacting forces that involved wishes and defenses against those wishes based on intrapsychic agencies within the mind.

In the century or so that has followed the early formulations of Freud, substantial innovations to psychodynamic therapy and theory have been made such that Freud might not recognize the way that current psychodynamic clinicians conceptualize the patient's inner world and the treatment strategies to deal with the patient's concerns. When Freud developed psychoanalysis, there was a great emphasis on the unconscious phenomena in his formulations. Essentially, Freud viewed the human condition as one in which we are consciously confused and unconsciously controlled. His first model of the mind was known as the *topographic model*. In this model, there were three systems: the conscious, the preconscious, and the unconscious. One gained access to the unconscious through slips of the tongue (parapraxes) and through dreams.

His early clinical work involved trying to make conscious what was unconscious. To that end, he would attempt to hypnotize the patient and use suggestions to assist the patient in retrieving memories that had been repressed in the course of development. Freud became disenchanted with this model as he realized that some memories could not be brought back into consciousness, while also recognizing that often the patient's condition did not improve just because memories were retrieved.

Freud also noted that patients often resisted what he was trying to do with them, so this led to his next model of the mind – the *structural model*. This model involved the ego, the id, and the superego. This topic is covered in elsewhere in this encyclopedia. Associated with the ego, id, and superego were

defense mechanisms that defended the patient against recognizing his or her unconscious conflicts. Defense mechanisms are covered in detail in elsewhere in this encyclopedia. In brief, defenses deal with anxiety, conflicts, and forbidden wishes.

Clinical example: Mr. A was a 25-year-old accountant. He kept undermining his success at work and came to treatment to figure out why he was so self-defeating. He feared his boss, who was approximately the same age as his father. In psychotherapy, it became clear to the therapist that one origin of the fear was that the boss would detect his rivalry and contempt for him and punish him for it. The aggressive wishes from the id were in conflict with his superego prohibitions that he had internalized from his parents. Because of his anxiety that his boss would become enraged with him, he used the defense of reaction formation and acted overly ingratiating in all his interactions with him.

Post-Freudian Development of Theory

Since Freud's death in 1939, the theory has evolved in many directions. The structural model turned into ego psychology, in which intrapsychic conflicts between the ego, id, and superego occupy center stage. In this model, a therapist or analyst attempts to understand and explore these conflicts as well as the patient's defensive attempts against accepting them. Beginning in the 1930s and 1940s, the object relations theory came into psychoanalytic discourse, primarily in London, where the focus shifted from drive discharge to the internalized world of relationships and how they manifested themselves in everyday interactions with others.

Beginning in the 1960s, another development in the theory was the focus on the self, which turned into self-psychology. Based largely on the writings of Heinz Kohut, this view evolved in a direction in which self-cohesion and self-esteem were the focus rather than intrapsychic conflict. This model also focused

more on deficit, that is, what was missing in the self, rather than conflicts between agencies.

Attachment theory has also become an important element of modern psychodynamic theory. John Bowlby, working in the UK, wrote a series of books that drew attention to the role that secure attachment plays in healthy development. This point of view has now been integrated into the theoretical underpinnings of psychodynamic theory so that early attachment relationships are seen as highly influential in the development of the child.

Most recently, the field has begun to accept postmodern theories that question objective truths or 'factual' observations about patients. These models involve such schools of thought as intersubjectivity, constructivism, and relational theory. In brief, they view the clinical situation as involving two perspectives: that of the therapist and that of the patient, each stemming from highly subjective experiences that influence the way one views external reality. Hence negotiation is necessary between therapist and patient to take both views into account.

A few core principles run through all psychodynamic theory. These are summarized in [Table 1](#).

In psychodynamic theory, a great emphasis is placed on the unique, the idiosyncratic, and the subjective in each patient. In other words, unlike descriptive psychiatrists, psychodynamic clinicians would not be so concerned about how patients are similar to each other and how they fit into large diagnostic groups. Rather, they would be more interested in how patients are different from each other based on diverse life experience.

Unconscious mental functioning continues to be at the core of psychodynamic thinking since the time of Freud. Contemporary neurobiological research has confirmed that much of mental life operates unconsciously, and, as a result, the understanding of the unconscious has been revised over the years.

Psychic determinism refers to the notion that our symptoms, feelings, thoughts, and behaviors are mentally determined by factors largely outside of our awareness. Different influences from childhood converge to make our behavior meaningful. The choice of profession, romantic partner, and personal choices are often markedly influenced by the patient's early life experience.

The principle that the past is prologue simply refers to the developmental emphasis in all of psychodynamic theory. Genetic factors in concert with early experiences shape who we are as adults. Current genetic research has confirmed the notion that the expression of genes is heavily influenced by life experiences, and the two are inextricably tied together in shaping the human person.

Transference refers to the automatic and unconscious tendency in all of us to look at a clinician as a significant figure

from our past. This phenomenon also occurs outside treatment settings. In short, all of us are unconsciously reenacting our past relationships, attributing qualities and characteristics of significant figures from our past to other people.

The counterpart of transference is known as countertransference. In other words, each time a psychotherapist is sitting with a patient, that therapist is experiencing a number of feelings toward the patient that may derive from the therapist's past. In addition, patients induce certain feelings in the therapist in their unconscious effort to recreate past experiences. Hence countertransference includes both feelings from the therapist's past as well as those induced by the patient.

The last common factor among the psychodynamic theories involves the construct of resistance. Patients may wish to get better, but that wish is opposed by anxiety about change. Hence patients often resist the therapist's efforts to help them by hanging on to patterns of behavior, symptoms, or perspectives on reality. This resistance may manifest itself by not talking in a session, coming late to a session, forgetting a session, or arguing with anything the therapist offers by way of observations or insight.

In the material that follows, we survey each of the leading theoretical perspectives that are in use today among psychoanalysts and psychodynamic clinicians. We then outline the fundamentals of technique in psychodynamic psychotherapy and survey the research data attesting to the efficacy of psychodynamic psychotherapy. The application to dynamic psychotherapy is also briefly addressed in the course of this theoretical overview.

Object Relations Theory

Object relations theory is one of the most popular conceptual models in use among dynamic psychotherapists today. It emphasizes unconscious relationships that have been internalized in childhood and which continue to influence adult relationships. The term 'object' is used synonymously with 'person,' and in object relations theory the self seeks an object from early in life. The building blocks of the individual's inner world are object relations units of the self and another (object) linked to one another by emotional states. These units begin their development in the relationship of infant and parent/caregiver early in life. These relationships are internalized in the first few years of life and are unconsciously repeated over the course of an individual's life. These patterns of relationships are not fixed but are changeable with new experiences, which is a basic premise of dynamic psychotherapy. The restructuring of these patterns can occur within the context of a therapeutic relationship where the clinician offers new forms of relatedness and invites reflection on the old forms.

The development of object relations is credited to Melanie Klein, who initially described a connection between the drives of sexuality and aggression and deeply unconscious internalized relationships. Klein proposed that drives developed in concert with a relationship. An essential component of the theory is the infant's tendency to use early experience in the infant-mother dyad as the template for internal object relations. An example of this phenomenon is the nursing experience. A loving, pleasurable experience occurs when the infant is

Resistance

nursing. This positive experience is internalized as a satisfied self, an attentive and nurturing mother and a loving emotional state that links them. In contrast, when the mother is not available and the infant is hungry, a different experience is internalized. The infant begins to feel anger and a different object relations unit is laid down in the psyche of the child. This one involves an angry, demanding self, an unavailable, depriving mother, and an emotional state of desperation and rage. The infant keeps the positive object relations unit separate from the negative counterpart to assure that the hateful, angry feelings do not destroy the positive, loving feelings or the loving representation of the mother. This defense mechanism, which persists into adult life, is known as splitting.

Paranoid and Depressive Positions

Klein's theory was derived from her psychoanalytic work with children and was focused on unconscious fantasy. Hence the infant does not internalize an exact replica of reality but rather distorts the object because of fantasy. The child might, for example, internalize a view of the mother as sadistic when unavailable for a feeding even though the mother might be taking care of other children and have no sadistic intent. Klein also believed that the early relationships that were internalized persisted in the form of unconscious fantasy about self and others. Hence, an abused child might have a persistent unconscious fantasy that others will mistreat him.

Klein also maintained that there were two principal positions in development: the paranoid-schizoid and the depressive positions. These modes of organizing experience were persistent and influenced one's adult life in a similar manner to unconscious fantasy. In the first several months of life, the paranoid-schizoid position involved the infant's tendency to use splitting to divide the world into good and bad objects. According to this theory, infants project their own badness onto others and then fear that those containing the projected badness would attack them. Hence they experience paranoid anxiety. The depressive position begins somewhere between age 6 and 9 months and is characterized by the integration of the bad and the good that had been split from each other. Thus the infant feels both love and hate at the same time and is ambivalent toward parents and other significant objects. The leading anxiety is depressive anxiety that the infant can harm those he or she loves.

Clinical Example: Ms. B, a 31-year-old patient with borderline personality disorder, was admitted to a psychiatric inpatient unit because of self-mutilation, suicidal thoughts, and anger that was out of control. Several days after she arrived, she told her doctor that there was only one nurse on the entire unit who was competent. This nurse was empathic, listened well, and truly understood Ms. B. By contrast, the other nurses and aides were 'stupid, cruel, and useless.' Ms. B suggested that they should be fired. She said while she was in the hospital, she would only talk to her favorite nurse and not to the others. This example of splitting, typical of the paranoid-schizoid position, divided up her world of relationships into all-good, idealized figures and all-bad, devalued figures, with no middle ground.

While Kleinian thinking is in use throughout the world by psychoanalysts and psychodynamic clinicians, the theory has

come under criticism for attributing an abstraction ability to the infant that exceeds the cognitive-perceptual capabilities during the first year of life. Hence the developmental timetable is not corroborated by infant observation. Another major criticism is the minimization of the way that real abuse shapes the personality of the child in favor of an emphasis on fantasy. Much of Kleinian theory depends on innate aggression without regard to the environmental influences at work.

The British Independents

Other prominent theorists who contributed to the object relations theory include D. W. Winnicott, W. R. D. Fairbairn, and Michael Balint, who are often referred to as the British Independents. They were sufficiently different from the Kleinians and the traditional Freudians and are recognized as a separate group.

The British Independents viewed the infant's environment as integral to development and deemphasized the drives of sexuality and aggression that were fundamental in Klein's theory. These psychoanalysts viewed the seeking of a maternal object as the primary motivator of the infant instead of gratification of drives as Freud had argued. They also gave greater emphasis to the real environment, in contrast to the Kleinians, who stressed the role of unconscious fantasy.

Many concepts developed from this shift in focus within the object relations theory, including the concept of the 'the good-enough mother,' a term coined by Winnicott. The infant's development depended on a mother or caregiver providing a nurturing and loving environment that met the infant's basic needs. Winnicott also developed the distinction between the 'true self' and the 'false self.' The true self is the inborn tendency to seek self-realization and this can be buried if the responses of the mother/caregiver do not facilitate its emergence. A 'false self' seeking to please the caregiver may emerge instead. Winnicott also made the 'transitional object' part of developmental thinking. This object could be a blanket, or pacifier, or any other object that symbolized the mother during times of separation. The transitional object comforts the child who misses the mother.

Self-Psychology

The theoretical model known as self-psychology was developed by Heinz Kohut and was derived from his observations during the psychoanalytic treatment of patients with narcissistic personality disorder. Unlike object relations theory, which focuses on the internalization of relationships, self-psychology emphasizes external relationships and their impact on the development of self-esteem and self-cohesion. Moreover, Kohut sharply departed from the works of Freud and subsequent ego psychologists by stressing that psychopathology arose from deficits in the self rather than from internal conflict. Hence borderline personality disorder arises from the inability to hold on to others as internal structures who are capable of soothing the self, drug addiction results from a need to fill missing parts of the self, and narcissistic personality disorder arises from being developmentally arrested at an early stage in the evolution of the structure of the self. This developmental

stunting is regarded as secondary to empathic failures in the mother or other caretaker. Subsequently, the personality is forged by attempts at restoring wholeness and balance to a fragmented experience of self.

Mirror Transference

Two fundamental transferences derived from self-psychology and observed in psychodynamic psychotherapy and psychoanalysis are the mirror transference and the idealizing transference. The mirror transference is the patient's attempt to capture 'the gleam in mother's eye' by impressing the therapist. This transference relates to the developmental stage where the child's self-esteem is enhanced by validating responses from the mother or caregiver. If loving and encouraging responses are forthcoming when a young child is performing for the parent, the child's sense of self-worth is validated. On the other hand, when a parent or caregiver fails to empathize with the child's age-appropriate developmental need for a mirroring response, the child has a difficult time developing a healthy self-esteem and is likely to become developmentally arrested at this stage. He is thus 'stuck' in a phase of development in which he is constantly in need of validating, affirming responses from others or he feels fragmented and empty. This mirror transference can be noted during the course of treatment in patients who 'show off' for their therapist as a way of seeking approval.

Clinical Example: Mr. C was a 41-year-old man with narcissistic personality disorder. He came to psychotherapy because he said that his girlfriends, his parents, and the people with whom he worked were constantly hurting his feelings by not giving him the respect and the validation that he warranted. He told the therapist that he was hungry for love and approval, but those in his world were too 'self-absorbed' to provide what he needed. He told the therapist that he was struggling with the same issues that Shakespeare described in Hamlet: 'How weary, stale, flat and unprofitable seem to me all the uses of this world.' Mr. C then looked at his therapist to see if he was getting the response he wished. After a brief silence, he asked his therapist, 'Do you know the play well?' He was showing early signs of a mirror transference in which he hoped to impress the therapist with his knowledge of Shakespeare and capture the 'gleam' in the therapist's eye, a validation of his self-worth.

Idealizing Transference

Idealizing transference emerges in psychotherapy and psychoanalysis when the patient attributes highly positive or even perfect qualities to the therapist or analyst. It stems from a developmental phase when the child's sense of self-esteem and wholeness arises from being in the shadow of an admired and idealized parent who is not only empathic with the child's needs but also provides a positive example for the child. The lack of such an experience is thought to doom the individual to a lifelong search for people in his environment whom he can idealize and from whom he can draw self-esteem. For example, some may seek to be in the company of an idealized politician or rock star because they feel their own self-esteem is enhanced by the reflected glory of the idealized figure.

Kohut proposed that individuals who do not obtain the mirroring or idealization needed from parents will develop a fragmented sense of self and will seek out responses from others to shore up their self-esteem. While Freud suggested that narcissistic needs for self-esteem are ultimately superseded by investing one's love in others (object love), Kohut proposed that these narcissistic needs are never outgrown and that the quest for mirroring and idealization continues throughout life. Those individuals who do not obtain them continue to experience significant psychological distress.

Self-Object

Kohut used the term self-object to describe how others are used as an extension of the self. In other words, a patient in therapy may use the therapist to make up for deficits in the self by trying to influence the therapist to admire and validate the patient. He referred to the patient's need for idealizing and mirroring as self-object functions that were necessary for the maintenance of the self. Late in his career, Kohut viewed these as lifelong needs that are never transcended. He also added a third self-object function, which was described as twinship, or the need to have others who are exactly like the patient. The concept of self-object does not refer to an actual physical person but rather to the responses that the person provides. These responses by others are integral in maintaining a strong sense of self-esteem throughout life. During psychotherapy, a clinician using self-psychology as a conceptual model would seek to strengthen and preserve self-esteem through empathic and validating responses to the patient's needs.

Critics of self-psychology have pointed to its emphasis on parent-blaming, that is, drawing a one-to-one correlation between empathic failures in parenting and subsequent psychopathology in the child. This rather reductive view does not take into account the inherited temperament of the child and the genetic contributions to psychiatric syndromes and personality disorders. This model has also been criticized for minimizing the role of infantile sexuality as a motivator of behavior. However, self-psychology has influenced psychodynamic clinicians to regard the maintenance of self-esteem as a motivator of equal importance to the drives of sexuality and aggression in classical Freudian theory. It has also called attention to the psychotherapist's technique – interpretation of unconscious conflict may need to be accompanied by empathic validation of the patient's needs for self-esteem regulation.

Postmodernist Views

Freud's classical model of psychoanalysis involves a positivist search for objective truth that resides in the patient and is detected and uncovered by the analyst or therapist. A group of psychodynamic models have arisen in response to this modernist position. Collectively, they are known as postmodern theories and they include intersubjectivity, relational theory, and constructivism. They all are skeptical about the existence of absolute truth based on objective observation, and they all hold in common the view that the clinician's perceptions of the patient are inevitably colored by the clinician's subjectivity. They acknowledge the existence of external

reality but stress that both patient and therapist bring their own individually idiosyncratic perspective to bear on that reality. Hence, these theories involve 'two-person' psychologies.

Similar to the British Independents, those therapists who espouse these models tend to view object-seeking as more relevant to human motivation than the pursuit of pleasure. The relational theory of Stephen Mitchell emphasizes conflict like classical ego psychological theory. However, Mitchell conceptualizes the conflict around relational configurations, whereas ego psychology views conflict as involving defense-drive configurations: conflict is between the intrapsychic agencies in the structural model – ego, id, superego.

The intersubjective view is associated with a number of different authors, but the essence is that it is a developmental achievement to fully recognize another person's subjectivity. The theory informs psychotherapy in that it emphasizes the need to see the patient's point of view as growing out of a unique set of experiences in life and working diligently to appreciate that perspective rather than imposing the therapist's perspective on the patient. Moreover, the therapists working from this conceptual model know that they can never transcend their own subjectivity and must take that into account in their efforts to understand the patient.

Constructivism, sometimes referred to as social constructivism, is less concerned about the shift from the drive model to the relational model. This theory emphasizes the need to replace the positivist orientation of the therapist with a constructivist view, namely that there is an ongoing, continuous effect of the therapist's personal involvement on how he or she understands the patient and the therapist–patient interaction. From this perspective, transference is not just the patient's tendency to project figures from his or her past onto the therapist. Rather, the transference is reflecting the REAL behavior of the therapist. In other words, a silent, stone-faced therapist will contribute to a transference in which the therapist is perceived as cold and aloof.

Attachment Theory

Attachment theory was largely developed from the works of John Bowlby, who proposed that attachment is a biologically driven goal of the child to desire physical proximity to the caregiver. Later in life, this converts to a psychological need to develop a bond with a caregiver. The style of attachment can affect an individual's ability to form and maintain relationships with others. Attachment styles are continuous and begin in infancy and are thought to remain relatively stable. Attachment styles are tested in the experimental design known as the Strange Situation in which a toddler is separated from the caregiver, and the toddler's behavior is observed during separation and upon the caregivers return.

During this experiment, four behavior styles have been observed, and later studies have correlated these with attachment styles in adulthood. These behavioral styles are described as secure, avoidant, anxious–ambivalent, and disorganized–disoriented. The secure infant has a desire to be near the caregiver upon return and is able to return to play once this occurs. Adults who show this profile as children usually turn out to be secure and autonomous and value attachment

relationships. The avoidant style involves anxiety with separation followed by being upset with the caretaker on her return. This style correlates with the insecure and dismissing adult who vacillates between idealizing and devaluing past and current relationships.

The third attachment style is the anxious–ambivalent toddler who is observed to have significant distress and anger with separation followed by clinging to the caregiver upon return. This adult version appears as one who is confused and frustrated with past and current relationships. The fourth style, the disorganized–disoriented group, exhibits random and chaotic behavior when coping with the separation. This fourth group correlates with an adult attachment style linked to experiences of trauma or neglect. These adults tend to remain disorganized in attaching with others.

As of yet there are no definitive correlations between these attachment styles and specific forms of psychopathology. However, these modes of relating have a significant impact on adult relationships and may be useful in the dynamic psychotherapy of patients with interpersonal problems. Attachment theory is a foundation in the understanding of neglect and trauma in early childhood and its association with the development of fragmented mental schemas with resultant difficulties in forming and maintaining relationships.

Mentalization refers to a person's ability to conceptualize and understand one's own and others' behavior as a product of their life history, unique subjectivity, biases, thoughts, and feelings. In other words, perceptions are not absolute. They are influenced by one's own mind and do not necessarily correlate with the perceptions of others. This capacity may be impaired in patients with autism spectrum disorders and certain personality disorders like narcissistic and borderline. Mentalization provides a useful conceptual framework for the psychotherapist in understanding the mental state of their patients and its role on behaviors.

This theory evolved from attachment theory and was developed by Fonagy, who noted that the capacity to mentalize grows out of a secure attachment situation in infancy. An individual's ability to mentalize begins during the first few years of life and is believed to be a consequence of the mother or caregiver's capacity to reflect the infant's experiences while providing her own perceptions as well. The mirroring and modeling that occurs during this interaction allows the infant and later adult an understanding of his own internal state. This process is referred to as social biofeedback. The infant finds its own self in the eyes of the mother or caregiver.

The child also learns to interpret interpersonal cues through these early interactions with the mother or caregiver. Core components to this function include understanding affect, emotional regulation, effortful control, the ability to 'read' others, and the development of mental capacities. Thus in adulthood, for example, one can experience a disagreement and understand the other person's emotional state of anger.

All caregiver–infant interactions do not automatically result in one being able to mentalize. These interactions are limited by the congruent mirroring of the caregiver to the infant's emotional state. In addition, the caregiver must be able to simultaneously demonstrate his/her own emotional state as unique from the infants. Hence, a child who injures himself and is saddened can have a caregiver who can identify and

acknowledge this emotion and express empathy. However, she simultaneously expresses her own emotional state of calm and provides comfort to the infant.

Psychopathologic states described in mentalization theory are frequently noted in patients with personality disorders and are the result of failures in the early attachment relationships. Mentalization-based psychotherapy can provide the framework for patients to develop this technique late in adulthood through similar mechanisms as those demonstrated with the caregiver–infant dynamic.

The Use of Psychodynamic Theory in Clinical Practice

As the foregoing material illustrates, psychodynamic theory is not monolithic. The key theoretical perspectives are summarized in Table 2. Psychodynamic psychotherapists are often trained in one particular theoretical model, and they may try to apply that conceptual framework to the clinical material they hear from their patients. Others are deliberately eclectic or pluralistic, drawing from several theoretical models according to which theory seems to fit the patient's problems and personality best. Often psychotherapists develop their own private mixed model that reflects their training, their personal preferences, and their understanding of theory. As all psychodynamic models suggest, therapists will inevitably be drawn to theories because of unconscious factors evolving from childhood experiences. For example, a therapist who grew up with an unempathic mother might well be taken with the model of self-psychology because he/she is still working on issues of self-esteem and self-coherence. Another therapist with a harsh conscience might be attracted to ego psychology because of the emphasis placed on superego forces in that model.

Most psychotherapists would agree that theory should not be artificially imposed on clinical material. The patient's thoughts and feelings must be allowed to go in whatever direction they wish to go. If a theory is not a good fit for the problems of the patient, the therapist must be prepared to think outside of the extant models and learn from the patient. Above all, therapists must tune into the patient to learn about the unique features of each individual regardless of whether there is a perfect fit with a theory.

Technique of Psychodynamic Psychotherapy

Technique in psychodynamic psychotherapy is tailored to the needs of the patient. In general, patients are allowed to set their own goals with the help of the therapist and pursue self-understanding through the process of saying whatever comes to mind and processing personal meanings and patterns that are largely unconscious. Hence the therapist uses a number of interventions with the intent of helping patients become aware of feelings, fantasies, wishes, and relational patterns that may be largely outside of their awareness. Technical interventions are often conceptualized as residing on an expressive–supportive continuum, with the most expressive interventions focused on providing insight through interpretation. The most supportive interventions are designed to bolster adaptive defenses and enhance the patient's self-esteem. Each of these interventions will be briefly defined starting from the most expressive or exploratory and moving toward the most supportive:

- *Interpretation*: an effort to make something conscious that was previously unconscious by explaining a linkage of which the patient was not aware.
- *Observation*: the therapist, stopping short of explanation, simply points out a behavior or pattern to the patient of which the patient was not aware.
- *Confrontation*: the therapist draws the patient's attention to something that was being avoided.
- *Clarification*: the therapist 'repackages' information he/she has brought up to bring greater clarity to it.
- *Encouragement to elaborate*: the therapist simply indicates the wish to have further thoughts or feelings from the patient – for example, 'can you tell me more?'
- *Empathic validation*: the therapist confirms the patient's perspective and acknowledges the patient's feelings.
- *Praise and advice*: these are highly supportive interventions to help the patient's self-esteem or guide the patient through a difficult situation.

All these interventions are used in the context of assisting the patient in the goal of a search for truth about the self. A solid therapeutic alliance must be formed by listening empathically and nonjudgmentally to the patient's life narrative and by

Table 2 Psychodynamic theoretical models

<i>Theoretical models</i>	<i>Major contributors</i>	<i>Core concepts</i>	<i>Key terms</i>
Ego psychology	Sigmund Freud	Conflict between id, ego, and superego	Structural model Defense mechanisms
Object relations theory	Melanie Klein D. W. Winnicott	Unconscious internalized relationships recreated in adult life	Paranoid and depressive positions Transitional object Good enough mothering
Self-psychology	Heinz Kohut	External relationships impact the development of self-esteem and self-cohesion	Mirror transference Idealizing transference Self-object
Attachment theory	John Bowlby Peter Fonagy	Safety based on physical proximity to caregiver	Attachment styles Mentalization
Postmodern theories	Stephen Mitchell Irwin Hoffman	Continuous influence of therapist on patient and vice versa	Intersubjectivity Constructivism

collaborating with the patient in the pursuit of therapeutic goals. Transference is generally not interpreted until it becomes a resistance that interferes with the work. This development could involve negative transference or intensely loving or sexualized transferences.

As the patient talks, the therapist oscillates between empathizing with the patient's subjective view, on the one hand, and offering an outside perspective, on the other, from the therapist's more objective viewpoint. However, therapists must continually monitor their own countertransference, both as a potential interference with the task of helping the patient and as a source of useful information about how the patient affects others in outside relationships. Dreams and fantasies are also carefully explored as valuable sources of unconscious material.

A useful approach to analyzing fantasies and relationship patterns is Luborsky's *core conflictual relationship theme*. This theme usually involves a wish, a fantasy about how others might react to that wish, and then a subsequent response to that reaction. Hence a young man may wish to have a girlfriend, but is convinced that women will reject him. So he avoids the humiliation of rejection by spending all of his time playing videogames. The therapist spends a good deal of time working through these recurrent patterns and themes while attending to resistance, transference, and countertransference. Psychodynamic therapy is usually divided into brief or short-term psychodynamic psychotherapy (STPP) and long-term psychodynamic psychotherapy (LTPP). The former is variously defined as anywhere from 24 to 40 sessions, while the latter is often defined as more than 40 sessions and is generally open-ended, that is, a natural termination is reached when the therapist and patient both agree that the therapeutic work is completed or can be taken over by the patient on his/her own.

In summary, psychodynamic psychotherapy can be usefully defined as a treatment that focuses on thoughtfully timed interpretation of transference and resistance while sensitively appreciating how the therapist contributes to the interaction with the patient.

Empirical Evidence for the Efficacy of Dynamic Therapy

While it was once true that there was little systematic research confirming the efficacy of psychodynamic psychotherapy, there is now a growing body of randomized controlled trials that impressively demonstrate that this form of treatment is highly efficacious. When psychodynamic studies are compared with those of other therapies, the effect sizes for dynamic therapy are as large as those reported for the other forms of psychotherapy. In addition, evidence suggests that patients who receive psychodynamic treatment maintain therapeutic gains and often continue to improve after treatment has ended when follow-up measures are included in the research. In this review of the research, we will first survey the evidence for STPP and then for LTPP.

Short-term psychodynamic psychotherapy

In a meta-analysis of STPP, defined as fewer than 40 sessions, Leichsenring and colleagues found no differences between

STPP and cognitive behavior therapy (CBT) in regard to changes in target problems, general psychiatric problems, and social functioning. The authors concluded that STPP is an effective treatment for a range of psychiatric disorders, including major depression, posttraumatic stress disorder, eating disorders, opiate and cocaine dependence, Cluster C personality disorders, borderline personality disorder, somatoform pain disorder, chronic functional dyspepsia, and social phobia. Another meta-analysis by Abbas and colleagues in 2006 used the same number of sessions to define STPP. The efficacy of STPP was evaluated relative to minimal treatment and non-treatment control subjects for adults with common mental disorders. Outcomes from most categories of disorder suggest a significantly greater improvement, maintained in medium- and long-term follow-up, in the treatment groups versus the control groups.

Long-term psychodynamic psychotherapy

The number of randomized controlled trials that focus on extended or LTPP is smaller than those devoted to STPP, but the number is gradually increasing. Winston and colleagues conducted a controlled trial of 25 patients with Cluster C personality disorders who were treated in dynamic therapy with a mean length of 40.3 sessions. The sample improved significantly on all measures compared with control patients on a wait list. At 1.5 years' follow-up, continued benefits were demonstrated in the subjects.

In a Norwegian study conducted in 2004 by Svartberg and colleagues, therapists were randomly assigned 50 patients who met the criteria for Cluster C personality disorders to 40 sessions of either dynamic psychotherapy or cognitive therapy. The therapists were all experienced in manual guided supervision. The full sample of patients showed statistically significant improvements on all measures during treatment and during the 2-year follow-up period. Patients who received cognitive therapy did not report significant change in symptom distress *after* treatment, whereas patients who underwent dynamic therapy treatment did. Two years after the treatment, 54% of the dynamic therapy patients and 42% of the cognitive therapy patients had recovered symptomatically. The investigators concluded that there is reason to think that improvement persists after treatment with dynamic psychotherapy.

Bateman and Fonagy, in 1999, conducted a study in which 38 patients with borderline personality disorder were randomly assigned to a psychoanalytically oriented partial hospital treatment or to standard psychiatric care as a control group. The primary treatments in the partial hospital group consisted of once-a-week individual psychoanalytic psychotherapy based on mentalizing and three-times-a-week group psychoanalytic psychotherapy similarly geared to mentalization. The control subjects received no psychotherapy. At the end of treatment at 18 months, the patients who received the psychoanalytically oriented treatment showed significantly more improvements in depressive symptoms, social and interpersonal functioning, need for hospitalization, and suicide and self-mutilating behavior. These differences were maintained during an 18-month posttreatment follow-up with assessments every 6 months. Moreover, the treatment group continued to improve during the 18-month follow-up period.

Eight years after entry into the study and 5 years after mentalization-based treatment had stopped, those who received the treatment continued to show clinical and statistical superiority over those in the 'treatment-as-usual' group.

A meta-analysis on the effectiveness of LTPP conducted by Leichsenring and Rabung was published in 2008. Studies of LTPP from 1960 to 2008 were identified by a computer search in this meta-analysis. Only studies with at least 50 sessions or more were included. Eleven RCTs and 12 observational studies made the cut. Effect sizes were calculated for overall effectiveness, target problems, general psychiatric symptoms, personality functioning, and social functioning. These effect sizes were calculated separately for end-of-therapy and follow-up assessment to examine stability of outcome. LTPP showed significantly higher outcomes and overall effectiveness for target problems and personality functioning when compared to shorter forms of psychotherapy. LTPP also yielded significant large and stable within-group effect sizes across various diagnoses and particularly complex mental disorders involving comorbidity of extended duration. Hence the investigators concluded that in the more-difficult-to-treat patients who have a greater comorbidity and more complicated clinical presentations, LTPP may be the best choice.

To gain a greater understanding of the role that length of treatment plays in psychodynamic therapy, Finnish researchers studied 326 outpatients, 84.7% of whom had mood disorders and 43.6% of whom had anxiety disorders. One hundred twenty-eight patients were randomly assigned to LTPP, 101 to STPP, and 96 to solution-based therapy. Forty-two of the patients discontinued treatment prematurely.

To measure outcome, the investigators used standard measures of depression, anxiety, and overall symptomatology. During the first year, STPP was significantly more effective than LTPP. However, at 3-year follow-up, LTPP was more effective than STPP. No significant differences between STPP and solution-based therapy were found at any of the follow-up assessments.

Summary

Psychodynamic psychotherapy is a time-honored mode of in-depth exploration of the patient's internal world and the derivatives of that internal world in the patient's world and daily life. There are a variety of theoretical models that are typically used by psychodynamic therapists, and these models are tailored to the specific characteristics of the patient with the notion that no one conceptual framework explains all the psychopathology. A critical aspect of psychodynamic psychotherapy is to use what transpires within the therapeutic relationship as primary data to understand what happens in relationships outside the therapy. Psychodynamic psychotherapy has now accumulated sufficient empirical evidence

through randomized controlled trials to support it as an efficacious treatment modality. Both STPP and LTPP have been shown to be useful in a range of psychiatric disorders.

Psychological Predictors of Heart Disease

H S Friedman and M L Kern, University of California, Riverside, CA, USA

© 2012 Elsevier Inc. All rights reserved.

Glossary

Coronary heart disease (CHD) Blockage and hardening of the coronary arteries that supply blood to the heart muscle, due to buildup of fatty plaques on the artery wall.

Fight-or-flight response The body's physiological response to significant challenge, involving activation of the sympathetic nervous system and the release of stress hormones.

Hostility Negative thoughts and beliefs about others, including cynicism, mistrust, and denigration.

Self-healing personality A psychosocial reaction pattern that leads to good physical health, characterized by an enthusiastic, positive emotional style, an alert, energetic motivation, and secure, constructive interpersonal relations.

Social support Emotional, informational, or tangible resources provided by family or friends.

Type A behavior pattern (TABP) An emotional and behavioral style characterized by a chronic aggressive struggle to accomplish more and more in the shortest possible time period.

There is substantial evidence that psychological factors predict heart disease and premature mortality. However, the precise causal pathways and causal mechanisms are less clear. Many people assume that stress increases the likelihood of heart disease – a blockage (occlusion) of a coronary artery or an irregular heartbeat (arrhythmia). There is relatively little surprise among observers when a heart attack victim is a stressed-out 50-year-old obese businessman who is known for his habit of chain-smoking cigarettes and compulsively devouring doughnuts while simultaneously screaming into two telephones. The scientific challenge comes in separating fact from stereotype – that is, in discerning which psychological and behavioral patterns predict increased likelihood of heart disease, and why.

There are three basic ways in which psychology and heart disease may be linked. First, psychosocial factors can play a direct causal role in the initiation and progression of coronary disease. That is, specific emotional, cognitive, behavioral, and social aspects of the individual directly and indirectly alter physiological process and cause disease. Second, disease may cause psychological problems. For example, depression may follow a heart attack. In such cases, psychological interventions will obviously not affect health risk unless the factors are also tied through other pathways. Third, underlying (third) variables such as certain genetic patterns can produce both distinctive psychological profiles and elevated disease risk. In such cases, psychological patterns are associated with disease but interventions to affect the psychological factors may or may not have any effect on the likelihood of disease; it depends on the causal paths. All three of these ties between psychological factors and heart disease exist, thus making explanation and simple amelioration a challenge. Nevertheless, much is known about healthier and unhealthier psychosocial living patterns.

Historical Perspective

Psychosocial predictors of heart disease have been noted since ancient times. Biblical proverbs such as “gladness of the heart is the life of a man, and the joy of a man prolongs his days” (Apoc. 30:22) suggested a mind–health connection. The ancient

Greeks were especially keen observers of the relations between psychological factors and illness, and they proposed four bodily humors – black bile (or melancholy, depression); blood (a sanguine, ruddy disposition); yellow bile (choler, an angry bitterness), and phlegm (apathy, lack of feeling). Although their causal mechanisms were wrong, the ancient Greeks correctly observed key psychosocial correlates. Depression, optimism, hostility, and apathy are indeed useful patterns for the understanding of psychology and health.

In the first half of the twentieth century, interest in the psychological predictors of heart disease reemerged, with the influential medical educator Sir William Osler proposing a link between high-pressure activity and coronary heart disease (CHD). The well-known psychiatrists Karl and William Menninger asserted that heart disease is related to repressed aggression. Psychosomatic theorists developed and applied the psychoanalytic notions of Sigmund Freud to their patients, looking for repressed conflict as a cause of chest pain and heart disease, and psychological treatments often seemed helpful. These physicians were trying to account for the dramatic rise in CHD that was occurring in the twentieth century. As the twentieth century was also a time of rapid social and technological change, it made sense to look for explanations in the pressure and demands of modern-day life. However, most of this work was clinical and speculative. It was not until the 1950s that two cardiologists noticed that their patients possessed a distinctive constellation of psychological characteristics and proposed research on the Type A behavior pattern. The cardiologists and their associates began a systematic search for psychosocial predictors of heart disease, which eventually led to four decades of intensive and ever-broadening study, upon which our current understanding rests (even though the initial conceptions were eventually discarded).

Current research indicates that certain people are psychologically vulnerable or resilient because of a combination of temperament and early socialization. When vulnerable people encounter psychosocial environments that are a poor match for their needs, chronic negative emotional patterns often result. These reactions are accompanied by physiological disturbances – high levels of sympathetic activation and

stress-related hormones. Moreover, unhealthy behaviors such as substance abuse also often cooccur. These disturbances interact with disease proneness caused by heredity (e.g., proneness to the buildup of plaque in the coronary arteries) and environment (e.g., diets high in saturated fat), resulting in increased risk of illness that is comparable in size to that of many other commonly noted health risks.

Disease-Prone Personalities

There is strong reason to believe that stress, chronic negative emotions, and poor social relations, usually accompanied by sleep disturbances and unhealthy habits, play a role in the development or triggering of cardiovascular disease and heart attacks. Unfortunately, this psychosocial evidence often receives insufficient attention from a biomedically oriented health care system. For an individual who suffers a heart attack or is diagnosed with CHD, the disease usually has been developing slowly over years or decades. There is a hefty percentage of the population heading for expensive and dangerous coronary bypass operations or coronary angioplasty while psychosocial preventive measures are often given minimal resources.

Initial research (in the 1960s and 1970s) on the Type A behavior pattern focused on individuals who are aggressively involved in chronic struggle to quickly achieve more and more in less and less time (called *time urgency*). However, many active, expressive people often tend to work hard and hurry around like Type A people, but are not at all coronary-prone; on the contrary, they are especially healthy. Research now documents that hurrying around, being very involved with one's job, or working hard is not necessarily unhealthy. Rather, negative emotionality – characterized by chronic negative responses such as hostility, aggression, anger, cynicism, depression, and anxiety – is predictive of disease. Even here, however, the negative emotionality is often not necessarily the cause of the disease. Sometimes, earlier biological predispositions and unhealthy life pathways (involving social instability) are leading to poor coping, negative emotions, and disease.

Use of the statistical technique called meta-analysis (a quantitative method to combine the results of multiple studies) has allowed investigators to address the broad issue of psychological predictors of heart disease by looking at the size of effects, patterns of findings, and reasons for discrepancies in the scientific literature. Across both cross-sectional and longitudinal studies, hostility, anger, and depression are linked to CHD, often even after controlling for many other risk factors (age, sex, smoking, blood pressure, cholesterol, physical activity, diabetes and insulin resistance, social class, and heavy alcohol use).

Interestingly, the same patterns of psychosocial disruptions that predict heart disease also often predict incidence of other diseases and all-cause premature mortality. Therefore, Howard Friedman has developed the concepts of *disease-prone personalities* and *self-healing personalities*.

Social Integration

A variety of sociological and epidemiological investigations indicate that people who are well integrated into a stable community are less likely to develop heart disease or to die

prematurely. Friendly ties with family, friends, associates, and the community – often called *social support* – are beneficial in coping with stressful events and life changes, as well as in promoting healthier life patterns. Conversely, loneliness and the loss of social ties can have negative health effects. Lonely, anxious individuals experience more stress, both objectively and subjectively, and may experience higher levels of chronic physiological arousal. Bereaved individuals, especially men, have an increased risk of heart attack and sudden death – dying from a 'broken heart.'

How does social support work? Social support can influence how an individual views stressful events – the perceived severity of the situation and the need for an ensuing emotional response. Second, social support can help the stressed individual to develop coping strategies by providing practical information. Third, social support can provide tangible resources, such as healthy meals or rides to the doctor. Many times, an individual also benefits by assisting someone else who is facing similar challenges. Each of these types of support can be helpful, although it may be most beneficial when the type, amount, and provider of support match the needs of the recipient. Support might be harmful if it makes the individual feel inadequate, indebted, or unduly manipulated.

Social support is especially important when a person faces a severe challenge such as managing chronic cardiovascular illness. One of the biggest challenges is adhering to medical recommendations such as eating a heart-healthy diet, engaging in daily moderate exercise, and taking medication that will control symptoms, prolong life, and maintain quality of life. Family and friends can provide reminders, encouragement, and motivation to adhere to treatment regimens. However, individuals who need social support the most often receive the least support. Depressed individuals often become apathetic and withdraw from others, losing the chance for benefits that social integration provides. Hostile and cynical people are more likely to have interpersonal conflict, which can destroy social ties while simultaneously exacerbating tendencies toward physiological hyperreactivity (and stress on the cardiovascular system). There is good evidence that people who live in stable families and in stable communities are more protected from heart disease, especially if the quality of these relationships is good, and if there are associated patterns of healthy behaviors such as staying active and avoiding smoking and substance abuse.

Causal Mechanisms

There are two main pathways through which psychological factors can bring about increased likelihood of disease: psychophysiological mechanisms and behavioral mechanisms. Both of these also often involve biopsychosocial predispositions that develop earlier in life.

Psychophysiological Mechanisms (Nervous, Endocrine, and Immune Systems)

In response to danger – real or perceived threats – there is a physiological disturbance involving high sympathetic activation in the autonomic nervous system. Commonly termed

the 'fight-or-flight response,' this activation is an automatic and immediate internal response. Stress hormones such as epinephrine and norepinephrine affect all parts of the body, with both sudden and long-term effects.

An immediate effect may be sudden death via autonomic nervous system-induced arrhythmias of the heart. A severe psychological stress, such as witnessing a shocking scene of mutilation, can be as disruptive as a severe physical stress such as shoveling heavy snow. The heart may beat uncontrollably and irregularly, and then fail, causing sudden death. Such irregular, fatal heartbeats are much more probable when there is partial preexisting heart disease. However, such fatal events are relatively rare, especially as compared to slowly progressing chronic artery obstruction.

Links to chronic CHD are slower and more complex. CHD starts with an accumulation of lipid (fat) within the coronary arteries. To attempt a repair, the body deposits lipoproteins in the artery walls. Calcification (hardening) occurs, forming plaque, and over time the artery walls thicken, partially blocking the artery (called atherosclerosis). As blood flow is slowly impeded or a clot suddenly forms, oxygen needs may exceed supply (myocardial ischemia), and can lead to chest pain (angina pectoris) and unstable heart rhythms (arrhythmia). If enough of the blood flow to heart muscle is blocked, the heart will begin to die and stop beating – a myocardial infarction. Such clinical manifestations of the disease may occur decades after the damaging processes begin, affected in part by psychological and behavioral contributors.

Individuals who show an exaggerated psychophysiological response to stress or face excessive stressful challenges show high levels of what is termed *cardiovascular reactivity* (CVR), evidenced by high blood pressure and heart rate, increased sympathetic activation, reduced parasympathetic deactivation, and increased cardiac output and resistance. Both animal and human studies suggest that CVR contributes to or hastens the development of CHD. For example, in a series of experimental studies with monkeys, social stress (and competition) promoted atherosclerosis among monkeys straining to maintain a position of social dominance. When the composition of monkey groups was changed by the experimenter, the monkeys struggling for dominance faced ill health. Monkeys with the greatest heart-rate reactivity showed the most coronary artery damage and acted more aggressively, again suggesting the relevance of the 'fight-or-flight' physiological response. These experiments confirm clinical studies of humans regarding excessive aggressiveness, hostility, and struggle. All else being equal, the regulation and modulation of sympathetic arousal is likely to promote physical health, in both monkeys and people.

A second but related pathway linking psychosocial factors and CHD is through the endocrine system. In the fight-or-flight response, the endocrine system is also activated, as cortisol and related stress hormones are released. Both nervous system arousal and other forms of psychophysiological imbalance such as depression alter the usual complement of bodily hormones. Stress, helplessness, and depression are linked to high cortisol levels, and stress, anger, and frustration are linked to high levels of catecholamines (such as of norepinephrine). Other stress-related or stress-influenced hormones such as thyroxine and testosterone have also been shown to play a

significant role in stress-related homeostasis and physical health. Depression and the related hormonal irregularities are thus a common correlate but not simply a cause of heart disease. Treating depression may have no effect on the likelihood of recurrent heart disease unless other processes related to the atherosclerotic processes are also affected.

A third pathway linking psychosocial factors and CHD is through the immune system. There is increasing evidence that immune dysfunction is linked to CHD. For example, leukocytes play an important role in tissue repair; when overactive, these can adversely affect the cardiovascular function. After a cardiac event, the immune system helps repair damage; when it is malfunctioning under stress, this repair goes awry. Inflammation – the organism's reaction to infection or injury – involves the immune system and the vascular system attempting to heal the body, and such inflammatory processes are thought to play a role in many disease processes including heart disease. Inflammation can be exacerbated by stress and is known to be associated with chronic depression, and so it is increasingly a focus as a mediating link to disease. However, the links are undoubtedly complex, as inflammation, immune response, stress, depression, and behavior are all known to affect one another.

For each of these psychophysiological mechanisms, research studies have uncovered psychosocial factors that predict reactivity, hormonal imbalance, and disrupted immune function. However, no study has yet followed the whole process in humans, showing for example that hostile people develop certain psychophysiological disturbances that impair metabolism and thereby bring on heart disease, but there is increasing support for the different pieces of the model.

Behavioral Mechanisms

Personality-based behavioral patterns directly influence cardiac health and interact with psychophysiological mechanisms to indirectly influence health outcomes. There is strong evidence that smoking, substance abuse, physical inactivity, poor diet (high in saturated fats and low in vegetables), and obesity increase risk of heart disease. Many of these behaviors are affected by individual differences. For example, hostile, impulsive, and neurotic people are more likely to smoke, drink to excess, overeat, and/or use drugs, thereby increasing their risk of heart disease.

One of the most important health behaviors affecting the course of heart disease is adherence to treatment. Although logically a person with CHD should follow the doctor's recommendations, a host of individual psychosocial characteristics affect whether a patient will take medication, follow a proper diet, return for follow-up, and so on. The patient's sense of self-efficacy, confidence that success is achievable, perceived behavioral control, internal motivation, support by others, and personality traits relate both to healthy behavior and success in changing unhealthy behaviors. In particular, conscientious individuals are likely to adhere to treatment and to engage in more healthy behaviors and fewer risky behaviors. Conscientiousness is a solid predictor of both CVD and risk of all-cause mortality. Hostility and anger can also endanger the doctor-patient relationship, making adherence more challenging. Further, tendencies toward denial, isolation, or excessive optimism may result in a deadly delay in seeking treatment.

Depression is not only associated with a range of hormonal disruptions but is also correlated with a host of behavioral risk factors for disease, including disturbances in eating and sleeping, impaired social relations, and substance abuse. Here again, multiple causal pathways are implicated, but the full causal model has not been tested. Prospective clinical studies of depression and disease in humans, combined with experiments using animal models, could prove especially informative if they also included genetic predispositions, psychophysiological measurement, assessment of health behaviors, and heart disease and other disease outcomes over long periods of time.

Noncausal Effects

A part of the association between psychological variables and heart disease is due to noncausal pathways, or to effects that are only partially causal. This is important because if the psychological predictor is a correlate but not a causal element of disease, then changing the psychology will not prevent or treat the disease.

The development of heart disease can produce dramatic psychosocial changes in the patient's life. Heart attack victims (who survive) may become angry at the world for their plight, or they may become depressed over the new limitations on their activities. They may lose their job or be treated differently by their employers or colleagues. Sexual relations with one's partner may change, as fear, fatigue, or resentment enters the relationship. Immune system alterations may further induce depression and isolation. In all of these cases, psychological and behavioral patterns are a result rather than a cause of heart disease. Nevertheless, these factors or patterns sometimes may then predict or contribute to further deterioration, through the causal mechanisms described above.

Some disease predictors may act differently following a heart attack. For example, anxiety sometimes contributes to the development of heart disease, but not its progression. In fact, anxiety after angina or an attack may prove helpful if it leads the patient to cooperate more fully with medical treatment. We should not expect the same factors always to predict disease and recovery from disease, although this error of inference is often made.

Spurious relations (falsely seen as causal) between psychological variables and heart disease may result from underlying third variables that produce both the psychological characteristics and the disease. A more complicated case involves various genetic patterns that affect both personality and health. For example, aspects of the same genetic predisposition may make one more susceptible to both anxiety or depression and heart disease. In such cases, interventions to change these aspects of personality would not necessarily lead to improvements in health, unless other mediating mechanisms are also affected.

A final type of noncausal association between psychological variables and heart disease results from methodological artifacts – errors in the design of the study. A common artifact in this field is a selection artifact or bias. For example, neurotic individuals are more likely to report symptoms and seek out medical care than nonneurotics, even when there is little or no discernable organic disease. In a study of personality and heart

disease, a large percentage of the patients may be neurotic, because those worriers are the individuals who are especially likely to visit the doctor and be included in the studies. Similarly, an interesting relation can emerge in which neuroticism appears to be inversely related to arterial blockage, as only the neurotics with clean or with damaged arteries, and the nonneurotics with true blockage-caused pain, are in the sample. The nonneurotics with clean arteries do not worry, and do not wind up in the doctor's office, so they are inadvertently omitted from the study. This artifact might obscure a true causal relation between neuroticism and the development of disease, and so such artifact-biased studies should never be undertaken.

Self-Healing Personalities

In the field of medicine, it is too often assumed that health is simply the absence of disease. A negative test result is good news – it means the disease is not there. Studies and theories tie stress and negative emotionality to illness, disease, and mortality. However, until relatively recently, little attention has been paid to the positive, proactive elements of good health.

What is a healthy psychological pattern? A self-healing personality can be characterized by enthusiasm for life and emotional balance, with good social relationships. Such people are curious, secure, constructive, responsive, and conscientious. They may be alert and energetic, or calm and self-assured. They are people one likes to be around, infecting others with their natural *joie de vie*. Self-healing individuals are hardy, feeling a sense of personal control in their lives, being committed to a higher ideal or cause, and interpreting stressful events in terms of meaningful challenge. They are inspired toward continual growth and resilience. These characteristics of the self-healing personality are not merely the opposite of disease-prone characteristics such as suspiciousness, bitter cynicism, despair and depression, loneliness, or repressed conflicts, but are positive, meaningful motives in their own right.

Positive emotionality and psychological maturity may protect one from illness and promote health through multiple pathways. Physiologically, positive emotions may buffer autonomic and hormonal responses to stress and restore parasympathetic processes sooner, essentially undoing the effect of CVR and physiological arousal. If there is less need to constantly reestablish homeostasis, there is less accumulated strain on the cardiovascular system over time. Socially, positive and mature individuals tend to have better relationships with others, and so will tend to have better individual and social coping resources. Behaviorally, positive and psychologically mature individuals tend to have healthier behavior patterns – more physical activity, better diet, and less smoking and substance abuse.

Dr. Walter Cannon, who developed the ideas of homeostasis upon which modern notions of self-healing are built, emphasized that the body has developed a margin of safety. By this, Cannon meant that the body has allowance for contingencies that we may count on in times of stress. The lungs, the blood, and the muscles have much greater capacity than is ordinarily needed. In other words, the body naturally prepares itself for the rare 'extra' challenge, and self-healing people do what they can to increase these margins of safety.

William James, who anticipated much of our modern scientific understanding of emotional responses, summed up this idea succinctly as he advised:

Keep the faculty of effort alive in you by a little gratuitous exercise every day. That is, be systematically ascetic or heroic in little unnecessary points, do every day or two something for no other reason that you would rather not do it, so that when the hour of dire need draws nigh, it may find you not unnerved and untrained to stand the test (*Principles of Psychology*, 1890, Chap. 4).

Like much of social and behavioral science, psychosocial prescriptions for good cardiovascular health often sound like 'common sense,' until the matter is examined more closely. In actual fact, it is very difficult to walk the fine line between narrow-minded biomedical views of the nature of health that exclude psychosocial factors, and the unscientific touchy-feely health gurus who proclaim oversimplified and overgeneralized prescriptions for good health.

Interventions

What psychosocial interventions can be made to prevent, reverse, or halt the progression of heart disease? Given that cardiovascular disease is by far the greatest cause of premature mortality in economically developed countries, and given that social and economic costs of heart disease are overwhelming for both families and society, what can be done? Because the various elements of a self-healing personality are usually inter-correlated, teasing out the causal pathways and the best interventions remains a major challenge.

There is good evidence that lifestyle changes affect the incidence of heart disease. Most of this evidence is epidemiological and anthropological, showing that when people move from one country or one cultural group to another, their heart disease rate can change dramatically. There is also some experimental evidence indicating that dramatic lifestyle changes can improve aspects or correlates of cardiovascular health. A serious problem with this work is that little is known about which components of the healthy, self-healing lifestyle are the necessary causal elements.

For example, consider Japanese immigrants entering America. They leave a close-knit, well-ordered society with an Asian diet and Asian recreation patterns, and they (or their children) enter an individualistic, heterogeneous American society with very different social and recreational patterns and a hamburger stand on every corner. If heart disease rates rise, what is to blame? Nutritionists might point to fish oils or fat intake; religionists may point to meditation patterns; sociologists may point to family structure; psychologists may point to stress reactions. We simply do not know for sure. There is evidence that some or all of these points may be valid.

What about specific recommendations that are often heard regarding individuals at risk for an initial or recurrent heart attack? For example, is it unhealthy to work long hours? There is no evidence at all that it is unhealthy to be a 'workaholic' if all the other elements of self-healing are in place. That is, hard work and long hours themselves have not been shown to be a risk factor. On the contrary, for example, many powerful or influential executives, leaders, artists, and scientists work

exceedingly long hours and live long and healthy lives. Instead, the individual's response to and success in the work environment are more important.

Is it healthy to retire and get away from the stresses of the workplace? In fact, retiring may be helpful or it may be very stressful and unhealthy, depending upon the particular individual and the particular situation. Retirement may be healthy if it reduces the psychosocial stress of the workplace and increases opportunities for healthy habits. Retiring has been shown to be unhealthy if it results in a diminution of social ties, inadequate financial resources, and psychological states of uselessness or boredom. In addition, changing societal reactions to retirement can be extremely important – in terms of social security programs, health insurance, laws that prohibit age discrimination, opportunities for educational and social activities, and so on.

Can heart disease be prevented or reversed by relaxation techniques? With the attention to the negative role of stress, some studies consider stress-reduction techniques, such as yoga and meditation. However, the general efficacy of these programs is still unknown. Is chronic stress a risk factor for heart disease? Yes. Has it been shown through controlled study that meditation is key to reducing the incidence of heart disease? No. Meditation is wonderful for some people, but others may find it stressful or impractical. It may be more important to match stress-amelioration techniques to individual preferences and situations.

Is it healthy to be optimistic and look on the bright side? Although it seems to be the case that a sense of willpower and positive hopes for the future can help us through difficulty, it is also true that optimism can lead us to be shocked by reality or to avoid taking necessary prophylactic measures. It makes sense, as has been found, that for a heart disease surgical patient, optimism is helpful. It does not, however, make sense to assume that optimism will prove helpful to a chain smoker or an ice cream addict. The emphasis on optimism without sufficient regard to context is an example of the futile search for the psychosocial equivalent of a 'miracle drug' that can cure all diseases.

Are societal pressures that encourage jogging the key to protecting one's heart? It is very clear that a cigarette-smoking obese person who cannot walk up a flight of stairs is at markedly increased risk of heart disease; and this often has led to the incorrect belief that being in shape means the ability to run 5 miles every morning. Moderate exercise, such as a brisk walk each day, may be sufficient to provide cardiovascular benefits. It is probably even better if the individual develops a more active daily lifestyle, even if it does not include any formal 'exercise.' Such lifestyle changes are more likely to be maintained. People who constantly struggle to 'get in shape' may be harming their health.

Few specific recommendations to make psychological changes to prevent heart disease are supported by strong, systematic, long-term human research. Further, most studies have focused on male participants or ignored possible gender differences, even though there is some indication that women experience different stressors and have different psychophysiological responses. Psychosocial factors do increase risk of the development and progression of heart disease. However, it remains unclear what interventions work, who should receive them,

and when we should intervene, beyond the encouragement of psychologically mature individuals who are well integrated in their communities.

Conclusion

Contrary to some common conceptions, most of the increase in life expectancy in the developed countries has come not from high-technology medicine but rather from improved sanitation, infection control techniques, low-cost inoculations, better nutrition, and other public health improvements. Antibiotics have also made a significant difference, but visits to super-specialized cardiac surgeons at university hospitals produce limited impact overall when the big picture is considered. This is not to say that a heart disease patient would not be wise to seek out a cardiac specialist, but only that the overall public health benefit of such high-cost cardiac surgery is relatively small. However, there is reason to suspect that dramatic (and lower-cost) improvements can be realized if we put our knowledge of self-healing to good use. Societal and lifestyle changes may be the psychosocial equivalents of improved sanitation, nutrition, and infection control.

Major reports are regularly published breaking the 'news' that some medical researchers are now urging that psychological and emotional reactions of patients be taken into account. Such considerations generally still lie outside the traditional medical model of disease that focuses primarily on pharmaceuticals and surgery. Individuals who learn their own psychosocial needs, expand their social ties, and develop appropriate techniques of self-regulation and better habits can maximize their potential for good health. Moreover, these psychological styles can be significantly complemented by societal structures that promote such healthy reaction patterns and behaviors.

Glossary

Entheogens A term preferred by scholars of religion who believe that certain chemicals, formally called psychedelic, can facilitate religious or spiritual experiences.

Extrinsic religiosity Motivation for religion based upon utilitarian motives.

Fundamentalism Originally a Protestant movement affirming the Bible as God's revelation and rejecting hermeneutical based criticisms of the text. It is now controversially applied to any faith tradition that rejects modern and postmodern criticism of a sacred text or tradition.

Intrinsic religiosity Motivation for religion as an end in end in and of itself.

Parapsychology Refers to a range of experiences, such as telekinesis, clairvoyance, and channeling that may be seen as

embedded within religious traditions or as alternatives to them.

Postmodern A generic term that refers to a multiplicity of perspectives and methodologies none of which is viewed as privileged.

Quest religiosity Religious motivation primarily focused upon existential concerns.

Reductionism The claim that complex phenomena can be sufficiently explained by simpler phenomena upon which they are dependent.

Spirituality Refers to connection to the transcendent that may or may not be interpreted in religious terms.

Transcendent Refers to the ultimate object of interconnectedness, whether interpreted in religious or secular terms.

Psychology and Religion

Religion Defined

Religions have (1) a concern with transcendent reality (whether or not perceived in personal terms); (2) a sense of ultimate concern; (3) a consensus of belief concerning the nature of ultimate reality that is institutionally supported; and (4) imperatives to act according to beliefs regarding transcendence, often including specific rituals that affirm faith. Few would accept as religious any tradition that was devoid of all four criteria. Increasingly religion is seen as a pejorative term linked with a Eurocentric perspective.

Psychology Defined

Psychologies have (1) a concern with a specific method or range of methods to acquire knowledge; (2) a focus upon how it is that reality is constructed by mental processes; (3) the exploration of sequential changes that occur across the life span; and (4) treatments for psychopathologies. Few would identify as psychological any discipline devoid of all four criteria. It is the lack of consensual definitions of both religion and psychology that forces us to explore what particular psychologies have to say about particular religions.

History of Psychology and Religion

As a cultural phenomenon, religion is at least as old as recorded history. The roots of scientific psychology had been laid by philosophical developments that influenced the natural sciences, especially the union of empiricism and mathematics. By the middle of the nineteenth century, European and American scientists had begun to measure the speed of nervous

transmission and to conduct psychophysical experiments. Psychology had its uneasy origins in such activities as it attempted to emulate the natural sciences. Many date the origin of scientific psychology with the founding of a laboratory at Leipzig in 1879 by the German psychologist William Wundt. Psychological interest in cultural phenomena such as religion was seen as requiring methods other than those of the natural sciences. In American culture, psychology and religion were at odds and neither could be explained by the other. William James was most articulate in exposing this dilemma and argued that natural science assumptions were only a provisional beginning for psychology and need not exhaust the metaphysical options available. The debate over the natural science constraints on knowledge continues to characterize psychology today.

American Psychology and Religion

Interest in spiritualism was strong in nineteenth century America and associated in the popular mind with psychology, largely in opposition to mainstream religious denominations. In Europe, the Society for Psychical Research was founded in 1892 to investigate paranormal phenomena. In America, spiritualism was associated in popular culture with psychology and helped account for the establishment of psychology departments in American universities. William James founded the American Society for Psychical Research (ASPR) in 1894. Many members (who were also to become members of the American Psychological Association whose first annual meeting was held in 1892) assumed that a scientific psychology would dispel the reality of parapsychological phenomena in favor of reductionist explanations based upon natural science assumptions. Several of America's newly identified psychologists quit the ASPR when the organization was perceived to support the reality of spiritual claims. The rapid growth

of psychology in America was due to the paradoxical alliance of psychologists who took as their task the establishment of the validity of psychology by debunking paranormal and spiritualist claims and the common cultural view that the new science was providing support for the reality of paranormal phenomena. This uneasy alliance characterizes the study of psychology and religion in America today, especially in terms of large funding organizations that are perceived to encourage psychologists to support religious and spiritual claims.

Hall, Starbuck, and Leuba: The Clark school

G. Stanley Hall was the first president of the APA and one of those who quit the ASPR. He also founded the first American journal for the psychology of religion (*The American Journal of Religious Psychology and Education*) and established the only school of psychology of religion in America, the Clark school. Two members of that school illustrated the tensions between psychology and religion noted above that continues today.

Edwin Starbuck utilized questionnaires to study religious experience and development. He also employed simple quantitative methods to determine the age at which conversion was most common. His sympathy to religion, particularly evangelical Protestantism, accounted both for his interest in conversion and his avoidance of reductionist explanations. He was content in simply charting the path of religious development.

In contrast, the other most notable member of the Clark school, James Leuba, noted the clash between religious beliefs and advancement within the natural sciences. He used questionnaires to document the decline in belief in a personal God and personal immortality among the more accomplished natural scientists. He also provided reductionist assessments of mystical experience.

James and Pratt: The descriptive tradition

William James, a founding member of ASPR and twice president of APA, illustrates another uneasy alliance between psychology and religion. James' Guilford lectures, published as *The Varieties of Religious Experience*, have proven to be the one undisputed classic in the psychology of religion. It has been continuously in print since the first edition in 1902 and is the text most cited in the contemporary study of psychology and religion in America. In the *Varieties*, James painstakingly described extreme cases of religious experience in sympathetic fashion, and affirmed the pragmatic nature of their truth. James Pratt, a student of William James, extended his mentor's work by focusing upon less extreme and more common religious experiences. His *The Religious Consciousness* (1920) is second only to James' *Varieties* in the number of reprinting in America. Neither James nor Pratt relied heavily upon the emerging methods of scientific psychology. The popularity of their work rests largely upon rich descriptions of and sympathy for religious experience.

By the end of the 1920s American psychology was firmly established and, as it courted measurement and experimentation, the study of religion waned. The emergence of behaviorism left little room for the study of religion other than as a system of behavioral controls. Not until the early 1960s would the psychology of religion reemerge, largely linked to the

counter cultural revolution that arose on America's west coast. However, the focus was less upon denominational religion than new religious movements and the psychology of altered states of consciousness. The shift to spirituality as opposed religion had its roots here. Religiously affiliated schools offered APA accredited graduate psychology degrees assuring a sympathetic study of religion. Thus, the contemporary psychology of religion in America is following its early history, swerving between the Scylla of a religious apologetics and the Charybdis of a naturalistic reductionist interpretation of religion.

Classical psychoanalysis and religion: Freud

We have emphasized that there are varieties of psychologies associated with various schools based upon incommensurable assumptions. Psychoanalysis, founded by Sigmund Freud, emerged from the medical tradition and a concern with psychopathology. As with analytic and object relations theory to be discussed shortly, psychoanalysis was largely European but had an influential effect on American culture that only today is waning. No psychology has had as much influence on culture, arts, and literature as psychoanalysis. It also provided a powerful reductive explanation of religion. Critics of psychoanalysis note that it postulates its own myth of early childhood drama (the ontogenetic thesis) and of early humankind (the phylogenetic thesis) in what became the cornerstone of classical psychoanalysis. The Oedipal drama, especially for males, linked the desire for the mother with that of disposing of the father in a dynamic seen as thinly masked in both Judaism (a religion of the father) and Christianity (a religion of the son). Ultimately Freud saw religion as a falsification of reality. God was interpreted as a projected idealized father derived from the Oedipal drama. The decline of religion was predicated on Freud's assumption that it characterized the infantile stage of humankind. While American academic psychology largely ignored religion from 1930 through 1960, psychoanalysis in its classical Freudian variety produced literally thousand of articles and books providing a huge cultural impact on how Europeans and Americans viewed themselves. Efforts to test psychoanalytic theories by naturalistic scientific methods have, not surprisingly, found psychoanalytic theories largely deficient. However, whether theories based upon radically different assumptions can be tested by a single set of methodological criteria remains philosophically problematic. Furthermore, there are contemporary psychoanalysts who use Freud's theory to support traditional religious beliefs, especially by focusing upon the role of illusion (desire) in motivating belief while rejecting the claim that psychoanalysis can be provided criteria by which culturally shared beliefs can be proven delusional. Psychoanalysis is thus no longer interpreted as necessarily hostile to religion. This parallels the phenomena already noted with other American psychologies.

Analytic psychology: Jung

Among Freud's most famous early followers and one of the few non-Jewish psychoanalysts was Freud's hand-picked successor and eventually his greatest rival in the study of religion, Carl Jung. Jung quickly rebelled from the reductive explanation of religion proposed by Freud. He proposed a collective

unconscious centered upon the identification of archetypes seen as conscious manifestations of inherited instinctive tendencies. While academic psychology has largely ignored analytic psychology, Jung's theories continue to be influential in religious studies; they are seen by some as a spiritual alternative to traditional religion.

Object relations theories

Within the psychoanalytic tradition, continued interest in religious experience has been maintained by object relation theorists. The term comes from the focus upon objects confronted by infants' experience of the world. Obviously the earliest objects of experience include the primary caretaker, typically the mother. Characteristic of object relations are pre-Oedipal experiences, giving the mother (or parts of her body, such as breasts) a prominent role in theorizing. This has produced a variety of theories more sensitive to gender issues since many religious experiences are seen as rooted in infantile pre-Oedipal experiences with the mother and hence minimize the role of the father so prominent in classical psychoanalysis. While extremely diverse in their views, object relation theorists share a sympathetic view of religious experience, so much so that they have often been accused of being apologists for religion.

Transpersonal psychology

Interest in integrating spiritual phenomena directly into psychology has long been championed by transpersonal psychologists. Emerging out of the humanist psychology championed by Abraham Maslow, transpersonal psychology aims to explicitly provide an alternative to both the scientific psychology and the variations of dynamic psychologies discussed above. Transpersonal psychologists tend to integrate spirituality and science in what many see as a modern form of Gnosticism. Thus, few American universities have courses in transpersonal psychology. However, the influence on popular culture in Europe and America is great. While some free standing schools offer degrees in transpersonal psychology, most with a clinical focus, its influence remains largely associated with various forms of New Age Religion and popular culture, not academic psychology.

Cultural psychology

The mere fact of methodological pluralism and the inability of psychology to become a unified discipline contributes to its continued fragmentation such that histories of psychology often organize their texts around schools of psychology. Among the more recent schools is cultural psychology. Since religion is treated as a cultural product there can be no psychological explanation of religion per se. Cultural psychologists explore how individuals meaningfully appropriate religious beliefs. The focus for cultural psychologists is on religious diversity and not upon an overarching theory that explains something called 'religion' in the singular.

The Dominance of American Psychology

The success of psychology in America has always been associated with its rapid development as a profession, especially clinical psychology. Major journals published by the APA

assure the world dominance of American psychology and set what is the gold standard for publications. What emerged as a counter-organization to the APA focused more upon research that the clinical practice of psychology, the American Psychological Society (APS), has from its inception allowed identification of religion as a specialty.

However, it has not been able to make a serious challenge to the APA. In 2009, the division of the Psychology of Religion of the APA launched *Psychology of Religion and Spirituality*, beginning the first official APA journal dealing exclusively with religion. The inclusion of spirituality in the title indicates a broadening of the field that promises to be a permanent part of the religious landscape in American psychology discussed more fully below. The number of journals that deal with the psychology of religion continues to increase, indicating both the strength and fragmentation of the field. The Religious Research Association continues to sponsor a journal, *The Review of Religious Research*, favoring empirical studies of interest to churches and denominations. The Society for the Scientific Study of Religion has long sponsored the flagship journal in the scientific study of religion, *Journal for the Society for the Scientific Study of Religion*. More recent journals include *Research in the Social Scientific Study of Religion*, *Mental Health, Religion, and Culture*, *The International Journal for the Psychology of Religion*, and *Spirituality and Mental Health International*. Despite the tendency to include 'international' in many of the titles, research reported in journals devoted to the study of religion continues to be dominated by Americans or by researchers employing the methods championed by American psychologists. The longest continuous publication in the psychology of religion, *Archive for the psychology of Religion* (*Archiv für Religionspsychologie*) continues to be published in Germany and in 2009 switched from a yearly publication to three volumes per year. New journals devoted to the study of religion and spirituality compliment long standing journals with more explicit confessional concerns such as *The Journal of Psychology and Theology*, *The Journal of Psychology and Christianity*, and the *Journal of Psychology and Judaism*.

Psychology of Religion in Global Perspective

The emergence of journals devoted to the study of religion and spirituality with 'international' as noted above indicates that a distinctive American psychology of religion is becoming more global. While still primarily focused upon the Christian tradition and employing methodologies and statistical procedures championed by American psychology, the psychology of religion in Europe continues to be substantial. However, European psychology of religion remains more receptive to phenomenological, dynamic, and hermeneutical studies than does American psychology.

The psychology of religion in countries such as Australia, Canada, Israel, and the Scandinavian countries have only recent histories and thus do not reflect a reemergence that characterizes American psychology of religion. In contrast, Asian and Eastern cultures have been long histories of the psychology of religion minimally influenced by American psychology and have developed psychologies less distanced from philosophy and religion than American psychology.

Major Methodological Stances in the Psychology of Religion

Given that there is no unified science of psychology, one cannot expect consensus on either methods or procedures for the psychology of religion. Within American academic psychology in general, the emphasis has been on measurement and experimental studies. However, even among the most vocal proponents of this American style, psychology is the recognition that at best the psychology of religion can be approached by quasi-experimental studies in which true random assignment of participants to experimental and control groups and control over independent variables are impossible. Those not convinced that psychology can or should be a natural science employ methods uniquely adapted for humans, including a wide variety of phenomenological and hermeneutical studies. Below we shall explore some of these diverse methods.

Quasi-Experimental Studies

American psychology has long elevated the experimental method to the gold standard for empirical research. American psychologists of religion have thus striven to elevate the respect for their discipline by emulating this method. The experimental method requires that participants be randomly assigned to experimental and comparison groups so that true variation between groups can be assessed and attributed to a factor or factors manipulated by the experimenter. For a variety of reasons, this often cannot be done with studies in the psychology of religion. Studies of the efficacy of prayer are a notable exception. Hence, psychologists have turned to quasi-experimental methods as the closest approximation to the true experiment. Quasi-experimental designs are employed when randomization is impossible. They are often employed in natural settings where differences between groups can be assessed even though participants were not randomly assigned to these groups. Still differences between experimental and comparison groups can be measured. Three areas in which quasi-experimental studies by psychologists have been common are in isolating religious determinants of helping behavior, in conditions that facilitate the report of religious and mystical experiences, and in studies of the relationship between religion, spirituality, and health.

Measurement Studies

Many psychologists consider the ability to assign numbers to phenomena an essential characteristic of scientific psychology. Religious phenomena are no exception in this view insofar as their scientific study requires their ability to be measured. Questionnaires and scales have been developed for the widest possible range of religious phenomena, from beliefs about God, to reports of religious experience, to the motivational basis for religious involvements, to fears and anxieties about death. Most measurement studies are rooted in paper and pencil self-reports but increasingly psychologists of religion are relying upon implicit measures of religion using such indices as delayed response time.

Correlation Studies

Modern sophisticated statistical techniques allow for multivariate research in which several variables can be simultaneously related. Various types of factor analysis allow for the construction of scales with reliable subscales permitting more sophisticated assessments. Regression analyses and structural equation modeling allow for the prediction of religious variables suggesting but not confirming possible causal explanations. The fact that no matter how sophisticated the statistical technique, essentially correlational data cannot prove causation assures a range of disputes as to the causal meaning of any correlation data. This is especially common in studies exploring the relationship between religion, spirituality, and physical and mental health.

Phenomenological Studies

Phenomenological methods have not been widely accepted by American psychology despite the fact that such methods have produced many of the classic works in the psychology of religion. Phenomenological studies focus upon careful description of the content and structure of what appears to consciousness. An interface between phenomenological and measurement studies characterizes much of the contemporary study of mysticism with the use of scales to measure the report of mystical experience derived from phenomenological studies of mystical experience.

Hermeneutical Studies

Hermeneutical studies include a variety of methods that seek to interpret the meaning of phenomena. The psychoanalytic tradition and its off-shoots are viewed by many as hermeneutical rather than causal, and hence part of a distinctive human science. Typically, hermeneutical theories in the psychology of religion seek to understand religious claims in light of systems of meaning derived from more general psychological theories such as psychoanalysis.

Ethnography, participant observation, and field research

While there are various approaches to field and participant observation research in the psychology of religion, we can note one major distinction. Field research occurs in a natural as opposed to a laboratory setting. The difference does not, however, mean that measurement or quasi-experimental studies cannot occur in these settings. Ethnography overlaps considerably with participant observation research. Ethnographers are more committed to 'thick' descriptions of phenomena from many points of view of the various participants. Participant observation can include any study in which the researcher is present with and involved with the object of study. These types of research seek to understand religion from the believer's perspective. They essentially explore religion as a form of life.

Neurophysiological studies

Perhaps the most rapidly emerging method in the psychology of religion is due to advances in neurophysiological methods that allow for the noninvasive study of the brain during various

religious acts, such as prayer or meditation. Many neurophysiological studies correlate a given experiential state with ongoing neurological processes. Among the functional neuroimaging techniques are single-photon emission tomography (SPECT), positron emission tomography (PET), and functional magnetic resonance imaging (fMRI). What is crucial is that these techniques are relatively noninvasive and can allow researchers to determine which areas of the brain are active when individuals are in various spiritual or religious states.

Major Content Areas in the Psychology of Religion

Since its reemergence in the 1960s, the psychology of religion in America has been characterized by a number of content areas that have been investigated by a variety of the methods discussed above. Investigators using some combination of measurement or quasi-experimental designs dominate the mainstream journals in the psychology of religion. Less common are phenomenological, hermeneutical, psychoanalytic, or object relations studies. This creates a series of discreet literatures that seldom dialogue with one another. Therefore, even within specific content areas it is difficult to find a consensus opinion and still be fair to the variety of methodologies and hence other psychologies that claim to possess insight of knowledge into religious phenomena.

Conversion and Deconversion

Conversion has been one consistent phenomena studied in all periods of the psychology of religion. Influenced by the history of Protestantism in America, psychologists since William James focused upon factors that produce sudden or gradual conversions. Recently, the same analyses and procedures have been used to study leaving religious groups, a process identified as deconversion. When either conversion or deconversion is sudden, psychoanalytic psychology has proven useful, focusing upon unconscious motivations that have erupted. Gradual conversion or deconversion is seen as more likely associated with conscious and intentional actions focused upon a search for meaning or involved in the maintenance of various social networks.

Religious Experience

Like conversion, since the time of William James, religious experience has been a continual focus of study. Included are any experiences perceived by the individual to be religious. Thus religious experiences need have no one common characteristic – almost anything can be religiously experienced, from a sense of a divine presence to the handling of serpents. Studies from a variety of methodological perspectives have shown that persons with intrinsic religious motivations derive special experiential awareness from their religious commitments. Particularly among those employing hermeneutical methodologies, religious experience has been found to identify a transcendent meaning that correlational and quasi-experimental studies can only identify in terms of proximate causes. The distinction between experience and its interpretation is heavily studied and debated. For some, all experience is interpreted

experience and hence linguistically and culturally constructed. For others, at least some experience is unmediated by language and culture. Mystical experience has been extensively studied and is perhaps the single experience most frequently cited as providing a transcendental unity to a variety of faith traditions based upon the distinction between experience and interpretation. Within the study of religious experience, the distinction between religion and spirituality noted above has become dominant. While most persons who identify themselves as religious also identify themselves as spiritual, a growing minority of persons identify themselves as spiritual but not religious. These persons often have similar experiences to religiously identified persons but refuse to accept either religious language or authority to interpret what otherwise might be identical experiences. Among the religiously devout, many have experiences that simply confirm their faith.

Religious Development

Theories of religious development are common in the psychology of religion. Classical Freudian theory saw religion as a stage in both individual and cultural development that is fated to be outgrown in the face of developed rational capabilities. Others have proposed that religion is a process that develops in stages, from more concrete acceptance of literal claims to more universal awareness of the symbolic meanings associated with mature faith commitments. Some have posited religious development as an endless quest for answers to existential concerns, including awareness of finitude. No stage theory has unequivocal support and all have been challenged as having implicit if not explicit value judgments as to what constitutes mature faith. Recently, empirically oriented psychologists have followed in the footsteps of object relation theorists and have focused upon early infant attachments to their primary caregivers. As with object relationship theorists, attachment theorists explore how images of God are related to early experiences, suggesting that one's image of God is a function of the nature of these earliest infant experiences. Efforts trace religious development across age groups in Western cultures tend to indicate that religious commitment of whatever form begins with childhood socialization, reaches a peak in adolescence, declines, then emerges strong again in late life. However, there are many exceptions to this generalization, including a general seeking for spirituality that continues unabated and without religious commitment across the life-span.

Psychopathology

From its origin, much of the psychology of religion has focused upon claims as to the psychopathology of particular religions or religion as a generic form. Most famous of these is Freud's final conclusion that religion is a mass delusion. However, contemporary psychoanalysts have used Freud's insights into the dynamics involved in religious belief to contrast pathological aspects of religious commitment from a mature and healthy religious commitment. Jung argued for the essential contribution of religion to psychological health, a tradition continued by analytical psychologists who continue to descriptively explore the range of spiritual experiences across the life span as do object relation theorists. Empirically,

measurement-oriented psychologists have focused upon relating various aspects of religion (belief, experience, and practice) to objective measure of psychopathology. No consistent pattern has emerged. Numerous factors interact to foster or mitigate psychopathology. The immense complexity of research in this area is exacerbated by the fact that neither mental health nor psychopathology are objective terms. While these states can be reliably measured they necessarily imply both normative and evaluative judgments. This is evident in research on fundamentalism which is seen by many psychologists across various schools as hindering or limiting psychological development as well as fostering prejudice and violence. Despite limited objective evidence that this characterizes all fundamentalists, it is clear that most psychologists are explicitly or implicitly satisfied with viewing fundamentalists as representing at best an immature stage of religious and psychological development.

Coping

Closely related to the study of psychopathology is the study of coping. By coping, psychologists refer to strategies by which individuals adjust or fail to adjust to difficult situations. Rather than attempting to judge the truth content of religious belief or the maturity of religious beliefs, psychologists focus upon how individuals use their faith. Thus, extrinsic motivation is involved in the use of a faith in the face of tragic circumstances. The literature on coping is largely empirically based, using measurement and correlational techniques. It tends to reveal that religion can provide a meaningful system of beliefs within which to frame even otherwise negative events as positive. Especially important in religious coping is how one images their God. Having a loving image of God is a powerful means to secure meaning and to provide a reservoir from which to draw comfort and solace in difficult times.

Religion and Social Psychology

Second only to clinical psychology among psychologists who study religion is social psychology. It is fair to say that the revival of interest in the psychology of religion in the 1960s in America had its roots in concern with the relationship between religion and prejudice.

Prejudice

American interest in the study of prejudice was an aftermath of WWII. Clinical and social psychologists united in an effort to understand anti-Semitism in particular and prejudice in general. Two strands of research began that continue to this day. One united psychoanalytic theory with measurement and correlational research to identify particular personality type attracted both to various forms of religious fundamentalism and to extreme political conservatism. This personality type came to be identified as an authoritarian personality, now identified by three characteristics: authoritarian submission, authoritarian aggression, and conservatism. These are persons likely to be prejudiced, especially when the target person has characteristics devalued by one's religion. The second strand of research was associated with Gordon W. Allport and the development of his widely influential *Religious Orientation Scale* that

empirically identified the dimension of intrinsic and extrinsic religion. Intrinsic religion or mature faith was rare but characterized by a lack of prejudice. Extrinsic religion, a less mature form of faith, was common and related to prejudice. Hence the apparent relationship of overall religion and prejudice masked a subtle distinction that mature faith actually unmakes prejudice. Research surrounding this claim still dominates the social psychology of religion with Allport's original findings challenged by claims that intrinsic religious persons seek to appear to be unprejudiced when in fact this is not the case. Confounding this research has been the debate concerning the evaluation of behaviors mandated by religious beliefs and whether such religiously sanctioned evaluations can meaningfully be defined as prejudice. The issue is far from settled and has been taken up fresh, especially by psychologists of religion in Eastern Europe, where religion and ethnic identity are confounded in complex ways that make it difficult to tease out how they determine prejudice. Thus, religion and prejudice promises to be a continued topic of interest in the future.

Altruism

It was a natural progression from the study of religion and prejudice to what for many is the opposite of prejudice, altruism. Just as many researchers have argued that intrinsic religious orientation is negatively related to prejudice, researchers have found that it is positively related to altruism. However, other researchers have challenged this claim, documenting that the intrinsically religious simply wish to appear unprejudiced and altruistic as part of presenting a desirable religious image to others. Researchers using a measure of quest, which focuses upon existential concerns, have marshaled evidence to show that a quest orientation is related to altruism. The debate continues and reflects a uniquely American psychology of religion focusing debates upon data derived from quasi-experimental studies. More recently, many social psychologists have adopted evolutionary psychology as a metapsychological frame and argued that altruism is only apparent and is based upon what are ultimately motivations that actually serve to enhance reproductive success. Included in the claim are debates concerning whether selective mechanisms for reproductive success operate for groups as well as individuals.

Sects and cults

Among the more sociological-oriented psychologists, extensive debate and research into religious groups have utilized a classification of sect, cult, and denomination. Denominations have little tension with their larger host culture. Sects are defined by tension with the larger culture. Often this tension is produced when the emerging sect breaks away from an established denomination either because the denomination refuses to accommodate cultural change (as with fundamentalists) or when the denomination endorses cultural change at a more rapid pace than the host culture supports (as with gay rights). Often sects are in tension because of rejection of all or aspects of secular medicine (as with Christian Scientists or Jehovah Witnesses). Cults are similar to sects but emerge de novo and are often led by a charismatic figure. Both sects and cults represent forms of cultural deviance and have been the targets of intense psychological investigation and of legal scrutiny. Issues have focused upon whether or not cults utilize

specific psychology techniques to coerce members to join. The metaphorical claim to 'brainwashing' is unsupported by empirical evidence. However, techniques of coercive persuasion, common to many groups, have been extensively studied. In cultures with religious freedom, noncoercive psychological process characterizes both entry into and exit from religious cults and sects. Most cults fail and most recruits leave cults within a year of joining. Those that succeed are often fundamentalist groups that provide a meaningful lifestyle lived in opposition to the large culture they oppose.

Atheism, agnosticism, and nontheism

A recent emerging area of study in the social psychology of religion is the study of atheism and nontheism. American psychologists have recognized that America is an outlier with respect to the importance both culturally and individually of religion compared to Europe. There are European cultures that are thoroughly secular, for instance, Sweden. Americans' participation in religious groups and belief in God are atypical and globalization referred to above has made psychologists aware that a psychology of religion based largely upon American studies results in a highly skewed view of religion. While rare, atheism (a denial that God exists) or agnosticism (the claim that one can have or have only uncertain knowledge about God) occurs only as secondary phenomena in reaction to religious socialization. One can deny that God exists for the same reasons that one affirms God, including conscious cognitive processes or more unconscious motives associated with psychoanalytic psychology. Having an absent father or an emotionally absent father in early childhood has been identified as a factor in atheism. Likewise, in purely secular cultures or among children raised in nonreligious families, religion and belief in God need not be rejected. Individuals are socialized without regard to religion or God and hence are simply nontheists. However, some atheists and nontheists identify themselves as spiritual (but not religious), accepting a sense of connectedness with nature that is expressed in purely secular language.

Controversial Issue in Psychology and Religion

Since little consensus exists either among various forms of psychologies or religions, one is tempted to define the entire area of psychology of religion as controversial by default, yet two areas are especially justified in being labeled controversial: entheogens and parapsychology.

Entheogens

Among psychologists of religion, entheogen has become the preferred term for chemicals such as psilocybin that are psychoactive drugs that have profound effects on consciousness. Researchers have long noted that naturally occurring entheogens have been used by religious groups such as the Native America peyote cults to facilitate religious and spiritual experiences. The use of entheogens to facilitate mystical experience or a sense of union with God or a larger reality have produced some of the most frequently cited textbook cases of true experimental research in the psychology of religion. Set and setting

have been documented to be important factors in facilitating positive experiences and a religious interpretation of them. Denominational opposition to chemically facilitated experiences is well documented, making research using religiously committed participants difficult. However, recent studies employing entheogens with religiously committed participants have suggested a bright future for this controversial research area. This is especially the case given that mystical experiences facilitated by entheogens have been documented to be identical on empirical measures of reported mystical experience to those occurring either spontaneously or facilitated by normative religious practices such as prayer.

Parapsychology

As noted above, the founding of psychology of religion in America was linked in the popular mind with parapsychological phenomena, especially those associated with spiritualism. William James believed that both religious experience and parapsychological phenomena would stand up to the empirical tests of science. Contemporary studies consistently find that those who report religious experiences also report paranormal experiences. Multidimensional measures of spirituality often find parapsychology phenomena to emerge as a separate factor. Psychological theories postulate that belief in parapsychology can be an alternative to religious commitment or an integral part of one's religious beliefs. Recent speculations about quantum effects in neurophysiology are leading to methods by which the existence of parapsychology effects can be documented, suggesting that the study of religion will continue to be linked with the study of parapsychology.

Future Prospects

The psychology of religion will continue to be filled with tensions only some of which can be empirically resolved. Yet since the first edition of this encyclopedia, psychology of religion has proven to be even more vigorous, especially as it has incorporated both religion and spirituality into its ever broadening vision. In a postmodern perspective, the claims of a narrowly conceived science that refuses to explore its foundational assumptions can do little to illuminate an equally narrowly conceived religion that refuses to do the same. There has been a widely accepted call for a paradigm for the psychology of religion that is multilevel, interdisciplinary, and nonreductive. Psychology will be unable to stand alone as an arbitrator of either the content of religious beliefs or the conditions that give rise to them. Efforts for a single overarching paradigm to explain religion such as evolutionary psychology will generate considerable research. New disciplines such as cognitive science in which psychology is only one voice have begun to focus on explanatory theories of the origins of religion often in cooperation with evolutionary views. However, for every effort to create a single, monolithic paradigm for psychology of religion, there will be resistance from what still amounts to schools of psychology, or simply psychologies. As for religion, history suggests there is little chance there might be a unified religion for humankind. Thus, pluralism in both psychology and religion will continue.

Glossary

Dyslexia Literally, 'problems with words.' A specific reading problem, in a person with near-normal (or higher) intelligence, adequate instruction and motivation, and sufficient practice.

Grapheme The written symbols of a language.

Perceptual span The amount of material that can be detected by the eye in a single glance; in readers, estimated to be no more than 15–20 characters; furthermore, it is asymmetrical, extending about 12–15 characters to the right of the fixation and about four characters to the left (for English readers; the pattern is reversed in Hebrew readers, who read from right to left).

Phoneme Categories of speech sounds; the smallest unit of sound in a language.

Phonics Reading instruction emphasizing the mapping of visual symbols to auditory sounds.

Phonological recoding The process of converting the written symbols of a language into their sound-based components. In readers, especially skilled readers, this sound-based component may be internal.

Whole-language instruction A type of reading instruction that emphasizes 'natural' meaning and contexts in which reading and literacy takes place.

Whole-word instruction A type of reading instruction in which words are learned as entire units, rather than in individual, sound-based parts.

Introduction

Perhaps the most complex and important cognitive skill that humans acquire is language. Furthermore, we acquire language easily and with no special instruction, much as we master a skill like walking. As the cognitive scientist Steven Pinker puts it, "people know how to talk in more or less the sense that spiders know how to weave a web." Despite this complexity, a 5-year-old child has mastered most of the subtleties of language use. In addition, language appears to be as old as (anatomically modern) humans themselves. Every child, given a remotely normal environment, will acquire language. Similarities in children's developmental sequence hold true despite vast cultural and socioeconomic conditions.

This is true, however, only of spoken language. Acquiring written language, in contrast, is difficult and time consuming. Some individuals, even after considerable time and effort, will not learn to read, or will read poorly. In some very important ways, then, learning to read has more in common with learning calculus than it does with learning to speak. Written languages have been developed only in the past 5000 years or so. Therefore, it can be said that the use of written language is a skill which is not innate, nor is it a skill that all humans can or will acquire. In fact, literacy rates did not reach 50% worldwide until the twentieth century. Reading clearly hinges on the spoken language, but reading is not something we are innately predisposed to do.

Historical Review

The History of Written Language

True writing systems emerged about 5000 years ago, but other types of written communications were used long before

then. The earliest kinds of written communication employed 'logographs,' in which each symbol represents an object, with the symbol drawn to resemble that object. Although logographs have some advantages, such as relative transparency, they have some significant drawbacks. For example, symbols for some words would be difficult to draw. How would one draw a symbol for 'hope,' or 'integrity?' Many of the nouns might be able to be drawn, but verbs, adverbs, and adjectives would be considerably more difficult. Egyptian hieroglyphics, for example, used logographic representation for many words. 'Reading' these ancient hieroglyphs is anything but simple. Also, the absolute number of symbols needed in a logographic language would be overwhelming. In fact, Chinese is the only popular language today written with elements of a logography, although contemporary scholars consider modern Chinese to have 'morphosyllabic' mappings (i.e., characters map to syllables, and these are usually morphemes).

Languages such as Chinese are fundamentally different from English, which is known as an 'alphabetic' language. In an alphabetic language, each symbol stands for a sound, and reading is accomplished by decoding the letters into their corresponding sounds. Languages vary according to how 'good' this mapping is. Italian, for example, has a very good symbol-to-sound map, English somewhat less so. All alphabetic languages derive from Phoenician, which was developed a little more than 3000 years ago. The earliest Phoenician languages contained only consonants. While this may seem confusing, *n xmpl wll shw hw ths knđ f wrtng cn b ndrstd wth ltl trbl* (i.e., 'an example will show how this kind of writing can be understood with little trouble'). Later, the Greeks added vowels; in fact, all European written languages derive from the Greek alphabet, which remains relatively unchanged in the past 2000 years. (The other alphabetic systems, widely used in the Near and Middle East – Hebrew, Arabic, the languages of India – derive from the Aramaic alphabet.)

Early Reading Research

Research into the process of reading is among the oldest topics investigated by psychologists. Researchers in Wundt's laboratory, set up in Leipzig more than 125 years ago, addressed many of the same topics still being investigated by contemporary researchers. These studies, for example, focused on topics such as a reader's perceptual span – how much can readers perceive without moving their eyes – and eye movements associated with reading. Such early work culminated in Huey's classic text, *The Psychology and Pedagogy of Reading* in 1908. Although much of the work reviewed by Huey involved techniques that seem archaic compared to contemporary research, contemporary researchers have confirmed many, if not most, of Huey's central findings.

Relatively little research on the basic reading process occurred after the publication of Huey's text, most likely attributable to the rise of behaviorism in American psychology. Educators continued to debate about the appropriate methods of reading instruction, but this was generally applied (rather than laboratory) research. Furthermore, empirical findings played a less important role in such key issues as whether beginning reading instruction should focus on phonetic instruction or whole-word processing. Consider, for example, Flesch's influential book *Why Johnny Can't Read* in 1955: Flesch argued – correctly, as it turned out – that whole-word approaches to beginning reading instruction were seriously flawed, and he advocated a phonetics-based approach instead. While Flesch's argument was compelling, he had very few data to support his position. In large part due to the debates framed by Flesch and colleagues, reading research began to flourish in the 1960s. A number of specialized scientific journals specifically devoted to reading research were developed. In 1984, *The Handbook of Reading Research* was published, followed 6 years later by a second volume of the same name, and Vol. 3 was published in 2000. A number of textbooks on the psychology of reading were published in the late 1980s and early 1990s and in many ways those remain the best introduction to the field. (Several of those books are listed in the references.)

Perceptual Processes in Reading

The reading process is constrained by limitations of the perceptual human information processing system. For example, readers can move their eyes only as quickly and can see only as much as their eyes can in the periphery of their vision. Images that hit the retina last for only a fraction of a second before fading. Also, readers have a limited capacity short-term memory store that can easily get overloaded. Each of these stages introduces a 'bottleneck' into the reading process, limiting the speed with which the process can operate.

Eye Movements

Although early researchers like Javal observed (and crudely measured) eye movements of readers, recent and more sophisticated techniques allow a precise understanding of exactly how readers move their eyes. Casual observation gives readers the impression that their eyes are moving smoothly across the

page. This is not the case. Rather, readers' eyes are moving in a jerky, abrupt manner called 'saccades,' (from the French for 'jumps'). Saccades impose the first limitation on reading. Each eye movement in reading has two components: the actual movement of the eyes from one location to another (during which almost no information can be extracted) and the time when the eyes stop and focus on a word, called 'fixations.' While reading, the movement takes about 25–50 ms (a millisecond is one one-thousandth of a second; 50 ms, then, is one-twentieth of a second), while the fixations last considerably longer, from about 200 to 250 ms (about 1/5–1/4 of a second). When one is engaged in reading, rather than skimming, one is limited to a maximum of about five saccades per second.

Perceptual Span

The second determinant in reading rate involves the amount of information that can be derived from a single glance, without moving the eyes, what is called the 'perceptual span.' Visual acuity is best for information at the center of the retina, called the 'fovea.' The fovea is lined with cells (called 'cones') that perceive sharp detail. Farther out into the periphery, though, acuity fades. Again, you can demonstrate this for yourself. Hold a book a foot or so in front of you and focus on one word on the page. *Without moving your eyes*, try to recognize words on either side of where you are focusing (you'll probably have difficulty not moving your eyes, a demonstration of the automatic nature of eye movements in skilled readers). You can recognize some letters, perhaps, but you'll also see how rapidly the information becomes unusable.

McConkie, Rayner, and colleagues developed an extraordinarily useful technique for measuring perceptual span in reading, called the 'moving window.' Contemporary eye tracking equipment works by shining a harmless beam of light into the eye and measuring the angle of deflection from the eye. As the eyes move, the angle of reflection changes, and these changes can be mapped onto the visual field. Rayner and his colleagues took the output of the eye tracker and used it to control the nature of visual display. Imagine a computer screen displaying text, and then imagine that the text was covered up by a series of Xs. A sample display is shown in [Figure 1](#). As with any eye tracker, McConkie and Rayner could determine where the readers were looking. Next, they gradually removed the Xs that covered the text, displaying what was underneath. Each time the readers moved their eyes, the 'window' moved along with them. When this window was small, readers had to move their eyes many times to uncover even a single word.

```
XXXXXXXXXXXXXXXXXXXX a XXXXXXXXXXXXXXXXXXXXXXXX
XXXXXXXXXXXXXXXXXXXXte a wXXXXXXXXXXXXXXXXXXXXX
XXXXXXXXXXXXXXXXXXXXicate a window XXXXXXXXXXXXXXXX
XXXXXXXXXXXXld indicate a window of sXXXXXXXXXXXXX
XXXX would indicate a window of size XXXXXXXXXXXX
This would indicate a window of size forty-eight
```

Figure 1 An example of the Moving Window Procedure. Each line indicates a larger window.

Obviously, this greatly reduced the overall reading time. As the window increased in size, readers got faster, but only up to a point. Eventually, increasing the size of the window no longer increased the rate at which the text could be read. The point at which the reading rate levels off indicates the limits of the perceptual span. Adding more information outside that span had no effect because this additional information was presented outside the area where it could be perceived. Readers' maximum perceptual spans were about 20 characters and it was asymmetrical. Readers could make use of information about 15 characters to the right of the fixation and about four to the left. (The fact that the asymmetry is reversed in readers of Hebrew, for example, indicates that it is learned, rather than resulting from physiological factors.)

These numbers reflect reading under ideal circumstances. In typical reading situations, the movements are usually less than optimal. About 10–15% of the time, even in skilled readers, saccades are actually *backwards*. Furthermore, saccades of 20 characters are highly uncommon. Usually, saccades average about eight characters, or about one word. Though there is some evidence that readers do not focus on every word (readers are more likely to skip short and common words like 'the' and 'of,' for example), researchers now understand that readers do focus on the great majority of words in a passage. Therefore, typical reading rates for normal college readers average about 250 words per minute.

The Role of Phonology in Reading

The earlier sections described some of the perceptual limitations involved in reading. Readers cannot train themselves to see all 80 characters in the line of a text at a single glance, for example. The limitation is one that is perceptual in nature, resulting from the distribution of cones in the retina. Once information is extracted from the text, though, the bottleneck in the reading process lies with our limited-capacity working memory (WM) spans. WM can hold relatively few items (about 5–7, by most estimates); without constant rehearsal, this information lasts no more than a few seconds. Thus, efficient use of WM is critical for good reading.

Translating Visual Symbols into Sounds

For readers of an alphabetic language like English, the first task in reading is converting arbitrary visual symbols (letters) into the corresponding sounds (phonemes). Common wisdom is that English is a difficult language to learn because of the numerous inconsistencies in symbol-sound mapping. In truth, this is less of a problem than it first appears to be. Many such inconsistencies occur with high-frequency words like 'of' and 'was,' for example, and the exceptions are learned fairly rapidly. Furthermore, some of the inconsistencies in symbol-sound mapping preserve shared morphologies, such as in the words 'young' and 'youth.'

The process of converting visual symbols into sound is called 'phonological recoding,' and in many respects it is the central task of reading. This is obvious when watching a child learn to read (as they sound out letters and words), but adults do it as well (as shall be seen shortly). In fact, phonological

recoding appears to play a central role even in nonalphabetic languages like Chinese. Indeed, in recent decades, Chinese children who are learning to read are often taught an 'intermediate' alphabet called *pin yin*, which uses Western letters to represent Chinese words. Only after mastering this phonological recoding skill do Chinese readers move on to mastering more complicated symbols like radicals.

How Phonology Influences Reading

The progression of reading usually moves from oral reading, to reading while moving lips, to subvocalizing, and eventually to silent reading. The term 'silent reading,' however, is a bit of a misnomer. Recent studies indicate that even highly skilled readers read by means of recoding information into 'inner speech,' a voice (literally) inside the head. The relationship between inner speech and external speech is close; things that take longer to read out loud, like tongue twisters, take longer to read silently as well. To illustrate, read the following two sentences silently:

- a. Miss Jones' lobster sauce shop rarely sells halibut.
- b. Miss Smith's fish sauce shop seldom sells shellfish.

The two are roughly comparable in length, but most people find that the second sentence takes considerably longer to read. Why? Almost certainly because the printed words on the page are converted into inner speech, and things that take longer to speak externally also take longer to 'speak' internally. Importantly, this appears to be true of many profoundly deaf readers as well.

Note that 'inner speech' and 'subvocalization' are not necessarily the same thing. If readers are asked to eliminate subvocalization (by reciting 'la la la' while reading, for example), but inner speech is not disrupted, reading progresses fairly normally, particularly for simple material. But if inner speech is disrupted, reading is seriously impaired.

The importance of inner speech is demonstrated with profoundly deaf individuals. Only one-fourth of congenitally deaf individuals will learn to read at a level we would consider literate (roughly a fourth-grade level). Why? While the answer to this question is complex, the lack of external phonology certainly plays some role. The key task for beginning readers is to learn the mapping between a visual symbol and its corresponding sound. For hearing children, these external sounds are well learned before the symbol-sound mapping occurs. In contrast, the deaf child does not have this set of sounds on which to draw.

Further evidence of the importance of phonology in reading can be taken from those deaf readers who do learn to read. Interestingly, readers – despite never having 'heard' these words pronounced – make phonetic judgments similar to those of hearing readers. For example, they respond differently to rhyming words ('save' and 'wave') than the nonrhyming, but orthographically similar words ('have' and 'cave'). They can also name the real-world equivalents for nonwords that would be pronounced similar to real words in English ('cruise' for 'krews,' and 'broom' for 'brume'). Finally, as stated before, deaf readers exhibit tongue-twister effects. In short, though they have never heard external sounds, the inner speech of (at least some) congenitally deaf readers seems to parallel

that of hearing readers. It should be noted, however, that the precise nature and importance of phonological representation in deaf readers is far from settled. Some studies indicate internal visual representation, particularly in native signers. What is beyond question is that the lack of external phonology makes reading acquisition considerably more difficult for deaf children.

Developmental Aspects of Reading

As previously stated, reading is not merely a natural extension of speech. Rather, reading is a complex cognitive skill, and like all such skills, requires considerable time, effort, and practice. Furthermore, not all types of instruction are equally effective. Finally, the hundreds of hours of reading practice required for proficient reading are likely well beyond what a child will receive in school. Therefore, children who acquire critical pre-reading skills prior to formal instruction in a school setting have significant advantages.

Fluent Letter Identification

The first skill children must master is to be able to identify letters quickly and accurately. Many studies find that this ability is the best predictor of early reading success: prereaders who were fluent with the alphabet learned to read more easily and achieved a higher level of competence. Fluent letter identification does not mean memorizing the alphabet. Rather, the skill involves mastering basic orthographic skills: a rapid and automatic identification of a letter, given the visual representation. Although somewhat distinct from phonological skills, one can see the advantages of an alphabetic language in this situation. Fluent letter identification means that given the symbol 'B,' the child rapidly identifies not only the letter ('B') but also the underlying sound [bee]. Thus, identifying the letter also allows the child to access its phonology, at least in languages with clear symbol-sound mappings. For this reason, many early reading programs in English use limited alphabets, that is, use primarily those letters that have an unambiguous symbol-sound mapping. Once the letter identification process is automated, limited cognitive resources can be devoted to 'higher' reading processes, such as word recognition (and ultimately comprehension).

Phonetic Awareness

The second skill essential for beginning readers is what psychologists call 'phonetic awareness.' Earlier, reading was defined as the process of matching symbol to *sound*. A more accurate characterization would be to say that reading is a process of matching symbols to *phonemes*. While phonemes are often defined as "the smallest unit of sound in a language," a more accurate definition would be, "the categories of speech sounds in a language." When one examines different speakers trying to make the same sound, say "[bee]," there are some subtle differences across different speakers. Yet those sounds are heard as being the same because the categories important to speech have been learnt. Across languages, there are about 100 different phonemes. English uses about 44 of them

(scholars disagree about the precise number, but all agree that the number is between 40 and 45).

Phoneme acquisition by infants demonstrates the innateness of language in humans. A 9-month old, who has been raised in an exclusively Chinese-speaking environment, will respond to a change from [r] to [l], as in the words 'rah' and 'lah,' even though it is a phonemic distinction that the Chinese language does not make. (It is partly this lack of a distinction that gives natives of China their characteristic accent when speaking English.) Just a few months later, the same child, still being raised in a Chinese-speaking environment, will no longer differentiate those two sounds. This child has learned to ignore a phonemic distinction not used in the native language. This is all the more remarkable when one considers that this is done without any explicit instruction or feedback on the part of the parents. Children are genetically prepared to identify important categories of speech, those relevant to their native language.

Though speakers innately develop the categories necessary for phonemic detection, they are not innately *aware* of them. Prereaders who develop an awareness of these phonemes have greater advantage in reading, which hinges upon matching symbols with the appropriate phonemes. Early instruction clearly helps. An example of this instruction would be asking a child, "Take the word 'mop,' and replace the [m] with a [t]. What new word do you get?" As children develop phonemic awareness, they begin to appreciate things like alliteration or rhyme. Dr. Seuss, either by design or clever intuition (or very likely, both), uses rhyme and alliteration very effectively, which communicates phonemic awareness to children. 'Hop on Pop,' for example, is full of rhyming words that differ by a single phoneme. Very young readers, those just 2 or 3 years old, might enjoy Dr. Seuss for his clever stories and wonderful illustrations. Kindergarteners, however, will likely begin appreciating the rhymes, a demonstration of phonemic awareness.

Reading instruction on the PBS show 'Sesame Street' provides another example of how these two tasks can be combined in ways that children find interesting. Each episode of Sesame Street usually highlights a single letter ('Sesame Street was brought to you by the letter "s"'). The letter (say, 'S') is usually displayed by itself to allow the child to identify it prior to the name being read by the narrator. Then, the letter name is spoken while the letter is being displayed on the screen. Next, the letter is shown in ways that exploit the phonemic properties. For example, the 'S' turns into a snake, while the narrator might say, "Simon, the slippery snake, slides slowly." These lessons combine symbol-phoneme match and segmenting of phonemes in real words and give the child a concrete image (the picture of the snake, which looks like the letter) to aid learning.

Enhancing Children's Reading Readiness

What can parents do to enhance their child's reading potential? One of the most important is reading aloud to them. This serves several critical functions. Children practice their comprehension skills, especially if the parent asks the occasional questions while reading: "what else do you think the bunny could do to get the carrots?" Children practice matching letters to sounds, as they watch the letters on the page. In fact, most

children, as they get closer to school age, will ask if the parent can point to the letters they are reading. Equally important, though, the child sees that reading and literacy are valued, and reading is something that the parent does and enjoys. Given the hundreds of hours of practice that lies ahead for the child, anything that increases the intrinsic enjoyment of reading is a boon.

Some estimates indicate that children whose parents read to them each night enter school with some 1000 h of practice with print. In addition, children may spend nearly that much time watching *Sesame Street* or other educationally relevant programs. Other children, in contrast, have little or no print exposure before schooling. Schooling has little chance of making up these preexisting differences. In addition, remediation faces several enormous obstacles. First, reading instruction, like many areas of education, exhibits what Stanovich calls the 'Matthew Effect': those who have advanced reading skills are more likely to benefit from additional reading practice. In addition, they are also more likely to read outside of school. In other words, the 'cognitively rich' get richer. (The term is derived from the gospel of Matthew, Chapter 25: *For to all those who have, more will be given, and they will have an abundance; but from those who have nothing, even what they have will be taken away.*)

These differences are not trivial. A fifth-grade child in the 90th percentile of reading ability (meaning, one who reads better than 90% of his or her peers) reads *two hundred times* more text in a given year than does the child in the 10th percentile. Given the magnitude of these differences, any kind of remedial reading program faces significant challenges.

Phonetics, Whole-Word, or Whole Language?

During the middle part of the twentieth century, educators argued vehemently about the methods of reading instruction: should reading be taught using a 'whole-word' method, which focused on reading entire words without sounding them out? Followers of this approach believed that readers should experience 'authentic context' (meaning real books), and that at its core, reading was best viewed as a 'psycholinguistic guessing game,' in the memorable phrase of Kenneth Goodman. Others, perhaps best exemplified by Flesch in *Why Johnny Can't Read*, argued for a phonetic approach, teaching reading through explicit instruction via symbols-sound matches. Although some schools continue to teach 'whole words' to beginning readers, from the perspective of most reading researchers, the question is virtually settled: phonetic, code-based instruction is vital to learning to read any alphabetic language. 'Whole-word' approaches to beginning reading and abandoning the teaching of symbol-phoneme matches are misguided.

Most recently, an alternative approach, called 'whole language,' has emerged. In some respects, whole-language approaches differ from whole-word. For example, phonemic awareness is acknowledged as a skill to be acquired by readers. In addition, whole-language approaches stress the motivational aspects of reading instruction, using stories more likely to be interesting. However, most whole-language approaches share two flaws with whole-word methods. First, they share a disdain for explicit phonetic instruction, under the belief that such instruction is unnecessary (at best) and potentially

harmful because of the time it would waste and the frustration it may induce. If a child picks up phonetic skills during the course of learning to read (as did many of us who were taught using whole-word approaches in the 1950s and 1960s), that is fine. But there is no need for dedicated, isolated phonetic instruction. The second flaw is more philosophical: reading is viewed as a natural and logical extension of innate language mechanisms. As was discussed previously, most reading researchers no longer believe this to be true. Reading is a complex and difficult task, one that involves rapid identification of symbols, conversion of those symbols into sounds, and combining sounds to produce syllables and ultimately words and sentences. Nothing about these early, critical stages of reading is 'natural' in any sense of the word.

As reading skills develop, the educational emphasis shifts to the so-called 'higher' reading skills, like comprehension. No one denies that the final reading process involves recognizing realistic materials in a real-world context. But trying to teach a beginning reader this way would be like trying to teach someone to ski by placing them at the top of a steep mountain. A skilled skier could navigate that mountain because that skier has already learned the basic skills and has practiced for many hours. But that does not mean a beginning skier should learn to ski that way. A beginning skier would likely fall repeatedly, become frustrated, and eventually give up. The same occurs with beginning readers. We need not be concerned that beginning skiers on the shallow slopes do not look like expert skiers gracefully descending steep mountains. The skills developed on the bunny slope are a necessary prerequisite for expert skiing down steep Olympic courses.

The beginning reader, then, reads by matching symbol to phoneme, and then stringing the phonemes together to recognize words. This is a tedious process. As a result, the beginning reader will encounter the problems associated with the limited-capacity WM buffer. Readers may well forget the initial sounds of a word by the time they get to the end of the word. (Adult readers often have similar problems stringing together words when sentences are too long. Everyone is familiar with the experience of forgetting the beginning of a sentence by the time we get to the end of it.) Eventually, then, reading progresses beyond this 'sounding-out' stage.

Once basic phonetic skills are in place, the next task involves automating. Like any cognitive skill, highly skilled and fluent reading requires substantial practice. As with many cognitive skills, high-level performance requires hundreds, even thousands of hours of practice. (Anders Ericsson, a psychologist who has studied expert performance in domains from music to chess finds that between 1000 and 2000 h of practice are generally required to master a skill, five to ten times that much to become 'world class.' Those numbers are perfectly consistent with Stanovich's work on print exposure.) As the reading process develops, readers begin to recognize similarities among words. They use these regularities to allow them to recognize familiar words automatically, rather than having to sound out every word. With much practice they begin to recognize words directly. This additional way of accessing words has been incorporated into what has been called a 'dual-route' theory of reading. One of the routes, as we have already seen, involves phonological mediation – the words are accessed by their sounds. Skilled readers, though, begin to bypass the phonologically mediated

route (at least, most of the time). Skilled readers begin to access words directly.

That is not to say that the role of 'inner speech' becomes any less important. As has been stressed throughout, inner speech is crucial to reading. What happens as reading becomes more skilled is that words no longer require relatively slow letter-sound recoding and recombination. Instead, words become recognized as 'wholes.' When words are retrieved from the lexicon, it can be done without requiring the individual letter-to-phoneme mappings.

Does phonology play any role in skilled reading? Curiously, more than researchers once thought. Consider Chinese readers, who do not use an alphabetic language: although their language does not rely on a conversion of characters into sounds, phonology still plays a large role. Skilled readers of English are likely to be influenced by underlying phonology, even when a word is directly accessed: for example, if readers are asked, "is this something you would see in a garden?" they are significantly more likely to make an error if shown the word 'rows,' a homophone of 'rose.' Skilled readers may not need to access phonology when seeing the word 'rows,' but they still do.

There is an important lesson with respect to reading here. Skilled reading requires rapid, direct, and automatic access to words. As with any skill, much of reading also becomes automatic through practice. Grade school children vary dramatically in the level of print exposure they have, but it is not unreasonable to expect an above-average sixth-grade reader to read more than 1 million words a year. Even so, more practice provides the child with additional opportunities to develop fluent, automatic access to words. Therefore, children should be encouraged to read *anything*. Parents and teachers may shake their heads in disbelief when the child picks out another book about wizards and Hogwarts, or another mystery in the *Magic Tree House* series. Critics often bemoan the loss of cultural literacy when a child selects *Harry Potter* rather than *Moby Dick*. Should children be pushed away from reading these popular books, and into something that will be 'good for them?' Quite the contrary: developing these basic reading skills *is* good for them. A child is much better off, in terms of developing reading skills, reading 10 000 words of *Twilight* than 2500 words of James Joyce. Unless reading is considered pleasurable, few children will pursue it without being coerced. Children should be encouraged to read everything – magazines, newspaper, comic books, even cereal boxes! All of these provide important practice and hasten the development of skilled reading.

In summary, the most successful early reading instruction is provided by explicit instruction devised to develop phonetic skills. As readers become more skilled, phonological skills become less important. At the same time, some aspects of the whole language approach produce positive outcomes. For example, the emphasis on students reading meaningful and interesting material likely produces important motivational gains. Furthermore, these approaches may be more successful with more advanced students, those who have mastered basic phonetic skills.

Speed Reading

Advertisements for 'speed reading' courses are ubiquitous, especially on school campuses. Sometimes the claims are fairly

modest, for example, promising to double one's reading rate. Sometimes, the claims are extraordinary: "increase reading rates to 10 000 words per minute, *with no loss of comprehension!*" Such claims are impressive, and if they could work, would be a great benefit. The question, of course, is: do they work?

The answer is twofold, in some respects. First, it is impossible to increase true *reading* to 10 000 words per minute, for reasons discussed previously with respect to physiological limits on perceptual spans and saccade frequency. Readers may be developing a related, and also highly useful skill – skimming. During skimming, readers do not read every word, but when they finish can often tell the 'gist' of the passage. Skimming articles, for example, can allow a reader to make a useful assessment as to whether the article may be worth (genuinely) reading. Under the best possible circumstances, skimming rates might be a thousand words per minute.

That having been said, skimming is not the same as true reading. As mentioned earlier, the limitations on reading are physiological and perceptual, not purely cognitive. Readers are limited, by the physiological limitations of their neurons, to a maximum of about five saccades per second. Perceptual spans are similarly limited, but in this case by the resolution power of the retina outside of the fovea (essentially, the distribution of cones in the eye). The only way to increase saccade rate would be to increase the rate of firing of our neurons. The only way to increase the resolution power of the retina would be to add additional cones in the parafoveal regions. Neither, obviously, can be done. Programs that tell students to learn to move their eyes more rapidly or to attend to information in their distant peripheral vision are equivalent to a runner coach who tells a sprinter that she can sprint 100 m in 5 s by taking 12-foot strides or by doubling the rate at which she moves her legs.

Maximum Reading Rates

How fast can readers read, then? One can derive this using generous estimates of saccade frequency and perceptual span. First, assume that a reader makes five saccades per second and makes no backward saccades. Assume next that the reader can see three words with each saccade. Thus, the reader can see 15 words per second, and since there are 60 s in a minute, can read 900 words per minute. Few typically read half that fast. Using more realistic upper estimates (four saccades per second, 1.5 words per saccade) produces approximately 350 words per minute, a speed occasionally (though rarely) observed in skilled readers.

Dyslexia

Dyslexia is a specific reading problem. We might define dyslexia as a specific reading (not language) problem in individuals

1. with roughly normal (or above) intelligence
2. who have been provided adequate instruction
3. with sufficient practice
4. who are motivated to read
5. with no general neurological deficits that produce more global impairments.

Such a definition excludes many people – individuals who were never schooled, those with inadequate levels of intelligence to read, those with brain damage, etc. True, those individuals may well display poor reading skills, but they should not be confused with true dyslexics. The term ‘dyslexia’ has traditionally been reserved for those readers who, despite otherwise normal educational achievement, fail to read. Often, readers will be diagnosed as dyslexic if they read two grade levels below where they should be reading, or if they are 2 standard deviations below the mean reading ability for their peers (roughly, the bottom 2.5% of the distribution).

One important question, with respect to dyslexics, is whether they are *qualitatively* unlike normal readers. That is, do they read differently from normal readers, or are they simply readers at the bottom end of a normal distribution? (Recall that with any normally distributed population, 2.5% fall 2 standard deviations or more below the mean.) The answer to this question is more important than it may appear. If dyslexics read like normal readers, just less effectively, no specialized intervention would be necessary. If, however, dyslexics read *differently* (and not just worse) than normal readers, different types of instruction may be warranted.

Unfortunately, this is not easily answered. Although the term ‘dyslexia’ is often used as if it referred to a unitary phenomenon, this is wrong. Dyslexia is better understood as describing a family of reading problems. That is, any number of different underlying problems can lead to poor reading skills. Indeed, even when readers display the same symptoms, the underlying cause might be different. As a result, we should not expect to find ‘the’ cause of dyslexia, nor should we expect educators to develop a single treatment program. To say someone has dyslexia is in some ways no more informative than a physician telling someone they have a virus.

Acquired and Developmental Dyslexia

Dyslexics can be subclassified in several ways. First, researchers distinguish between *acquired dyslexia* and *developmental dyslexia*. Acquired dyslexia is dyslexia that can be attributed to known, identifiable brain damage – that’s what makes it ‘acquired.’ There are two particularly interesting subtypes of acquired dyslexia, surface dyslexia and deep dyslexia. Both result from brain damage, but the resulting reading problems are quite different. Surface dyslexics appear to read only by using the phonological route – they sound out every word. Not all words are equally accessible through the phonological route. English has a number of irregular words, those where the symbol–phoneme match is poor. Examples would be words like ‘island,’ ‘colonel,’ and ‘stomach.’ A surface dyslexic would read those words as ‘iz-land,’ ‘kol-o-nell,’ and ‘stow-match.’ However, surface dyslexics lose the direct-access route of reading. Deep dyslexics, in contrast, read only via the direct-access route – they have lost their ability to access words through phonology. They are most likely to make word substitution errors; shown the word ‘dresser,’ they may say ‘bureau.’ Given the word ‘car,’ they might say ‘automobile.’ Notice that the errors will often serve to preserve meaning, though the reader changes the exact wording. Finally (and importantly), deep dyslexics have extreme difficulty with pronounceable nonwords, like ‘blave.’ Even though ‘blave’ is not a word (fans of the movie ‘The Princess

Bride’ notwithstanding), it *could* be a word, as it conforms to the rules of English.

Although acquired dyslexia can be devastating, it is less of a puzzle for readers and educators. The cause is clear, and treatment options usually limited (or even nonexistent). The deficits seen in acquired dyslexics, though, provide powerful clues to the manner in which reading proceeds, as will be covered in the next section.

In developmental dyslexia, on the other hand, there is no identifiable brain damage. Rather, a child with developmental dyslexia has traditional learning experiences, adequate opportunity, yet still displays significant reading impairments. Developmental dyslexics account for the majority of the individuals diagnosed, and provide the greatest challenges for parents, educators, and researchers. Often, these are bright, motivated students, doing well in other subjects, who simply read poorly.

Individuals known as ‘backward readers’ provide an interesting comparison to developmental dyslexics. Backward readers may also read two grade levels below their age-appropriate peers, but they also have a level of intelligence 2 years below their peers. That is, they may be 10 years old, reading at an 8-year-old level, but have an IQ of 80 (which, roughly speaking, is a way of saying that they have the level of intelligence of an average 8-year-old). Several differences are striking and counterintuitive. Although backward readers are almost equally divided between males and females, about three-fourths of all dyslexics are males. Backward readers are more likely to display other signs of neurological impairment, such as problems with fine motor control. Perhaps most surprising is the outlook for the two groups. The prognosis for dyslexics is poor; currently, educators have a fairly low success rate with dyslexics. In contrast, the prognosis for backward readers is comparatively good. Backward-reading children may always read at a level below their age, but they will continue to make progress. Ironically, then, if two 10-year-olds – one a bright but dyslexic child, the other a less-intelligent backwards reader – are in the same remedial reading class, chances are very good that in 5 years, the less-intelligent child will be reading better.

What Acquired Dyslexia Says About Developmental Dyslexia

The two subtypes of acquired dyslexia, surface (all reading done via phonology) and deep (all reading done via direct access), suggest something important about the reading process in general, and about developmental dyslexia specifically. First, surface and deep dyslexia provide perhaps the strongest evidence for a dual-route model of reading. In acquired dyslexia, of course, loss of one of the routes results from neurological impairment. As is so often the case in psychology, researchers learn about normal functioning by looking at what is lost in abnormal cases.

Second, the nature of developmental dyslexia often mimics what is seen in acquired dyslexia: many developmental dyslexics have reading problems similar to those seen in (acquired) deep dyslexics. Many developmental dyslexics make word substitution errors, and almost all have problems with pronounceable nonwords (‘prume’ or ‘krell’). Given what is known about the impairment of the phonological route in deep dyslexics, it is not surprising that deficient phonological processing is suspected in developmental dyslexics as well.

Potential Causes of Developmental Dyslexia

When the general public first became aware of dyslexia, the problems were often assumed to be perceptual in nature. For example, it was believed that readers saw letters reversed or out of order. Now, researchers believe those kinds of perceptual problems to be relatively rare, and uncharacteristic of most dyslexics. When compared to normal children on perceptual/spatial tasks (which did not involve verbal materials), dyslexics typically perform as well as normal readers. Despite anecdotal evidence to the contrary, dyslexics do not consistently reverse letters or numbers.

Researchers have long known that the eye movements of dyslexics were abnormal. Dyslexics take longer to make saccades, their saccades tend to be shorter, and they make regressive saccades more frequently. In short, they move their eyes much less efficiently. However, the fact that dyslexics have faulty eye movements begs the question: are the faulty eye movement the *cause* of the dyslexia, or are they the *result* of poor reading behavior? After all, if an unfamiliar language was presented to readers of English (especially a language that was written from right to left), their eye movements would be considerably less efficient than those of skilled readers of that language. Recent evidence indicates that the faulty eye movements are the result of faulty reading, not the cause of it. If normal readers are given very difficult texts to read, their eye movements become more like those of dyslexics. If dyslexics are given easy material to read, their eye movements become much more like those of normal readers. Therefore, it seems unlikely that dyslexia is caused by faulty eye movements.

The central problem for developmental dyslexics appears to be related to poor phonological processing. One unresolved question is whether this reflects generalized deficits in processing sound-based information, or whether those deficits are language- and speech-specific. As is the case with most such questions regarding dyslexia, it is likely to be both: some will have a generalized auditory deficit, while others will have deficits only in speech-related areas.

Regardless of the precise nature of the phonological difficulties, genetic factors play a significant role. Concordance rates between monozygotic twins (the likelihood that one twin will be dyslexic given that the other is also dyslexic) are as high as 65% or 70%. Elevated rates are also seen between siblings, and between parents and children, although they are not as high as those between twins. Collectively, it appears that between 40 and 60% of the developmental dyslexia can be attributed to genetic factors. Researchers at the University of Colorado have been able to separate orthographic skills (reading letters) from phonological skills (turning symbols into sounds). The genetic contribution to phonological skills is significantly greater, as high as 90% in some studies. The genetic contribution to reading is much like genetic contributions to success playing basketball. There is no 'basketball gene,' but height has a significant genetic component, and height is certainly related to success in basketball. That is not to say that someone who is 5 ft 6 in. cannot be successful playing basketball (nor does it mean that a person 7 ft tall is automatically successful). But the shorter player is at a significant disadvantage. Likewise, having poorer phonological skills, whether generalized or language-specific, does not prevent one from reading, but it makes reading more difficult.

Educational Interventions for Dyslexia

Because of the serious and profound affect of dyslexia on academic performance, a number of interventions have been proposed over the past decade. Since early reading skills are cumulative, early intervention is critical: most successful interventions are initiated before the child ends the second grade. Some have focused on solving perceptual problems, perhaps by having readers read through colored lenses or through special glasses. Few, if any, of these have produced widespread or significant benefits.

The most promising programs are those that address phonological deficits directly, that recognize the importance of motivational factors, and that encourage the child to take advantage of accommodations such as extra time to complete exams. These programs are based on an understanding of the critical role of phonological processing in reading, and children with difficulty in this area require additional practice (perhaps significant additional practice). Early reading skills are stressed, and beginning readers are directed to books that emphasize phonology (like the Dr. Seuss books mentioned earlier). Early diagnosis and intervention are also encouraged.

Early intervention may well have effects above and beyond facilitating phonological skills – intervention is likely to prevent the student from perceiving reading as unpleasant and aversive. Reading problems often induce a vicious cycle: the child struggles in early reading exercises, reading skills develop slowly, and the child becomes frustrated. Because of the frustration, the child avoids reading, meaning that his skills do not improve as quickly as his classmates'. He reads poorly the next time in class; so his teacher assigns extra practice, which the student finds aversive and so avoids it, and so on. Developmental dyslexics need extended practice with precisely the same skills they lack, and few of us enjoy repeating things when we experience failure. Interventions that encourage the enjoyment of reading, while also affording the child extra practice on the skills they lack, are most likely to be successful.

Summary

Language is innate to humans, reading is not. Though its ties to speech are clear, reading involves different and highly specialized skills, combined with vast amounts of practice. Early reading instruction that stresses phonics has proven to be the most successful approach, and prereaders who have mastered the building blocks of reading – letter detection skills and phonemic awareness – are at a tremendous advantage. As reading becomes more skilled, the reliance on phonological mediation lessens but is never entirely eliminated. Words become directly accessible and the reading process becomes more efficient.

Skilled reading is the result of several factors. Readers must possess a nonintuitive grasp of their spoken language (phonemes). They must learn the symbols-to-phonemes match inherent in their alphabetic language. They must gradually learn to recognize patterns of letters (and eventually, words). All of these factors require many hundreds of hours of practice.

Glossary

Astrology A belief system based on the view that strong correlations exist between the positions of constellations and planets and their relationships with human social affairs.

Birth chart A grouping on paper of information obtained from the heavens. These 'birth maps' are interpreted by astrologers as allegedly providing information about the subject (person, animal, country, company, etc.).

Pop psychology Popular psychology of the marketplace. It relies on testimonies and experiences of the writers rather than critical reflection and research. Testing of essential claims is not conducted. Negative cases and alternative conceptions are typically ignored or insufficiently considered.

Pseudoscience A theory or approach that portrays itself as a science, but at the present time, falls short in a number of essential aspects. It is usually not based on diverse supporting evidence from well-conducted studies, and the

conceptual structure of the theory has not been refined over time adequately in response to research findings. In addition, it has not contributed research suggestions to new areas, nor is it compatible with well-supported theories in related domains. The label 'pseudoscience' is not a permanent label as new discoveries or alternative conceptions of a discipline may require the rethinking of its status (or parts of it).

Psychology The scientific study of human behavior, including overt behavior, mental and neurological processes.

Science An approach to understanding the natural world using a diverse set of investigative methods. A central component of science is its reliance on public testing of claims rather than reflection alone or appeals to authority and intuitions. The results of well-conducted and replicated studies in science are, whenever possible, applied by practitioners at the applied level.

The main goal of psychological science is to fit our theories about ourselves to the social and physical world. Such knowledge can be used to explain, understand, under some circumstances predict, and even change human behavior. Unlike other disciplines or perspectives that also claim to contribute to our knowledge about ourselves and the world (e.g., religion, philosophy), science relies in a central way on the public testing and reliability of the very claims it makes. In contrast to commonsense, personal beliefs, or intuitions this is accomplished by the development of paradigms or research traditions that advocate ways of solving problems and what problems are solvable. Of course, the expression 'bad science' implies that there exists a contrast, namely, science proper. The distinction is not always clear and at times it is difficult to determine if some description of human behavior is scientific or not. However, there are approaches that *pretend* to be something they are not. They suffer from deficiencies both in quality of their research findings and in the rigor of the research methods employed that would allow them to claim to be a science.

Psychology: The Scientific Study of Behavior

Psychology is a science that studies and develops theories about behavior and mental processes such as thoughts, attitudes, feelings, personality, problem solving, and underlying neurological processes. As a science, psychology employs a variety of systematic procedures for obtaining and analyzing information. Attempts to organize the observations and findings often result in theories. While a theory attempts to explain

particular findings, it also generates new ideas or hypotheses that can be tested. Thus, a theory is not so much right or wrong as it is either more or less useful as a practical tool for studying human behavior.

Psychologists create hypothetical constructs to aid in discussing human behavior. Thus, concepts such as intelligence, extroversion, anxiety, achievement motivation, sensation seeking, and self-concept describe hypothesized internal conditions of the individual, while concepts such as social support and cultural climate refer to external features of the psychological environment. Many of these concepts are referred to as variables, since they are not static or fixed. For example, psychologists have demonstrated that the traditional notion of intelligence has a strong genetic basis.

The Role of Theory in Science

As research findings accumulate about concepts and principles, theories are created to attempt to pull them together into a more coherent, organized, and consistent system. In the process, these theories then allow for the generation of new hypotheses or predictions that may either be confirmed through rigorous testing or suggest that the theory is less useful for explaining the very phenomenon it was designed for. If the former holds true and consistently strong support emerges for these hypotheses, the theory, in turn, is supported. Alternatively, a lack of confirmation or support for the hypotheses generated by the theory requires that the theory be modified, restricted in application, or that it be abandoned in favor of alternative theories. Testability is of central concern.

For example, Hans Eysenck's original theory of extraversion relied very heavily on Pavlovian views of inhibition and excitation, but the results of various research investigations suggested that the initial theory was inadequate. Thus, Eysenck refined his theory so that introversion and extraversion were hypothesized to be related to differences in cortical arousal associated with the ascending reticular activating system (ARAS).

While scientists and research psychologists seem to be able to patiently test ideas and cope with the various different theories put forward to describe human behavior, this can be very confusing and irritating to the general public. Thus, while psychologists debate the intricacies of human memory or argue over reinforcement being, or not being, necessary in learning, the general public wants immediate answers. Parents who refer their child for learning problems are not interested in discussions about various hypothetical causes of learning disabilities, but rather in what can be done to improve their child's situation in school and future life in society. Of course, we all wish for a complete understanding of the cause(s) of cancer and heart disease, as well as autism and more importantly cures, but in the meantime we must continue to actively research the disease and use all of our current knowledge to assist those individuals with such conditions. Wishful thinking and pop remedies (some of which are fraudulent and only intended to benefit the seller) will not cure such diseases or psychological concerns. The same applies to the study of human behavior; pop psychology and pseudopsychologies may have great surface appeal to many people, but in the final analysis, they bring us no closer to a greater understanding about human behavior.

Scientific Method

Psychology's claim to being a science is grounded in the use of systematic observation and data collection with the attempt to minimize bias as the basis for gaining increased understanding about human behavior. Various quantitative and qualitative research methods are used to gather information and to test hypotheses and generate new findings. Correlational research is designed to explore the extent to which the two or more variables are related. Information is often carefully collected through questionnaires measuring particular psychological variables (e.g., IQ, anxiety, self-concept, attitudes), naturalistic observations (e.g., observing the frequency of occurrence of inattentive behaviors exhibited by an ADHD child), interviews (e.g., 'how do you most effectively cope with job stress?'), and other qualitative and narrative techniques. Through such research, it may be determined that, for example, school success of children is highly related with such home factors as parental encouragement to achieve and the opportunity for language development. While these specific findings are only correlational and therefore do not imply a causal relationship, they do describe and can be used to predict behavior. As always, the results need to be replicated, and the studies must be carefully conducted in the first place. The saying regarding computer data, 'garbage in-garbage out' also applies to psychological research. Like scientists from other disciplines such as physics and biology, psychologists are most interested in discovering causal or cause-and-effect relationships among variables. While the chemist knows that a mix of hydrogen

and oxygen produces water, the psychologist is interested in addressing questions such as 'Can intelligence be raised by creating more stimulating environments for children?' 'Does cognitive-behavioral therapy result in greater improvement in depressed patients than other therapies?' 'Does viewing TV violence result in increased aggression among children and adolescents?' Whenever possible, psychologists are interested in conducting *experimental* studies to investigate these questions.

Ideally, the focus of an experiment is to impose the necessary controls that will allow the researcher to determine what (causal) factors are responsible for any changes observed. Often there is one or more 'treatment' groups and even a control group that receives no treatment. Participants are carefully assigned to groups so as to ensure there are no pretreatment conditions or characteristics unique to one group that could affect the results. Once assignment to the experimental or control groups has occurred, the treatment(s) is administered and the effects are carefully observed, measured, and recorded. The treatment variable or the one believed to be responsible for any observed changes is called the independent variable. The dependent variable is the one that changes because of the treatment. A simple example should assist in clarifying the nature of a psychological experiment, although it should be remembered that most experiments are extremely complex.

Let us say that a university professor is concerned about the lack of participation and involvement by students registered in a first-year psychology course. Despite the professor's request for students to ask questions or respond to questions posed in class, there is very little student participation. Further, the professor is convinced that greater student interaction in class should have a positive effect on student grades. Since the professor teaches several sections of introductory psychology where students are randomly assigned to each given class, a study is created whereby group 1 is verbally reinforced ('thank you for such a good question, Cameron,' or 'that was a great answer, Genevieve; you have quite correctly outlined the purpose of the clinical interview') for questions asked and answered, or information sharing on an appropriate topic. Group 2 is told that a bonus mark of up to 5% will be awarded to students who volunteer to provide answers, ask questions, or share content-related information in class (average of one question/answer/comment per class = 1% up to five or more questions/answers/comments per class = 5%). Group 3 receives only the usual request to participate in class. A graduate student is asked to record the class participation on a specially designed data sheet. At the end of a 3-week unit on memory and forgetting, a carefully constructed objective test is administered to the three classes. The results suggested that the average participation rate per person and exam mark, respectively, for group 1 was 2.9 and 78%, for group 2 the results were 2.5 and 76%, while the results of the control group were 0.6 and 70%. Groups 1 and 2 were very similar in achievement and participation and certainly more active than group 3. Further, the results comparing the two treatment groups with the control group were found to be statistically significant ($p < .05$). Thus, the professor was able to conclude that even though these were all university students who were quite intelligent, their learning could be enhanced through the use of strategies designed to promote more active participation in the class.

A question that is often asked by psychologists is 'Are the groups really different, or did the differences between groups occur by chance?' The above example indicates that the probability that the differences between groups were due to chance is unlikely; if this study was repeated 100 times, such a difference among groups would occur less than five times if only chance was operating. If the differences between the groups are very unlikely due to chance, then the psychologist will conclude that there is likely a difference worthy of further investigation. Other psychologists will then try to successfully replicate the results and extend the study using other designs or variables to further increase our knowledge base.

Psychology is the scientific study of human behavior in a variety of contexts, but other scientific and nonscientific claimants also profess to further our understanding of humankind. For example, cultural anthropology, philosophy, history, and sociology, all contribute ways of conceptualizing human behaviors ranging from aggression to altruism. While these disciplines vary along the scientific continuum and may even, as in the case of philosophy, employ a more reflective and conceptual approach, they all employ critical analyses and/or rigorous testing procedures to validate their claims and applications. The results of inquiry in all these fields in turn modify the tenets of the discipline. In contrast, other efforts to characterize human behavior fall short with respect to a critical, reflective usage of their own tenets and findings and can in the extreme case be considered pseudoscience. Many of these approaches vary in their testability and plausibility. Some of these problematic approaches are acupuncture, faith healing, healing touch, tai chi (and similar 'energy treatments'), and much of the field of alternative and complementary medicine. A comprehensive consideration of all of these examples would require a large textbook. However, one popular problematic approach is astrology, which directly overlaps with and is often put forward as an alternative to personality theories and counseling techniques in psychology. We use popular astrology as an example of the problematic type of enterprise that shares many of the dubious underpinnings of the previously mentioned problematic areas.

Astrology: An Example of Bad Science

Astrology contends that there is a strong relationship between particular planetary and stellar configurations in the heavens and human personal and social affairs. More specifically, the birth time and place on earth of an entity (person, animal, country, company, etc.) allows the construction of an astrological chart for the frames of reference provided by the astrologically significant indicators such as signs, houses, and planetary aspects. On the basis of the symbolic interpretation of the birth chart, astrologers claim that they can obtain information about a particular individual's character and life (or prospects for a country or company). The astrological interpretations are not based on physical characteristics of the planets but mythological associations established by reading ancient traditions. In other words, the sizes and compositions of the planets do not play a role in their alleged astrological effects. The contrast with psychology is clear, given that astrology covers the same ground as psychology and other social sciences. Indeed, according to many astrologers, the planetary effects

are so strong on human behavior that psychology itself is seriously deficient in ignoring the most powerful relationships that allow understanding of human beings.

Astrology is based on several principles. One is 'as above, so below,' implying an association (not necessarily a causal relationship) between the lives of people, and institutions and heavenly configurations. Another principle is 'the stars incline, they do not compel.' This states that the relationship between the heavens and human behavior is one of tendency and is not simple cause and effect. A third principle is that 'the whole is more than the sum of its parts,' namely that the astrologically significant indicators such as signs, houses, and planetary aspects cannot be viewed in isolation. Rather, they interact and modify each other. These interactions are again based on mythological associations with the astrological symbols.

Many astrological practitioners (astrologers) contend that the tenets of astrology are based on 'practical' research or clinical observation, rather than on the findings of studies. In other words, these tenets have allegedly been arrived at by the 'critical' observation and discussion among astrologers of case studies of clients (including presumably, countries, companies, and pets).

Astrological Theory: A Critique

Theories can be evaluated according to their track record of past successes and their research potential. These involve an examination of a theory's empirical/conceptual performance over a specified interval of time. Some relevant considerations here are the success of the theory's problem-solving ability in its domain, and whether the theory has opened up new empirically investigable areas of investigation or extended fertile problem-solving resources without extensively resorting to 'face-saving' ad hoc hypotheses (face-saving hypotheses). The track record of a theory can also be evaluated on the elaboration and progress of its conceptual resources in helping us understand the social/natural world. The conceptual changes should direct and facilitate empirical research.

The conceptual/empirical performance of the field of astrology (as is the case of the other problematic approaches mentioned earlier such as acupuncture, healing touch, and energy treatments) is extremely unimpressive. There is little or no understanding or interest by astrologers of the kinds of biases and human deceptions in judgment that plague clinical observation in all areas of inquiry, including the social sciences and medicine. The reason careful studies and (whenever possible) experiments are used in psychology and other disciplines such as biology in the first place was to rule out as much as possible memory, perceptual, and reasoning biases and deceptions as well as alternative explanations. While case studies may play a role in generating hypotheses, they are too often fraught with error to be convincingly used as methods of confirmatory research.

If the basic claims of astrologers were based on observation, as many claim, then they would have been confirmed long ago by statistical tests, which basically do what any astrologer does (i.e., look for correspondences), only with a much greater sensitivity. But they have not. The claim that astrological interpretations developed as a result of clinical observation is like claiming to know the effect of each of 20 chemical elements on

every feature of every plant in your garden. Any reader who has tried to interpret a four-way interaction in an analysis of variance (ANOVA) will appreciate the problem if 15–20 or more factors are involved! The problem of examining the relationship between many variables has led to the development of sophisticated research tools in psychology such as LISREL, path analysis, and multivariate statistical models.

Astrology has an unimpressive scientific track record. Its problem-solving ability in the domain of understanding human behavior is noteworthy by its lack of success. Well over 100 controlled studies of signs, aspects, whole charts, and so on now exist, and indicate that overall the effect sizes (the impact of the variables in questions) are, at best, trivial. Moreover, there is nothing hinting at the sort of internal consistency that would arise if it was all real, like the effect size for whole charts being bigger than for parts. A meta-analysis (a statistical method of combining the results from many research investigations) on studies involving a number of prominent astrologers clearly showed that astrologers (even world famous ones) tend not to agree on an interpretation of birth charts.

The status of astrology as a science is therefore questionable. Further, studies on astrology play no serious role in theory development or astrological practice. Positive studies are given propaganda value, while negative findings are dismissed or ignored, and no scientific studies (positive or negative) have any influence on the daily practices of astrologers, as they do on the practices of practitioners of the physical and social sciences.

Many astrologers have responded to such criticisms and negative findings by claiming that astrology is an occult science, a divination approach or a philosophy. But in all such forms of unconstrained speculation, astrologers are not responsive to cogent criticism and have adopted varieties of postmodernism or relativism to avoid serious confrontation with their critics. In all its manifestations, astrology is made compatible with whatever happens or whatever studies show, and here lies one of its greatest present-day weaknesses.

The Scientific Research of Michel Gauquelin

A number of astrologers have made much propaganda over the research conducted by the late Michel Gauquelin of France and colleagues. His empirical research into astrology was conducted over a 40-year period in the second half of the twentieth century. Gauquelin's negative results regarding zodiac signs, planetary aspects, and tests of astrologers are seldom mentioned by astrologers or are explained away. Instead, astrologers have emphasized, and misinterpreted, Gauquelin's positive empirical findings as support for astrology.

Gauquelin forwarded three scientific findings that are relevant to a scientific evaluation of astrological theory. The first is that there is a relationship between planetary positions in the sky at the birth of *eminent* people in *some* occupations. For example, Mars tended to occur more often in certain sectors of the sky at the birth of outstanding athletes in some (but not all) sports. The planetary relationships did not hold with ordinary people or less eminent sportsmen. The effects were also very weak, generally needing large sample sizes for detection.

When astrologers cite Gauquelin research as supporting astrology, they neglect to inform people that Gauquelin only

found planetary relationships at the birth of *eminent* individuals and not the rest of us. Second, Gauquelin only found that *some* of the planets were associated with eminence, namely, the moon, Venus, Mars, Jupiter, and Saturn. He uncovered no relationship with the astrologically important sun, Mercury, Uranus, Neptune, and Pluto, and no relationship between zodiac signs or planetary aspects and the occupations of eminent or ordinary people. Third, the relationships uncovered by Gauquelin were very weak; there was little overall difference between effective and ineffective planets. Hence, while the results would have been of theoretical interest, they would have no practical benefit for astrological practice. Indeed, his negative findings, like the negative findings of other studies of astrology, were ignored or dismissed!

Gauquelin later offered two other claims, partly to explain the link between eminent individuals in some occupations and planetary positions at birth. One of these was to suggest a relationship between planetary position at birth and human temperament. The stronger the traits, as exhibited by top individuals in certain fields, the stronger the relationship uncovered. For example, Mars is, on Western myths, associated with strength and violence, and individuals outstanding in careers needing those traits should have, more often than those less eminent, Mars in certain sectors of the sky at their birth. However, Suitbert Ertel, a German psychologist, has found substantial biases on the part of Gauquelin's studies regarding the temperament (trait) hypothesis and has published a number of papers on this topic. Gauquelin's temperament research was based on trait extractions from the biographies of famous individuals. Ertel found that, using the same biographies as those of Gauquelin, the latter extracted more 'typical' traits for the relevant planets than did extractors who were 'blind' to planetary position. When coupled with other biases found by Ertel, it seems likely that Gauquelin's planetary-trait hypothesis will be, at best, severely weakened, and at worst, demolished.

The combination of an occupation/trait link to planetary position suggested a third hypothesis to Gauquelin, namely that the planetary relationships might be linked to hereditary factors. An initial study by Gauquelin with 24 961 parents and children showed that children tended to be born with the same particular planets in certain sectors of the sky as their parents. However, a replication by Gauquelin himself with 50 942 parents and children in 1988 found no relationship. This leaves the reality of the Gauquelin hereditary effects also in doubt.

The British astronomer Percy Seymour has written several books on astrology that have received media attention. Like Gauquelin, Seymour rejects much of astrology, including zodiac signs. Seymour's entire case for astrology rests on the Gauquelin data, which as we have seen, are now far less solid, at least in regard to his trait and heredity hypotheses, than it was two decades ago. Seymour has attempted to explain Gauquelin's findings in terms of geomagnetic activity, which induces currents in an individual's neural network by resonance. Seymour fails to answer the most important question of all: How does the fetus connect with the relevant planets in the first place? In addition, the planetary frequencies Seymour refers to are so microscopically weak that it seems doubtful to say the least that any organism could respond to them. Finally, Ertel in Germany found no evidence of geomagnetic influences in his reanalysis of Gauquelin's data, which in effect, nips

Seymour's theory in the bud. The reader should also notice that any *physical* explanation put forward for astrology creates other problems for astrologers. Astrologers will produce not only a birth chart for people and animals but anything that has a 'moment of birth,' including a company or a country. How could a physical force imprint itself on the nature of a company or country at its 'moment of birth?'

Astrological Practice: A Critique

Astrological *practice* has also not produced concrete evidence of its efficacy. When astrologers are asked to produce evidence of the validity of astrological practice, they usually cite testimonials, or case histories, or successful predictions by astrologers. Popular astrology books contain case studies involving the birth charts or horoscopes of famous individuals, which after the fact, invariably show a close connection between the interpretation of these individual's birth charts and their significant personality characteristics and life events. These case studies, however, should not be persuasive because of the large number of components in a birth chart that allow, by selection of factors, the chart to be made to fit almost any individual's life. As an example of this, at a British conference dealing with research into astrology, Australian ex-astrologer and critic of astrology, Geoffrey Dean, showed that British singer Petula Clark's horoscope matched her biographical details exactly; the horoscope was then revealed to be that of US murderer Charles Manson.

Counseling success with clients carries the most weight with astrologers. The assumption here is that a horoscope based on an individual's true birth date would be more accurate and informative than the one based on wrong birth dates or someone else's birth date. However, this assumption, which lies at the heart of astrology, is not supported by the evidence. Let us briefly consider reasons to support this skepticism. First of all, astrologers themselves do not seem to be able to distinguish between correct and incorrect horoscopes for well-known individuals most of the time. There are a number of published horoscopes that are based on incorrect birth data but purportedly describe the people involved perfectly. The German astrologer Peter Niehenke came across three different astrological publications, each containing a different horoscope of the late ex-Beatle John Lennon, each based on a different birth time, and each indicating 'definitely' the time of Lennon's tragic death. Second, most investigations of the validity of personality interpretations based on horoscopes have found that people or clients of astrologers were unable to distinguish between authentic interpretations and false interpretations at rates commiserate with astrological claims. In other words, wrong horoscopes are accepted as readily as right horoscopes.

The 'remarkable correspondences' that astrologers report between horoscopes and the lives of their clients are therefore unpersuasive. Every suspect system from phrenology to three-cycle biorhythms can produce similar 'remarkable correspondences.' One should also keep in mind that some startling coincidences should be expected to occur in such situations, given the length of the typical horoscope, the number of astrological elements involved, the leeway in interpretation of the statements contained in the horoscope, and the human tendency to concentrate on successes and ignore failures. Astrologers have failed to provide evidence that clients would

find more startling correspondences in birth charts based on an individual's correct birth data rather than incorrect birth data. In reference to Peter Niehenke again, he produced a horoscope for a client who was thrilled with its accuracy. The client told him that she had received horoscopes (based on accurate birth data) from several other astrologers and that this was the most thorough and accurate of them all. Niehenke's pride was diminished when he discovered that the horoscope he produced was based on incorrect birth data – 20 years earlier than the client's actual birth date!

Successful predictions similarly become suspect when the number of astrological predictions made are considerable and negative predictions are ignored or explained away. If astrology was a predictive discipline (as popular belief contends), one would expect large numbers of astrologers accurately predicting relevant important worldwide events, rather than the odd successful prediction made by one or a few astrologers. However, while making predictions is considered essential for popular astrology, it should be noted that the social sciences tend to be little better, in general, in their success rate in predictions of worldly affairs.

In a related vein, a number of studies have addressed the ability of astrologers using the complete horoscope to match individual horoscopes and various personal qualities, life events, handicaps, and so on. Some individual tests were made by the psychologist Vernon Clark in the later twentieth century. He carried out three tests, and each gave weak but positive results in favor of astrology. The studies by Clark are important because they have been widely cited as evidence for astrology. One problem with the studies is that no follow-up was conducted to measure the astrologers' skill again in a second test along the same lines or to extend the study in new areas. Also, equally competent astrologers from other countries (e.g., France) who tried Clark's tests failed and there was no evidence that the professional French astrologers had abilities inferior to those from other countries. In a later study conducted by Geoffrey Dean in Australia, individual's horoscopes were altered to make them as opposite in meaning to the authentic horoscopes (based on correct birth data) as possible: the extraverted indications were substituted for introverted, stable for unstable, tough for tender, ability for inability, and so on. It was found that reversed interpretations were accepted as accurate by clients just as readily as authentic interpretations. In another set of studies, Dean tested whether astrological theory or astrologers could predict two of the most important personality factors, namely, extraversion and emotionality in ordinary people. To this end, subjects with extreme scores on the Eysenck Personality Inventory were selected from over 1000 people. The average pair of opposite extremes used in the test was roughly equivalent to the two most extreme persons in a random sample of 15 adults. In the first experiment, Dean tested whether computer analyses of astrological factors such as tropical signs, elements, sidereal signs, aspects, Gauquelin plus zones, angularity, and so on, both individually and in combination, could predict extraversion and neuroticism (emotionality) in extreme subjects. None of the astrological factors, either singly or in combination, performed better than chance. In a second experiment, Dean tested whether 45 astrologers using the entire chart could predict extraversion and emotionality in ordinary people. He found that the

well-known astrologers did no better than chance. In addition, there was no relationship with the astrologer's experience, sex, confidence, personality, or technique. The cumulative verdict based on many such studies indicates that horoscopes are not useful in this regard.

Fourth, and most importantly, Dean found (as in other similar studies) there is poor agreement among astrologers regarding which astrological factors should predict various personality characteristics, and even astrologers using the same technique were found to show little agreement. This suggests that each astrologer's technique and interpretation are highly individual. In other words, the results of Dean's study showed that astrologers do not usually agree on what a chart (horoscope) indicates, even when using the same factors! In practice, this means that a client visiting equally competent astrologers is unlikely to get similar readings. Yet the client is likely to be satisfied with either horoscope. This is strong evidence that factors other than astrological ones are responsible for the perceived success of astrology.

Conclusion

Science and psychological science is characterized by an emphasis on the demonstration of its claims to the satisfaction of other scientists. To this end, theories are constructed, refined, tested against the alternatives, and reconstructed and refined, or rejected. Theories exist on a continuum regarding quality and usefulness. These attributes reflect the track record of past successes and the theory's research potential. A good theory has successes in its own domain, has opened up new areas of successful research, and has been conceptually modified in light of research findings. Theories can also be evaluated on the basis of their promise or research potential. While the past track record of a theory is relevant to the consideration of a theory's promise, other indices might be the production of analogies that direct researchers to examine problems in a new way, the introduction of new fruitful procedures for solving outstanding problems in an area, and the theory's consistency with well-established findings/theories in related domains.

As many of the expository articles in the *Encyclopedia of Human Behavior* show, psychology is a thriving, creative discipline. Many of the theories in psychology cannot yet duplicate the precision of those in the natural sciences – the sheer complexity, the newness of many areas of psychology, and conceptual problems in the field mitigate against this, yet the field has advanced both conceptually and empirically over the last 100 years.

The reader will be able to contrast the expositions given in other parts of the *Encyclopedia of Human Behavior* with the practices of astrology. If we appraise astrology's present status, we find a theory that has a very poor record of success in terms of studies obtaining positive evidence and, even less support once effect sizes are taken into account. Present-day astrology has not opened up new promising areas of research. While some astrologers have written books on the position of astrology in medicine, politics, crime, economics, and so on, the books are notable more for their authoritative postures than research studies and calculations of effect sizes.

Astrology does not appear to have any prospect in sight for providing a plausible mechanism that would explain human

behavior. While astrologers continually pose new models, they are not carefully examined or tested against each other in the astrological community. Instead, in response to criticism of claims, astrologers have resorted to many face-saving hypotheses; for example, that the relationship between an individual's planetary positions at birth exhibits patterns that are acausally related (synchronicity) to that individual's earthly activities, or that astrology is only involved in subjective human experiences that involve individual perceptions, or that astrology is a transcendent occult or divinatory discipline rather than a scientific one. These are precisely the situations where misinterpretation of data and biased evaluations of ambiguous data are most likely to occur.

Astrological claims (albeit not the Gauquelin effect) are readily explained by the perceptual, inferential, and small-sample biases to which people in general are quite prone. For example, knowing that Scorpios are supposed to be secretive, our observations will invariably confirm it, simply because everyone is secretive at time and we are disinclined to test non-Scorpios. Such findings underscore the importance of making sure those of us in the social sciences include both aspects of critical thinking along with readings on the extent of bias and deception in human life and investigations in our courses. The same lessons we can learn from our example of astrology are applicable to areas such as acupuncture, healing touch, and energy treatments.

Lest the reader come away with the impression that all that is put forward in the name of psychology is scientific, in contrast to other pretenders such as astrology, numerology, Tarot, past life regression therapy, and so on, we would caution the reader that there exists within psychology the same continuum. In psychology, there exist areas of developed theory, confirmed laws, well-conducted replicated studies, in contrast to areas that are on par with astrology. As an example of the latter, we would classify much of what could be termed pop psychology. Many pop-psychology books are bestsellers, selling millions of copies, and involve New Age (now misleadingly called 'New Science') psychobabble regarding 'co-dependency,' 'spirituality,' 'the adult child,' 'addictions,' 'psychological Laws of Attraction,' and a host of 'recovery programs.' These books and articles involve poorly articulated theory, the use of selected testimonials instead of clinical research, appeals to authority, the neglect of plausible scientific alternative explanations and cognitive biases, and contradictory assumptions. In the final analysis, a useful understanding of human behavior will be best achieved by the development of rigorous testable theories that can be improved upon by careful analysis and evaluation in both laboratory and real-world settings. Psychology is committed to this ideal.

Glossary

Abnormal behavior The behavioral component of dysfunction.

Functioning Behavioral, interpersonal, emotional, cognitive, and/or physiological patterns.

Insanity A legal term that addresses the question of whether a particular person can be held criminally responsible for his or her actions.

Mental disorder Descriptive term for psychopathology that does not connote an illness substrate.

Mental health The absence of psychopathology and positive characteristics such as subjective well-being, optimal development and use of mental abilities, social adaptation, and achievement of goals.

Mental health problems Synonymous with psychopathology or mental disorder.

Mental illness Similar to psychopathology, but implies that the dysfunction reflects disease or illness.

Psychopathology An aberrant or dysfunctional way of functioning.

Definitional Issues: Abnormalcy Versus Normalcy

The definition and conceptualization of psychopathology have long been subjects for discussion and debate. Psychiatric and psychological professionals have primarily led the dialogue and several related terms have held favor at different times within the discipline. In order to discuss the diagnosis, assessment, and classification of psychopathology, it is important to first define and distinguish some of the terms associated with the discipline. Psychopathology is a general term which refers to an aberrant or dysfunctional way of functioning, where functioning is defined in terms of behavioral, interpersonal, emotional, cognitive, and/or physiological patterns. Abnormal behavior is a similar term, but it focuses on the behavioral component of dysfunction. In contrast, although mental illness is largely synonymous with psychopathology, it is more closely aligned with a medical model as it carries the implication that the dysfunction reflects some form of disease or illness. Mental disorder, in contrast, is a more descriptive term, which does not connote a disease or illness substrate. Mental health is a term which is growing in popularity for its alternate focus on the positive attributes of human functioning. Mental health is not only defined as the absence of psychopathology, but also as positive characteristics such as subjective well-being, optimal development and use of mental abilities, social adaptation, and achievement of goals. Mental health is a term now often used to refer to the whole spectrum of mental experience from function to dysfunction. For example, mental health problems or issues are largely synonymous with psychopathology or mental disorders.

Insanity is a term that is sometimes confused with psychopathology. Although insanity and its derivatives, such as mad or lunatic, were used historically in much the same way modern society uses the terms psychopathology or mental illness, insanity is now a specific legal term that addresses the question of whether a particular person can be held criminally responsible for his or her actions. As such, whether or not a person is legally insane is determined by a judge or jury, not by a mental health professional. The tests necessary to inform the legal counsel are conducted by a mental health professional, who also provides

his or her expert opinion on the matter, but ultimately the decision is a legal one. Further, an individual, without a diagnosable form of psychopathology, may be deemed legally insane by the courts. In the same vein, many forms of psychopathology do not meet the criterion for insanity. In sum, while insanity and psychopathology have had similar definitions in the past, they are currently distinct concepts.

As exemplified above, different ways of conceptualizing psychopathology emerge as a result of different approaches to determining what is abnormal. One such method uses a statistical approach that conceptualizes function and dysfunction along a continuum. As such, the distribution of functioning in society can be conceived as forming a bell curve. Based on this model, statistical procedures can be used to determine at what distance a particular functional pattern falls from the norm, or the majority of the general population. If the functional pattern is determined to be statistically rare, then it is deemed dysfunctional. Alternatively, a deviance approach to abnormalcy may determine whether a behavioral pattern falls outside of current social norms or values and is thus considered a deviant pattern of behavior. Abnormalcy may also be determined by the level of distress experienced by the individual, or by the distress experienced by those in their environment. In contrast, the prototype approach provides a set of criteria for abnormalcy, a certain number of which must be met.

Theories of Cause

Beliefs regarding the cause of abnormal behavior have evolved over time. Historically, theories such as demonic possession predominated as an explanation for aberrant behavior. Contemporary explanations of psychopathology are based on scientific research and draw from at least one of three areas. Biological explanations of abnormal behavior view the cause of psychopathology in the individual's biological composition, specifically the brain. Some biological models focus on the location within the brain where problems may occur, while other models focus on biological processes such as neurotransmission to

explain abnormal behavior. Explanations for the cause of depression, for example, draw from evidence that individuals with depression have lower levels of the neurotransmitter serotonin in the brain. Psychological explanations of abnormal behavior are based on research on emotion, thinking, behavior, and personality, among other things. Using the example of depression once again, research has provided consistent evidence that certain patterns of thinking and certain personality styles increase one's vulnerability to depression. Third, social or environmental explanations view the individual's context as a causal factor in the development of abnormal behavior. For example, negative life events and harsh living conditions, trauma, and the loss of a loved one by death or separation, are viewed as playing a role in the possible genesis of depression. The most commonly accepted current conceptualization of the cause of psychopathology, however, is a combination of all three of these areas: termed the biopsychosocial model. The biopsychosocial model views each of the three areas as contributory to the development of psychopathology, in differing amounts depending on the disorder. Diathesis-stress models take this view one step further and typically suggest that biological and psychological factors constitute a vulnerability for psychopathology, and social factors trigger the expression of this vulnerability.

Classification and Diagnosis

The classification and diagnosis of abnormal behavior have also evolved over time. As early as in ancient Greece, there was a limited system for the classification of abnormal behavior. However, it was not until 1883 that the template for the majority of current diagnostic systems was developed by Emil Kraepelin. Similar to the medical model, his approach evaluated different symptoms that form cohesive patterns called syndromes. These syndromes, once identified, were then labeled. Following this general model, current diagnostic conceptions of psychopathology view abnormal behavior as discontinuous with normal behavior; as something that has a qualitatively different sense to it. Such conceptions often include ideas of illness or disease processes, as these processes are those that distinguish normal from abnormal functioning. The categorical approach to psychopathology is heavily subscribed to because diagnosis is often considered to be a necessary precursor to treatment in psychiatric settings. In contrast, dimensional approaches view functioning on a continuum, where some levels of functioning are more or less dysfunctional than others. Diagnosis and labeling are less accepted within a dimensional approach, except to the extent that labels are applied to individuals at agreed upon points along a continuum. For example, if a person bites his or her nails more than 3 times a week, we might label that as 'abnormal' and label such a person a 'nail biter.' Dimensional approaches are often used in combination with statistical conceptions of what is 'average' or normal, and abnormality is defined as being atypical or highly different from the 'average.'

The International Classification of Diseases

There are two predominant contemporary diagnostic nomenclatures used in the mental health professions. Both nomenclatures

adopted categorical approaches to diagnosis. In 1948, the World Health Organization (WHO) published the sixth edition of the *International Statistical Classification of Diseases, Injuries, and Causes of Death* (ICD-6) that included for the first time a section on mental disorders. Although ICD-6 was revised to ICD-7, the section on mental disorders was not modified. Efforts were made in the ICD-8 (1968) to improve the utility of the list of mental disorders across all member countries of the WHO. Further improvements to the system were made for ICD-9. Specifically, a descriptive glossary was provided for each disorder. ICD-10 was published in 1992 and is the version in current use. There are a total of 78 major categories of mental disorders in the ICD-10 (see [Table 1](#)), and many of these categories contain a number of more specific forms of psychopathology. ICD-10 is available in 42 world languages, and is the official coding system throughout much of the world.

The Diagnostic and Statistical Manual

Due to problems with earlier versions of the ICD, the American Psychiatric Association developed its own system for diagnosis. Referred to as the Diagnostic and Statistical Manual (DSM), the system was first published in 1952, and has since been updated and republished four times. The current DSM is the fourth edition with text revision (DSM-IV-TR), which was published in 2000, and a 5th edition is currently in development. Most versions of the DSM were coordinated with publication of each new revision of the ICD. Publication of DSM-I corresponded with ICD-6, DSM-II with ICD-8, DSM-III with ICD-9, and DSM-IV with ICD-10. However, the newest revision of DSM will not likely follow publication of ICD-11. Rather, if there is a revision of the mental disorders section, ICD-11 may be coordinated with the DSM-V.

The first two editions of the DSM had many similarities to the ICD. Distinctions were made between psychotic and non-psychotic disorders, for example, and the diagnostic system included many etiological terms in the diagnoses. The DSM-III made a major departure from this approach and deleted, as much as possible, references to putative causes of disorder and theory-based terminology. Instead, the DSM-III attempted to label disorders solely on their objective features, with as little inference about cause of the disorders as possible. In addition, more descriptive information for each disorder was provided, including criterion sets for each disorder, and an expanded discussion of each disorder (onset, course, gender differences, etc.) within the text. The DSM-III was also innovative in other ways, which garnered wide applause as a major step forward from earlier versions of the DSM. Notably, DSM-III incorporated a multiaxial diagnostic system, which was a way to examine different 'axes' or dimensions of functioning within the person being diagnosed, in order to achieve a more complete assessment (see [Table 2](#)). This multiaxial system was retained for subsequent versions of the DSM, and is expected to also be used in the DSM-V.

The success of DSM-III solidified the reputation of the DSM nosology and garnered significant investment in the system by mental health professionals. Publication of the DSM-III-R was largely propelled by changes in some of the diagnoses in the field, as well as a desire by the American Psychiatric Association to have a bridge between the DSM-III and DSM-IV.

Table 1 Major diagnostic categories from ICD-10

A. Organic, including symptomatic, mental disorders
1. Dementias in Alzheimer's disease
2. Vascular dementias
3. Dementias in other diseases classified elsewhere
4. Unspecified dementia
5. Organic amnesic syndrome, not induced by alcohol and other psychoactive substances
6. Delirium, not induced by alcohol and other psychoactive substances
7. Other mental disorders due to brain damage and dysfunction and to physical disease
8. Personality and behavioral disorders due to brain disease, damage and dysfunction
9. Unspecified organic or symptomatic mental disorder
B. Mental and behavioral disorders due to psychoactive substance use
10. Mental and behavioral disorders due to use of alcohol
11. Mental and behavioral disorders due to use of opioids
12. Mental and behavioral disorders due to use of cannabinoids
13. Mental and behavioral disorders due to use of sedatives or hypnotics
14. Mental and behavioral disorders due to use of cocaine
15. Mental and behavioral disorders due to use of other stimulants, including caffeine
16. Mental and behavioral disorders due to use of hallucinogens
17. Mental and behavioral disorders due to use of tobacco
18. Mental and behavioral disorders due to use of volatile solvents
19. Mental and behavioral disorders due to multiple drug use and use of other psychoactive substances
C. Schizophrenia, schizotypal and delusional disorders
20. Schizophrenia
21. Schizotypal disorder
22. Persistent delusional disorders
23. Acute and transient psychotic disorders
24. Induced delusional disorder
25. Schizoaffective disorders
26. Other nonorganic psychotic disorders
27. Unspecified nonorganic psychosis
D. Mood (affective) disorders
28. Manic episode
29. Bipolar affective disorder
30. Depressive episode
31. Recurrent depressive disorder
32. Persistent mood (affective) disorders
33. Other mood (affective) disorders

L. Unspecified mental disorder
78. Mental disorder, not otherwise specified

The revision process for the DSM-IV also brought improvements to the nomenclature. Notably, the writers focused on the empirical literature to guide diagnoses, and they expanded the text for each disorder to include cultural, ethnic, and gender variations in presentation. The impetus for the publication of the DSM-IV-TR was thus to further update the text material.

The DSM-IV-TR multiaxial system comprises five major axes. Axis I contains the major psychopathology diagnoses, while Axis II is used to diagnose personality disorders and mental retardation. Axis III is used to diagnose general medical conditions. Some of these disorders or conditions may be relevant to the other psychopathology diagnoses, as malnutrition may be to anorexia, for example, whereas other medical disorders or conditions may simply help to round out a picture of the person's current problems. Axis IV is used to rate the severity of psychosocial and environmental stressors. Similar to reported general medical conditions, some stressors may be

Table 2 Major diagnostic categories from DSM-IV-TR*Axis I* – Clinical disorders/other conditions that may be a focus of clinical attention

1. Disorders first diagnosed in infancy, childhood, or adolescence (excluding mental retardation, which is diagnosed on Axis II)
2. Delirium, dementia, and amnesic and other cognitive disorders
3. Mental disorders due to a general medical condition
4. Substance-related disorders
5. Schizophrenia and other psychotic disorders
6. Mood disorders
7. Anxiety disorders
8. Somatoform disorders
9. Factitious disorders

51. Problems with access to health care services
52. Problems related to interaction with the legal system/crime
53. Other psychosocial and environmental problems

Axis V – Global assessment of functioning

relevant to other psychopathology diagnoses, whereas others may simply provide a context for current functioning. Axis V consists of a global assessment rating of the individual's current overall functioning, ranging from 1 (worst possible functioning) to 100 (highest possible functioning). In order to diagnose a person using the DSM-IV-TR, information should be provided on each of the five axes. Thus, only Axes I and II are comparable to the ICD's diagnostic labels, the DSM is more comprehensive than the ICD, and the DSM provides

more of a complete context in terms of the patient's medical and psychosocial issues than the ICD.

Current Questions and Issues*Categorical versus dimensional models*

A significant amount of research has been conducted on issues of relevance to DSM that may be addressed in the DSM-V. A long-standing debate in the field is whether the choice of a

categorical approach to the classification of psychopathology is valid, and whether a dimensional approach might be more accurate. A large number of conceptual, research, and ethical issues regarding the categorical approach to psychopathology have been raised. At the conceptual level, issues of validity (i.e., accurate portrayal of reality) have taken a number of forms. For example, the fact that the total number of diagnoses has increased over time, and the fact that the ICD and DSM systems have different numbers and types of diagnoses, leads to the question about which system best reflects the 'real' range of psychopathology. Ideally, diagnostic systems should be both comprehensive (i.e., include all potential diagnoses), as well as distinctive (i.e., each diagnostic category should be distinct and minimally overlapping with other categories). It is not clear that either the DSM or ICD meets these criteria. Nor is it easy to imagine how they could demonstrate that they are both comprehensive and distinctive.

Another validity issue that has been raised is the extent to which a categorical system best represents psychopathology. This issue has been particularly raised in the case of the personality disorders, where it has been argued that rather than being discrete disorders they represent the extreme ends of personality dimensions. According to this view, rather than diagnosing personality disorders such as Dependent Personality Disorder, psychopathologists should speak about the relative strength or weakness of certain personality dimensions such as dependency.

Although the issue of whether disorders are dimensional or categorical in nature is most acute in the case of personality disorders, it is also clear that in other disorders, judgments must be made about when a given behavioral pattern or symptom falls outside the range of normal. Consider, for example, the diagnosis of anorexia nervosa. Within that diagnosis are a number of dimensional judgments that a diagnostician makes, including what is an 'expected' body weight, when a fear of being overweight is 'intense,' when thoughts about body size are 'disturbed,' and when body weight or shape has an 'undue influence' on self-evaluation. While at the extremes of such judgments there would likely be high agreement across diagnosticians, less extreme fears and disturbances are more difficult to judge with certainty. Put otherwise, some of the symptoms are themselves not dichotomous, but reflect dimensions of disturbance, which are identified only if they cross some imaginal 'line' of dysfunction. Decisions about how to recognize where that line has been crossed require some agreement among diagnosticians about what that line is, and how to recognize it is being breached.

Arguments about the dimensional nature of disorder have been made with respect to most forms of childhood disorders, as these disorders are typically conceptualized in terms of extreme forms of behavior (e.g., too much aggressive behavior). Determining when the 'line' of dysfunction has been crossed is even more difficult in the case of children, since development is not a uniform process in all children in any event. It is also often the case that the child him/herself does not have the insight to recognize that there is a problem and so adult caregivers (e.g., parents, teachers, extended family) in the child's life determine if behavior is abnormal. Aside from potential conflicts in the opinions of caregivers of what is normal or abnormal behavior, one must take into consideration the

developmental stage of the child. For example, while some behavior may be abnormal behavior for a preteen, it may be quite normal for a preschooler. Further, developmental stages only roughly correspond to age. Gender, culture, and other individual differences also affect the progression through developmental stages and so it is difficult to determine when each individual child should be at a particular developmental stage.

It has been suggested that diagnoses do not reflect the real world of psychopathology, but rather society's beliefs about and experience of abnormal behavior. Critics of diagnosis have pointed out that the 'emergence' of new disorders and deletion of others reflects changing societal values, rather than scientific advances that could validate such changes. For example, the diagnosis of homosexuality has had an interesting history within the DSM system. Homosexuality was defined as a psychopathology diagnosis in the DSM-II. By the time of the DSM-III in 1980, only 'ego-dystonic homosexuality' (i.e., sexual preference for a same-sex person, but where the individual felt that this preference was inconsistent with their own wishes) was a recognized disorder; instances where the homosexual patterns were 'ego-syntonic' (i.e., consistent with the person's wishes) was not considered abnormal. Homosexuality was totally deleted as a diagnostic label in the DSM-III-R. In contrast, the ICD-10 continues to include three related diagnostic labels: sexual maturation disorder (where an individual is confused about their gender identity or sexual orientation, resulting in anxiety or depression), ego-dystonic sexual orientation (similar to ego-dystonic homosexuality), and sexual relationship disorder (in which gender identity or sexual orientation is responsible for relationship difficulties with a sexual partner). It has been pointed out that this evolution of approaches to homosexuality mirrors a growing recognition and acceptance of homosexuality in Western society. It has been argued, therefore, that the changing diagnoses related to homosexuality do not reflect changes in the scientific basis of that diagnosis, but rather reflect changes in the attitudes and biases that the developers of diagnostic systems share with society at large.

At the scientific level, the major issues for categorical systems of psychopathology relate to the internal consistency and reliability of diagnostic categories. If a perfect diagnostic system existed, then every person with psychopathology should be captured in the system, and every trained diagnostician should recognize an individual's unique diagnoses in a manner consistent with other diagnosticians. Research on these issues suggests that our current systems, although better than their precursors, do not closely approximate these goals. Clearly, further research and development is needed to clarify why consistency and reliability have been elusive.

Finally, there have been ethical arguments raised about the practice of diagnosis. It has been argued that diagnosis is an artificial process of labeling people, and that labels are not taken as descriptions of the individual's current functioning, but rather become long-term crosses for the individual to bear. These abuses of the diagnostic process have been used by some to argue that the utility of diagnosis is more than offset by its costs, and should be abandoned.

Dimensional models view psychopathology as deriving from underlying dimensional constructs that explain both normal and abnormal functioning. For example, it is possible

Figure 1 A dimensional approach to dependency.

to imagine a construct called interpersonal dependency. At one end of this construct is extreme dependency, as would be marked by such thoughts as being insufficient without others, having to have others around to feel comfortable, and marked by such behavior as seeking out others to be with, talking to others, etc. At the other end of this construct is interpersonal independency, which would be marked by such thoughts as never needing others, having to be alone to feel comfortable, and such behaviors as spending time alone, not starting conversations with others, etc. A person functioning at either end of this dimension would be considered dysfunctional, while a wide range of normal dependency–independency lies between these extremes.

Research has shown that most constructs are more common at their middle range, and less common at their extremes. As such, if the constructs that are related to psychopathology could be identified, it would be possible to identify those points along the continua where abnormal or extreme patterns could be identified. For example, using the dimension of interpersonal dependency–independency, it might be possible to identify a point along that continuum where the person is either so dependent or independent it causes distress and/or interpersonal problems for the person. It would be at those points we would talk about the person crossing an imaginary line from normal to psychopathological functioning (see [Figure 1](#)).

Trait versus symptom approaches

Dimensional models of psychopathology are often one of two types. Some dimensional models focus on underlying theoretical dimensions or traits that might explain abnormal behavior, while others focus more on the range of symptoms or descriptive features of the dysfunctional behaviors themselves. There are a number of trait approaches to psychopathology, and all cannot be described here. The work of Hans Eysenck is a good example of this approach. In Eysenck's earlier research, two basic trait dimensions were related to normal and abnormal behavior. One of these dimensions was introversion–extroversion, which had extremes of high introversion (shy, retiring, isolated) and high extroversion (outgoing, sociable). The other was neuroticism, which had two extremes of stable versus unstable patterns (where instability is marked by such attributes as anxiety, physical complaints, moodiness, etc.). According to Eysenck's research, these two personality dimensions were unique from each other, and an individual's placement on each dimension reflected a basic disposition, which likely could be seen in different situations, and across time.

Within Eysenck's model of functioning, psychopathology was identified at the extremes of each dimension. He developed questionnaires to measure these dimensions, and

established normative scores, to allow clinicians to assess if an individual was in the normal range of functioning or not. Later, Eysenck added a third dimension to this model, referred to as psychoticism. This dimension was theoretically distinct from the other two, and reflected an underlying tendency toward more extreme forms of abnormal behavior, including insensitivity toward and lack of caring about others, and opposition to accepted social customs. A mental health professional using Eysenck's system to describe psychopathology would not talk about a given individual as 'extroverted,' 'neurotic,' or 'psychotic,' but would rather talk about an individual as being low or high on these dimensions. The mental health professional would know that certain forms of thought, emotion, and behavior are related to these dimensions, and would explain psychopathology in terms of these underlying trait dimensions.

Contemporary developmental models also use a dimensional trait approach to the conceptualization of psychopathology. However, not only do they view abnormal behavior on a continuum from normal to abnormal, but they consider the development of psychopathology on a continuum across the lifespan. Research on behavioral inhibition versus behavioral disinhibition serves as a good example of the dimensional developmental model. Behavioral disinhibition is defined as the inability to restrict socially undesirable actions, whereas behavioral inhibition is defined as the restriction of socially undesirable actions. While the latter may seem to be a positive trait, at its extreme it can lead to over-inhibition of a wider range of emotions and behaviors, some of which may be socially desirable. Behavioral disinhibition at its negative extreme is exemplified by psychopathological diagnoses such as oppositional defiant disorder, conduct disorder, and attention deficit hyperactivity disorder in children, or by antisocial personality disorder and substance abuse in adults. In contrast, extreme behavioral inhibition is exemplified by psychopathological diagnoses such as social anxiety disorder, generalized anxiety disorder, and major depressive disorder. A well-adjusted, mentally healthy individual would be at the center of this continuum, able to strike a balance between restricting those behaviors that are socially undesirable without restricting prosocial behaviors or becoming worried and depressed. The behavioral disinhibition dimension is not unlike a composite of Eysenck's three dimensions: extroversion, neuroticism, and psychoticism.

Research on gender differences in brain development has examined the developmental trajectory of behavioral disinhibition due to the differential prevalence of externalizing disorders and internalizing disorders in girls and boys. The externalizing disorders are typically defined as problems directed toward the environment and others, whereas the internalizing disorders are typically defined as problems directed toward inner experience. These dimensions map loosely onto the behavioral inhibition/disinhibition dimensions mentioned above; the internalizing disorders correspond to those disorders listed at the extreme end of the behavioral inhibition dimension, and the externalizing disorders correspond to those disorders listed at the extreme end of the behavioral disinhibition dimension.

It has been found that boys have much higher rates of the externalizing disorders, and girls have much higher rates of the internalizing disorders. That said, the gender difference in

the prevalence of externalizing disorders is generally apparent from a young age, whereas the gender difference in the prevalence of internalizing disorders tends to emerge at puberty. The research on gender and brain development suggests that brain maturation tends to be delayed in boys relative to girls. Advanced brain maturation results in more rapid development of abilities such as the ability to read and follow social cues, empathy, and greater emotional expression and understanding. Once again, although these traits would appear to be positive, theories postulate that extreme traits predispose girls to behavioral inhibition and internalizing disorders. Delayed neural maturation would result in the opposite of advanced neural maturation (i.e., low prosocial behavior, etc.) which may predispose boys to behavioral disinhibition and externalizing disorders.

In contrast to trait models of psychopathology, there are symptom dimensional approaches. For example, there are 11 recognized personality disorder diagnoses within the DSM-IV-TR. As is true for other diagnostic categories, DSM-IV-TR lists the descriptive features of these disorders, and presents them as unique (although a given individual could have 'comorbidity,' in which the person qualifies for more than one diagnosis simultaneously). An alternative perspective is to conceptualize personality as having a number of dimensions, which at their extreme represent dysfunctional patterns of interpersonal relating. Such an alternative approach would view personality features in terms of their symptoms, as well as in terms of the severity of these symptoms. In recent years, there has been considerable discussion about a dimensional model referred to as the 'Big Five' or the 'five-factor' model of personality. This model was derived from research on normal personality and describes five personality dimensions on which people can be rated: extraversion (active, loquacious, and assertive, vs. reticent, silent, and passive); agreeableness (warm, kind, and trusting, vs. mistrustful, hostile, and egocentric); conscientiousness (dependable, organized, and thorough, vs. unreliable, imprudent, and negligent); neuroticism (nervous, irritable, and emotionally labile vs. even-tempered); and openness to experience (creative, imaginative, and inquisitive, vs. petty and imperceptive). While we will not discuss the adequacy of this model here, it is important to note that many theorists are beginning to converge on the importance of these five factors in personality. Further, one of these dimensions – neuroticism – is explicitly oriented toward identifying abnormal neurotic behavior (anxiety, physical complaints, nervousness, edginess).

Both the categorical and dimensional approaches to psychopathology face the issues of comprehensiveness and distinctiveness. How many diagnoses or dimensions, respectively, adequately account for the range of human dysfunction? Are these distinct diagnoses and dimensions, does their overlap call into question the theoretical basis for the approach to psychopathology? Despite the above issues, the Kraepelinian model of psychodiagnosis is dominant, and unlikely to be supplanted.

Assessment

The nature and severity of the problem must first be assessed, to proceed with the appropriate treatment. Assessment can be defined as the process of collecting information about an

individual in a systematic and objective way. There are several different kinds of information that can be collected, dependent on the purpose of the assessment and the hypothesized problem. Among the various pieces of information that may be of interest are the individual's intellectual functioning, behavior, cognition, personality, and emotions. Although the purpose of assessment is often seen as diagnosis, diagnosis is not always the end result. Assessment can also inform case planning, prediction, and prognosis, as well as provide descriptive information.

There are several assessment methods available to the psychodiagnostician. The three most commonly used methods are interviews, behavioral observation, and psychological testing. Other methods such as neuropsychological testing and collateral reports (i.e., information obtained from outside sources such as grades or hospital charts, or interviews with significant others in the individual's life) are also common, but used only in specific circumstances. For example, neuropsychological testing is typically only used when brain damage is suspected, and collateral reports are typically obtained when the information provided by the individual is not sufficient. While some diagnosticians use only one assessment method, comprehensive assessments that involve multiple methods are generally preferred. Such an assessment may include a clinical interview, review of the hospital chart, and a battery of psychological tests selected based on the reason for referral, the psychometric properties of the tests, and the practitioner's training, experience, and familiarity with the relevant literature. The psychometric properties of tests are the reliability and validity of the tests. Strong reliability and validity are determined by empirical assessment of the tests. While reliability and validity have diverse definitions, reliability can generally be defined as the degree of stability, consistency, predictability, and accuracy of the test. On the other hand, validity can be defined as how accurately the test measures the variable it was intended to measure.

Interviews

Clinical interviewing helps to both establish rapport and obtain information. There are three general types of clinical interviews: unstructured, semistructured, and structured interviews. Unstructured interviews are free-flowing, and are generally guided by the client. The interviewer does not prepare a list of set questions in advance, but rather begins with a general question and allows the client to determine the content of the interview, and then uses probes to gather more information on certain topics. Structured interviews consist of a precise set of questions, with specific wording. The interviewer follows a script and takes responsibility for guiding the interview in order to obtain the specific requested information.

Semistructured interviews are structured, in that they provide a set list of questions; however, the client's responses to the questions will lead the interview in different directions. For example, if a client responds 'no' to questions about the two key diagnostic criteria for depression, the interviewer may discontinue assessing for depression and proceed to ask questions about the next diagnosis under investigation. The Structured Clinical Interview for DSM-IV Axis I Disorders (SCID-I), the Autism Diagnostic Interview Revised (ADI-R), and mental status exams are good examples of semistructured interviews.

There are advantages and disadvantages to each type of interview. The risk in conducting an unstructured interview is that interviewer biases may affect the direction of the interview and the interpretation of the results. For example, the interviewer may focus on one outstanding piece of information provided by the client and make global inferences from that piece of information, about the client, without adequate further inquiry. Alternatively, the interviewer may exercise a confirmatory bias, by making an inference about a certain topic and asking questions to confirm the inference. Last, the interviewer may infer certain personality traits in the client based on limited situational information. Unreliability in structured interviews can derive from an inappropriate choice of interview that does not target the real issues at hand, inaccurate observations on the part of the interviewer, differences in the criteria assessed by the interview and the diagnostic nomenclature, and inaccurate or selective information provided by the interviewee. Structured interviews pose less of a threat of lack of reliability, but they take longer to conduct. Further, unstructured interviews are superior to structured interviews because they permit the development of rapport between interviewer and interviewee. The choice of interview should be selected based on the purpose of the assessment and the training of the diagnostician.

Psychological Tests

Psychological tests vary widely in method and scope. There are psychological tests to assess intelligence, cognition, a range of symptoms for a particular diagnosis, emotion, personality, behavior, neuropsychology, etc. Psychological tests can be used for a variety of purposes, including treatment planning, informing diagnosis, case conceptualization, and determining treatment progress or current functioning. Appropriate test selection involves consideration of such factors as the theoretical construct the test is supposed to measure, the validity of the test, whether or not the test was appropriately standardized (i.e., Was the population the test was standardized on similar to the population being tested? How well do the instructions allow for standardized administration? Was the size of the standardization sample adequate?), the reliability of the test and practical considerations such as reading level, and the duration of the test (i.e., can the client sustain attention for long enough to complete the test).

A diagnosis is rarely made on the basis of psychological testing, as most tests do not assess all of the various symptoms of a particular disorder. Rather, they provide information on one or a few symptoms, or related traits. The Wechsler Intelligence Scales (adult and child versions) are a good example of well-used tests that provide one piece of information that may contribute to a diagnosis (e.g., autism) in conjunction with other information. The Minnesota Multiphasic Personality Inventory (MMPI), the Hamilton Rating Scale for Depression (HAM-D), and the Beck Depression Inventory (BDI) are other examples of tests that are frequently used in conjunction with other information to provide a diagnosis. In addition, the HAM-D and BDI are often used in both research and clinical practice to assess treatment progress. A listing and descriptive information for all published questionnaires and psychological tests can be gained by examining the *Mental Measurements Yearbook*, which is an annual publication of the Buros Institute.

Behavioral Observation

Behavioral observation is concerned with determining antecedents or determinants of behavior, as well as its consequences, in other words, the situational determinants of behavior. Behavioral observation is a functional, utilitarian approach in that it focuses on the clearly observable ways in which the client interacts with his or her environment. Behavioral observation may be used informally as part of an interview or in a testing session, or as a method in its own right. Behavioral observation may be the most informative type of assessment in certain cases, such as with very young children, the developmentally disabled, resistant clients, and clients lacking in insight. Behavioral observation may be conducted by the psychodiagnostician, by other individuals in the client's life (e.g., teachers, parents, spouses, other caregivers), or by the client themselves through self-monitoring.

The first step in behavioral observation is to select a target behavior, or set of target behaviors related to the problem behavior, for observation. There are then several recording methods from which to choose depending on the goal of assessment, the nature of the target behavior and the practicality of the method for the particular client. Narrative recording is what is frequently done during other psychological testing as an additional source of information. It involves simply taking note of any behaviors of interest. There is a lot of flexibility in terms of how descriptive or inferential the recording is, and little quantification is used. Interval recording, also referred to as time sampling, interval sampling, or interval time sampling, involves recording selected behaviors within a predetermined time interval (e.g., for 5–30 s every 5 min). Interval recording is used, for example, with behaviors such as walking, listening, or playing because they occur with moderate frequency and do not have a clear beginning or end. As opposed to using a predetermined time interval as a guide for recording, event recording relies instead on the occurrence of the behavior itself to record details of the behavior such as frequency, duration, and intensity. Behaviors of low frequency are best suited to event recording. Last, ratings recording is more general and global than the previously described methods; the evaluator provides a rating of a particular behavior, in terms of frequency or quality, after a defined period of observation. The advantages to ratings recording are that it can be applied to a wide variety of behaviors, it can be statistically analyzed, it is time-efficient, and the ratings can be made for individuals or groups.

Considerations for Assessment

The selection of an assessment strategy requires consideration of the needs of the client and the referral source. It would be inappropriate to ask that a client complete a number of superfluous questionnaires or undergo testing that is not directly relevant to the referral question. In addition, it is important that the diagnostician recognizes his/her role in the assessment process. Assessment goes beyond description into interpretation; put otherwise, assessment is not simply the accumulation of data, but rather includes the integration and interpretation of data to address specific questions for a specific purpose (e.g., case conceptualization, treatment planning, diagnosis, etc.). As such, psychodiagnosticians are intimately involved with

the data analysis process and outcome, and their own biases, strengths, and weaknesses are reflected in the assessment process and outcome.

Diagnosticians must recognize that their reports can have wide-ranging effects on their clients. In order to remain responsible to their clients, they must recognize their role, educate others, and stay within their limits of competence. They must also recognize and inform their clients that an assessment is one 'snapshot' of functioning, and cannot capture the person's lifetime functioning or the individual in their entirety. While clinical interviewing tends to be performed by a variety of mental health professionals (psychiatrists, psychologists, psychiatric nurses), psychological testing is almost exclusively administered and interpreted by clinical psychologists, sometimes with the assistance of a psychometrician.

Glossary

Absolute threshold Traditional term for the magnitude of a stimulus that is just discriminable from its null.

Accuracy Denotes how close a psychophysical measurement is to its physical representation.

Adaptive procedure Method for estimating the parameters of a psychometric function (PF) in which the stimulus magnitude on each trial is based on the observer's responses on previous trials, such that the amount of information gained from the trial is optimized.

d' (d -prime) A measurement of observer sensitivity or stimulus discriminability derived from Signal Detection Theory.

Difference threshold Traditional term for the magnitude of a stimulus difference that is just detectable when both stimuli are above detection threshold.

Discriminand One of the stimuli in a discrimination experiment.

Discrimination scale A perceptual scale derived by integrating JNDs. Also termed a Fechnerian scale.

Fechnerian scaling The method of deriving a perceptual scale by adding up or integrating discrimination thresholds (or JNDs).

Just-noticeable difference (JND) The smallest difference in stimulus magnitude that is just discriminable.

Perceptual scale The function describing the relationship between the perceived and physical magnitudes of a

stimulus dimension. Examples are perceived contrast as a function of contrast, perceived velocity as a function of velocity, perceived depth as a function of retinal disparity.

Point of subjective equality (PSE) The physical magnitude of a stimulus at which it appears perceptually equal to that of another stimulus. An example is a stimulus with, say, a contrast of 0.5 that appears to have the same contrast as a larger stimulus with, say, a contrast of 0.4.

Precision (of psychophysical measurement) The inverse of the variability of a psychophysical measurement. The measure of variability may be the slope of the psychometric function or the standard deviation of a set of measurements.

Psychometric function A function that describes the relationship between observer response and stimulus magnitude.

Signal detection theory A theory of how observers make perceptual decisions based on the premise that the internal representation of a stimulus magnitude is a sampling distribution with a mean and a variance.

Threshold The difference in magnitude between two stimuli or stimulus states needed to make them just discriminable. Examples are a contrast detection threshold, a contrast discrimination threshold, and the threshold for binocular rivalry.

Psychophysics is the primary scientific tool for determining how the physical world of colors, sounds, odors, movements, and shapes translates into the sensory world of sight, hearing, touch, taste, and smell. The advantages of psychophysics over other methods for studying sensory behavior are that it is non-invasive, is able to provide large amounts of data in a relatively short time, and measures behavior under relatively normal sensory conditions. Gustav Fechner (1801–1887) is widely credited with being the father of psychophysics, and his *Elements of Psychophysics* set out the principles behind the various procedures used to map the relationship between matter and mind. Fechner launched psychophysics not just as a methodology but as a research area in its own right, and new psychophysical procedures, new methods for running psychophysical experiments, and new methods for analyzing psychophysical data are in constant development. Although this article concentrates on psychophysics as applied to vision, the concepts and procedures described are applicable to all sensory modalities.

Components of a Psychophysical Experiment

A psychophysical experiment consists of the following components: *stimulus*, *task*, *method*, *analysis*, and *measure*. The stimulus

is the least generic component since it must be individually tailored to the specific question about sensory function being asked. Since the advent of digital computers, psychophysical stimuli are typically generated by a computer and presented on a device such as (in the case of vision experiments) a CRT (cathode-ray tube) monitor. The psychophysical *task* is the 'action' the observer must perform on each trial, for example selecting a stimulus from the two presented, pressing a button as soon as the stimulus is detected, or recognizing an object. The *method* refers to the way the stimuli are presented and the manner in which the observer's responses are recorded. For example, with the *method of adjustment* the stimulus is adjusted by the observer via a dial or keypad until a prespecified criterion is met, whereas with the *method of constants*, the stimuli are preselected by the experimenter and presented to the observer, typically in random order using a forced-choice paradigm (see section '[Varieties of Psychophysical Procedure](#)').

The term *analysis* refers to how the psychophysical data are converted into measurements. For example, with the method of adjustment, an observer's settings might be averaged to obtain an estimate of a threshold. On the other hand, using a forced-choice procedure in conjunction with the method of constants, the proportion of correct scores may be fitted with a function whose shape is chosen to approximately match the data.

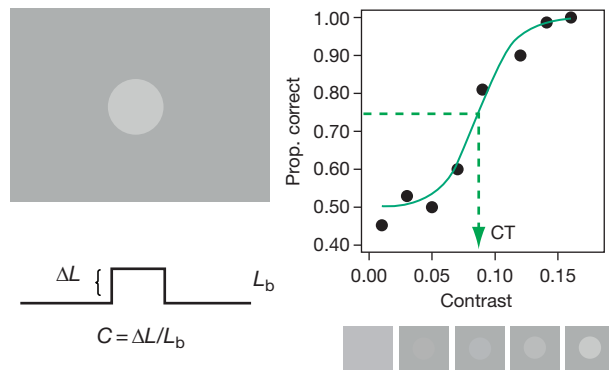

Figure 1 Example of psychophysical experiment to measure a visual contrast detection threshold. Top left: circular test patch on a uniform background. Bottom: luminance profile of patch and the definition of contrast C . Right: results of a standard two-interval forced-choice (2IFC) experiment. The various stimulus contrasts are illustrated on the abscissa. Black circles give the proportion of correct responses for each contrast. The green line is the best fit of a psychometric function, and the calculated contrast detection threshold (CT) is indicated by the arrow. See text for further details. L = luminance; L_b = luminance of background; ΔL = difference in luminance between patch and background; C = Weber definition of contrast. Reproduced with permission from Kingdom FAA and Prins N (2010) *Psychophysics: A Practical Introduction*. London: Academic Press.

The *measure* is the result of the analysis. Examples of measures are thresholds, reaction times, and proportion correct. The term *procedure* is used ubiquitously in psychophysics and can refer variously to the task, method, analysis, or some combination thereof.

Figure 1 illustrates some of these components for an experiment aimed at measuring a contrast detection threshold for a circular patch on a uniform background. The hypothetical data are obtained using a two-interval forced-choice (2IFC) procedure in conjunction with the method of constants. On each trial, two stimuli, one the patch the other a blank field, are presented in random order, and the observer chooses the interval containing the patch. Each point in the graph gives the proportion of correct responses for each patch contrast and the resulting psychometric function has been fitted with a logistic curve. The contrast threshold is estimated from the curve as the patch contrast producing 0.75% or 75% correct detections.

Classification of Psychophysical Experiments

This section considers the main ways in which psychophysical experiments have traditionally been classified.

Class A Versus Class B

An influential dichotomy introduced some years ago by Brindley is that between Class A and Class B psychophysical observations. Brindley used the term ‘observation’ to describe the perceptual state of the observer while executing a psychophysical task. The distinction between Class A and Class B attempted to identify how directly a psychophysical observation related to the underlying mental process involved.

For Brindley, a Class A observation refers to the situation in which two physically different stimuli are perceptually indistinguishable, while a Class B observation refers to all other situations. A prototypical Class A observation is the metameric match in color vision, in which the intensities of two colors in a mixture (say red and green) are adjusted until the mixture looks identical to a third test color (say yellow). The identification of an observation as Class A accords with the idea that when two stimuli look identical to the eye they presumably elicit identical neural responses in the brain. As the neural responses are identical, Brindley argues, it is a relatively straightforward matter to map the physical characteristics of the stimuli onto their internal neural representations. Other forms of Class A observations include thresholds, such as the contrast detection threshold (see **Figure 1**) and bisection acuity, in which a line must be bisected.

Class B psychophysical procedures include magnitude estimation, in which observers provide numerical estimates of perceived stimulus magnitude, and most types of matching experiment. For example, in an ‘asymmetric’ brightness match, the observer adjusts the luminance of a patch until it matches the brightness (perceived luminance) of another patch with a different surround. This is a Class B experiment because the two patches are always perceptibly different due to the fact that their patch surrounds are perceptibly different, even though the patches themselves are matched in brightness.

Type 1 Versus Type 2

An important distinction in psychophysics is between experiments for which there is a correct and an incorrect response on each trial, termed Type 1, and experiments for which there is no correct and incorrect response on each trial, termed Type 2. With Type 1 experiments, there is an external physical standard against which the observer’s response is judged; for example, the stimulus really was present, or the face was really was that of Abraham Lincoln. With Type 2 experiments, there is no such external physical standard, only an internal standard. For example, the color mixture only appeared to be identical to the single-color stimulus, or the face only appeared to look unhappy. In Type 1 experiments, observers may be provided with feedback during an experiment, such as a tone for a correct and/or a buzz for an incorrect response. Some researchers prefer Type 1 to Type 2 procedures because they regard them as more objective. However, a great deal about sensory function has been learnt from Type 2 experiments. For example, perceptual scales, which map the relationship between the perceived and physical magnitudes of a stimulus dimension, are primarily derived from Type 2 experiments (see section ‘Varieties of Psychophysical Procedure’).

Performance Versus Appearance

A distinction closely related to but not synonymous with Type 1 and Type 2 is performance versus appearance. Performance experiments measure *aptitude*, that is, ‘how good’ an observer is at a particular task. For example, if observer A’s threshold for discriminating two stimuli is lower than observer B’s threshold, one can say that observer A’s performance at the task is better than observer B’s. Examples of performance

experiments are those that measure detection thresholds, discrimination thresholds (or 'just-noticeable differences' (JNDs)), reaction times, proportion of correct responses, and precisions (the inverse of the amount of response variability). Appearance experiments on the other hand measure the *apparent magnitude* of some stimulus dimension, and appearance measures cannot meaningfully be judged as 'better' or 'worse' than any other measure. Examples of appearance experiments are matching the brightnesses of two patches with different surrounds, selecting the computer sketch of a stimulus that best matches its appearance, and labeling the most salient parts of an image of a natural scene. Two broad classes of appearance experiments are matching and scaling (see section '[Varieties of Psychophysical Procedure](#)'). Matching experiments measure points of subjective equality (PSEs) between physically different stimuli. Scaling experiments determine the relationship between the perceptual and physical magnitudes of a stimulus dimension, for example, that between perceived contrast and physical contrast, hue (or perceived chromaticity) and wavelength, perceived velocity and physical velocity, and perceived depth and physical depth. The relationship between performance and appearance measures of sensory function is a complex one but is critical to our understanding of the relationship between psychophysical measurement and sensory function.

Forced-Choice Versus Non-Forced-Choice

Forced-choice procedures are used extensively in psychophysics. The term 'forced-choice' as used here refers to any procedure in which the observer is required to choose from among two or more possible responses on each trial. It should be noted that in the literature on Signal Detection Theory, the term forced-choice tends to be restricted to procedures in which the observer chooses between two or more *stimuli* on each trial. Examples of forced-choice tasks are deciding whether a stimulus is in front or behind the background; deciding which of two stimuli, a blank field or patch, contains the patch; deciding which of two patches is brighter; deciding which of three lines, two oriented -5° and one oriented $+5^\circ$, is the -5° line. Typically at the end of a forced-choice experiment, the proportion of trials in which one response was given over the other(s) is recorded for each stimulus. These proportions may be used to derive performance measures such as proportion correct and thresholds, or appearance measures such as PSEs.

Criterion-Free Versus Criterion-Dependent

Some psychophysical procedures are prone to the effects of observer bias, and may entail the need for special measures. The best-known example of this is the yes/no task, in which a single stimulus is presented on each trial and the observer reports whether it contains the target. Different observer criteria lead to judgments being biased toward responding 'yes' or 'no' irrespective of the actual strength of the target signal. If a strict criterion is adopted, the signal must be relatively strong for the observer to respond 'yes,' whereas if a loose criterion is adopted, a weak signal is sufficient. The adoption of a particular criterion might result from an unconscious bias, or it might be part of a conscious strategy. For example, observers might

consciously bias their responses toward 'yes' because they want to maximize the number of correct target detections or 'hits,' even if this results in many false alarms, that is, 'yes' responses when the target is absent. On the other hand, observers might consciously adopt a strict criterion in order to minimize the number of false alarms, even if this means fewer hits. 2IFC tasks can also be prone to bias, but the bias is toward responding '1' (first interval) or toward '2' (second interval). This type of bias is less common than that observed in yes/no experiments, because with 2IFC, the two response choices are on an 'equal footing': the observer knows that on every trial the target will be present, so the option of consciously trading off hits and false alarms does not generally arise. The branch of psychophysics termed Signal Detection Theory has developed analytical tools for decoupling the effects of bias from the observer's actual sensitivity to the target in yes/no and other types of forced-choice experiment, and provides bias-free measures of performance such as d' (' d -prime').

Detection Versus Discrimination

The term detection is most commonly used to characterize experiments that measure thresholds for detecting the presence of a stimulus. For example, a contrast detection threshold is the minimum amount of contrast needed for a stimulus to be just visible, and a line curvature detection threshold is the smallest amount of curvature in a line required to make it just discriminable from a straight line. Discrimination on the other hand is generally used for experiments that measure the minimum perceptible difference between two stimuli that are both above their individual detection thresholds. Thus, in a curvature discrimination experiment, both stimuli in the forced-choice pair are curved and the observer decides which one is the more curved. However, the terms detection and discrimination are often interchangeable. Two terms closely related to detection and discrimination are 'recognition' and 'identification.' Both tend to be used to denote experiments involving relatively complex stimuli such as faces, animals, and household objects, where the task is to select from two or more objects, one either recently shown or previously memorized.

Threshold Versus Suprathreshold

A threshold is roughly defined as the stimulus magnitude that results in the perception of a new stimulus state. Traditionally, psychophysical thresholds have been divided into two categories: 'absolute' and 'difference.' An absolute threshold is the magnitude of a stimulus that enables it to be just discriminated from its null, as exemplified by a contrast detection threshold ([Figure 1](#)). A difference threshold on the other hand is the magnitude of stimulus difference needed to make two stimuli that are above their individual absolute thresholds just discriminable, as exemplified by a contrast discrimination threshold. These thresholds are performance measures. Not all thresholds are performance measures however. Binocular rivalry is said to occur when two stimuli presented separately to the two eyes are perceived to alternate in dominance. A threshold for binocular rivalry can be defined as the minimum physical difference between the stimuli needed to produce rivalry. This is an appearance measure.

The term suprathreshold has more than one meaning. Sometimes, it means any nonthreshold experiment, task, procedure, or measure. According to this usage, a simple matching experiment involving two visible stimuli is suprathreshold, but the curvature discrimination experiment described earlier is not because it measures a threshold. More often, however, the term suprathreshold refers to any experiment/task/procedure/measure that involves stimuli that are individually above their own detection threshold, irrespective of whether or not a threshold is being measured. According to this usage, the curvature discrimination experiment is also suprathreshold.

Varieties of Psychophysical Procedure

General Methods

The most basic method is the *method of adjustment*, in which the test observer adjusts the magnitude of a stimulus dimension, for example using a key-press, until some prespecified criterion is reached. The method of adjustment is most commonly used for appearance-based tasks, for example to measure PSEs. Although the method of adjustment is rarely used in performance-based experiments because forced-choice procedures are generally regarded as superior, the method of adjustment can be a useful way of obtaining a rough estimate of the measure in order to guide the choice of stimulus levels for a forced-choice procedure, a prudent strategy when there are a large number of different conditions.

A variation on the method of adjustment is the *method of limits*. Although rarely used these days, this procedure is a quick method of obtaining a rough estimate of a threshold and may be the most suitable method in situations where the experimenter needs to maintain close verbal contact with the observer. A verbal report, may be the only possible response with young children or clinically impaired persons, or indeed in any circumstance where it is difficult for the observer to be 'in the driving seat.' With the method of limits, the observer is presented with a series of temporally or spatially demarcated stimuli in increasing (ascending method of limits) or decreasing (descending method of limits) magnitude, including sometimes the null or baseline stimulus at one end of the stimulus continuum. On each presentation, the observer is required to report 'yes' or 'no' depending on whether the stimulus appears noticeably different from the null or baseline. The threshold in each case is measured as the stimulus magnitude at which the response switches from 'no' to 'yes' and/or vice versa. This is a Type 2 performance procedure because the observer's response cannot be evaluated in terms of whether it is correct or incorrect. Typically, the ascending and descending series are presented alternately and the thresholds from each averaged.

A potential disadvantage of the method of limits is that the observer may become accustomed to reporting that they perceive (or do not) a stimulus and as a result continue to give the same report even at stimulus magnitudes that are higher (or lower) than the 'real' threshold. This is termed the error of habituation. Conversely, the observer may anticipate that the stimulus is about to become detectable, or undetectable, and make a premature judgment. This is called the error of expectation. Errors due to habituation and expectation may

be minimized by averaging thresholds from ascending and descending series.

The standard method for presenting stimuli in forced-choice procedures is the *method of constant stimuli*, or simply 'method of constants.' In this method, the stimulus magnitude on each trial is selected, typically at random, from a predefined set. With a performance-based experiment, the set of stimulus magnitudes is typically chosen to straddle the expected threshold so that performance will range from near-chance to near-100% correct. This strategy generates data that, when fitted with the appropriate psychometric function, provides the most accurate estimates of the threshold as well as other parameters such as the slope of the psychometric function. The choice of stimulus set usually requires pilot work to obtain a rough estimate of the threshold, and the method of adjustment is sometimes useful for this purpose. The method of constant stimuli can also be used in conjunction with appearance-based procedures. For example, with forced-choice matching experiments aimed at measuring a PSE, all the above considerations equally apply, though the data here are not proportions correct but proportions of one stimulus being chosen over another.

To avoid the problem of selecting an inappropriate wrong range of stimuli when using the method of constants, an *adaptive (or staircase)* procedure is often employed instead. In an adaptive procedure, the stimulus magnitude on each trial is selected by an algorithm that analyzes the previous observer's responses, in order to 'zero in' on the threshold. Some adaptive procedures can be used in conjunction with conventional methods for fitting psychometric functions, enabling estimates of both the threshold and slope to be obtained. Adaptive methods can be used in conjunction with both performance-based and appearance-based tasks.

Forced-Choice Performance Procedures

Whether used in conjunction with the method of constant stimuli or an adaptive method, performance-based forced-choice tasks (all Type 1) come in different varieties. All forced-choice tasks may be termed by the generic acronym AFC (alternative forced-choice), or IFC (interval forced-choice), which is reserved for procedures in which the stimulus alternatives are presented in temporal order. The two acronyms are invariably prefixed by a number, usually the number of stimulus alternatives presented on each trial. The main varieties of performance-based forced-choice task are yes/no, symmetric 1AFC, 2AFC, MAFC, same-different, oddity, and match-to-sample. These are schematized in [Figure 2](#) for a task in which the observer is required to discriminate the orientation of a patch of grating (an arrangement of alternating dark and bright bars). In the yes/no task, termed here 1AFC, one of two stimulus states, 'target-present' or 'target-absent,' is presented on each trial, and the observer indicates whether the target is present. Symmetric 1IFC tasks are those in which the stimulus is selected from two that are in a metaphorical sense mirror-opposites, for example a left-oblique- and a right-oblique-oriented pattern.

2AFC procedures are the most popular procedure in psychophysics. In this procedure, two stimuli are presented on each trial, one of which is the target, and the observer must select the target. In an MAFC task, M stimuli are presented per trial, where $1 < M < \infty$, and with one stimulus being target,

and the observer must select the target. Same–different tasks come in two main varieties. In one variety, two stimuli are presented on a trial and the observer decides whether they are the ‘same’ or ‘different.’ In another variety of same–different, two *pairs* of stimuli are presented on each trial, one pair being the same, the other different, and the observer selects the pair that is different (or same). Oddity tasks involve three or more stimuli per trial, all but one of which are the same, and the observer chooses the ‘odd-one out.’ Match-to-sample tasks present a ‘sample’ stimulus, as well as two or more ‘match’ stimuli, one of which is the same as the sample, and the observer selects the match that is perceived to be the same as the sample. The same–different, oddity, and match-to-sample tasks offer an important advantage over other types of forced-choice tasks in that the observer does not need to know the basis on which the discriminands (the stimuli to be discriminated) differ.

Scaling Procedures

Perceptual scales describe the relationship between the perceived and physical magnitudes of a stimulus dimension. There are three types of perceptual scale relevant to psychophysics: ordinal, interval, and ratio. Ordinal perceptual scales rank-order stimulus magnitudes according to perceived

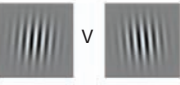

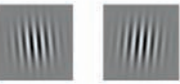

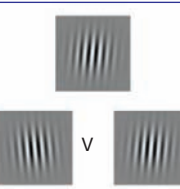

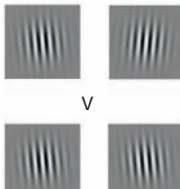

<i>N</i>	Task name	Stimuli presented during trial	Task
1	1AFC symmetric		Respond ‘left-oblique’ or ‘right-oblique’
2	Standard 2AFC		Select stimulus that is left-oblique
2	1AFC same–different		Respond ‘same’ or ‘different’
3	3AFC oddity		Select stimulus that is the oddity
3	2AFC match-to-sample		Select from the two bottom stimuli the one that is the same as the top stimulus
4	2AFC same–different		Select the pair (top or bottom) that is different (or same)

Figure 2 Varieties of forced-choice procedure for the task of discriminating the orientation of two grating patches. *N* = number of stimuli presented per trial. Reproduced with permission.

magnitude. Interval perceptual scales capture both the rank order *and* magnitudes of perceived difference between adjacent pairs of stimulus magnitude along the perceptual continuum. An interval scale can be transformed without loss of information by the equation $aX + b$, where X is the scale value and a and b are constants. Interval perceptual scales do not, however, capture the *relative* perceived magnitudes of the stimulus dimension. Perceptual scales that capture relative perceived magnitude are known as ratio scales and can be transformed only by the factor aX . Perceptual scales can be one or two dimensional. An example of a one-dimensional perceptual scale is the relationship between the brightness of a patch and its luminance. The best-known example of a two-dimensional perceptual scale is a color space, such as the CIE, in which each color is defined by a point on a plane with an X and a Y coordinate, and where the distance between points corresponds to the perceived distance in hue, or perceived chromaticity. Two-dimensional perceptual scales are invariably interval scales.

Figure 3 illustrates some of the types of procedure used to derive perceptual scales. Forced-choice scaling procedures are illustrated in the upper and non-forced-choice procedures in the lower half of the figure. With *paired comparisons*, two stimulus magnitudes are selected from a prespecified range, and the observer chooses the stimulus with the higher (or lower) perceived magnitude. With the *method of triads* (or ‘triples’), one of three stimuli is designated the target, the other two the comparisons, and the observer is required to compare the perceived

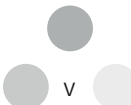

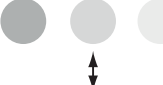

Forced-choice			
<i>N</i>	Task name	Stimuli	Task
2	Paired comparisons		Select the brighter stimulus
3	Method of triads		Select the stimulus from the bottom pair that is most similar (or most different) to the top stimulus
4	Method of quadruples		Select the pair (top or bottom) that is more similar (or more different)
Non-forced-choice			
<i>N</i>	Task name	Stimuli	Task
3	Partition scaling		Adjust middle stimulus until perceptually midway between the anchors either side
>3	Multipartition scaling		Adjust stimuli between the anchors at either end until all stimuli are at equal perceptual intervals

Figure 3 Varieties of procedure for measuring perceptual scales, illustrated for the scale of patch brightness. *N* = number of stimuli per trial. Reproduced with permission.

similarity (or difference) between the target and each of the two comparisons, and choose the pair that is the more (or less) similar. With the *method of quadruples* (or 'double pairs'), observers are presented with two pairs of stimuli on each trial, and the task is to decide which pair is the more (or less) similar. With the methods of triads or quadruples, the observer need not know the basis upon which the stimuli differ. With all these methods, the perceptual scale can be derived using statistical methods, for example maximum-likelihood fitting procedures, using the relative proportion of trials that one stimulus, or stimulus pair, is chosen over another stimulus, or another pair.

Turning to the non-forced-choice scaling procedures, a frequent method for deriving an ordinal perceptual scale is to present observers with the entire stimulus set together and to ask them to arrange the stimuli in rank order. The best-known example of this method is the Farnsworth–Munsell 100 hue test for color deficiency. Observers are presented with a randomly arranged series of disks that vary systematically along a particular color dimension (e.g., green to red) and are asked to arrange them in order according to hue (e.g., green, yellowish-green, more-yellowish-green, yellow, reddish-yellow, more-reddish-yellow, . . . , red). The resulting arrangement is compared to that typically made by a person with normal color vision. The pattern of errors made by observers with the Farnsworth–Munsell can be used to identify certain types of color deficiency. With *magnitude estimation*, the observer makes a direct numerical estimate of the perceived magnitude of the stimulus along the dimension of interest. Magnitude estimation produces a ratio scale if observers are instructed to allocate numbers that reflect the *relative* perceived magnitudes of the stimuli. In one form of magnitude estimation, the experimenter starts with a stimulus designated as an 'anchor' and asks the observer to suppose that it has a perceived magnitude of, say, 50. The other stimuli are then estimated relative to the anchor, that is, 25 (half-as-much), 100 (twice-as-much), 175 (3.5 times-as-much), etc. The scale values can then be normalized to the stimulus with lowest perceived magnitude by dividing all values by 50. Psychophysicists tend to regard magnitude estimation as a rather blunt tool because it requires observers to translate a perceptual experience into a numeric, that is, symbolic representation. Observers often find magnitude estimation difficult and unsatisfactory, and for this reason, other scaling methods are recommended wherever possible.

Partition scaling, sometimes termed '*equisection*' or '*bisection*' scaling, involves observers adjusting the magnitudes of stimuli until they appear to be at equal perceptual intervals. Partition scaling methods therefore generate interval scales. One variety of partition scaling method that is intuitively easy for the

observer but which has certain drawbacks is termed by Gescheider the '*progressive solution*.' The experimenter starts by providing the observer with two 'anchors' that define the start and end points of the stimulus continuum. The observer then divides the perceptual distance between the two anchors into two equal parts by adjusting a third stimulus to appear perceptually midway between the anchors. The resulting two intervals are then each bisected, resulting in four intervals, and so on. This method, however, suffers from the problem that errors will tend to accumulate as the intervals become smaller. Another version of partition scaling, termed by Gescheider as the '*simultaneous solution*,' presents observers with the full set of stimuli together on the display. Two stimuli at the ends of the continuum serve as anchors, and observers adjust the remaining stimuli until they appear to be at equal perceptual intervals. In general, this will not be an easy task, as adjustment to any one stimulus will tend to 'throw out' the previous adjustments, requiring a number of iterations to find the perceptually satisfactory solution.

Finally, *multidimensional scaling (MDS) procedures* are available for establishing whether two or more perceptual dimensions underlie a particular set of stimuli. The CIE color space is an example of a two-dimensional representation of perceived color similarities. MDS algorithms aim to provide an arrangement of the stimuli in which the distances between stimuli correlate with their perceived dissimilarity. The method of triads and quadruples can be used to generate the data for fitting with MDS.

Glossary

Corrective emotional experience The client is exposed, in the context of a nonjudgmental therapy relationship, to emotions and situations that they could not cope with in the past, in order to develop new perspectives and competence.

Eclecticism A recent therapeutic approach which involves integrating various elements of previously existing models of therapy.

Evidence-based practice The integration of research related to the results of specific intervention strategies with clinical expertise, in the context of a specific client's history and preferences.

Motivational interviewing An evidence-based approach to working with the person's ambivalence and facilitating change via a client-centered emphasis.

Postmodern A collaborative approach to therapy that emphasizes multiple perspectives and constantly evolving meanings (as opposed to traditional approaches that favor expert knowledge that resides with the therapist).

Psychotherapy The treatment of mental and emotional disorders by any of a variety of methods, which occurs in the context of a relationship between a trained professional and a client.

Resistance Conscious or unconscious efforts of the client to thwart the progress of therapy.

Self-actualization The lifelong process of fulfilling one's capabilities and achieving one's total potential.

Unconscious The sum of all thoughts, feelings, memories, and impulses of which an individual is not aware, but which influence emotions and behavior.

Introduction

One of the factors responsible for the rich diversity in the field of psychotherapy is the fact that therapists can receive their training in a variety of fields of study.

Such highly specialized training areas include:

- Clinical psychology
- Counseling psychology
- Psychiatry
- Educational and school psychology
- Marriage and family therapy
- Clinical social work
- Nursing
- Pastoral psychology
- Child and adolescent psychology
- Community mental health services

Therapists come to the profession with a variety of degrees, licenses, and credentials, as well as being trained in various therapeutic models. Despite the differences in emphasis and orientation among the various types of psychotherapists and psychotherapy, as well as differences in the treatment methods used, there are many areas of overlap between people trained in different fields. Regardless of background training, the common denominator between all psychotherapists is that they employ the relationship established between the client and the therapist to influence the client to modify maladaptive responses and to adopt healthier lifestyles.

The term 'psychotherapy' as used here reflects the diversity of disciplines that serve in the helping professions.

Recipients of Psychotherapy

During psychotherapy's formative years, ~1900–1950, the recipient of therapeutic intervention was typically an adult, treated in one-on-one sessions for a period of months or years. Although individual adult clients are still the most frequent recipients of psychotherapy, there has been a more recent movement toward offering therapy in other modalities, such as groups and families, and to children and adolescents.

Psychotherapy has become increasingly complex, due to the advent of new technologies such as the World Wide Web, the evolution of theory and information about specialized mental disorders, and the advances of specific treatment techniques.

Individuals

Many therapists conduct therapy with individual clients, which reflects the traditional and widespread belief that a one-on-one therapeutic relationship offers unique advantages over other types of therapy. Perhaps the strongest argument in favor of individual therapy is that it allows for an intensive focus on the subjective world of the client.

The development of a meaningful relationship with a therapist gives many clients a feeling of security which allows them to disclose material which they might be reluctant to reveal if other people were present. Therapy can offer a corrective emotional experience to address the emotional difficulties that lead to the recurrent and distressing patterns that the client suffers. In individual therapy, the client has the chance to consider issues of personal growth without outside distractions, and can

ideally experience being uniquely heard and understood in the therapeutic session.

Individual therapy is indicated for clients whose chief complaints are personal in nature, and whose complaints are such that the person has the power to do something to improve the situation. Individual therapy is also warranted for persons who wish to address distressing issues in the near or distant past, where the inclusion of other parties involved in the situation is either impossible or ill-advised (e.g., child abuse, death, or divorce). Individual therapy ideally presupposes a motivation on the part of the client to change, as well as a sufficient personal insight to make the therapeutic process useful.

Individual therapy may not be the optimal form of therapy in all cases. For example, some clients may derive greater benefit from involving family members or by participating in group therapy. Decisions about the most appropriate form of therapy are determined by a combination of the presenting problem, the therapist's experience, and the client's preference.

Families

Family therapy began to gain prominence as an alternative form of therapy to individual psychotherapy in the 1950s, essentially as an antiestablishment movement. The era was characterized by a growing dissatisfaction among some therapists with traditional forms of therapy, which tended to look at psychiatric symptoms in isolation, resulting in an emphasis on an individual's defects. The unique contribution of family therapists was their focus on understanding people's behavior in the light of their social context.

In the early stage of family therapy, perhaps borrowing from psychoanalytic/psychodynamic models, the individual's difficulties were seen as involving only that individual. A shift occurred in the second half of the twentieth century, as therapists focused on communication within the family. In the next phase, from the late 60s through mid-70s, there was a focus on the therapist as a skilled expert who strategically intervened to change the family system. Through each transition the therapist was an expert who could guide the family to adopt an appropriate model of family functioning.

In the last 20 years, there has been a strong influence of postmodern and social constructionist ideas in family therapy. The postmodern therapies challenge the idea of an independent, objective, and expert observer of the family reality. Issues of power and authority are also challenged, as the postmodern therapist encourages the recognition of multiple perspectives and multiple realities that contribute to the unfolding story of the family. The views of the client(s) and the therapist are viewed as equally valid, and it is in the constantly evolving dialog, with its emphasis on valuing the particular meanings that are attributed to the story being told, that treatment is focused.

The family has a critical role in offering support and an environment that will promote recovery and well-being. Hence, there can be particular value for all concerned if the family is involved in treatment, as all family members are affected by the illness or distress of one member.

Children and Adolescents

The specialized area of child and adolescent psychotherapy warrants a discussion of its own due to the unique

development, needs, and characteristics of children and adolescents. These needs have been highlighted by researchers, who have made important advances in the understanding of the nature and etiology of various forms of child psychopathology and healthy development. The challenge facing child therapists is to combine this growing knowledge base with the existing knowledge of developmental psychology in order to arrive at effective assessment and treatment methods for use with children and adolescents.

It is now clear that adverse outcomes in later life can often be attenuated or avoided by prompt and effective treatment of psychological difficulties detected in childhood. Trauma and abuse in the formative stages of a child or adolescent's development are especially important to consider. The provision of therapy to children and adolescents is also specialized according to the stage of development of the child or adolescent when treatment is sought. It is also important to consider the behavior, learning capacity, and social context of the child or adolescent, given that they are involved in a time of profound personal growth.

The techniques chosen for use in therapy with children take a number of forms, depending on the age and comprehension level of the child. Play therapy is often used with younger children, or older children who may have difficulty discussing troubling issues with an unknown adult. In play therapy, the therapist and the child spend time together in a play room, often moving from one activity to another (e.g., painting, puzzles, doll houses). The therapist usually makes inferences about the child's functioning on the basis of the child's play, and what the child says during the play time. The therapist also looks for 'teachable' moments which can facilitate therapeutic insight. Child therapists routinely treat children and adolescents who are depressed, have excessive fears, have been abused, have physical or mental handicaps, or have poor self-confidence. Specific problem behaviors, such as bed-wetting, biting, and temper tantrums, are also treated, and the therapist's role often involves teaching the child's caregivers how to administer a specially designed behavior modification program. 'Talking therapy' is generally more effective with older children and adolescents.

Therapists who work with children need to be mindful that children undergo developmental changes and that problem behaviors often wax and wane at different ages. The therapist must also be aware that many behaviors which may be indicative of severe maladjustment or emotional disturbance (e.g., lying, destructiveness) are also relatively common in most children. In general, the therapist needs to avoid a jump to conclusions on the basis of one or two pieces of behavioral evidence. Responsible therapy requires a thorough understanding of the child's situation, which implies a multimethod and developmental assessment approach. Such an assessment might include some or all of the following: child, parent, and/or teacher interviews; tests of cognition, personality, and academic achievement; and behavioral observation in the home, at school, and at play.

Groups

Group therapy has risen dramatically in popularity over the past 50 years, largely as the result of increasing pressure on

mental health professionals to treat growing numbers of clients. Therapists have found that group therapy can dramatically impact individual participants, yet therapists can provide service to more people than could reasonably be treated otherwise. However, the advantage of group therapy is not simply logistical. While it is true that members of a group usually do not have the luxury of exploring personal issues in the same depth that they would in individual therapy, they are rewarded in return with an expanded understanding of group dynamics and increased efficacy in interpersonal relationships.

Group therapy typically includes one therapist and six to eight clients. However, many variations of this model are offered, with common variants including multiple therapists and smaller or larger groups. Different types of clients can benefit from group therapy, and some heterogeneity among group members in terms of age, gender, and presenting problem is often considered desirable. At the same time, the group process is likely to be compromised if members represent too broad a range of functioning. The therapist must screen potential participants, with an eye to both the characteristics and needs of the individual, and the goals of the group. The therapist must also be prepared to modify the approaches and techniques normally used with groups of relatively healthy clients when forming groups consisting of clients with more severe challenges, as such groups are typically more modest in their goals.

It is advisable for the therapist to be aware of the developmental phases of a group, consideration of which will need adjustment according to whether or not it is a closed, open, or time-limited group process. A pregroup interview can be of benefit to participants to prepare for the group process and address expectations of membership. Attention to norms of group process, having a clear mandate as to the purpose and goals of the group, and ensuring that the group participants will have a sufficiently shared focus can also increase the likelihood that the membership will cohere and that a successful group experience will result. Successful group process will be realized if the experience allows participants to feel supported and accepted, less alone in their life, and that they can hope to enjoy a positive outcome.

Flexibility is required of therapists who become group leaders. The therapist with an advanced understanding of group dynamics will know that at times it is useful to be more or less active. An active therapist reduces the group's anxiety, which can be advantageous, especially in the early life of the group. However, too much activity on the part of the leader may promote the belief that the most important dynamics occur between individual members and the therapist, rather than among all the participants collectively. In contrast, a less active therapist may promote more group anxiety, but can also facilitate a group to develop a strength and identity of its own. The most effective group therapist is one who understands the changing needs of the group and is able to adapt his or her leadership style to meet those needs. Therapists must also be particularly aware of their own character traits and personal weaknesses, since it is not uncommon for therapists to adopt a leadership style based on their own needs at some point in the group process (e.g., the need to be in control or the need to appear perfect).

Basic Issues in Psychotherapy

Assessment and Therapy

Individuals who seek help from a therapist often have trouble pinpointing what is troubling them. To make the best use of the therapeutic time, the therapist conducts a thorough assessment of the client and the nature of their difficulty. The data gleaned from the assessment allows the clinician to arrive at a case formulation and provide specific directions for the therapy.

Although assessment is an ongoing aspect of therapy, the initial sessions with a new client will often focus on assessment. Adequate assessment at this stage includes the client's description of their chief complaint. The therapist should establish when the present problem began, previous occurrences of the problem, the duration of episodes, and specific symptoms. Any personal efforts to overcome the problems or prior treatment, including medications, should be investigated. Precipitating events that may have led to the current difficulties should be identified.

An assessment of the client's history often provides information to understand and help the client. The areas that are often discussed include birth history, early development, and attainment of milestones (e.g., walking, talking), relationships with parents and siblings, educational history, social contacts, and leisure activities, and occupational history and marital status.

As part of the assessment process, therapists often administer psychological tests or other assessment tools. These tests come in a variety of formats (e.g., verbal or nonverbal responses, fill-in-the-blank or complete sentences, timed or untimed) and are designed to measure a variety of aspects of psychological functioning (e.g., personality, intelligence, mood, aptitude). Established population norms are typically available for these tests, allowing the therapist to see how the client compares with his or her peers. Given the possibility of misinterpretation of statistically based data, therapists are ethically bound to administer and interpret only those tests for which they have received the requisite training.

The therapist may also seek additional data from outside sources. Potentially useful information can be provided by spouses, parents, teachers, physicians, or previous therapists. Of course, the release of such information requires the consent of the client or their legal guardian.

The Therapeutic Relationship

When one considers the strength of the arguments that are raised in favor of one theoretical orientation over another and the conviction with which they are raised, it would be easy to conclude that theoretical orientation is the most important variable affecting the outcome of psychotherapy. In contrast, one of the most important predictors of therapeutic outcome is the quality of the relationship between the therapist and the client. Good therapeutic rapport encourages clients to lower their defenses in the belief that they will not be judged or rejected, which may facilitate other therapy processes. It is unlikely that therapeutic goals will be met, even with a sound case formulation, if the quality of the relationship is poor.

The helping relationship is a unique relationship, which is not formed for social reasons, but rather to help clients achieve specific goals. The relationship is one-sided in that it is designed to meet the needs of the client, not those of the therapist. A successful therapist will do several things to establish a good relationship with a client. Most importantly, the therapist will communicate accurate empathy. Clients should feel that their concerns have been heard, clarified, and understood, and that they have been accepted despite any potential deficiencies. The therapist demonstrates care and respect through honesty with the client. An important part of honesty involves the ability to communicate feelings and intentions without distortion or facade. Such congruence between what the therapist feels, says, and does serves to establish trust and provides a model for the client to follow.

The therapist should be patient and not press for the exploration of difficult issues before the client is ready to discuss them. The relationship will also be facilitated if the therapist recognizes and acknowledges the client's strengths as well as weaknesses and works collaboratively with the client.

Resistance/Ambivalence

It is not uncommon for clients in therapy to hit roadblocks that impede their progress. Some of these roadblocks seem to be set by the clients themselves (e.g., being habitually late for appointments, missing appointments, not completing therapeutic assignments, resisting deeper levels of exploration by continually switching the discussion to trivial details or unrelated topics). The terms 'resistance' and 'ambivalence' have been used to describe these important parts of the therapeutic process, which often leave a therapist feeling confused or stymied.

In traditional psychotherapy, 'resistance' is usually seen as instinctive opposition displayed toward any attempt to expose a person's unconscious conflicts (i.e., conflicts that are so deeply rooted that the person is unaware that they even exist). Resistance is not viewed as an interpersonal problem between the patient and the therapist, but rather as a predictable demonstration of how invested the client is in trying to guard against the possibility of further pain or threat in a vulnerable area of his or her emotional life. From this view, resistance occurs when the probability of change becomes so real that the client's anxiety is aroused. Resistance thus serves as a natural signpost, telling the therapist that the material being mined is relevant. The therapist's job is not to address the resistance directly, but to use the quality of the therapeutic relationship to generate an imbalance that favors progress rather than maintenance of the status quo. The client will abandon resistant behavior when the perceived advantages of moving forward outweigh the normal anxiety associated with moving into uncharted territory.

Some therapists have argued that the concept of 'resistance' is better understood as an elaborate strategy which therapists use to explain their treatment failures (i.e., ineffective treatment is the client's responsibility, rather than a flaw in the therapist's interventions). If this view is accepted, it then becomes necessary for the therapist to move back to the assessment stage to ascertain if the correct target for intervention was originally identified. The therapist must also evaluate if

sufficient trust and rapport have developed with the client or if there is something about the client's social network which is serving as an impediment to change. The therapist should also question if incorrect techniques were used to combat the problem or if the correct techniques were incorrectly applied.

In recent years, clients who seem stuck in therapy are more likely to be conceptualized as expressing 'ambivalence' about change. This shift in terminology is deemed to be less blaming of both the client and the therapist, and reflects a growing awareness that weighing the costs and benefits of change is an important and ongoing part of the therapeutic process. Therapists who encounter ambivalence view it as a normal part of the change process that needs to be discussed, rather than pushing a client forward toward change precipitously. For example, if the client appears to be wrestling about whether or not to proceed with change, a discussion about the pros and cons of change may be indicated, with no discussion of specific action steps toward change until the client has articulated a clear desire to move in this direction.

Length of Therapy

The number of sessions devoted to a given client in a therapeutic relationship has undergone a substantial shift in recent years. Earlier therapeutic approaches, which were often largely based on the theoretical assumptions of Sigmund Freud, aimed at the resolution of unconscious conflict and the alteration of personality. Practitioners did not expect that these ambitious goals could be rapidly attained, and, as a result, patients often spent a number of years in therapy.

The current emphasis on therapy of shorter duration can be attributed to several factors. First, therapeutic approaches began to evolve after World War II to focus on specific problem behaviors or moods. Therapists who moved away from personality reconstruction as the fundamental goal of therapy found that positive changes could be realized in more limited areas of a client's functioning in much shorter time frames. This position was bolstered by research which validated the use of specific interventions to combat specific problems. Second, the advent of managed care has had profound implications for the practicalities involved in offering mental health treatment. These trends, coupled with ongoing refinements in the treatment of psychopathology, resulted in a realization that effective therapy could be accomplished more quickly than previously thought possible.

The move toward shorter therapy was also spurred on by the attitudes of the consumers of mental health services. Today's clients are often either unwilling or unable to devote several years and significant expense to psychotherapy. As the general population has become more sophisticated, their expectation of prompt, effective service has risen. This attitude is especially prevalent on the part of third-party payers (e.g., government agencies, the legal system, insurance companies), who have forced therapists to work within limited time frames as a cost-saving measure. Given the current cost of psychological care and the growing demand for mental health services, it is likely that the trend toward short-term therapy will continue.

Attention to relapse prevention can also affect the length of therapy or can lead to the conceptualization of therapy in episodic terms. Specific steps can be taken in treatment to

reduce the risk of relapse. This work can extend a course of therapy, but can also reduce the need for a new course of therapy resulting from relapse.

The length of therapy also depends on the nature and context of the presenting difficulties, the genetic vulnerability of the person, the possibly chaotic environment in which the illness incubated, the social supports available to the person over time, and the context in which the person presents for treatment.

Despite the movement toward brief therapy, a wide range of therapy durations still exist. The variables that are most likely to affect the eventual duration of therapy include the theoretical orientation of the therapist, the nature and severity of the presenting problem, the available funding for treatment, and the willingness/capacity of the client to engage in treatment.

Ethical Considerations

Ethical considerations play an important role in the way in which therapists conduct therapy. There is general agreement that therapists are in a position to wield considerable influence in their relationships with clients. A number of ethical codes have been evolved to protect against potential abuses of this power and to help clinicians make ethical decisions in specific situations.

The diverse educational backgrounds and current affiliations of therapists have made it impossible to develop one ethical code which is binding upon everyone who practices therapy. As a result, professional organizations have published their own ethical guidelines. While the details of the ethical codes vary among specializations, there are some almost universal aspects of the principles that should govern a therapist's conduct. First, therapists must be competent enough to practice by virtue of training and experience, and only provide services and use techniques for which they are qualified. Second, therapists must respect the confidentiality of all information obtained from others in the course of their work. Information may only be revealed with the consent of the client or their legal guardian, except in those unusual cases where failure to reveal information would result in a clear danger to the client or someone else (e.g., suicide, homicide, child abuse). Third, therapists must avoid any action that will violate or diminish the legal and civil rights of clients, and must adhere to government laws and institutional regulations. Fourth, therapists must make every effort to ensure that their services are used appropriately. It is considered unethical for clinicians to engage in professional relationships which limit their objectivity or create a conflict of interest. Fifth, therapists must not use their influence to exploit clients, especially in relation to sexual intimacies. Financial arrangements should be made with clients in advance of therapy, and therapy should be terminated when it is reasonably clear that the client has achieved the therapeutic goals established at the outset or when the client is no longer benefiting from therapy.

Apart from adherence to codes and laws, ethical practices are rooted in everyday relationships and interactions. Attention to how clinicians want to be with others (e.g., via ongoing examination of clinical interactions) can help therapists remain sensitive to the ethics inherent in all relationships.

Theoretical Orientations

As discussed earlier, therapists have adopted a wide variety of theoretical stances. There are dozens of separate approaches to psychotherapy today, and the techniques utilized by the advocates of these approaches number in the hundreds. For the sake of brevity and clarity, six influential approaches are presented here – psychoanalytic/psychodynamic, behavioral, cognitive, humanistic, postmodern, and eclectic.

Psychoanalytic/Psychodynamic

Psychoanalysis is the oldest recognized approach to explaining and treating psychological illness. The procedure, designed by Viennese neurologist Sigmund Freud, entails investigating mental processes by means of free association, dream interpretation, and other methods thought to provide the therapist with access to the client's unconscious mind. The client is encouraged to talk about whatever they wish and to associate thoughts, feelings, and fantasies with this material. It is expected that the client will exhibit defense mechanisms (e.g., denial, repression, projection) in the course of therapy, all of which serve to protect the client against the perceived danger associated with their long-hidden impulses and affects being brought to conscious awareness.

The role of the analyst is to interpret and point out the nature of the client's hidden, unconscious conflicts, in order to make the conflicts conscious. The client thus develops insight to 'work through' these conscious conflicts, culminating in the alteration of the client's inner psychological structure. Use is also made of the client's unconscious emotional responses to the therapist (transference). For example, the client may unconsciously respond to the therapist as a father or mother figure. It is the analyst's role to interpret and point out the nature of the transference and thereby facilitate understanding of the client's unconscious feelings toward their own father or mother. Psychoanalysis generally requires a commitment of several years before the process is considered complete.

Psychodynamic psychotherapy is a direct offspring of psychoanalysis. Most of the fundamental assumptions of psychoanalysts are shared by psychodynamic therapists (e.g., the importance of bringing unconscious conflicts to light). However, there are significant differences. For instance, while psychodynamic therapy emphasizes the past and its effect on the client, it is more concerned with the person's current personality dynamics and interpersonal functioning. Therapy aims at symptom reduction and the adaptive functioning of the client, and not necessarily core personality reconstruction. The therapist often takes a more active role than the psychoanalyst, and therapy is often completed in fewer sessions.

Behavioral

A dramatic shift in the theoretical underpinnings of psychotherapy began in the 1940s and 1950s. Based on emerging results of studies with animals, a view of neurosis developed which suggested that all maladaptive behavior is learned through normal learning processes. Behaviorists denied the concept of free will, suggesting instead that behavior consists of predictable responses which are contingent upon antecedent

events, with the likelihood of a given behavior being repeated being directly related to the reinforcement received by the person for performing the behavior. For example, a parent may learn to yell at a child at the slightest provocation if the yelling is quickly reinforced by the child's compliance. As behavior came to be understood in this way, the goal of behavior therapy became the modification of specific stimulus-response connections, which was often achieved via the alteration of the reinforcement schedule.

The role of the behavior therapist is to help the client modify maladaptive learning through the learning of new, appropriate responses. Behaviorists value the therapeutic relationship, but do not see it as a sufficient cause for change. More emphasis is placed on the therapist's role as a scientist and teacher. Part of that role involves very structured history-taking and behavioral assessment by the therapist in order to determine which of the client's behaviors are maladaptive, as well as the circumstances in which they occur. In addition to the specific behaviors and their antecedents, behaviorists scrutinize the real and perceived consequences of the behavior, since these are believed to maintain the problem. Interventions are designed to break these antecedent-behavior-consequence patterns, with the evaluation of therapeutic outcomes usually being characterized by a rigorous adherence to scientific method.

Among the more well-known behavior therapy techniques are systematic desensitization, assertiveness training, and aversive conditioning. Systematic desensitization is often used to help people overcome fears and phobias. The procedure involves relaxation training and a gradual exposure of the person to the feared situation, first in the person's mind and then in real life. By alternating between relaxation and approach toward the feared situation/object, the person learns that their worst fears are not confirmed, and the power of the pattern is broken. Assertiveness training has been used to help clients gain control over those social situations that tend to evoke their problematic behaviors. A given training program may include modeling, therapist coaching, group feedback, behavioral rehearsal, and repeated practice, which together teach patients a variety of skills for coping effectively with difficult situations. Aversive conditioning involves the pairing of a problem behavior with an unpleasant punishment, which is specifically designed to replace a positive reinforcement which maintained the behavior in the past. For example, chemical agents may be given to alcoholic clients to induce vomiting immediately after taking a drink. Before long, the very thought of taking a drink will make these clients feel sick to their stomachs. Although outcome data supports the use of aversive techniques, these methods are often seen as ethically less desirable and are generally used only after other attempts at intervention have failed.

Cognitive

As the applications of behavior therapy spread, it became evident that the behavioral model was unable to account for all psychological distress, and the therapeutic pendulum, which had swung away from Freud's heavy emphasis on internal processes, began to swing back. However, rather than relying again on unconscious conflicts, many theorists began to emphasize the way in which a person's conscious thoughts

contributed to their difficulties. Cognitive therapy, developed by the psychiatrist Aaron Beck, aimed to intervene in a person's life primarily at the level of thinking, developed as a natural by-product of the cognitive model of behavior. Research data emphasizes the immense benefit that effectively utilized cognitive therapy provides for people suffering from numerous disorders.

The main assumption of cognitive therapists is that a person's feelings or behavior in response to a given situation is not predicted by the situation itself, but rather by the person's interpretation of the situation. Thus, a person could feel either relieved or despondent in the face of the death of a loved one, depending on whether the accompanying thought was "I'm glad that his pain and suffering are finally over" or "I don't know how I can live without him."

Researchers have demonstrated convincingly that certain types of psychopathology (e.g., depression and anxiety) are associated with certain types of irrational thoughts and faulty interpretations. These cognitions, which seem to surface automatically in some people when faced with certain life events, are believed to reflect a person's core self-schema. The self-schema contains a person's basic beliefs about the self, which are usually based on childhood experiences. If the childhood experiences are sufficiently problematical, the self-schema may become negative, commonly containing ideas of defectiveness or inadequacy. The self-schema provides a filter through which events are interpreted throughout the course of a person's life. For example, a woman with a negative self-schema who is passed by a friend on the street without a wave or greeting may jump to the conclusion that the friend no longer likes her, which in turn strengthens the negative self-schema and results in subjective feelings of depression.

Cognitive therapy is a collaborative endeavor in which the therapist and the client join forces to investigate and challenge the thoughts that give rise to the client's actions and emotions in everyday life. Homework assignments are often used to help clients identify their negative thoughts and to test the assumptions on which they are based. Childhood issues are discussed to help clients gain insight into the source and content of their negative self-schema. This exploration can be a very painful process, but is usually seen as a necessary step toward the alteration of the self-schema. The ultimate goal of cognitive therapy is to help clients realize that the negative beliefs about the self which were formed in childhood are not valid, thus freeing them to respond to both good and bad life events in a healthy and realistic manner.

Humanistic

Humanistic therapies arose as a reaction to the determinism which is characteristic of both psychoanalysis and behaviorism. Rather than viewing behavior as primarily determined by childhood experiences or external rewards and punishments, humanistic therapists focus on the ultimate freedom with which people have to make choices which affect their lives. People are viewed as inherently good, and the therapist's role is to create a therapeutic environment that allows the client's innate tendency toward growth to surface. Although many humanistic approaches exist, only client-centered therapy and gestalt therapy are discussed here.

Carl Rogers' client-centered therapy is the best known of the humanistic therapies. Rogers' contributions to psychotherapy are immense. Surveys of the prominent figures in the field of psychotherapy consistently place Carl Rogers first (Smith, 1982; Cook et al., 2009). Rogers believed that individuals have problems in living because others impose conditions of worth on them. As people learn that they are expected to act, feel, or think in certain ways in order to be acceptable to others, they begin to conform to those expectations, at the expense of the person's own true feelings and impulses. This process results in an impediment in the individual's natural process of growth and self-actualization.

Key components of Rogers' contributions to client-centered therapy include unconditional positive regard, empathy, and genuineness. As the client experiences unconditional acceptance, they are freed to clarify their true feelings and come to value who they really are. The therapist maintains a nondirective stance throughout this process and strives to display empathy by accurately reflecting the client's thoughts and feelings, to ultimately result in the client's increased self-understanding and renewed growth as an individual.

Gestalt therapy, developed by Fritz Perls, is based on the idea that psychological problems arise from unresolved and repressed conflicts, and that these conflicts must be uncovered and worked through in order for a person's inherent potential for growth to be released. However, rather than dwelling on the past, emphasis is placed on the client's immediate thoughts and feelings (i.e., their experience in the 'here and now'). Clients are encouraged to express themselves openly and to take responsibility for their feelings and actions. Awareness of important psychological conflicts may be heightened by having a client stage a conversation between opposing parts of the self or by conversing with an emotionally significant person who is not actually present.

Postmodern Therapies

Recent years have seen the emergence of what are referred to as postmodern theories and therapies, also referred to commonly as social constructivism. These are exemplified by such developments as Solution-Focused and Narrative Therapy. These approaches emphasize the creation of meaning via evolving dialog in a collaborative therapeutic relationship. The idea of the therapist as an outside or objective observer and an expert on change for the client, with power and authority in the therapy resting with the therapist, is replaced by a collaborative search for meaning in the therapeutic dialog.

As a solution focus suggests, the principle orientation is on solutions to difficulties, rather than an exploration of the origins or maintenance of these difficulties. Exceptions to the problematic situation, drawing on the client's own resources and accomplishments, and a tendency for a shorter course of therapy sessions also characterize solution-focused therapy.

Narrative therapy emphasizes the significance of the meaning attached to experiences and stories that the individual holds about himself or herself. People's views of themselves and the world are shaped through these complex meanings. As well, the cultural context that contributes to human thought and actions is deserving of exploration, as these contribute to a person's story. Through therapy, the individual has an

opportunity to reexamine his or her story and to co-construct a different or preferred story that is more consistent with the individual's preferred values and purposes for that individual's life.

An appreciation of gender and culture can also be included under the rubric of postmodern therapies. Feminist theory and therapy attend to the broader social issues that the client must contend with, emphasizing collaboration, respect, a focus on strengths, and sensitivity to issues of power and control in the therapeutic relationship. The importance of nonsexist language and sensitivity to the implications of domestic violence are two additional contributions that have emerged since feminist theory and therapy became prominent in the 1980s. Feminist therapy articulates the long-held concern that traditionally accepted theories reflect patriarchy and male domination.

Eclectic

The majority of therapists today do not align themselves with one particular theoretical orientation, but prefer to think of themselves as eclectic in their practice. 'Eclectic' does not imply that therapists, overwhelmed by the diversity of the approaches available to them, resort to the random use of techniques in psychotherapy. Rather, eclectic therapists endeavor to include the specific models and techniques in their practice that have demonstrated efficacy in dealing with certain types of problems and populations. For example, therapists may develop skill in motivational interviewing for ambivalent clients, dialectical-behavioral therapy when treating individuals with traumatic backgrounds or difficulties in personality development, and transdiagnostic protocols when offering therapy for clients suffering with complex eating disorders. Additionally, techniques such as mindfulness meditation, which teaches clients to stay connected to the present moment in an open, nonjudgmental way, have been found to lead to numerous health benefits, and are finding increasing traction across a variety of therapeutic models.

Factors that Contribute to Therapeutic Success

New therapeutic approaches have often risen to challenge, augment, or supplant more established models, but this pattern of 'evolution' has led some critics to question the validity of the entire therapeutic enterprise. Unfortunately, determination of the factors that contribute to therapeutic success is not an easy task. The most accurate answer is that most therapies and modalities work for many people most of the time.

We have noted a number of factors that contribute to therapeutic success. These include fundamental attention to the development of a therapeutic relationship that can be experienced by the client as engaged, empathic, respectful, and collaborative. Matching a client and their concerns with a particular type of treatment, that is known to benefit that particular cohort of people, can increase the success of the therapeutic experience. Consistent foci on the goals of therapy and treatment expectations can set the stage for success.

Studies that compare the efficacy of different types of therapy have demonstrated that some types of therapy are better for treating specific problems than others. For example,

cognitive therapy has been shown to be especially effective in the treatment of major depression, while behavioral approaches have the best outcomes with phobias. These same studies have also consistently revealed that psychotherapy clients experience greater symptom reduction than control clients who receive no treatment. It should be noted, though, that these conclusions are based on statistical probability, and a minority of people who undergo therapy will not achieve their therapeutic goals. Given that therapy usually involves therapists who try to help clients whom they have never met with problems that they have never experienced, and given that clients come to therapy with widely ranging levels of motivation, insight, and commitment to change, it is unrealistic to expect that therapy will help everyone.

A recent focus on evidence-based practice has emerged in the field of psychotherapy. A 2005 American Psychological Association Presidential Task Force on Evidence-Based Practice has supported a prior evidence-based practice policy articulated by the Institute of Medicine (2001, p. 147 as adapted from Sackett et al.). Evidence-based practice involves the integration of research related to the results of specific intervention strategies with clinical expertise in the context of the client's history and preferences. Several treatment approaches are empirically supported and are designed for use with people suffering from distinct disorders or difficulties. One point of debate in this regard is how to ensure the validity of the interventions being studied, as it is difficult to guarantee the fidelity of each clinician's adherence to a specific training model. Evidence-based interventions are increasingly being offered in the form of specific treatment manuals in an effort to ensure that therapists deliver the interventions in the way they were intended to be delivered. There is also an ongoing debate about the dissimilarity between pure conditions of research and the circumstances that the clinician experiences when meeting with the client in the therapeutic process. Nonetheless, there is an emphasis on improving patient outcomes by integrating relevant research findings with continually evolving clinical practices and respect for the context and evolving story of the client.

Psychotherapists also need to be aware of other interventions that can be an important part of the change process. For example, specific medications used in the treatment of such illnesses as schizophrenia, bipolar disorder, major depression, and obsessive compulsive disorders (OCD) are continually being developed. There is considerable data in the literature that notes the positive outcome for the sufferer when psychotropic medication is combined with a course of psychotherapy. Where there is a role for psychotropic medication in the treatment, it is important for the therapist to be aware of the involvement of the prescribing physician, and ideally to consult with them about developing a coordinated treatment plan.

Future Directions

The current limitations of psychotherapy suggest some natural directions for therapists and theorists in the twenty-first

century. Further refinements of existing theories are necessary, and an increased emphasis on the integration of theories will likely prove to be fruitful. There is also a need for increased communication and research across disciplines. For example, the interaction between biological and psychological factors in the onset and maintenance of mental disorders requires further examination. Finally, as results in these areas of theory and research are reported, steps must be taken to ensure that the gap between research and practice is bridged. This connection can occur by encouraging more therapists who understand the unique demands of the therapeutic situation to become involved in theory construction and research. An insistence on continued education for all psychotherapists would also be beneficial, and efforts to disseminate current knowledge via academic journals, core textbooks, seminars, and workshops, both within and across disciplines, should continue. To the extent that these goals are met, the field will advance in its ability to match specific interventions to the needs of individual clients.

Glossary

Alphabetic principle The concept that written symbols correspond to consonant and vowel segments (phonemes) of spoken words.

Dyslexia Unusual, persistent difficulty learning to read; genetically influenced, requiring special instruction.

Mapping Correspondence between two sets of entities that associates each member of the first set with a member of the second (as between letters and speech sounds, i.e., phonemes).

Orthography The set of letters or other symbols used in writing and their conventional arrangement in the spellings of words.

Particulate principle Natural hierarchical systems, such as chemistry, genetics, and language, conform to the particulate principle of self-diversifying systems (Ablar, 1989; Studdert-Kennedy, 2000) by which discrete units from a finite set of elements are repeatedly sampled, rearranged, and combined to yield larger units (e.g., molecules, genes, words) which are different and more diverse in function than their constituents.

Phoneme Smallest segments of speech that distinguish one word from another in a given language.

Phonemic awareness Awareness of the phonemic segmentation of spoken words and recognizing the identity of shared phonemes across words.

Phonological decoding Applying one's knowledge of the correspondences (mappings) between letters and phonemes to determine the identity of a word and its pronunciation.

Phonological processing The incorporation and reproduction of a language's sound structure in the course of learning to speak the language, in learning to read and write, and in using the language in spoken or written form.

Phonology Study of the sound patterns of language. Also the set of distinctive sounds of a specific language, their systematic patterning and organization into syllables and phrases.

Pictograph Ancient stylized picture symbolizing a word or meaning.

Protowriting Early, prealphabetic forms of writing (e.g., pictographs), lacking the scope of modern writing.

Pseudoword A letter sequence that is not a word, but conforms to the sound pattern and spelling rules of a language, hence a possible word (e.g., zaik).

Rebus Symbols or pictures that suggest the sound of the word they represent.

Syllable A unit of speech, usually consisting of a vowel and abutting consonants, if any.

Reading and Writing Exploit Distinctive Properties of Spoken Language

Although we may tend to think of our language as a unity that spans both spoken and written forms, we also appreciate that each form draws on separate abilities. There was a time when each of us could speak but not read or write, and for the human species, spoken language existed long before any form of writing that we would recognize as such. The development of writing is so large a step that it is impossible to exaggerate its importance for human cultural evolution. But writing as we know it did not appear all at once but is the cumulative result of a number of small steps.

The first step on the road to writing was the creation of visual signs, usually stylized pictures (pictographs). Unlike writing as we know it, protowriting conventions were used for signifying broad meanings, but not specific words other than names. Far from being the flexible vehicle that writing now is, the early forms were cultivated to serve narrow and specific purposes: keeping records of accounts, recording names of kings and their family trees, recording names of deities and sacred places, to name three. Although the origins of protowriting are buried in obscurity, the possibility of comprehensive, general-purpose writing seems to have been grasped comparatively recently, dating back only a few millennia at most. The several varieties of comprehensive writing were created by peoples from early

centers of civilization surrounding the Mediterranean, in Mesopotamia and the Nile Valley, in portions of east Asia, as well as sites in meso America.

We can think of the words of a language as a union of sound and meaning. Each aspect plays a role in writing. The history of writing shows a progressive trend toward innovations that gradually enabled protowriting to evolve into comprehensive writing, unlimited in scope with the potential to convey precise meanings by indicating specific words. Discovery of the rebus principle, a prealphabetic way to represent a word by using pictures or other signs to cue word sounds, was the breakthrough that opened the door to fully comprehensive writing. However, students of early writing were slow to recognize that pictographic symbols do not necessarily have a pictographic function. In a rebus, each symbol represents a syllable. The word sandwich, for example, could be cued by a picture of sand followed by a picture of a witch. Of course, the meaning of sandwich has nothing to do with either sand or witches. The word sounds that are prompted by the pictures, not their meanings, are what are being cued to convey the intended word. As a vehicle for writing, the rebus principle has limited scope. Many words in English, for example, would not lend themselves to this way of cueing. Yet, as I note in section 'A Role for Phonology in Semantically Based, Nonsegmental Writing,' the rebus principle is still used, in combination with other principles of representation, in some varieties of modern writing.

Fully expressive writing, the last stage in the evolution of writing, creates a visible, running record of speech, such that each word in a spoken message can be paired with its written word equivalent. As writing became comprehensive, capable of transcribing the full vocabulary of a language, it became an actual surrogate for speech. To achieve this, it had to become more abstract. One way writing became abstract was by moving away from iconic and pictorial representation to create pure symbols. Another way was to make the symbols represent discrete, meaningless segments of speech: syllables or their consonant and vowel constituents.

Alphabetic Writing and Syllabic Writing Convey Linguistic Messages Visually by Creating Symbols for the Meaningless Particles of Words

To gain an appreciation of how writing and reading are possible, we must first consider the role of phonology in enabling a language to convey an indeterminate variety of meanings by incorporating meaningless segments. Phonology refers to the distinctive patterning of sounds of a language and the gestures of tongue, lips, and vocal cords that produce them. In functional terms, phonology supplies the building blocks of words and also principles for binding them into syllables and larger metrical structures.

Words, from the standpoint of phonology, can be regarded as compounds, made up of ordered strings of individually meaningless particles, which are the familiar vowels and consonants (phonemes). Because a very large number of combinations are possible, phonology may be seen to incorporate a powerful principle for creating diversity: the phonology of a language supplies the resources for creating vast numbers of words. In this respect, language seems to mirror the make-up of the physical world. Much as all the material stuff of the world is composed of combinations drawn from a few dozen atomic elements, so the myriad words of a language are made up of combinations of a small number of phoneme particles, numbering <50 for most languages. The particulate principle and recombination of parts is also basic to the way genes mediate diversity in the world of living things. An analogy in this respect between language and genetics has repeatedly been noted.

Unlike protowriting, comprehensive writing is tied closely to speech, capable of creating an actual word-for-word record of speech. There are limited ways to achieve a word-for-word written record. Alphabetic writing, as one form of comprehensive writing, taps into the layer of meaningless particles at the base of the spoken language to create a visual surrogate for speech, one that mimics the productive potential of the phonological component of the spoken language. The innovation of alphabetic writing was therefore part discovery, part invention. The discovery was to recognize that spoken words can be divided into meaningless segments, phonemes. The invention was to map phoneme segments using made-up graphic symbols. These were the two ingredients that came together to make alphabetic writing possible. Since its first full flowering in the Mediterranean world about 3000 years ago, alphabetic writing was adopted by the ancient Greek and Roman civilizations and subsequently spread over much of the globe. Numerous specific alphabets employing a variety of graphic shapes

have been invented at different times and places, but the same general phonological principle of mapping the segments of the spoken word applies to all.

In English and most languages that employ alphabetic writing, each phoneme is symbolized by its own letter or group of letters, hence there are symbols for both vowels and consonants. Arabic and conventional modern Hebrew writing are exceptions. In these languages, there are letters for each of the consonants but not for some of the vowels. Given the consonantal frame, the appropriate vowel can be inferred from the context, so symbols would be redundant and unnecessary for experienced readers. But in Hebrew, and to a limited extent in Arabic, vowels are explicitly marked in texts intended for novice readers.

The existence of alphabetic writing and the obvious fact that it is capable of being passed on from person to person and capable of being read by most members of a language group is perhaps the strongest evidence for phonemic segmentation of language. However, examination of the actual physical record of speech, either as sound pattern or as the pattern of movements of structures in mouth, nose, and throat that produce the speech does not reveal separate segments that correspond neatly to consonants and vowels. The growth of speech science in recent decades has made this quite clear, serving to highlight the problem that particulate phonology lacks a clearly discernible foundation in the speech signal. As a result, the phoneme has at present an ambiguous status within the sciences of speech and language, a state of affairs that is unsatisfying to those who seek a theory capable of integrating what we know about the physics and physiology of speech with our practical capabilities to manipulate segments of language and with theoretical entities posited by linguists to account for these abilities. Ways to solve the problems surrounding phonological segments by exploring their gestural origin are being actively pursued, but are beyond the scope of this article.

The phoneme segments on which alphabets are based must in some sense be natural. A writing system probably could not be constructed based on purely arbitrary divisions of speech. Phoneme divisions are not the only natural units of speech. Speech can also be carved perceptually into coarser syllable segments, and, in fact, the syllable has served as the base for several writing systems. Examples of syllable-based systems are found in present-day Japan and in ancient Mayan writing. Syllabic writing is a practical option only for languages that have relatively small numbers of syllables. In the invention of writing, speakers may have been guided by such factors. Characteristics of a language may impose some constraints on the development of writing. Nevertheless, alphabets and syllabaries, though differing in the grain size of the base unit, are both grounded in phonological properties of spoken language.

A Role for Phonology in Semantically Based, Nonsegmental Writing

Alphabetic and syllabic writing do not exhaust the possibilities, however. Another kind of comprehensive writing, character writing, which is not segment based was developed in China and elsewhere in East Asia. It is important to appreciate that character writing also incorporates phonological information, although it does so indirectly. In Chinese writing, for example,

graphic characters, each consisting of a number of strokes, represent whole words or syllabic parts of words. By exploiting the rebus principle (see section 'Reading and Writing Exploit Distinctive Properties of Spoken Language'), phonological information relevant for pronunciation is coded within this predominantly semantic form of writing. A high proportion of Chinese characters (at least 70%) are actually compounds, in which one sector, the semantic radical, often represents a semantic root, and another sector, the phonetic radical, supplies clues for pronunciation. The illustration 鞍 shows how the word for saddle is written by a Chinese compound character. It consists of two simple characters, run together. Separating them, the left part is the semantic radical 革, which by itself means leather. Abutting it on the right is the phonological portion, the phonetic radical 安, also a simple character, which indicates how the word for saddle is pronounced by representing another word, or in this case a group of homophone words (different words that are pronounced the same) that are all written by this character. These words have various irrelevant meanings, but all are pronounced like saddle. Noting this pronunciation using English orthography, it would say approximately, 'ahn' in Mandarin Chinese. The rebus principle can work for Chinese writing because the language contains so many words that are homophones. English has homophones, too, of course, such as plane and date, but far fewer than Chinese. In the course of learning to read Chinese writing, learners become tuned both to the semantic and phonological portions which together provide clues to a word's identity, as in the example.

We learn from this example that Chinese writing can and often does provide information that links the written to the spoken form. Phonology is represented in this form of writing, although it does not adhere to the alphabetic principle by representing the individual consonant and vowel segments. Chinese writing is therefore consistent with the claim of some scholars that the incorporation of phonology into a comprehensive writing system is mandatory, and that each of the varieties of writing that has the potential to represent all the words of a language exploits the possibility inherent in all languages of separating phonological form from meaning content. Although this article focuses mainly on learning alphabetic writing and its relation to phonological processes, we should not lose sight of the fact that nonsegmental systems exist that also meet the tests of comprehensive writing. It is significant that these also supply phonological information, though in a quite different manner than alphabetic or syllable-based systems. The successful learning and use of Chinese writing (and related systems in Japan and elsewhere in Asia) by many millions of people testifies to its viability as a writing system. Obviously, there exists great variety in human possibilities for writing, but plausibly there are constraints based on the characteristics of particular languages. Finally there seems to be a universal constraint on a workable writing system: some way to incorporate phonology appears to be at the very heart of the possibility of writing.

Awareness of Phonemes, Key to Grasping the Alphabetic Principle

Alphabetic writing, as we noted, is distinguished by the fact that meaningless, particulate phonological segments, phonemes,

form the basis of the system (the orthography). From this point on the discussion will be about how would-be readers learn to read and write in an alphabetic system and how the system is used in practice by people at each level of skill. Two ideas, phonological processing and phonemic awareness, will be important to this discussion. Phonological processing is the more general idea: it refers to the incorporation and reproduction of a language's sound structure by a person in the course of learning to speak a language, in using speech in everyday life, and ultimately (for those who become literate) in learning to write and read. Because reading is parasitic on speech, it is appropriate to begin by briefly considering the place of phonology in acquiring speech.

In the course of learning to pronounce and comprehend utterances of her native language, a young child will gradually internalize its sound system, that is, its phonology. The phonology develops by successive approximations guided by feedback. Through experimentation with babbled syllables, while at the same time hearing speech in meaningful contexts from adults and older children, the learner discovers which sounds are used in the language, how they are combined in its words, and how to produce them well enough to be recognized by people who already know the language. Acquiring a vocabulary by ear and mouth is a matter of implicit learning that comes about spontaneously with normal exposure to speech in a normal environment.

Learning to read is altogether different. To become a competent reader of a language that uses an alphabetic script, such as English or Spanish or German, a learner needs phoneme awareness, the ability to explicitly segment spoken words by phoneme and to recognize recurrences of the same phoneme in different words (to appreciate, for example, that spoken words *sit* and *mat* have the final phoneme, /t/, in common). A child aged 5 or 6, when reading instruction ordinarily begins, has a working knowledge of the spoken language and already recognizes thousands of words, but ordinarily has little awareness of particulate sound structure needed for grasping the alphabetic principle on which word spellings are based. This knowledge does not develop hand in hand with ability to speak and understand the language.

Awareness of the larger segments of words, syllables, and demi-syllables emerges earlier than awareness of phonemes. Full phonemic awareness develops hand in hand with ability to decode words, not generally prior to it. The insight that words can come apart into segments and the ability to identify the same segment in different words does not come easily for many children. Perhaps we should not find this surprising. After all, the alphabetic principle was the late comer in the history of mankind's efforts to write. Indeed, experiments conducted with made-up, artificial writing systems show that even adults with much experience in reading do not often spontaneously infer the alphabetic principle in attempting to learn a new system for writing spoken words, even though they have been provided with examples of matching words and scripts that would logically permit them to make the inference. Similarly, there is abundant evidence that most child learners will not infer the alphabetic principle from experience with print alone. Most will need an adult's help to grasp the principle, to retain it, and use it as a basis for learning to recognize printed words.

But why should phonemic awareness be a barrier? For one thing, people as they listen to speech probably do not routinely

hear consonants and vowels as such, much as the casual music listener apprehends the melody but is unaware of specific pitches or chord progressions. Becoming aware of phonemic segments, the nuts and bolts of speech, requires a special kind of analytic listening that, as the author of this article noted, usually needs to be explicitly trained. Young children confronted with alphabetic writing may labor under an additional handicap: for them, words may be stored in only partially differentiated form in their memories. Full segmentation, particulate, phonemic organization, may require more extensive experience with the language. The English vocabulary includes many word pairs (such as map and nap) that are potentially confusable because they sound similar, differing in only a single, closely related phoneme. As growth in children's vocabularies accelerates during the preschool years, the gaps in phonetic space become filled with the inclusion of more and more similar sounding words. To accommodate this expansion of vocabulary without loss of discrimination, the representations of words in memory would need to become more detailed. The age at which a critical density is reached will vary, of course. Prior to that point in vocabulary development, a child would be ill-equipped to become aware of segments and would lack the basis for understanding how alphabetic writing works.

A further reason that awareness of segments may be expected to be at least somewhat difficult for children to acquire is that the phoneme segments are themselves meaningless. In her earlier experience with the spoken language, a child is naturally seeking to correlate chunks of sound with meanings, hence it would be entirely natural that she would approach reading in the same way with a bias to try to associate any visual segment, even single letters, with a meaning, not a sound. If not corrected promptly, this misapprehension would become a further barrier to grasping the alphabetic principle.

Whether or not a child attains phonemic awareness during the first year of school is a strong predictor of later success in reading in an alphabetic system. This insight alone, however, will not guarantee success nor inoculate children against the possibility of reading difficulty later on. A would-be reader must also learn the sounds (phonetic values) of the letters and combinations of letters. At the beginning of this process, letter names can usefully serve as reminders of their sounds. But in English, only certain letter names are helpful; others are actually confusing, such as the names for h, w, and y, which don't sound at all like the sounds they have in English words.

Necessary though it is to learn the sounds of the letters, reading is not a straightforward matter of pairing letters and phonemes. The stubborn fact that words as ordinarily heard are not discretely segmented into phonemes is an issue for the scientist, as we saw (see section '[Alphabetic Writing and Syllabic Writing Convey Linguistic Messages Visually by Creating Symbols for the Meaningless Particles of Words](#)'). It is also a potential source of difficulty for a would-be reader. A word in print is conveyed by a sequence of letters that taken collectively suggests its pronunciation. The letters stand for phonemes, but many phonemes, certainly most consonants, are not pronounceable in isolation but only in combination with a vowel. Accordingly, in reading a printed word, successive letter segments must be blended into syllables. As a consequence, knowing the letter sounds may not suffice for a child to identify

the word. For example, a child attempting to sound out the word brag may succeed in producing more or less appropriate sounds for each of the letters buh, ruh, ae, guh, yet not appreciate that they spell the monosyllabic word brag. Again, the difficulty is that the individual letters in brag do not represent separate syllables, as they would if we spelled the word aloud, where each letter in turn is named. But, of course, spelling is not reading. For the letter sequence to be read as a word, the four letter sounds must be fused into a single syllable; the word brag has one syllable, not four. Consequently, in a written word, the sequence of letters can only suggest a pronunciation. When written words are pronounced aloud or to oneself, the phonemes that the letters represent are encoded over syllable lengths of speech.

Children can be helped over this potential difficulty by the teacher showing them that words can be built starting from a vowel nucleus. The exercise begins by writing a vowel letter, saying its sound, and then adding a consonant letter, preferably one that can be prolonged. For example, writing first a, then an, am, as, and sounding out the resulting syllables. Then, when a consonant is made to precede the vowel, the wise teacher will choose a consonant that can be prolonged and exaggerated, such as s, to produce s-s-s-s am, sam. This is an effective exercise both because writing helps to make segments concrete and because it draws the child's attention to the significance of left-to-right sequencing of letters for word construction.

Not all languages have a mainly closed-syllable structure, as English does, with one or more consonants preceding and following a vowel nucleus in the most frequently occurring syllable type. Building syllables from phoneme components should be easier in languages, such as Italian and Spanish, with simpler, open-ended syllables. Research in recent years has shown, in fact, that phonemic awareness and word decoding are grasped earlier by children who are learning to read an open syllable language, in which most syllables lack a final consonant, than a closed-syllable language.

Because most children will not discover phonemic segmentation unaided, teachers of beginning reading have a vitally important role in promoting this awareness and in clarifying how the segmentation of spoken words relates to the spellings of those words. The evidence is strong that this kind of teaching works for most children. Despite the evidence, not all children presently receive instruction that promotes phonemic awareness. A novice reader who has failed to gain awareness will be unable to understand how the system works. As a consequence, all spellings will appear arbitrary and will have to be learned by rote, placing an unnecessary burden on memory. The stakes are high. Children who do not acquire basic word-reading skills in the first grade are likely still to be poor readers when they reach high school.

An alert teacher can do much to help children get off to a good start. She will detect the use of nonproductive strategies, and wean children away from them, such as the futile attempt to recognize words by their overall visual shapes, or wrongly trying to associate the individual letters of printed words with a meaning. Unfortunately, it is still not always appreciated that among the qualities of an effective teacher of reading is mastery of a definite body of knowledge pertaining to the structure of language and its varied reflections in the orthography.

English Spelling Is a Hybrid, Based Only Partly on Phonology

The peculiarities of specific languages and the conventions that have developed for writing them can have important consequences for the learner. As anyone knows who has struggled with English spelling, most letters in English have more than one pronunciation, and some English words are written in ways that do not match their pronunciations well. One reason that English has many spelling irregularities is that the language over the course of its history has frequently borrowed words from related and unrelated languages, which are sometimes written with anglicized spellings but often with imported spellings that are not English-like. This makes for a diverse, inhomogeneous set of spelling conventions. A further source of irregularity is the existence of spellings of some old English words that have not kept pace with changes in pronunciation. Some words in common use, such as *night* and *although* (with the silent *gh*), are familiar examples of frozen spellings.

These complexities have led some people to complain that it is confusing and futile to teach children the phonetic basis of regular spellings when many irregularities and exceptions exist. Critics of English spelling often fail to appreciate, however, that some of the apparent irregularities in the spelling of English words reflect a plurality of mapping principles such that shared meanings can in some related words take precedence over shared sound. For example, *health* and *heal* are pronounced differently in the vowel, but the similarity of their spelling underlines their shared root, linking them semantically in a way that would not be apparent if *health* were written as it is pronounced, *helth*. Another spelling pattern that follows meaning more closely than sound is in writing affixes such as the *s* or *es* at the ends of nouns that make the noun plural. Because the plural-*s*, while written as *s*, sometimes says *z* (compare *cats* and *dogs*), this regularity of spelling is not strictly based on pronunciation, but, instead, reflects a similarity in meaning (both plurals). Experience suggests that most learners readily grasp these hybrid features of English spelling when they are explained.

Nonetheless, the fact that English words are not spelled according to a simple one-letter, one-phoneme principle undoubtedly does complicate and prolong the task of the learner, both in reading and spelling. A number of other languages, Spanish and German among them, are more consistent than English in representing pronunciation by their written forms. Simplicity and consistency of sound-based coding seems to speed the development of reading and spelling skills in these orthographies relative to English. For example, there is evidence that German-speaking children acquire good printed word-recognition skills in their language about 2 years earlier than English-speaking children. (By the sixth year at school, the latter catch up and learners from the two language groups are on a par.)

Differences in dialect that affect word sounds are still fairly marked in the English-speaking world, but these differences are not reflected in conventional spellings. This fact underlines the principle that spelling represents the phonology of words at some abstract remove from speech, generalizing across differences in dialect (and, of course, differences in idiolect, since both physical and social differences between people will affect

the details of speech production). The obvious fact that English spelling can achieve this level of abstraction shows that readers and writers do not require a precise match between the way they talk and the way the language is written. As a representation of speech, spelling conventions are therefore something of a compromise. That said, conventional spellings are clearly a better match for some dialects than for others. Mismatch is especially great for minority dialects. Certainly, a high degree of mismatch between spoken dialect and written forms can be an obstacle for a learner. Sensitive teachers who are themselves bidialectal can help to mitigate this disadvantage.

Further Steps Toward Literacy

In English, especially, the complexities produced by many-to-one mapping of spellings to phonemes guarantees that there will be more to learning to recognize spelling patterns in reading (and generating them in writing) than a simple matching of letter and phoneme. Vowels, in particular, are often written with more than one letter, as in *seat* or *sleigh*. The position within a syllable at which a particular phoneme occurs is also a relevant factor in spelling. For example, the consonant phoneme /k/ is more often written with the letter *c* than the letter *k* in English, especially when it occurs at the beginnings of words, as in *card*. Moreover, /k/ is often written as *ck* but only when it occurs at the ends of syllables, as in *tack*. The prepared teacher will introduce the major spelling patterns, with examples from children's vocabularies, and opportunities to practice reading and writing them. However, there are far too many spelling patterns to teach them all, hence orthographic learning is largely implicit.

For older children and adults, who are past the beginning stages, reading and writing themselves serve to promote awareness of phonology and refine it. The activity of writing helps to make the segmental composition of words apparent, reinforcing phonological awareness. The relation between phonemic awareness and literacy abilities is, in fact, a reciprocal one. Phonemic awareness, which in rudimentary form helps beginning readers to grasp the alphabetic principle, becomes refined and sharpened with the development of literacy skills. Remembering spellings necessary for writing words is especially helpful in promoting and fixing awareness. But it has also been observed that ability to demonstrate phonological awareness is weak in some adults who are competent readers. After a person has become well-practiced in reading and writing, phonological segmentation abilities may become autonomous to such a degree as to no longer be readily accessible to consciousness. Adults and older children often seem more aware of how a word is spelled than of the phonological underpinnings of the spelling.

The effects of reading on spoken language abilities extend beyond phonological awareness, reflecting the pivotal role of literacy as a means for acquiring knowledge and culture. Once a reader has acquired fluency with print, the act of reading itself may become a major source of new vocabulary. In people who read a lot, vocabularies continue to expand in the mature years, well into old age. It may be surprising, however, to learn that ease of learning new spoken words can also be enhanced by reading experience. To add a new word to one's vocabulary,

whether spoken or written, the phonological form of the word must be apprehended and stored in memory. The quality of the representation in memory will vary with the individual, but if it is to suffice for vocabulary learning, it must be good enough to serve two purposes, the purpose of enabling the learner to identify further occurrences of the word in the speech around her, and good enough to guide the learner to produce the word well enough for others who know the word to recognize her attempts.

In fact, it has been discovered that even the most basic level of reading skill in an alphabetic orthography changes speech imitation abilities. In one study, totally unschooled adults from isolated villages in southern Europe were matched with others from the same villages with only a few years of schooling. The illiterate adults were inaccurate in repeating spoken pseudowords (phonetically possible, but not actual words in their language), differing sharply from the matched comparison group with only basic literacy. Both groups were highly successful in repeating actual words, but the illiterates were largely unable to treat the novel pseudowords as segmented phonetic strings. It appears that the ability to readily pick up a new word on a single hearing, and the changes in brain organization that support this ability, are telling examples of how the capacity to retain a novel phonological pattern can be profoundly influenced by even a modicum of reading experience. These are further examples of the reciprocal relations between language and literacy.

In reading words in context, can learners compensate for poorly developed phonological decoding skills? Novice readers already know from their experience with the spoken language many of the words they will eventually learn to read. That being so, will they not be able to use their vocabulary knowledge gained by experience with the spoken language to guess the identity of written words even though they are unable to decode the sound pattern independently? The answer seems to be yes, but that the benefits may easily be overestimated. Among adult readers with widely varying skill levels, it has been shown that the quality of a person's spoken vocabulary knowledge can facilitate printed word recognition. A well-functioning semantic knowledge of words and their interconnections may benefit reading by tipping the scales toward correct recognition of a partially decoded word. So two readers who are alike in having matched partial decoding skills, but differ in general vocabulary knowledge, may be expected also to differ in overall reading ability.

But we should be cautious about making the further inference that context can, in general, permit a reader to identify individual words that couldn't be read independently. True, a word can sometimes be inferred from context. But the practical usefulness of context for word recognition is limited. Here's why: It has been estimated that one word in four is predictable on average. However, the most predictable words are high-frequency function words, such as articles, pronouns, and conjunctions. If one considers only content words, predictability drops to one in eight. Yet it is content words that pose the challenge for comprehension. Context can supplement a word's spelling in reducing uncertainty, but it cannot substitute for phonologically driven, code-based processes of word identification. Struggling readers with weak phonological decoding skills are the ones most likely to attempt to rely on context, but

they do so ineffectively because they are required to rely on guessing the identity of too many words, yielding especially low odds on being correct. Skilled readers are better able, but less likely to need to rely on context. Skilled readers who have learned to sound out a new word do not ordinarily need the assistance of context in deciding what word it is they are reading because they have accurate context-independent word-recognition skills. These are the hallmarks of a mature, skilled reader. So, to sum up, context facilitation can benefit learners who are in midcourse, with partially developed decoding skill, but, for different reasons, context facilitation is of little benefit either to the weak or to the strong.

The larger point is that the skills that underlie word recognition are necessary, though not sufficient, for comprehension of connected material. Although the goal of reading is comprehension, the core of reading is word recognition. If the basic analytic skills that are built around phonology are deficient, a reader's general language ability and background knowledge cannot be brought to bear most effectively on reading performance.

In addition to the benefits conferred by attaining an early grasp of the alphabetic principle, learners need to invest much practice to become effective, mature readers. To promote development of a high degree of skill, novice readers need to experience the rewards of reading from the outset (initially by enjoyment of being read to), so as to be motivated to apply sufficient time and effort to activities that promote fluent reading. It is a long process; for most of those who succeed in becoming effective readers of English, it will require the entire span of elementary school years before they can recognize words and track sentences as well by eye as by ear. Only when that benchmark is reached is a learner well prepared to use the written language as a stepping stone to gain further knowledge of language and vocabulary, and to use the medium of print as a means, perhaps the primary means, of acquiring knowledge of the world. Unfortunately, for many children in our schools this benchmark will not have been reached by the time of school leaving. For these young people, reading remains labored, often inaccurate, and unrewarding. This avenue to the general culture is shut off and the door is also closed on opportunities to enter the ever-growing number of occupations that require more than basic reading skills.

Dyslexia: A Phonological Deficit Affecting the Decoding of Print

The existence of dyslexia, undue difficulty in reading and learning to read, has been recognized as a distinct condition for little more than a century, and has been in the public eye for a much briefer time. In the recent past, dyslexic children were frequently stigmatized as dull or mentally retarded. It is now recognized that dyslexia can occur across the spectrum of general cognitive ability. The diagnosis of dyslexia should not be attempted on the basis of a single testing, no matter how comprehensive. Failure to benefit from instruction that is normally effective for promoting learning is a sounder basis for making the diagnosis. This is not to say that tests have no place. They are appropriate to guide in planning treatment for an individual child, and they are useful for research purposes.

Test can contribute importantly, for example, to disentangling the relations among a variety of disorders of child development in which reading problems are often a prominent feature and which may be confused with dyslexia, such as specific language impairment (SLI) and attention deficit disorder (ADD).

Researchers have reached near consensus regarding some of the cognitive markers of individual differences in learning to read. Typically, dyslexic children and adults have greater difficulty than learners who are better endowed in gaining phonemic awareness, in developing accurate and rapid word-recognition skills, and in coping with spelling and its irregularities. Twin studies have shown that these differences are moderately heritable over the range of abilities, as is dyslexia itself. That is not to say, that environmental factors contribute less importantly to reading outcomes than genes do. As has often been noted, poverty is strongly correlated with several adverse educational factors, school crowding, poor facilities, poorly qualified and overworked teachers, frequent moves necessitating change of schools, lack of reading materials in the home, and lack of parental support for literacy activities.

Failure to develop serviceable basic skills for whatever reason leads to difficulties in comprehending written material and an understandable tendency to avoid reading, leading, in turn, to fewer opportunities for the many varieties of learning that are facilitated by reading. Avoidance of reading-related activities leads to a cascade of negative consequences which are progressively hard to overcome once children are beyond the first grade or two. Even so, with prolonged effort on the part of the learner, remedial teaching, emphasizing the phonological foundations of the orthography, even if long delayed, can usually achieve a degree of success, often sufficient to make a real difference to the quality of life of the dyslexic person. Certainly, the fact that reading difficulties are to a degree heritable does not preclude the benefits of remedial teaching and remedial treatment. In fact, it renders these interventions all the more important. Research indicates that children and adults who are not well-resourced for reading require a more intensive version of the phonologically based regimen that serves for those who are better resourced.

The considerable investment in recent decades that governments and foundations have made in interdisciplinary study of dyslexia and its treatment has led to benefits in the teaching of reading for children more generally. Furthermore, the needs of dyslexic children have spurred research to identify the sources of reading difficulties more broadly. In general, the factors that make reading hard for dyslexic children are also sources of some degree of difficulty for children who are better resourced. Of course, the range of individual differences spans both extremes. Precocious readers are to be found at the other end of the reading continuum. Some children who learned to read well prior to schooling were intensively coached by parents or older siblings. But apparently, others were autodidacts who early on managed to break the code with little explicit teaching. There have been only a few published studies of highly precocious readers. In the main, these are biographical, diary accounts that are not based on experiment. More study needs to be directed to this group of learners. They, too, undoubtedly have lessons to teach.

The biological underpinnings of dyslexia and related disorders of development have received much study in recent

years. I have alluded to contributions from genetic studies. In the final paragraphs, I will state some conclusions from brain research that are also relevant to the issues we have been examining. Techniques are available that enable a researcher to eavesdrop on brain activity cooccurring with cognitive performances such as reading. Functional measures, based on EEG and neuroimaging techniques, chiefly PET and fMRI, generate records based on brain activity during performance of reading-related tasks, such as judging whether pairs of printed words rhyme. Records of brain activity have shown that learning of reading-related skills by normally developing children gives rise to changes in activity within several left hemisphere zones. Dyslexics relative to nonimpaired readers typically underengage these structures on the left side, with abnormally high levels of activity in some corresponding regions of the right hemisphere. These developments have opened up new opportunities to sensitively assess the effects of remedial intervention on brain function. Changes in activity patterns in response to successful remediation based on phoneme awareness and decoding have been observed within broadly the same left-brain regions that show effects of learning during normal reading development. Like most other language functions, normal reading relies primarily on the left side of the brain.

As these examples show, progress in recording brain activity during cognitive performances has presented new opportunities to assess the role of phonological processing in reading skill and its development. Researchers have recently exploited these tools to compare patterns of brain activity in users of different languages and writing systems. Across-language comparisons have shown substantial commonality in reading circuits among learners from different language communities. For example, normal learners engage the left hemisphere predominantly and difficulties in learning to read are everywhere associated with abnormal reliance on the right cerebral hemisphere. As might be expected, some differences are also found in distribution of brain activity across languages and writing systems that reflect the level at which the orthography maps the phonology, as well as visual-graphic characteristics of the orthography.

Glossary

Cognition Set of psychological processes that involves the construction, acquisition, maintenance, and utilization of knowledge.

Competence Abstract, universal idealization of a system of thought or reasoning. Regarding deductive reasoning, the competence system consists of a mental logic.

Conditional argument Four basic argument forms which include a conditional statement of the form “if p , then q ” as the major premise and affirmation or denial of the antecedent (p) or consequent (q) as the minor premise.

Two of these forms are determinate and valid while two are indeterminate and invalid.

Deductive inference Inference process that moves from the universal to the particular and where the premises provide absolute certainty for the conclusion.

Inductive inference Inference process where the premises provide probable or contingent evidence for the conclusion.

Logical necessity A relation holding among propositions where a conclusion follows with absolute certainty from the premises.

Mental model Presumed actual procedures and representations derived from the real world and that the individual employs when processing specific reasoning tasks in real-time.

Metalogic Conceptual knowledge of logic including the recognition that inference is a basis for knowledge, an understanding of key distinctions among types of inference, an appreciation that conclusions must be consistent with all possible states of affairs represented by the premises, and an understanding of logical indeterminacy, inconsistency, and necessity.

Procedure Actual or real-time strategy employed during thinking or reasoning. Provides access to, and implementation of, competence.

Reasoning The form of thinking that involves inference. Inference can be either inductive or deductive, hence, there is inductive reasoning and deductive reasoning.

The focus of this essay is on the nature and ontogenesis of reasoning. However, reasoning must be understood as one set of psychological processes that form part of a more general set of processes known as cognition. Cognitive processes are all those that involve the construction, acquisition, maintenance, and utilization of knowledge. Contemporary accounts of cognition often distinguish between heuristic cognition, involving relatively automatic, effortless, contextualized (domain-specific), and encapsulated processes, and analytic cognition, involving more deliberate, effortful, decontextualized (domain-general) processes that are accessible to consciousness. Perceptual processes and many aspects of language production or comprehension, memory encoding and retrieval, and even problem-solving are heuristic in nature. By contrast, reasoning falls squarely within analytic cognition. This is important to note because it distinguishes reasoning from associative, pragmatic, or highly schematized processes that may substitute for reasoning on any given task or occasion.

Reasoning involves ‘inference,’ which is the process where one proposition (i.e., knowledge claim) is arrived at and accepted on the basis of other propositions that were originally accepted. The originally accepted propositions are called premises and these provide the evidence from which inferences are made to the proposition called a conclusion. Reasoning, then, is distinguished from other types of relatively deliberate, effortful (i.e., analytic) processes such as fantasy thinking, creative thinking, and some kinds of decision-making that do not directly involve the inference process.

Reasoning is a specific type of cognitive process, but there are also several types of reasoning. Usually, these are divided

into inductive reasoning processes and deductive reasoning processes. Deductive reasoning is unique in several, interrelated respects. Most importantly, it is the only form of inference that can support judgments of necessity. In deduction, the premises, if true, provide absolutely certain evidence for the truth of the conclusion. This is because in a valid deduction, the conclusion is implicit within the premises. It is the form of a deductive inference, therefore, and not its content, that preserves the certainty of the premises in the conclusion. One important consequence of this is that deduction is monotonic. That is, the addition of new premises to a valid deductive argument cannot render the argument invalid. One last property of deductive inference worth noting here is that deduction proceeds exclusively from the general to the specific, thereby providing a basis for the application of general rules or categories to particular instances.

There are several forms of inductive reasoning including, for example, pragmatic reasoning (based on knowledge of the sociolinguistic context) and statistical reasoning (based on probability). These stand in sharp contrast to deduction as just described. Inductive inference cannot guarantee the truth of the conclusion and is nonmonotonic and defeasible. Although the truth of the premises may make the conclusion highly likely in inductive inference, there is always the potential for new information to render the conclusion false.

While the general focus of this essay is on reasoning, the specific focus involves the nature, origin, and development of logical or deductive reasoning. This is a domain that is central to scientific thinking and hypothesis testing, and central, as well, to the production of coherent arguments which can guide

a good deal of day-to-day life. Even if, as some claim, everyday reasoning involves more pragmatic and probabilistic inductive thought than deductive thought, an understanding of the nature of deductive reasoning forms a necessary foundation for considerations of when and under what conditions this type of reasoning is displaced by pragmatic reasoning and other types of cognition.

Reasoning and Logic

In order to clarify the specific nature of deductive reasoning and to clearly differentiate it from both inductive reasoning and logic, consider the following examples:

1. All trains from Philadelphia to Washington stop in Baltimore
The train on Track 6 goes from Philadelphia to Washington.
Therefore, the train on Track 6 stops in Baltimore.
2. All the trains I have ever seen that go from Philadelphia to Washington have stopped in Baltimore.
Therefore, all trains from Philadelphia to Washington stop in Baltimore.

Example (1) involves deductive inference, and example (2) involves an inductive inference. Here it is important to be clear that logic and deductive reasoning are not identical. Logic is a discipline of study that is not, in itself, interested in the reasoning processes (i.e., inductive reasoning and deductive reasoning) that produce these examples. The reasoning processes are the domain of cognitive and cognitive developmental psychology. Logicians are interested in the products of the reasoning processes which they term 'arguments.' From the perspective of psychology, examples (1) and (2) involve types of inferences – a deductive reasoning inference and an inductive reasoning inference respectively – but from the perspective of logic, example (1) is a deductive argument, and example (2) is an inductive argument. Logic identifies and analyzes arguments that are accepted as correct or incorrect. Logical reasoning concerns mental processes that are related to logical arguments.

For the logician, an argument is a sequence of sentences or propositions of which one (the conclusion) is said to follow from the others (premises), and the premises are said to provide evidence for the truth of the conclusion. Deductive arguments have the characteristic of being valid (correct) or invalid (incorrect). To say that a deductive argument is valid is to say that it is absolutely impossible to find situations in which the argument has true premises and a false conclusion. Thus, the conclusion necessarily or logically follows from the premises in a valid deductive argument. Inductive arguments cannot be valid/invalid because the premises provide only probable evidence for the truth of the conclusion. Regardless of how many trains to Washington that one sees stop in Baltimore, there may be some trains that go straight through.

The sentences that compose deductive arguments are true or false, but the argument itself is valid or invalid. Further, a valid argument may have true premises and a true conclusion (e.g., All parents have children; All fathers are parents; Therefore, All fathers have children); false premises and a false conclusion (e.g., All children have siblings; All fathers are children; Therefore, All fathers have siblings); or false premises and a true

conclusion (e.g., All children have siblings; All brothers are fathers; Therefore, All brothers have siblings). The validity of a deductive argument is relatively independent of the truth of its premises and conclusion. The only relation precluded by a valid deductive argument is true premises and a false conclusion.

The truth of a sentence or a proposition in a deductive argument is best understood through the concept 'possible worlds.' Roughly, a possible world is any situation that is conceivable or imaginable and can be described by a consistent story. This means there are many possible worlds (e.g., the worlds of novels, films, myths, etc.). The commonsense familiar world – called the 'actual world' – is one of these possible worlds. A sentence is true in a given possible world when the sentence correctly describes that possible world. Furthermore, a sentence is logically or necessarily true when it is true in all possible worlds.

Logic, then, is concerned with identifying the forms or patterns of valid arguments regardless of their specific content. Logicians begin this task from simple sentences and the sentential connectives that join them together (i.e., 'not,' called negation; 'and,' called conjunction; 'or,' called disjunction; 'if ... then,' called the conditional; 'if and only if,' called the biconditional) and demonstrate valid and invalid arguments related to these connectives. The elementary arguments that are established as valid constitute basic argument forms or rules of inference that are used to construct and to analyze more complex arguments. Three important conditional argument forms that involve reasoning with conditional statements are: Modus Ponens, Modus Tollens, and the Hypothetical Syllogism:

1. Modus Ponens (MP)	2. Modus Tollens (MT)
If p then q	If p then q
p	Not q
Therefore, q	Therefore, not p
3. Hypothetical Syllogism	
If p then q	
If q then r	
Therefore, If p then r	

In these and other valid argument forms, any content can be substituted for p , q , r and the argument remains valid (i.e., the argument remains valid in all possible worlds). By contrast, two argument forms that are invalid but are often mistaken for valid forms are Denying the Antecedent and Affirming the Consequent. In these forms, the conclusion (e.g., 'not q ' for DA) does not follow from the premises:

4. Denying the antecedent (DA)	5. Affirming the consequent (AC)
If p then q	If p then q
Not p	q
Therefore, not q	Therefore, p

The general deductive system that incorporates the connectives and inference rules is called a propositional or sentential logic. A more powerful system that includes the propositional logic but goes beyond it is variously called quantificational, predicate, or first-order logic. This system has features concerned with the internal structure of propositions and the

quantification of propositions (i.e., all, some, none) along with the features described by the propositional logic. The simplest kind of quantified arguments are the syllogisms. For example:

All *B* are *A*
Some *C* are *B*
Therefore, some *C* are *A*

Deductive propositional and predicate logics ultimately are formalizations of the commonsense correct deductive arguments that people engage in on a day-to-day basis. The logics are attempts to establish rules according to which such arguments proceed. A logic is a theory of the nature of arguments. By establishing the rules of valid deductive arguments, a logic also pinpoints the nature of error or incorrect arguments. When logic is seen in this fashion, it again helps to illustrate the distinction between logic and logical reasoning. If logic is composed of the rules of arguments, then logical reasoning concerns psychological processes that somehow reflect these rules. The major question then for psychology is: why and how do psychological processes come to reflect rules and operations within formal deductive systems? Among the various developmental theories of deductive reasoning, two very different answers to this question have been formulated, and yet, a kind of rapprochement among theories is possible.

Developmental Theories of Logical Reasoning

Even a cursory review of the empirical literature on deductive reasoning reveals some striking inconsistencies both within the developmental findings and between those findings and the results of adult research. Research with children has often been interpreted as indicating not only substantial innate deductive reasoning competence but also significant development from childhood to adolescence. The adult literature, by contrast, has generated considerable evidence of young adults failing to reason logically, even under reasonably favorable conditions. Resolving these inconsistencies represents a major challenge for any theory of deductive reasoning.

Overton's Competence-Procedural Theory

Competence-procedural theory claims that the rules of logic bear a nonarbitrary relation to the psychological processes involved in deductive reasoning. Therefore, the rules of logical arguments – as formalized in symbolic logic – can be understood as relatively adequate models of normative, idealized, abstract operations of mind in this domain. The individual in some sense acquires and has access to the operations characterized by these rules. The rules, thus described, constitute a 'competence,' and the competence is held to be a significant feature of the explanation for adequate performance on deductive reasoning tasks. It is important to note, however, that the competence is not to be thought of as mental representations used in actual reasoning. Competence is an idealization of the system of thought that the normal adult has access to. It constitutes an epistemic (i.e., universal) model. The actual individual mental representations used in accessing and implementing this competence constitute a procedural model.

There are numerous variations on the standard logical systems described previously in this article – some modest, and some substantially deviant – and, consequently, there are many candidates from which to choose in selecting a model for the competence system. The model favored by Overton's competence-procedural theory consists of a mental logic that resembles standard propositional logic, but is not isomorphic to it. Specifically, the combinatorial logic (INRC group) of Inhelder and Piaget revised as an entailment logic capturing the importance of relevance and meaningful implication to human reasoning has been proposed by the Overton group as a reasonable candidate for the competence model. For this reason, Overton's theory is Neo-Piagetian in nature. The propositional-entailment logic has a developmental precursor from which it can be formally derived. This precursor is a class and relational logic that represents the key competence system in middle childhood. Competence-procedural theory maintains that the logical competence systems emerge out of the general cognitive activity of the child interacting with her world. In particular, reflective-abstractive processes are stressed wherein logical organization implicit in embodied mental action is reflected onto more explicit, abstract levels of thinking.

Alternative mental logics have been proposed for the competence model within a competence-procedural account. The most influential in this regard has been the natural deduction system of Braine and O'Brien. This latter model differs from the Overton/Piagetian model in several key respects. The natural deduction system consists of relatively innate and heuristic core inference schemas and direct reasoning routines supplemented by a set of complex schemas and indirect reasoning strategies which are not innate or universal and which are particularly dependent upon formal tuition and related experiences. The primary or core schemas are employed automatically when the appropriate propositions are encountered. By contrast, the secondary or complex inference schemas are only employed under special conditions and are strategic, deliberative, and intentional. The Braine and O'Brien competence model resembles a production system more than a logic because the individual schemas and routines are not integrated into a recursive system the way logics are. The bulk of the theory's utility has been in explaining relatively automatic and isolated inferences such as might be involved in language comprehension. The theory has been less useful as an account of deductive reasoning as construed in this article and most other accounts, namely, deduction as deliberative, intentional, analytic cognition.

While competence systems function to promote understanding, procedural systems function to assure success on problems. They are composed of individuated real-time action systems that may be sequentially ordered but are not enduring in the way that the competence system endures. A procedure is an action means to an end or goal. It is context-dependent, and context includes both the available competence and information inputs (e.g., success at baking a cake requires stirring, mixing, and beating, but a recipe and ingredients form the necessary context for these procedures). A procedural system constitutes the psychological subject, and procedures are considered to be sufficient or insufficient, rather than complete or incomplete.

Because the kinds of procedures that can be used to account for the actual processing of deductive problems are limited

only by functional criteria – real-time processing and sensitivity to inputs, outputs, and internal states – the number of candidates for designation as procedures is large. For example, it could be the case that people process deductive problems by actually thinking in terms of truth tables, by actually thinking in terms of Venn diagrams, by actually thinking in terms of natural deductive procedures, by mental models, by pragmatic methods, or by various methods employing direct experience. Further, procedures may reflect individual differences or individual strategies. As a consequence, different people may – at different times and under different circumstances – use different procedures as they attempt to access and implement available competence in efforts directed at solving deductive reasoning problems.

Competence-procedural theory provides an account of the nature, origins, and development of procedural systems and their relation to competence. However, some of the most important empirical research on these systems and their relevance to performance on deductive reasoning tasks has been carried out within the frameworks of other, competing theories of reasoning. Nonetheless, with certain reconceptualizations, these theories are readily viewed as consistent with competence-procedural theory. This will be discussed below.

Competence-procedural theory has been successful in explaining a wide range of empirical findings on the development of deductive reasoning. The theory predicts, on an a priori basis, the various age-related effects that have been found for deductive reasoning along with a host of findings regarding key moderators of these age-related effects, including such factors as training, content, and SES. In general, research from within the theory indicates that deductive reasoning competence is lacking in fourth through sixth grades, coming on-line in eighth/ninth grade, and readily available in tenth to twelfth grades. This pattern has been confirmed through both cross-sectional and longitudinal research.

The theory is also able to reconcile the striking inconsistencies typically present when the adult and developmental literatures on deductive reasoning are compared. Evidence of early success on deductive reasoning problems is explained within the competence-procedural account in two ways. Some of this evidence appears to identify concrete precursors to formal deductive competence. These precursors are predicted by the theory on the basis of class and relational reasoning competencies present in middle childhood. Other evidence of early success consists of relatively isolated propositional inference forms such as MP or valid syllogisms and obtains in the absence of success on other, logically related inferences (e.g., AC or DA). In addition, children in these research settings generally fail to demonstrate an understanding of the deductive nature of the inferences they have made, suggesting that the cognitive processes involved are heuristic in nature and do not involve reasoning per se. Competence-procedural theory is able to explain apparent evidence of adult incompetence on deduction tasks as occasions where procedural obstacles to the accessing and implementation of a logical competence are present.

The competence-procedural account provides plausible explanations for a variety of content effects. Familiar content, meaningful content, and increased relevance of antecedent (p) to consequent (q) in conditional statements have been found to facilitate performance on deductive reasoning problems, but

only subsequent to the availability of the logical competence, and the greatest degree of variability in performance across content is found during periods of competence consolidation. Abstract content is problematic at all ages, but improvement is clearly evident from eighth through twelfth grades. Findings of this sort point to the importance of including a competence model in any viable theory of reasoning. Familiarity, relevance, and other aspects of content that would be expected to maximize the efficiency of processing in working memory support the application of an existing logical competence. Those same processes, however, are ineffective in the absence of that competence.

As noted previously, the Overton/Piagetian competence model for formal reasoning derives from a more fundamental logic of classes and relations and, as such, it comprises part of a theoretically viable and unique account of the emergence of deductive reasoning from earlier, more limited, logical competencies. Where children and preadolescents are still employing the precursor class logic, prior to consolidation of the propositional logic, they should be prone to conflate the two possibilities for the denial of the antecedent in a conditional statement (if p , then q), namely ($\neg p$ and q) and ($\neg p$ and $\neg q$). That is, they should fail to recognize that the truth of the conditional is consistent with both possibilities, and not merely with ($\neg p$ and $\neg q$). Such an error would be expected because class logic does not clearly distinguish between the two possibilities. This error amounts to interpreting the conditional as a biconditional (if p , then q AND if q , then p). For example, in evaluating the conditional statement, "If it is raining, then the street is wet," this conflation involves failing to distinguish between cases where "it is not raining and the street is dry," and "it is not raining and the street is wet." This kind of error is indeed significantly more common in childhood than in adolescence. In fact, it represents one of the most robust findings in the reasoning literature. The account of the emergence of conditional reasoning from class reasoning also predicts that this conflation should go hand in hand with a fundamental difficulty in generating alternative antecedents for the consequent q . That is, not only should children be more likely than adolescents to interpret conditionals as biconditionals, they should also be less likely to generate alternatives to p (e.g., a street cleaner is operating, a water main has broken, etc.) that could obtain along with q . Again, this prediction is substantially supported in the literature. For the competence-procedural account, then, the primary restriction on the range of possibilities that the child can generate in reasoning on deduction problems is a logical (competence-based) one – difficulty in appreciating that the truth of the conditional is consistent with situations where the consequent obtains despite the absence of the antecedent.

Alternative Accounts

Alternatives to competence-procedural theory generally reject the need for a competence model and make no explicit distinction between competence and performance. Their answer to the question of why psychological processes resemble the rules of argument is to claim that the resemblance is largely arbitrary. In this view, deductive reasoning per se plays only a limited role in human cognitive activity and does not reflect

operations within some kind of mental logic. Instead, deduction consists of psychological processes that are entirely shared with other forms of reasoning. From the standpoint of competence-procedural theory, these alternative accounts are essentially procedural theories that nonetheless maintain certain implicit, generally unacknowledged competence claims. Despite the seeming incompatibility, these alternative theories are potentially compatible with Overton's account if their implicit competence claims are acknowledged and the reduction of competence to procedure is avoided. From the standpoint of a rapprochement with competence-procedural theory, these alternative, essentially procedural, accounts accomplish one or both of the following: First, all of these theories serve to work out important components of the real-time processing involved in deductive reasoning and, in this capacity, are complementary to, and potentially compatible with, competence theories. Second, some of these theories include aspects of logical competence in a procedural form. As long as the reductionism is strictly avoided, research grounded in these theories could be interpreted as identifying important indicators, manifestations, or direct consequences of an emergent logical competence. The prime example here is research into the development of conceptual knowledge about logic (metalogical knowledge) in the metacognitive theories of Kuhn and Moshman.

The models employed as explanatory devices by the procedural group of theories are characterized as being attempts to imitate real or actual actions in real-time rather than being abstract idealizations of logical rule systems. Some, more narrowly applicable, models attempt to account for performance on deductive reasoning tasks strictly on the basis of domain-specific processes such as the application of pragmatic reasoning schemas induced from ubiquitous sociolinguistic activities including permissions, obligations, and causations. Other models are broader in the reasoning phenomena they propose to explain. In this vein, Johnson-Laird's work on mental models represents the most systematically developed procedural computational model of deductive reasoning. Johnson-Laird's mental models are presumed actual procedures and representations derived from the real world that the individual employs when processing specific reasoning tasks in real-time. Markovits and colleagues have extended mental models theory into a genuinely developmental account of deductive reasoning and this theory will be discussed at length here.

Markovits' mental models theory

Markovits' theory provides a thorough account of the encoding, retrieval, and inhibitory processes involved in deductive reasoning. Mental models theory maintains that the cognitive representations with which lay deductive reasoning proceeds are semantic, rather than syntactic, in nature. In this view, the cognitive processes employed by children and adults when engaged in deductive reasoning are not related to the rules of formal logic. A mental model is a real-time representation of possible states of affairs denoted by the premises of an argument. The theory focuses primarily on deduction problems that can be represented as conditional arguments. The particular mental model or models employed on a reasoning problem depends on which of three classes of objects/events happen to be activated.

One class consists of possibilities that are complementary to the conditional (if p , then q). These are cases where something other than p is combined with the denial of q . Using the previous example of a conditional – "If it is raining, then the street is wet" – the combination of "the sky is clear ($\neg p$)" and "the street is dry ($\neg q$)" would constitute a complementary case. A second class comprises alternatives to the antecedent. These are cases involving objects or events that are different from p and where q is affirmed. In other words, these are alternative ways in which q is realized, as in the case where "the street cleaner has passed ($\neg p$)" and "the street is wet (q)." The third class comprising this conceptual space consists of disablers of the conditional rule itself (if p , then q). Disablers represent conditions that, when paired with p , render the conditional false. Thus, cases where it is raining but something prevents the street from getting wet would represent disabling conditions or exceptions to the conditional. Disablers qualify the applicability of the conditional and must be suppressed or bracketed in order for the rule to hold.

Activation of the complementary class, solely, leads to the construction of a mental model featuring an interpretation of the conditional as a biconditional or equivalence relation ("The street is wet if and only if it is raining"). This model would represent the conditional as true when (p and q) or ($\neg p$ and $\neg q$) obtain and as otherwise false. Activation of the alternative antecedent class alerts the reasoner to the uncertain nature of the AC and DA argument forms. The resulting mental model represents (p and q), ($\neg p$ and q), and ($\neg p$ and $\neg q$) as each consistent with the truth of the conditional. Finally, activation of the disabler class leads to skepticism regarding the truth of the conditional rule itself and supports a tendency to represent MP and MT as indeterminate argument forms.

Whether or not a class is activated, and the degree of activation that potentially obtains, depends on a host of factors. The familiarity or novelty of the problem content, the availability of alternative antecedents or of disabling conditions, the degree of relatedness of antecedent and consequent, and constraints pertaining to speed of processing, amount of information to be retrieved, and the capacity of short-term store in working memory can all determine whether, and to what degree, a given class of object/event is activated. The resulting pattern of activation, in turn, determines the mental models that will be generated. At this point, various other considerations become relevant, including the number of models that can be accommodated by working memory and the availability of inhibitory processes that can block specific models in compliance with the demands of the task.

By situating performance on deductive reasoning tasks within a sophisticated model of the development of encoding processes, retrieval processes, and inhibitory mechanisms, mental models theory has been highly successful in predicting the extent to which indeterminate models will be generated on conditional reasoning problems leading to responses of uncertainty. For example, the likelihood of responding with uncertainty to AC and DA is associated with the number of alternative antecedents children and adolescents produce and the age of success on these indeterminate forms depends, at least partly, on the ease with which alternative antecedents can be generated. Similarly, the more readily disablers come to mind with regard to a particular conditional, the more likely a

participant is to indicate that MP and MT are uncertain or indeterminate and the greater the demand on inhibitory processes if the individual is to be required to accept the truth of the conditional.

It is clear from the available evidence that the Markovits model is able to account for a wide range of findings from both the developmental and adult literatures on conditional reasoning. At the same time, the theory seems best suited to explaining deductive reasoning with nonabstract, meaningful content problems. This is because concrete content allows, in principle, for activation of information in long-term memory and, therefore, construction of the three sets of potential models. Genuinely abstract content, that is, content whose semantic interpretation is wholly arbitrary ("If rems are full, then braks are soft," "If there is a vowel on one side, then there is an odd number on the other") is problematic for the theory because it provides no obvious basis for the activation of information in long-term memory. Yet, clearly, some individuals, including adolescents, can reason successfully with more abstract content. Further, success on abstract content problems increases across the adolescent years. Older adolescents are better at generating alternative antecedents under conditions of minimal support, that is, where there is less information in long-term memory or less real-world content that might yield concrete alternatives. Such findings seem to implicate an emerging competence system during adolescence.

By exclusively focusing on real-time psychological processes and their development, whether domain-general (improvements in retrieval, increases in working memory capacity and efficiency) or domain-specific (expansion of a knowledge base), mental models theory provides the best currently available account of the conditions under which an existent logical competence might be manifest on a deductive reasoning task. However, it provides little basis for explaining the development of that logical competence *per se*. The retrieval of alternative antecedents or of disabling conditions from long-term memory can prevent premature closure on a problem, but does it, in itself, amount to an understanding of logical indeterminacy or logical necessity?

Metacognitive theories

Metacognition is central to the developmental accounts of deductive reasoning offered by Kuhn and Moshman. Both theorists place significant emphasis on the basic notion of thought becoming an object for itself and, like Piaget, each maintains that the most powerful forms of reflexive thinking are largely an achievement of adolescence.

Kuhn's account of development across several areas of higher-order cognition, including deductive reasoning, scientific thinking, and argumentation, places particular emphasis on the progressive overcoming of belief-bias effects and other aspects of motivated reasoning. The belief-bias effect within a deductive reasoning paradigm refers to a tendency to accept or reject the conclusion of an argument on the basis of the believability of the premises and/or conclusion, rather than the logical form of the argument. Vulnerability to belief bias can be assessed by setting up a conflict between logic and belief. This can be accomplished by way of arguments that have an invalid form, but true premises and/or a true conclusion.

Alternatively, one could employ arguments with a valid form, but false premises and/or a false conclusion. Belief bias is evident when the former argument is judged to be valid and the latter invalid. When task instructions stress the importance of a logical or formal evaluation of the argument, susceptibility to belief bias tends to decrease across later childhood and adolescence, though it is substantially present even in adults.

Kuhn maintains that metacognition and executive functions are implicated in the ability to overcome belief bias in several respects. First, children and adolescents become less susceptible to belief bias as they develop knowledge of the formal properties of deductive inference and the advantages of using deductive strategies such as falsification. This is a kind of metalogical knowledge. Moshman, discussed next, provides a detailed account of what the development of knowledge about logic might involve. The second relevant aspect of metacognitive development concerns an increasing awareness of, and control over, beliefs. As with Markovits' mental models account, inhibitory capabilities are seen as key here. Where real-world knowledge and the rules of reasoning are in conflict on logic problems, that knowledge, which otherwise represents an aid and support to the application of inference rules, becomes a hindrance and must be suppressed. Overriding heuristic responses based in real-world knowledge and avoiding premature closure make it possible to consider alternatives and to recognize indeterminacy or invalidity despite believable content.

There are other metalevel elements of cognition that are both subject to development and potentially relevant to performance on deductive reasoning problems. In particular, the disposition to apply a competence is important in Kuhn's account. Dispositional factors provide favorable or unfavorable conditions for separating belief from evidence and for inhibiting more heuristic forms of processing. For Kuhn, disposition primarily involves intellectual values and level of epistemological understanding or awareness, where the latter concerns an appreciation of the nature of knowing and knowledge. Concerning intellectual values, deductive strategies are more likely to be invoked by individuals when the goal of arriving at veridical judgments and maximizing knowledge is given priority over the protection of existing beliefs and personal theories. Likewise, a personal epistemology in which knowing is understood to be a relatively transparent process that yields facts and opinions, rather than a theory-laden process yielding testable and falsifiable claims, is likely to favor inductive reasoning strategies over deductive strategies.

Moshman's theory of the development of deductive reasoning also places great emphasis on metacognition. In his view, reasoning involves explicit conceptual knowledge regarding inference (metalogical knowledge) and metacognitive awareness of, and control over, inference. Metalogical knowledge includes the recognition that inference is a basis for knowledge, an understanding of key distinctions among types of inference, an appreciation that conclusions must be consistent with all possible states of affairs represented by the premises, and an understanding of logical indeterminacy, inconsistency, and necessity.

The development of reasoning and rationality is viewed by Moshman as a process of reflection upon implicit metalogical

knowledge. This is essentially the developmental mechanism common to Piaget's notion of reflective abstraction and Karmiloff-Smith's representational redescription. Development involves a self-reflective process by which elements implicit in intellectual acts are rendered explicit and, as such, come under conscious, intentional control, thereby becoming applicable across a wider set of circumstances. This is an internal process, though it is supported by specific types of social interaction. It does not involve a process of transmission from external authorities to the child.

As noted previously, preschool and early school-age children are able to make various deductive inferences that comply with logical norms, but in Moshman's view these inferences do not represent reasoning because they are not consciously or purposefully constrained by particular inferential norms. Conclusions as the outcomes of inferential acts are not conclusions *per se* for the young child, but simply facts, in principle indistinguishable from observational facts. Moshman, however, considers some knowledge of inference and of inferential form and norms to be implicit in children's thinking at this stage. During the middle childhood years, these implicit elements become explicit. According to Moshman's account, we should see a developing awareness of inference as a source of knowledge across the elementary school years. This includes an appreciation of premises and conclusion as distinct components of inference and an increasing understanding of the premise-conclusion relation and of inference as a process which derives the conclusion specifically from the premises. However, still implicit during much of middle childhood are an appreciation of the different syntactic forms for premises (e.g., disjunction, conjunction, implication), and an understanding of key differences among types of inference, and between determinate (valid) and indeterminate (invalid) arguments. Explicit awareness of inferential validity as a function of argument form and independent of the truth and falsehood of the premises is alleged to emerge in adolescence, and this appreciation of logical truth as distinct from empirical truth enables success in reasoning with contrary-to-fact arguments.

Findings regarding child and adolescent metalogical knowledge provide a pattern of purely intuitive or implicit understandings of logical concepts preceding more explicit understandings. This pattern generally conforms to Moshman's predictions. There is also evidence of implicit understanding of more advanced concepts existing alongside explicit command of less advanced constructs.

Unlike mental models theory or domain-specific accounts, the theories of Kuhn and Moshman appear to include aspects of logical competence, but to represent these in procedural form. Logical competence becomes, in effect, conceptual knowledge about logic and about logical strategies along with adherence to intellectual values and personal epistemologies that entail a conscious conformity to logical norms in approaching certain problems. In this way, the theories attempt to avoid any notion of a mental logic. The claim here is that explicit conceptual knowledge about logical necessity and validity can obtain in the absence of an inherently logical-mathematical organization to thought itself. From within the metacognitive perspective, mature thinking is not inherently logical, but it can avail itself of different rule systems, including that of symbolic logic, in

order to accomplish specific goals. These theories also posit the development of metacognitive functioning as contributing in key ways to the controlled and strategic use of deductive inference.

Comparison and Conclusions Regarding the Theories

At this point in time, and despite considerable focus on deduction in developmental research, the available empirical evidence does not allow any decisive test of the competing theories of deductive reasoning because the majority of these findings are consistent with more than one theory. In the absence of decisive tests which might rule out particular theories, it may be profitable to seek some means of reconciling ostensibly competing claims. In this regard, a rapprochement afforded by competence-procedural theory offers a promising basis for resolving differences and preserving the obvious strengths of each theory.

The role of encoding, retrieval, executive, and pragmatic-interpretive processes in age, task, and content effects in deductive reasoning have been significantly clarified by research within domain-specific, mental models, and metacognitive theories. The proposed rapprochement requires interpreting the findings from research conducted within the procedural group of theories as providing important elaborations of the procedural component of a competence-procedural model while, at the same time, rejecting interpretations that blur distinctions between competence and performance or that reduce aspects of competence to procedural factors. The competence-procedural account also recognizes the findings of Kuhn and Moshman regarding metalogical development and some aspects of broader, metacognitive development as confirming the logical competence model of the theory and as identifying key indicators, manifestations, and consequences of an emergent logical competence. The course of development for conceptual knowledge about logic, documented by Moshman, is entirely consistent with the emergence of a class-based mental logic supporting concrete precursors to deductive competence followed by the emergence of a propositional mental logic supporting a mature formal competence. In addition, at least some aspects of metacognitive or executive functioning that have been linked to success on deductive reasoning problems by Kuhn, Moshman, and others could be seen as a manifestation or consequence of an emergent logical competence. For example, there are parallels both empirical and theoretical between the formal operational model of Inhelder and Piaget and certain metacognitive or executive functions such as planning, cognitive flexibility, and cognitive monitoring.

To many psychologists studying reasoning processes, the seeming choice among contemporary theories of deductive reasoning is between, on the one hand, a competence-based account that takes seriously the numerous parallels between rules and operations within formal systems of argument and the psychological processes involved in everyday argumentation, and, on the other hand, a group of what we have described as procedural accounts that deny these parallels or view them as arbitrary and coincidental. Rather than accepting this either/or option, however, a more profitable approach involves a partial division of labor among the theories with mental models and

domain-specific and metacognitive research programs providing key elaborations of procedural systems within an overarching competence–procedural account.

Glossary

Anticipatory socialization The process by which an individual adopts the values and behaviors of a specific group that she or he will incorporate into a new role(s).

Blurred retirement A gradual role transition marked by repeated reentries and exits from the workforce that may encompass months or years.

Bridge employment Employment that takes place between a long-term or career job and complete withdrawal from the workforce.

Career job The occupation which an individual is attached to for a substantial portion of his or her working life.

Crisp retirement A single transition that is a clear-cut exit from the labor force.

Retirement A process – influenced by the sociostructural, cultural, and political climate – that encompasses a worker's personal experience as she or he undergoes the change in balance of work and leisure. This usually includes the following phases: preretirement, the decision to retire, the act (or acts) of retirement, and the continual postretirement adjustment. Manifestation may include a permanent exit from the workforce, employment in a new arena (i.e., bridge jobs), and/or a decision to return to work full or part time.

Introduction

Retirement is often defined as a withdrawal from one's position or occupation, which usually entails giving up one's job. Retirement is not a sudden event; instead, it is a process by which people prepare for living in the later years. There is no one way to retire. Each individual needs to create a plan for himself or herself based on his or her needs and wants in later life. Preparation helps in the decisions about later life choices and facilitates a well-adjusted retirement.

There have been major changes in our understanding of the concepts of aging, work, and retirement. Beginning in December 2007, a change in the economic and social environment, described as a 'recession,' resulted in a clarion call to employees across the life span about the instability of one's work role and retirement. Past expectations and assumptions about retirement need to be carefully reviewed and revised to guide an individual's choices and timing of the transition from workforce participation to full- or part-time retirement.

As part of the decision-making involved with retirement, employees must carefully consider choices in health care coverage, use of retirement savings and pensions, and lifestyle (e.g., housing, travel, social milieu). Keeping these considerations in mind, individuals need to consider how long and under what conditions they will continue to work full- or part time. Many individuals say they want or need to stay in the workforce longer due to lack of resources and the scarcity of future employment opportunities. One of the strongest considerations held by employees is the desire to maintain health care and other benefits; without such benefits, many workers remain at or return to work, either full or part time. Similarly, those employees who have enough resources and are in good health may also choose to continue to remain in the workforce, or they make the transition to retirement. It is important to note that there are individuals who would like to work and cannot find employment either full or part time; considered as discouraged workers, these individuals eventually become retired as a result of the lack of employment opportunities.

As gerontological research indicates, there have been a number of continuing issues that are important to the understanding of work and retirement. Such issues include, but are not limited to: training; maintaining professional competence; job loss; retirement savings and pensions; housing choices; age discrimination in the workplace; and changes in the local, national, and global economy.

Over the last decade, some researchers have been suggesting that organizations need to prepare for the shortage of workforce due to the upcoming retirement wave of baby boomers. Others assert that there will not be shortages, or that predicted shortages will be industry-specific. In some cases, it may be important to retain or attract older workers.

History of Retirement

The evolution of retirement in the United States is a continuing saga. The workforce transitions from agriculture to industrial to the postindustrial technology boom were accompanied by changes in the attitudes, understanding, and policy proposals for retirement. Through the 1700s and mid-1800s, retirement was rather uncommon; about 70% of older men remained in the labor force. Many of these older workers held high-status and prestigious positions. The aged were valued for their wisdom and experience, and forced retirement was not supported by the social ideology of the time.

For those who did retire, it was commonplace to rely on the family for economic support during the retirement years. Almost one-fifth of the population of working-class held little to no financial savings, and in the mid-1920s, surveys of nondependent elderly showed that about 20% held assets or property worth less than one year of a retired couple's expenditures.

The growth in retirement was influenced by two trends in the early industrial era: the development of labor unions and mandatory retirement. In the agricultural era, society tended to value the elderly for their contributions and jobs

were typically flexible enough to allow changes in work demands for those with diminished capacities. The prevailing beliefs that older workers were worn out and useless reinforced the notion that older workers were unable to work. Thus, mandatory retirement emerged as a reflection of these beliefs and became a mechanism for removing older workers. Mandatory retirement served to insure companies against the high cost of continuing to employ older workers over the younger, cheaper, and believed-to-be more 'capable' workers.

The institutionalization of retirement – which gave employees the right to financial support in old age as a result of deferring income during one's years of employment – resulted from the establishment of Social Security Act of 1935 and employer pensions. The purpose of both Social Security and pension systems was to counteract the large population of elderly who were left in poverty due to the lack of private pensions at the time. Additionally, both were passed to protect individuals against the loss of income from unanticipated events such as retirement, disability, or death of the family breadwinner. Social Security payments began in 1940 and were based on careful analysis, considering cost and numbers of older workers. The US government selected 65 as the age for full retirement benefits.

Following the Great Depression and World War II, several improvements in retirement emerged: private pensions became more commonplace and Social Security coverage was extended to cover most workers. The minimum retirement age for Social Security was also lowered to 62 years of age for women in 1956 and men in 1961 for reduced benefit. Over time, the attitude toward retirement began to change from a negative standpoint to one where retirement was a right to those who earned it.

At mid-twentieth century, men aged 65 and older were close to 50% being employed; by the end of the century, fewer than one in five were in the labor force. Early retirement became usual for many. For individuals (aged 40–65) who wanted to continue to work, the 1967 Age Discrimination in Employment Act (ADEA) was passed to protect them from age discrimination. This act was revised in 1978 to prohibit mandatory retirement before the age of 70 years and no mandatory retirement for federal employees. It was amended in 1986 to prohibit mandatory retirement for workers aged 40 and older in most occupations.

By the early 1990s, private pension plans were commonplace, if not expected, by most employees and employers as a portion of income paid to workers. At peak, about 50% of the workforce was covered. Since that time, there has been a shift from defined benefit plans that guarantee a fixed retirement income to defined contribution plans, in which benefits depend on returns from invested funds. Defined benefit programs are subject to economic downturns, and thus make employees' financial future less certain.

The economic downturn starting in 2007 has made many workers aware that defined benefit programs can have a major loss of value. One way of dealing with this is for individuals to work longer, either in full- or part-time retirement. The result of this has been an increase in the average age of retirement, with workers choosing to work longer.

Definitions of Retirement

As stated earlier, retirement is often defined as a withdrawal from one's position or occupation, which usually entails an individual giving up his or her job. However, retirement is still evolving today as evidenced by changing transition patterns and ages of labor force exits. Retirement is not necessarily a complete withdrawal from the workforce and work activities. An estimated 20–30% of older workers continue to work or reenter the workforce, although the likelihood of reentry decreases with age. Postcareer bridge employment may involve changes in industry, occupation, hours, or salary. The multiple pathways from work to retirement highlight the importance of viewing retirement as a process and the need to study this process over time. A crisp retirement transition is a single, unreversed, and clear-cut exit from the labor force. A blurred retirement transition is a gradual role transition marked by more than one exit and reentry and may encompass months or years.

Crisp and blurred transitions are found to differ by age, financial resources, and health status. Individuals with poor health are more apt to demonstrate blurred transitions. Individuals with the poorest health are more likely to demonstrate a crisp exit pattern. It is clear that examining exit patterns is very important in understanding the retirement process: considering retirement as a single transition does not adequately capture the complexity and the dynamic nature of the retirement process.

Three retirement definitions found in the literature include self-definition of retirement, receipt of Social Security or pension income, and hours worked. Under current Social Security rules, people can work full time and receive the benefit with additional earnings, if above the full retirement age. If a worker uses Social Security benefits before his or her full retirement age, there may be an earning penalty. This is another example of the elusive nature of a definition of retirement.

The Retirement Process

Retirement is a process rather than a single event. The phases that have been identified as a normative experience include: preretirement, the decision to retire, and the continual postretirement adjustment. The initial stage, preretirement, deals with three major areas of concern: social, financial, and time management. Essentially, workers begin the contemplation of retirement and anticipatory socialization. Studies indicate that this stage can begin as early as young adulthood. During this phase, workers typically begin discussing retirement with loved ones, peers, and coworkers; engaging in retirement-oriented activities; and financially preparing for the life change.

The decision to retire, the second phase, addresses two major concerns: when and how to retire. The timing of retirement depends on whether or not retirement is voluntary or involuntary. If the decision is voluntary, it is likely that for many workers, the decision is considered over several years taking many elements into account such as health, finances, attitudes toward retirement, and family obligations. On the other hand, workers can be faced with involuntary retirement,

a result from employment constraints rather than a preference for leisure. Such constraints may include allowable mandatory retirement policies, organizational restructuring, a worker or loved one's ill health, or pressure from the employer. Additionally, an older worker may be forced to choose involuntary retirement because of the few choices he or she may have available. Overall, the decision to retire may or may not rest in the hands of individuals themselves, but they do have control over how they prepare for the transition.

Finally, retirees enter a period of postretirement adjustment, a continuous process that begins once a worker has determined when and how he or she will retire. The workers begin to discuss specific plans with others and enter a period where they experiment with and explore leisure activities. Individual differences exist in terms of available resources and also in what activities a retiree may find satisfying. Additional factors that affect a retiree's adjustment include preparation, socioeconomic status, health, marital status, and social support.

Self-Management

In response to changing social and organizational environments, self-management has emerged as a major theme. Individual responsibility is required for maintaining and updating knowledge, skills, and abilities when workers change employers, occupations, and/or jobs within their current company. Similar to work, retirement has moved into the realm of self-management. The individual has to take on the planning and decision-making of when and how to retire. Retirement is still evolving as can be seen by changing transition patterns and labor force exits. The transition from work to retirement can take many forms including bridge jobs, part-time work, or new careers.

Currently, the emphasis is on how individuals will be able to plan for future employment opportunities and retirement. Being creative in reshaping the later life period to fit continued work, retirement, and work in retirement is a challenge for many workers. The resolution to this dilemma is captured in discussions of the protean career.

The protean career concept stresses continuous learning and self-direction of both one's life and career, in that self-management of career and retirement entails taking personal control of decision-making. Not everyone has a career as such but may have a series of jobs that may be unrelated. Many individuals may have limited control of their employment situation. Some individuals may accept this responsibility and respond proactively with success. Others may respond ineffectively or may be immobilized by decision-making. These individuals may not have the needed skills, psychological resources, or may not know what their work future will be like. A major decision is whether a person will remain in the same career, change his or her career, or retire.

Career development training and retirement education need to be offered to workers of all ages in order to promote understanding and provide workers with important information about future planning which can include retirement. Employees cannot rely on their employer for career

development and/or retirement planning but need to make this a personal responsibility.

Along with the above issues, we need to consider the multidimensional aspects of decision-making in self-management of work and retirement. There are four dimensions that can influence self-management of career and retirement: self-concepts, work/employment environment, relationships with others, and community. Each dimension is influenced by many factors, which could affect the decision-making process of whether individuals would continue work or leave partially/entirely.

The first arena of self-management is a person's self-concept. Self-concept is influenced by many factors in consideration of retirement issues. One consideration is the need to understand one's past self and what values, preferences, and desires are based in the past. This is countered and complemented by one's future self. The possibility of new lifestyles, new living environments, new friends, and new actions are options. Three factors are important here: (a) the understanding of change and an awareness of the passage of time, (b) how an individual views change in others and oneself over time, and (c) how one sees and understands the implications of time into the future is a major aspect of personal cognitive integration leading to increased self-understanding.

Another consideration influencing self-concept is the perceived control that one has about his or her life at the personal level in relation to significant others as well as her or his work, career, business situations, etc. An individual may feel in control based on economic resources and position held, or may feel extremely vulnerable based on the current financial situations and business climate. During an earlier economic downturn in 2002, the United States went from the highest level of employment to a realization that many employment situations were vulnerable. The summer of 2002 made many potential early retirees come to terms with the fact that they would have to work longer based on the decline of their investments. In many cases, people in retirement have had to modify their daily choices or return to work in order to maintain their desired lifestyle.

A third factor impacting self-concept is personal insight, which takes into account how well an individual understands himself or herself with regard to motivations, personal desires, work approaches, and relations to family, friends, and organizations. Self-study, education, and counseling may aide this process. In addition, organizational based self esteem (OBSE) and perceived norms are important factors to consider. OBSE reflects how valued an individual feels in relation to one's fellow workers and the feeling of contribution that one gets from one's work. Perceived norms refer to how one perceives the work and retirement norms around one's self. It has been found that workers were more likely to retire early when they categorized themselves as older adults. Thus, one's personal social clock and one's understanding of social norms will influence self-perceptions and actions to be taken. The orchestration of all of these influences on the self is included in self-management capability.

The second arena of self-management of career and retirement focuses on the work environment. One is concerned here with one's self-evaluation of the employment situation. Part of

this relates to one's appraisal of the current employment situation. Beliefs regarding how one is viewed by supervisors, outcomes of performance appraisals, perceived growth opportunities within the organization, and observed treatment by others are of great influence. Also, it is important that individuals understand personal strengths and weaknesses in their working styles.

Employment-based appraisal refers to the formal and informal feedback that one receives from supervisors, which may result in various outcomes such as salary increases (or decreases), promotion (or demotion), and involvement in organization planning and policy. Work opportunities refer to future plans within the work context and potential opportunities over time. New work opportunities may be an important incentive to continue to work as a bridge to retirement. Other bridge opportunities may provide a gradual change in responsibilities to part-time employment. Another major factor is one's activities in continuous learning and maintaining professional competence. Remaining competitive with up-to-date skills may make one valuable to the organization.

Relationships to coworkers are also extremely important in continued employment. How an individual feels about his or her work situation is highly influenced by coworker interactions in many cases. Middle-aged and older workers value relationships on the job. A negative relationship with coworkers may lead a valuable older worker to take retirement. Supervisors may want employees to stay but may not be aware of interaction difficulties. On the other hand, an older employee who feels the need to work longer than he or she really wanted to for financial reasons may be a challenge for coworkers and supervisors.

Perceived organizational culture is another factor that provides important messages to current employees. Choices made by current organization leadership and how these are transmitted to current employees provide important general information that would shape retirement decision. Middle-aged and older employees are usually very aware of changing climate and how long service employees are being treated.

Another factor is possible new opportunities, namely looking for new employment opportunities within or outside of one's organization. This can be preplanned in terms of second or third career education and training or may be related to chance encounters or in response to a corporate recruiter. However, often middle-aged and older employees may not be in a position to choose when to retire as discussed elsewhere.

Self and work environment relationships with significant others and with community can be important dimensions to consider. These areas can have major influence on decisions regarding work and retirement. Considering important relationships and having spouses or significant others involved in retirement planning are essential for planning to be successful. Family relationships may become more important and become a major influence in self-management of retirement. Choosing to be near children, grandchildren, or other important family members may be a reason to retire from one's current job, move, and reestablish one's household in a new location. New part- or full-time employment may be a choice after such a move. Migration research tells us that ~80% of older adults choose to stay in their home communities to be near family and friends. This does not preclude new and

exciting choices as part of a new life period. In addition, caregiving responsibilities may be a major concern for many people. In many cases, an employee may choose or feel forced to retire in order to provide care to loved ones. Corporate eldercare services have been available for over two decades to assist employees who have care responsibilities. Such services may make it possible for employees to be able to continue to work.

What keeps people in their home communities or what aspects of community may be important in providing a meaningful context and sense of belonging? Much of the classical retirement literature has focused on these dimensions of community. What is important here is how these dimensions relate to one's self-concept and how this influences our decisions to continue to work or retire. Some individuals feel alienated by their community relationships and wish to reestablish themselves in a new community context. Others may have more than one residence and move back and forth between the new and the old locations, empowered by both, and others totally enjoy being a part of roles and involvements that are longstanding.

Self-concept is influenced in many of the above-described ways. What is critical is one's ability to bridge from the individual level to the broader work and societal context. Taken together, decisions regarding working longer, retiring, or finding a new job made by older workers can be influenced by many dimensions and factors in a dynamic way. Economic factors and business climate may limit opportunities for self-managements of retirement and work issues. Self-management entails greater resilience and flexibility and can be an important aspect for older workers to survive in changing work environments. In the following section, factors relating to retirement decisions, as well as retirement planning and process, will be discussed.

Retirement Planning

Retirement planning is one of the most important factors to facilitate later retirement satisfaction and adjustment. People need to consider financial aspects as primary. In addition, retirement education includes, but is not limited to, such aspects as the use of leisure time, where to live, health care and other benefits, wills and other legal documents, and the consideration of part- and full-time work in retirement. Those who have engaged in retirement planning have been more likely to retire earlier, and feel confident and satisfied with retirement decisions. However, retirement planning can also lead to other choices such as new full- or part-time employment, volunteer activities, later life learning, and other creative endeavors.

Due to the recent economic downturn, many people have been forced to take retirement before they had planned, which may make them feel more insecure and vulnerable. Thus, retirement planning should be started at an earlier career stage so that the worker is ready to confront unpredicted situations. Having financial resources can help to meet future needs and choices. Individuals who have higher internal locus of control and higher self-efficacy might feel that they have more control, resulting in better decision-making and adjustment. However,

the current sense of vulnerability shared by many middle-aged and older employees leaves a sense of little control. Unemployed individuals have to regain their self-efficacy and begin the process of seeking employment in a very difficult job market, which recently has included an unemployment rate as high as 10%.

Some researchers have suggested that the retirement process needs to be considered as a coupled process between husbands and wives, which indicates that retirement planning should include spouses or significant others. If husband and wife are retiring at different times, this may or may not create some marital strain. This may depend on the need for additional financial income and/or the sharing of leisure activities.

Another concern is caregiving, which is particularly relevant to women's experience of retirement. Women are traditionally the predominant caretakers in families for children and adults. The services that they provide to their loved ones are not compensated. Women's caretaking responsibilities are one of the factors that keep women out of workforce longer than their male counterparts. On average, women spend significantly more years out of the workforce than men, and while they are in the workforce they have interrupted careers. Because Social Security benefits are calculated based on an individual's average earnings over 35 years, many women are likely to have less money during their retirement. Unequal pay and systematic biases in policies also contribute to the economic constraint experienced by women. Women's jobs pay less than men's do, and women tend to work at jobs without pensions. It is also important to note that both men and women minorities also experience less lifetime pay and systematic bias, which results in lower pensions and retirement funds.

In retirement planning, it is suggested that one should examine at least four domains: financial planning, health planning, interpersonal/leisure planning, and postretirement employment plans. In sum, retirement planning should start from understanding one's own current situation, including health status, family responsibilities, financial status, and personal interests and desires. Considering recent economic developments, older workers may be even more interested in bridge employment than they were in the past. Individual differences are a key concept here. Some individuals will continue to have fairly traditional careers with job continuity and others may have interrupted and difficult job histories. Many middle-aged and older adults will continue to work longer out of choice or necessity. Others may experience layoffs and may need to find new employment. Older workers need to be resilient and have self-initiative.

Many older workers have strong skill levels, can successfully update their skills and abilities, and can be trained in new areas. They can also successfully make the transition to retirement. For many, there may be a need for more supportive job-finding situations such as employment coaching or job club. Additionally, they may need additional training to be competitive and may need assistance in planning for retirement.

Multiple pathways from work to retirement highlight retirement as a process. Changing economic environments have had a dramatic effect on individual financial well-being and have altered individual approaches to when and how individuals plan to retire. Another aspect is that workers may have to work longer than anticipated or may have to accept an early buyout

package rather than risk being laid off or fired at a later date. Individual characteristics, work-related, and other factors have an impact on work and retirement choices. These factors influence anticipatory retirement planning and decision processes.

The Changing Nature of Retirement

From 1969 to 1979, more than one-third of workers left their career employment before the age of 55, and half left before the age of 60. Improved health care and increased life expectancy have opened the door for significant shifts in the timing of retirement. Work life versus retirement length on average has changed from 46 years of work with one year in retirement in 1960 to 37 years of work with 12 years in retirement in 1995. Since that time, the trend toward early retirement has reversed with workers once again working longer. Change in the future may be related to Social Security moving to full benefit retirement at age 67. Recent data show many people taking Social Security at an earlier age especially if there is no earnings penalty.

How Do Future Generations View Retirement?

Many studies of retirement are cross-sectional and as such focus on age differences. Such studies may involve multiple generations at different points in the life span which may not represent what workers actually experience. Longitudinal studies, looking at individuals across time, may be generation-specific. Thus, retirement literature collected on earlier generations may not generalize to later generations. Different generations have had or are having different experiences at critical points in the life span that may lead to very different attitudes and values about retirement.

Upcoming generations are concerned about what their retirement period will be like. Will Social Security make the changes to meet the expected levels of benefit? Will people make the choice to build up defined benefit pensions that will provide the needed level of support? Will people be more conservative about their use of credit? And, will people plan to work longer to maintain their standard of living?

Many adult and older adult workers have made the voluntary/involuntary decision to work part time in retirement. Others are concerned that they may have to work full time to meet their needs in retirement. Many people today expect to have a lifestyle in retirement that is similar to their working years. Previous generations realized that the retirement period might require a more conservative and scaled down lifestyle. Future generations will need to come to terms with the realities of later life living.

New Concepts of Later Life

On a more positive note, a major issue is how to use extra decades of life and how to re-envision long life to include public engagement and personal growth. It is suggested that many people in their 50s and 60s should be considered in mid-career, rather than on the edge of retirement. Expectations

regarding working longer should become more normative. Many authors are suggesting that we redesign the later life period. This requires exploring new roles and activities. However, we must be aware that not everyone will be able to do this. Poor work histories, health problems and disability, and family caregiving responsibilities also need to be considered. Retirement policies need to include individuals who may need help and assistance in the 60s if not before. The challenge is to be able to accommodate a full spectrum of need and capability. Future public policy will play an important role in defining the retirement of the future.

Glossary

Exogenous Outside the control of the individual decision-maker.

Expected utility Satisfaction that one can reasonably expect to obtain in an uncertain situation; measured as the sum of the possible outcomes times their respective probabilities.

Probability Likelihood that an event will occur.

Risk Probability that an event with negative consequences will occur; the opposite of safety.

Utility Satisfaction one derives from an activity (e.g., consumption).

Background

The justification for legislation requiring safety belt use in automobiles is the reduced risk of death and/or injury, given the occurrence of an accident. Likewise, attempts to reduce risk in the home (e.g., tamper-proof packages and safer cigarette lighters), during recreation (e.g., sunscreens), and/or in the workplace (e.g., Occupational Safety and Health Administration (OSHA) regulations) are designed to create a safer local environment. However, the expected results from these risk reducing activities can be partially or fully offset if individuals behave in a risk-compensating manner. Risk compensation occurs when individuals, in response to an exogenous improvement in safety, voluntarily accept greater risk by reducing individual safety activities. The net effect is a reduction in the effectiveness of the safety-enhancing program. There exist numerous examples of risk-compensating behavior in home, recreation, and workplace situations.

Tamper-proof packages for household cleansers and prescription drugs were designed to reduce accidental household poisonings. However, the increased safety was largely offset by risk compensation, as these items were made more accessible to children through inadequate storage practices, which caused a documented increase in household poisonings after the adoption of tamper-proof packages. Likewise, individuals appear to have decided to spend more time in the sun in response to the availability and use of sunscreen products. Thus, increased sunscreen use has had little impact on the number of cases of melanoma and nonmelanoma (basal and squamous cell) skin cancer. In fact, the trend lines for these cancers of the skin are positively sloped over the period 1975–2006. The OSHA has been regulating health and safety conditions in the workplace for several decades. However, the policies of OSHA are less effective than expected, as workers compensate for safety regulation by behaving in a riskier manner; that is, workers reduce individual safety because of the perception that they are protected by government policy. Thus, while work-related death rates have been reduced over the past 35 years (from 18 to 3.6 deaths per 100 000 workers), ~5100 workers lost their lives in 2008. For the period 1988–97, the rate of cases with ‘days away from work’ declined 40%, but there was a 140% increase in the rate of cases with restricted work activity. Thus, while there exists information that points to the effectiveness of

OSHA regulations, there also exists countervailing evidence. A specific example of workplace risk compensation occurred in major league baseball. The number of batsmen who have been hit in major league baseball has increased markedly today when compared to the period before major league baseball mandated helmet use (mid-1950s). Specifically, the hit-by-pitch rate has increased from approximately one hit batsman for every 10 games in 1946 to one hit batsman for every 2.5 games in 2007. Thus, behavior of players has responded to safer batting situations by, for example, leaning over home plate because they feel safer.

Risk-compensating behavior is often described as an optimal response to a change in the existing situation. The individual decision-maker is confronted with new information and adjusts in an effort to increase utility or satisfaction-producing activities. An increase in exogenous safety can cause individuals to participate in activities that were formerly avoided because of their inherent negative consequences. For instance, the birth control pill, by reducing the probability of unwanted pregnancy, allows people to be more comfortable with increased sexual activity, which then may increase pregnancies. Helmets for bicycle riding and/or skiing permit faster speeds and more risk-taking behavior, resulting in more violent accidents and canceling the intended safety benefit. Improved automobile safety allows greater speed and driving under what were formerly hazardous road conditions.

Risk compensation is also applicable in converse conditions. An increase in exogenous risk often causes individuals to behave in a safer manner. Thus, as weather causes deterioration in road conditions, drivers generally compensate by driving slower. It has even been suggested, in jest, that mounting a dagger on the steering wheel pointed at the driver may incite safer driving.

In the next section, we describe in detail the decision process that underlies risk-compensating behavior. This is followed by a discussion of the empirical results concerning driving behavior, the most studied example of risk compensation.

Theoretical Construct

Risk compensation is derived from an economic model of behavior. In general, individuals possessed with full

knowledge are assumed to behave in an optimal manner and maximize utility or satisfaction, subject to an income constraint. In this context, safety (or risk reduction) is only one argument in the utility function. Note that the objective is to maximize overall utility, not minimize risk. The primary outcome of this model is that individuals will choose activity levels to the point where the incremental or marginal benefits equal the incremental or marginal costs of any specific action. As with other utility-producing goods, an optimal level of safety will be chosen by the utility maximizing individual.

In the real world, there exists considerable uncertainty concerning the effects (benefits and/or costs) of possible decisions. Thus, the standard utility maximizing model is not applicable to situations characterized by uncertainty. In these uncertain situations, individuals are assumed to maximize *expected* utility, which is the algebraic sum of outcomes multiplied by their respective probabilities. The optimal conditions for this model specify that individuals will undertake an action until the incremental expected benefits equal the incremental expected costs. This decision process can be seen in the following model, where subscripts refer to partial derivatives.

Let

- s = individual safety measures.
- e = exogenous safety measures beyond the control of the individual, such as required seat belt use laws.
- $P = P(s, e)$, the probability that an individual is involved in an accident where probability is influenced by individual actions ($P_s < 0$, $P_{ss} > 0$) and exogenous factors ($P_e < 0$, $P_{ee} > 0$); that is, as individual and exogenous safety measures increase, the probability of an accident declines with a declining rate because of diminishing returns.
- $L = L(s, e)$, the loss associated with an accident where loss is influenced by individual actions ($L_s < 0$, $L_{ss} > 0$) and exogenous safety measures ($L_e < 0$, $L_{ee} > 0$).
- $D = D(s, e)$, the disutility associated with practicing individual safety ($D_s > 0$, $D_{ss} > 0$) and from exogenous safety measures ($D_e > 0$, $D_{ee} > 0$). Disutility may also result from the interaction of individual and exogenous actions ($D_{se} > 0$).

Also, note that no assumption is made concerning the relationship between s and e in either the probability function P or the loss function L . If P_{se} and L_{se} are nonnegative, then individual and exogenous actions are substitutes in production. However, if these values are negative, then individuals perceive s and e as complementary goods, which are goods that make each other more valuable.

The individual is assumed to maximize expected utility (U), constrained by income. In the simplest case, there are only two states of the world: (1) the accident occurs with probability P and (2) the accident does not occur with probability $1 - P$. This simple optimization problem is written as follows:

$$\text{Maximize } U = P(s, e)[I - D(s, e) - L(s, e)] + [1 - P(s, e)][I - D(s, e)]$$

or

$$\text{Maximize } U = I - D(s, e) - P(s, e)L(s, e) \quad [1]$$

The individual will take safety measures until the benefits of additional action (benefits of reduction in expected loss) are just offset by the additional disutility. Thus, optimal individual

safety effort, determined by maximizing eqn [1] with respect to s , will conform to

$$-D_s = P_s L + P L_s \quad [2]$$

where the right-hand side is the extra benefits (change in probability times the loss function plus change in the loss times the probability) and the left hand side is the additional disutility.

The relationship between individual and exogenous safety measures can be determined by treating eqn [2] as an implicit function and using the implicit function rule to solve for ds/de .

$$ds/de = (D_{se} + P_{se}L + P_s L_s + P_e L_s + P L_{se}) / (-D_{ss} - P_{ss}L - 2P_s L_s - P L_{ss}) \quad [3]$$

The theoretical construct can be used to make a number of predictions concerning risk-compensating behavior. First, $ds/de < 0$ if individual and exogenous actions are assumed to be substitutes (see description above) in the probability and loss functions. This is the formula for compensating behavior. That is, increases in exogenous safety measures relax the constraint and allow the individual to substitute exogenous safety for individual safety. The individual reallocates scarce resources, purchasing less individual safety and more of other utility-producing goods. However, it should be noted that the sign of ds/de is indeterminate if s and e are assumed to be complementary in reducing risk and loss. In this case, risk-compensating behavior does not always occur and will depend on the extent that complementarity produces additional safety that offsets the extra disutility of any exogenous safety measure. The manner in which individuals treat individual and exogenous safety measures is, therefore, an empirical question. A priori one might expect that relatively risk-averse individuals would demonstrate the least amount of compensating behavior. Specifically, exogenous safety measures might not be offset by reductions in individual actions. Likewise, risk lovers may be relatively strong candidates for compensating behavior. In the next section, we present the relevant data concerning this hypothesis.

The second prediction of the model is that risk compensation will be heightened in situations in which there exist individual activities that substitute directly for the exogenous safety measures. If none exists, then there is no opportunity for risk-compensating behavior.

Third, risk compensation (ds/de) will be large when the probability change (P_e) corresponding to the change in exogenous risk is large. Thus, one can expect that policies that have a large (small) effect on perceived risk will (will not) produce compensating behavior, *ceteris paribus*.

Fourth, the benefits of risk-taking must be relatively large to induce risk-compensating behavior. If there is little to be gained in terms of utility from risk-taking, then the individual will lack the necessary incentive to alter behavior.

Finally, risk compensation will be larger for exogenous safety measures that affect the accident probability than for those measures that affect the severity of damage from the accident. For example, illegal immigration from Mexico is largely unaffected by a change in apprehension rates because deported illegal immigrants simply make more attempts to enter the United States. Thus, risk compensation offsets any increase in

apprehension rates. In this case, a change in the severity of punishment would likely have a greater impact because of the occurrence of less risk compensation.

Empirical Results: Driving Behavior

Automobile travel is risky business, with over 40 000 deaths and millions of injuries per year in the United States. Worldwide, these numbers are magnified considerably. The growth in deaths and injuries worldwide will likely increase substantially over the next two decades considering the rapid growth in vehicle ownership in China, India, and other countries. A recent study suggests a potential 66% increase in worldwide automobile-related fatalities over this period.

In the mid-1960s, Ralph Nader called into question the safety of automobiles and the complicity of automobile companies in producing a dangerous product. Regardless of the truth of the issue, the federal government responded with new regulations requiring installation of safety devices. This initially meant padded dashboards, collapsible steering wheels, and seat belts. Over time, the regulations became very extensive, leading to the basic redesign of the automobile to incorporate numerous safety factors. Individual states also became involved by passing laws requiring seat belt usage, changing speed limits, and setting lower limits on driving while drinking (including much higher penalties for violation of the law). Today, 30 states have primary seat belt laws (a person can be stopped for not wearing a seat belt) and 19 have secondary seat belt laws (a person must be stopped for another violation before the seat belt law can be enforced). The only state without a seat belt law is New Hampshire. Consequently, over the last 15 years, seat belt usage has increased in the United States from ~60 to 83%, and the vehicle occupant fatality death rate has declined from 1.4 deaths per 100 million vehicle miles traveled to 1.1 deaths per 100 million vehicle miles traveled.

Considering the above, it is clear that the magnitude of the potential cost of accidents and the associated response of the government through regulation presents an important and interesting area of study regarding offsetting behavior that perhaps allows for a natural experiment. Researchers in the early to mid-1970s first suggested the possibility that forcing drivers to consume more safety via regulation might lead drivers to offset the beneficial effects by driving more intensely. The first empirical study of this phenomenon was authored in 1975 and found that after the introduction of the initial federal safety regulations in the late 1960s no beneficial effect existed. The result was attributed to an increase in the deaths of nonoccupants who were involved in collisions with automobile drivers who were driving more intensely. This study came under heavy criticism with respect to the model setup, the empirical results, and their corresponding interpretation. The primary criticism focused on the highly correlated nature of the explanatory variables and the consequent inability to separate the independent impact of a specific variable. Some authors offered ad hoc models that found no offsetting effect. In general, the group most critical of this seminal research represented the public health community, which was outraged that an economist would be so bold as to invade their territory

and offer an alternative view on the impact of safety regulations. A similar reaction occurred among criminologists when an economist offered the economic concept that crime was subject to incentives (both positive and negative) and that new insights could be gained from such a view.

The initial empirical work on risk compensation led to a number of other studies using more sophisticated models and higher quality data. Some studies found offsetting behavior, and others did not. Work in the early 1990s in New Zealand using observational data on seat belt use, in the United States using Center for Disease Control data on self-proclaimed seat belt usage, and in the case of rear seat passengers being injured as a result of greater driving intensity of belted drivers, found offsetting behavior. Others researchers using pooled state data found no offsetting behavior. Probably the most significant work using a long, pooled, aggregated data set (state-level data across time) and the best econometric techniques was published in 2003. This study found a positive effect for seat belt usage (fewer deaths associated with seat belt usage) and no offsetting behavior. But the favorable effect was estimated to be only about a 13% improvement in lives saved, which is much below estimates from laboratory tests and the number cited by the National Highway Traffic Safety Administration, the main governmental regulatory agency.

Recent papers have developed another approach to testing for offsetting behavior. This work stresses the development of experimental data and/or the use of data gathered from individuals through some combination of surveys and established individual data sets. The only truly experimental study was completed in 1988. The authors of this study set up an experiment to gather data from a go-kart track that they built and operated solely for the purpose of the experiment. College students were given extra credit in a course for participating. Drivers were asked to drive the course a number of times with and without a seat belt. Speed and other measures of driving intensity were recorded. It was found that offsetting behavior was statistically significant for a group that first drove the course without the seat belt and then drove the course with a seat belt when compared with the group that drove the course both times using a seat belt. However, the reverse showed no statistically significant difference for those who drove the course with the seat belt and, then, without the seat belt.

In 1992, an attempt was made to develop a more detailed understanding of risk compensation by using individual-specific observations obtained from a regional survey (most previous authors used aggregate level data). The authors of this study also accounted for individual preferences toward relative risks and controlled for other individual-specific variables (besides seat belt use) that might affect driving performance. These confounding factors included the number of years individuals had worn seat belts, age, miles driven to work, education level, gender, and annual income. Finally, they used a more sensitive indicator of risk-compensating behavior. As discussed above, the aggregate studies have analyzed the impact of safety belts or safety belt laws on the number of fatalities and/or the number of accidents. However, these are rare events and much risk compensation may occur without the occurrence of an accident or a fatality. The 1992 study analyzed the impact of an individual's seat belt usage on the number of moving violations or tickets. The premise was that if

seat belt using drivers were practicing risk compensation by taking additional risks, then such behavior would result in a larger number of moving violations, *ceteris paribus*.

Econometric models based on individual-specific survey data were estimated to investigate the relationship between seat belt usage and the number of citations for moving violations. The analysis incorporated the risk preferences of individuals as revealed by the degree of precaution exhibited against everyday risk. The results indicated that risk-compensating behavior was undertaken only by those individuals who were not strongly risk-averse. Conversely, seat belt use was associated with relatively fewer moving violations for the individuals who exhibited risk aversion. Thus, individuals who had a relatively low regard for various risks practiced greater risk compensation. On the other hand, risk-averse individuals did not compensate (for the additional safety provided by a seat belt) by driving more recklessly. Clearly, tastes for risk are an important dimension of risk-compensating behavior.

A study in 2006 used individual data gathered through the Washington Department of Transportation. On the basis of this disaggregate data, the authors found that offsetting behavior existed with regard to the selection of vehicles equipped with airbags and/or antilock brakes. Specifically, they found that safety-conscious drivers were more likely to purchase automobiles outfitted with airbags and antilock brakes, but the safety benefits of these measures were offset by driving more intensely. The finding of offsetting behavior by risk-averse individuals is contrary to the results of the earlier 1992 study described above that found that offsetting behavior was concentrated among the less risk-averse. This additional evidence may imply that offsetting behavior is more widespread than previously believed, as it seems to extend even to the relatively risk-averse. These studies, taken together, suggest that individual risk preferences are an important dimension which should be considered when testing for risk-compensating behavior.

Finally, the most recent study (2007) of risk-compensating behavior using disaggregate data (individual driver information) is based on data from the National Association for Stock Car Auto Racing (NASCAR). These individuals, given their profession, are most likely characterized as 'less risk averse.' The estimated relationships, which include a set of rigorous control variables, strongly suggest that drivers practice risk compensation by driving more recklessly after safety regulations are instituted. However, the study also found that the impact of the offsetting behavior is relatively small. For a 10% increase in NASCAR safety measures, there is about a 1.8–2.8% increase in reckless driving. For a total offset to occur, it would be necessary to have a 10% increase in reckless driving.

Concluding Remarks

A commonly-used approach for assessing the effectiveness of an exogenous change in safety is to examine the technological aspects of the change. For example, if occupant movement can be restrained with a safety belt during the occurrence of an automobile accident, a prediction can be made regarding the number of injuries and lives saved by the given safety belt usage. However, this technological approach ignores any behavioral change that may accompany the technological

change. To the extent that behavioral change occurs, the estimate of injuries and lives saved will be in error. In general, if individuals tend to compensate for exogenous safety changes and thereby behave in a riskier manner, the effectiveness of the exogenous changes is reduced. Thus, a technological approach is incomplete and a more general model of behavior must be used to accurately assess exogenous safety changes. This is the objective of the economic model of behavior discussed above.

In the empirical research discussed herein, we find evidence that supports the existence of risk-compensating behavior for automobile safety measures. Of course, the nature of the risk, the age and gender groups the risk affects, and the culture could affect the relative magnitude of estimated risk compensation. That is why many of the confounding factors that could potentially influence the results are included in the econometric analysis. Thus, in the case of automobile safety, variables such as road quality, weather, driver age, miles driven, speed, race/ethnicity, gender, alcohol, automobile quality, time, space, education, income, and others have been included along with the variables related to automobile safety measures. The econometric models, most often regression models, are designed to allow for all these confounding variables to be held constant while determining the impact of the focus variables. Therefore, when a researcher suggests that automobile safety legislation might result in an offsetting effect, the researcher is stating this with the proviso that all reasonable factors have been included in the model and not allowed to change. Obviously, if everything were changing at once there would be no way to determine a suggested sequence of causation.

Risk compensation (or offsetting) has several important implications for the design of social policies that promote safety in the home, in the workplace, and during recreation. First, programs should be designed to achieve the largest direct impact on safety because offsetting behavior (an indirect effect) could reduce their effectiveness. For example, seat belt laws that are enforced as primary laws will provide greater overall risk reductions than those enforced as secondary laws; while risk compensation will occur in both situations, primary laws will provide greater direct risk reductions, which translates into greater overall risk reductions. Second, policies should be designed to reduce the expected loss from the event rather than the probability of the event. Policies that affect the probability of the event (e.g., better tires, shorter stopping distances and turning radii, and wider traffic lanes) provide direct feedback to the individual and heighten the potential for risk compensation. However, policies that reduce the loss given occurrence of the event (e.g., high penetration resistant windshields, breakaway sign posts, and seat belts) provide less direct feedback and reduce risk compensation.

There exist many policies that can be adopted to enhance safety and minimize the offset associated with risk compensation. However, the anticipation of risk-compensating behavior should be an inherent part of policy design.

Glossary

Environment of evolutionary adaptedness (EEA) The environment in which a behavior was selected for via the processes of natural selection.

Evolutionary psychology A perspective that emphasizes the importance of understanding both ultimate and proximate explanations of psychological mechanisms and behavior.

Intersexual competition Competition between members of the opposite sex.

Intrasexual competition Competition between members of the same sex.

Paternal uncertainty Whereas women who give birth can be completely certain that the infant shares their genes, men do not share this certainty. This biological fact is believed to produce differential investment in the child from

mothers and maternal relatives than from fathers and paternal relatives.

Proximate-level explanation An explanation of a mechanism or behavior that focuses on factors in an organism's immediate environment.

Risk-taking A specific type of decision-making and behavior in which the outcome of the decision is associated with a relatively great amount of variance in expected outcomes. By engaging in risky behaviors, individuals face consequences in which they have more to gain and more to lose compared to low-risk behaviors.

Ultimate-level explanation An explanation of a mechanism or behavior that focuses on the trait's adaptive evolutionary origins.

Young Male Syndrome

The increased tendency for young men to be more risk-oriented and aggressive than other demographic groups was first referred to as 'young male syndrome' by Martin Daly and Margo Wilson in a 1985 paper in which they elaborated upon a proposed ultimate explanation for this pattern and provided supporting data from a study of those who were convicted of homicide and their victims. This article explains the empirical finding that young men are more prone to take risks than members of other groups by addressing three fundamental questions: (1) What functions do risky and aggressive behaviors serve? (2) Why are men generally more likely to take risks and behave more aggressively than women? (3) Why do young men, in particular, tend to take more risks and act more aggressively than men of other ages or women?

Much like Wilson and Daly's original explanation of this phenomenon, the approach taken in this article relies heavily upon the perspective provided by evolutionary psychology. This perspective suggests that many of the behaviors and cognitive processes observed in animals evolved to perform specific adaptive functions. Contrary to perspectives that suggest that risky and aggressive behaviors are typically the symptom of some pathology, a functional perspective suggests that these patterns of behavior are, to some extent, typical of psychologically healthy individuals. In spite of this proposed normalcy of aggression, it cannot be denied that aggressive acts in the modern world frequently occur in such a way that they are maladaptive at the level of the individual. For example, a man who is convicted of homicide will lose his freedom, resources, and possibly, his life. For these reasons, it is easy to understand why someone might consider such behaviors to be maladaptive. The evolutionary perspective, however, requires taking into account the environment in which a behavior was selected for via the processes of natural selection. This environment is

typically referred to as the environment of evolutionary adaptedness (EEA). Anthropological evidence suggests that homo sapiens first emerged during the Pleistocene era, which began ~1.8 million years ago and ended about 12 000 years ago. Because evolutionary change occurs relatively slowly, it can be concluded that most human adaptations are tailored to a world which was fairly different from the world that we currently inhabit. Modern technological innovations in weaponry have enhanced the destructive potential of human aggressive behavior. Although ancient man possessed primitive weaponry that was capable of killing, such as stone spears and axes, these weapons still required a considerable amount of physical strength to produce lethal force. Mass-produced firearms, which have existed for fewer than 200 years, grant lethal force to any individual who is physically capable of pulling a trigger. In spite of the fact that most acts of human aggression remain nonlethal, the introduction of modern weaponry has produced an environment in which normal and functional aggressive responses that might have been nonlethal in the ancient world are somewhat more likely to produce more extreme and potentially lethal consequences. The extreme nature of homicidal incidents demands one's attention and may lead to a common-sense conclusion that human aggression is dysfunctional. However, an understanding of the self-presentational functions of risk-taking during the EEA reveals this conclusion to be somewhat misleading.

Sex Differences in Risk-Taking

As is the case in most animal species, constraints on human reproductive success differ between males and females. The number of offspring that a woman can produce is limited by physiological factors that determine her ability to carry and bear offspring. Given a 9-month gestation period and a period

of lactation following each birth that is typically associated with infertility, one can determine that the maximum number of children that the average woman can bear in her lifetime is ~15. Although physiological factors such as sperm count are important to male reproductive success, access to fecund mates is thought to explain more of the variance in male reproductive success than the reproductive success of females. Whereas a woman is physiologically limited to giving birth to ~15 children through the course of her entire life, a man could conceivably father 20 children in a matter of days assuming that he could gain sexual access to 20 fertile partners.

These biological facts lend themselves to an economic perspective of mating such that fertile women might be considered to be a 'resource' over which men compete for access. Although it is true that women also compete with one another for desirable mates, men tend to compete with greater intensity. Evolutionarily minded theorists typically attribute this increased intensity of male competition to the fact that there is greater reproductive variance among men than among women. In other words, women can give birth to between 0 and 15 children in a lifetime, whereas men can father between zero and several thousand children. This difference, compounded across the evolutionary history of our species, is thought to have resulted in a reproductive advantage for men who were willing and able to take risks and compete fiercely with competitors. Those men who were most fierce and dominant would have gained access to more mates than men who were submissive or noncompetitive. By comparison, traits associated with violent competitiveness had considerably less adaptive value for women.

Two basic biological realities can lead us to the conclusion that the reproductive resources desired by men are scarcer, and therefore likely to be perceived as more valuable, than those required by women. The first reality is the fact that women reach an age at which they become infertile far earlier than men typically do. Menopause typically occurs between the ages of 40 and 60. Although evidence suggests that sperm production can decrease with age, healthy men can continue to produce sperm into their 80s or longer. The second biological reality is that whereas men are biologically capable of becoming fathers at almost any given time throughout their postpubescent lives, women's fertility fluctuates during the menstrual cycle such that she cannot become pregnant unless inseminated at a time that is proximate to ovulation. Women are also incapable of conception from the beginning of a pregnancy until a period of time has passed after birth or the termination of pregnancy. Therefore, we can conclude that at any given time the number of potential fathers will always exceed the number of potential mothers in a human population with a gender ratio that is ~50% female. Although, this tendency may be compensated for the fact that men, cross-culturally, have higher mortality rates than women do. The basic economic principles stemming from differing ratios of supply and demand dictate that because the supply of potential mothers is far less than the supply of suitable fathers at any given time, men will value fertile women far more than women will value potential fathers.

Compounding the aforementioned issue of differential scarcity of reproductive resources is the fact that additional resources sought by women in potential mates can be

replaced by alternatives. Besides desiring a mate who has good genes, women tend to prefer men who are willing to make a commitment to them and who have resources that they are willing to devote to the care of a child. Although these characteristics are desirable, they are not essential to successful motherhood. Even in prehistoric times, women who faced a situation in which they were carrying the child of a man who was no longer present during the periods of pregnancy and child-rearing could presumably obtain support from family members. Inclusive fitness theory and the principle of paternal uncertainty (or maternal certainty) support the notion that maternal kin members should typically be willing to provide for a woman's child regardless of the status of the father. Furthermore, women who had maintained active sexual relationships with more than one man could potentially lead a man to believe that he is the biological father of her child regardless of the validity of this claim, therefore rendering the biological father unnecessary as a vehicle for parental support. The existence of potential alternatives to commitment and resources from biological fathers may explain the existence of cross-cultural variation in the extent to which women value these attributes in mates.

In summary, the reproductive resources sought by men tend to be scarce compared to those sought by women. Although it is doubtful that people consciously incorporate these facts into their mental calculus when it comes to mating-related behavior and decision-making, evidence suggests that these factors have shaped human nature and are ultimately responsible for the evolution of sex differences in aggression.

Intrasexual competition (competition between members of the same sex) over mates does not always take the prototypical form of two men fighting each other for direct access to a desirable female. Surveys of women's mate preferences typically reveal that women prefer men who possess resources and are therefore capable of providing for children. This is thought to be an important factor influencing male competitiveness for resources.

Although the modern world presents an environment in which wealth is durable and can be accumulated to the extent that a person can potentially support oneself using inherited stored wealth alone for an entire lifetime, this was not the case throughout much of human history. The earliest form of durable wealth is thought to have been agricultural resources such as harvested grain that could be securely stored for an extended period of time. Even this development can be considered to be relatively recent in terms of evolutionary time. Anthropological evidence suggests that for most of human history, people adhered to a hunter-gatherer lifestyle. This way of living is not amenable to the accumulation of wealth since it requires a degree of mobility. Therefore, it is likely that women evolved a preference not for modern accumulated wealth but for male displays of ability to obtain resources. Ancestral men who were more successful hunters would have been perceived as good providers. Although they could have also displayed skill in gathering, evidence regarding division of labor in modern hunter-gatherer societies in combination with anthropological studies suggests that male resource acquisition more typically took the form of hunting animals, whereas female resource acquisition centered around gathering roots, berries, and other resources.

Regardless of the nature of the resources, ancestral men likely competed with one another to display their ability to obtain these resources to potential mates. Those who possessed a stronger motivation, greater intellect, and greater physical prowess would have been more successful providers. Hunting success, however, tends to be highly variable such that individual hunting success is not a reliable source of food. A successful hunt will often yield a large quantity of meat that will only be preserved for a brief period of time without advanced preservation techniques. People living in hunter-gatherer tribes are, therefore, reliant on one another for shared meat. Contrary to the myth of the noble savage who shares equally among all members of the tribe, individuals with higher social status tend to get preferential treatment when resources are divided. Because higher status is associated with greater access to shared resources, men can be expected to compete for status as well as for resources.

Male intrasexual competition also serves a self-presentational function. In addition to placing a premium on mates who have access to resources, women have been shown to desire mates who possess physical strength and a degree of social dominance. A physical altercation with another male serves as an opportunity to display both of the aforementioned characteristics. This is a risky strategy because the possible outcomes include the potential for both significant benefits and substantial biological costs. A successful bout would result in a situation in which one's competitors have been bested and the perception of the victor as socially dominant and physically superior to his rival. Of course, violent altercations can also result in physical injury, death, or the appearance of physical inferiority upon suffering a defeat. Even if one emerges victorious following an altercation, the loser or his friends and family might seek vengeance for the initial offense at a later time. In modern times, physical fights carry the added risk of legal consequences, as individuals engaging in violent and aggressive behavior could be charged with assault, homicide, or other related offenses that could result in penalties ranging from minor fines to incarceration or even capital punishment.

Age Differences in Risk-Taking

Now that we have developed a satisfactory answer to the origins of sex differences in aggressive behavior, we must understand why young men in particular tend to favor risky strategies. Whereas the commonly accepted explanation of sex differences in risk proneness is relatively straightforward, explanations for age differences tend to be more diverse, incorporating ultimate explanations for the evolution of these differences with proximate causes of risky behavior that happen to be more common among young men than among young women or older individuals.

Upon reaching adolescence, young men become physically capable of reproduction. Although this involves tremendous changes in hormone levels in both young men and young women, men experience a drastic increase in testosterone levels that greatly exceeds testosterone levels in women. Testosterone levels have been shown to correlate with risky and aggressive behavior across a number of mammalian species such that higher levels of testosterone are associated with more risky

and aggressive behaviors. After men have children, they typically experience a decrease in testosterone levels and engage in fewer risky behaviors.

In addition to the aforementioned biological realities, young men typically possess few resources, and are still in the early stages of developing a social identity and reputation, and are frequently without a mate. This set of circumstances is neither novel nor unique to a particular culture. On the contrary, it is believed that young men have found themselves facing similar social challenges under similar circumstances throughout most of the history of the species. These situational forces have interacted with the aforementioned forces of sexual selection across evolutionary time to shape human nature. In other words, young men have evolved a set of psychological adaptations that help them to solve the adaptive problems of how to successfully compete with other young men in the domains of resource acquisition, impression management, and ultimately, mate acquisition. Because these selection pressures remain relevant in the modern world, one can also expect that they will have a proximate influence on behavior.

Evolutionary models of risk, based on optimization, as well as proximate utilitarian analyses of risk-taking suggest that individuals who have less to lose and more to gain should be more willing to take risks. Young people have typically not had time to amass much wealth or settle into a career and typically have less to lose compared to older individuals who have had more time and opportunities to develop these resources. Younger people should, therefore, be more willing to take risks. Although a youthful dearth of resources may contribute to risky decision-making on the level of the individual, this explanation fails to help us to understand why young men tend to take more risks than young women. After all, members of both sexes are likely to be relatively poor in youth. The aforementioned explanation of the origins of sex differences in risk-taking provides one piece of the puzzle. Evolutionary theorists have also suggested that women have evolved to be more risk-averse, particularly when pregnant. Physically risky female behavior during this period would be likely to damage a developing fetus and would therefore be selected against.

Recent empirical work has also revealed a positive relationship between mating motivation and risk-taking in young men when they believe that an available opposite-sex target is viewing their behavior. This suggests that risk-taking behavior, aside from serving as a directly competitive strategy, may serve a social function. By taking a risk in this context, men signal to potential mates that they possess qualities that are typically desired by women such as ambition, confidence in one's abilities, and social dominance. Indeed, single men, including those who have been widowed and divorced, tend to take more risks than men who are involved in a romantic relationship, which is consistent with the idea that single men have more to gain and less to lose via their risky actions. Although it has not yet been demonstrated by research, it is possible that this social function could generalize to members of the same sex, effectively communicating that one is a fierce competitor. In short, risk-taking may serve to help one develop a reputation. By engaging in behavioral displays of dominance, ambition, and skill, a young man can simultaneously garner admiration from potential mates and respect or fear from his competitors. Even if a young man has acquired a mate, a

reputation as a dominant individual with physical strength can serve functions helpful in relationship maintenance. Such a reputation might help a man to convince his current partner that alternatives to their relationship are not worth pursuing while simultaneously deterring potential mate poachers who might seek a romantic or sexual involvement with that partner.

Conclusion

Fundamental differences in reproductive biology have led men and women to evolve fairly different mating strategies. The relative scarcity of the reproductive resources sought by men compared to those sought by women has led to greater degree of intersexual competition (competition between members of the opposite sex) between men than between women. Men are believed to have evolved patterns of behavior that reflect the enhanced functional utility of aggressive and dominant behavior in solving male adaptive problems. Although these behaviors can be influenced by environmental factors as an individual develops, they are believed to have deep genetic roots and can therefore be expected to persist to some extent across human cultures.

Glossary

Calendrical calculation Naming the day of the week on which a particular date will fall or fell without reference to a calendar.

Functional magnetic resonance imaging (fMRI) A type of MRI (noninvasive) scan that measures the flow of oxygenated blood throughout the brain in order to study brain function.

Mnemonist An expert memorizer capable of storing and recalling vast quantities of data.

Synaesthesia A condition in which experiencing one sensation (e.g., hearing) results in the involuntary experience of another stimulus modality (e.g., vision); such as 'hearing a color.'

Theory of mind The ability to recognize and represent other's mental states (e.g. beliefs) in order to predict and explain their behavior.

Transcranial magnetic stimulation (TMS) A noninvasive tool (using a strong magnet placed outside the head) used to study brain function by temporarily disabling brain activity in a specific region.

Introduction

A mute teenager who can complete a written sequence of prime numbers, a 4-year-old who spontaneously names the pitch of a door bell, a preschooler who draws realistic sketches of animals, using perspective and shading, an intellectually disabled adult who has memorized all the names in the local telephone directory, a blind pianist who can reproduce complex melodies after a single hearing, and improvise in the style of famous composers – these types of astonishing feats, often seen in the context of disability, capture public imagination and have made 'savants' popular elements of news and fiction.

What Is Savant Syndrome?

The term 'savant' comes from the early label 'idiot-savant,' a name first used by John Langdon Down in 1887 to refer to apparently paradoxical levels of expertise in a specific area ('savant,' from the French 'savoir,' to know) alongside intellectual disability ('idiot' was a technical term for those of IQ less than 20–25 in common use in the nineteenth century). Because of the pejorative connotations of this term, and identification of very similar astounding skills in individuals of near-average or superior intelligence, the terms 'savant skills' or 'savant syndrome' are now preferred. Nonetheless, most definitions of savant skills reflect the notion of a contrast between skills in the area of expertise and the level of general ability in other respects.

Treffert devised a three-tier system for describing savant skill levels. 'Splinter skills' are those that are considered remarkable given an individual's overall functioning level. Splinter skills could therefore be the result of an uneven cognitive profile, as typically seen in developmental disorders such as autism. Specific skills (e.g., puzzle completion) might be consistent with chronological age expectations but considerably exceed those based on mental age. The other two levels in the system are 'talented,' which indicates that a savant's skill is exceptional in comparison to other individuals with intellectual

impairments, and 'prodigious,' which describes a savant whose skill is remarkable in contrast to the general population. So-called prodigious savants are very uncommon, with Treffert suggesting that ~100 such cases might exist worldwide. In the largest study to date, Young applied Treffert's criteria to 51 potential savants she identified worldwide in the 1990s. Based on this study, she suggested that savant status should be reserved for those best described as talented or prodigious based on Treffert's system, validating the use of this and other systems that evaluate savant performance using comparison groups.

A striking aspect of the savant phenomenon is that skills are typically manifest in a relatively narrow range of areas: maths (calendar calculation, lightning mental calculation, prime number generation), memory (often for facts in a very specific area, sometimes for dates, events, routes), art (accurate 3D and perspective drawing without tuition), and music (perfect pitch, reproduction by ear, improvisation and even composition). Visuospatial skills (e.g., completing jigsaws picture-face down) and mechanical skills are also reported. Hyperlexia (perfect decoding in reading, well beyond comprehension, and sometimes acquiring reading before speaking) can occur, but its status as a true savant skill is debated because the absolute level of skill is notable for precocity but does not outstrip that eventually attained by the general population. In Treffert's classification, then, hyperlexia could be considered 'only' a splinter skill.

History of Savant Syndrome

Case reports of savant skills date back to more than 200 years. In what may be the first documentation of savant skills, a farmhand calculator and mnemonist, Jedediah Buxton (b. 1702), was described in the Gentleman's Magazine. A letter from George Saxe was published in February 1751 in which Saxe refers to "this surprising genius Jedidiah Buxton who could not even read or write and was indeed a farm laborer, yet he was able in his mind to multiply or divide large figures

sooner than the more precise of your arithmeticians pretend to." Perhaps the first case series of savants was presented by J. Langdon Down during his famous 1887 lecture to the Medical Society of London. He described individuals with remarkable skills and talents juxtaposed against a background of considerable disabilities. Down's work, along with that of Tredgold (in his 1914 book, *Mental Deficiency*), provided striking depictions of the range and variety of skills displayed by savants. Indeed, Tredgold's description of skill areas was remarkably prescient: the areas he highlighted (calendar calculation, lightning mental calculation, musical abilities, mechanical skills, and visual artistic abilities) remain the most frequently described in the modern scientific literature. As a method for quantifying talent level, he compared a savant's skill level to expectations based on the general population, which Treffert later expanded upon in his three-tiered talent description.

During these early times, there were several notable individuals designated as 'idiot-savants.' Thomas 'Blind Tom' Wiggins (1849–1908) was an African American pianist, apparently with autism, who began composing (on his slave-master's piano) at the age of 5, played for the president at the White House, and was chronicled by Mark Twain. Gottfried Mind (1768–1814) was known as 'The Cat's Raphael' because of his realistic depictions of cats. Over the ensuing decades, similar case studies appeared in the literature, largely echoing these earlier descriptions and findings. Modern examples include Nadia, who at the age of 4 drew beautiful sketches likened to Raphael's; the 'twins' described by Oliver Sacks, who, despite little functional spoken language, instantly saw the number of matches dropped from a box, and traded prime numbers. Other stunning modern savants include Stephen Wiltshire, an artist with autism whose amazingly accurate and detailed drawings of landscapes are astounding in quality and production: after only a brief helicopter ride above Tokyo, for example, he was able to complete a 360° cityscape with no memory aides. Derek Paravicini's skills as a pianist, his ear and memory for music and his precocious development in this area despite blindness and learning disability, are described by his musical mentor, Adam Ockelford, in his book *In the Key of Genius*. Daniel Tammet has written about his own synaesthesia, phenomenal memory (he holds the European record for reciting Pi from memory to 22 514 digits) and calculating skills, in his book *Born on a Blue Day*. Perhaps the most famous modern savant is Kim Peek (1951–2009), who was the model for the autistic savant, Raymond Babbitt, played by Dustin Hoffman in the 1988 film *Rainman*. Despite below average measured IQ, Kim Peek (who had agenesis of the corpus callosum) is described by his father (and life-long companion) as follows: "Known as 'Kimputer' to many, his knowledge-library includes World and American History, People and Leaders, Geography (roads and highways in the United States and Canada), Professional Sports (baseball, basketball, football, Kentucky Derby winners, etc.), the Space Program, Movies and movie themes, Actors and Actresses, the Bible, Mormon Church Doctrine and History, Calendar Calculations (including a person's day of birth, present year's birthday, and the year and the date the person will turn 65 years old so he or she can retire), Literature/Authors, Shakespeare, Telephone Area Codes, major ZIP Codes, all TV stations and their markets.

He can identify most classical music compositions and tell the date the music was written and the composer's birth date and place of birth and death. Kim has read (and can recall) some 7600 books."

Darold Treffert's seminal book, *Extraordinary People*, brought the savant phenomenon to a much wider audience, with numerous case descriptions and his own speculations regarding the mechanisms leading to savant skill expression. Treffert continues to be perhaps the world's leading expert on the savant phenomenon, and his website at the University of Wisconsin provides information about and links to dozens of savant individuals throughout the world.

How Common Are Savant Skills?

There are no systematic epidemiological studies of savant skills. Current estimates of prevalence are based on parent or carer surveys, often with selected samples. In the late 1970s, Bernard Rimland's postal survey of 5400 parents of children with autism yielded 531 cases of reported savant skills (9.8%), most commonly music (53%), memory (40%), maths/calculation (25%), and art (10%) – with 53% reporting more than one special ability. A more recent study by Bolte and Poustka, using standardized diagnostic interviews with parents, found 33 of 254 individuals with autism (13%) were said to have a special skill. The most thorough in-person study of savant skills to date, by Patricia Howlin and colleagues, found 39 of 93 (28%) adults with autism had a skill that was outstanding in relation to their own cognitive profile and/or in relation to the general population. Many more males than females in this sample showed a special skill (32 M:7 F): almost a third of males showed a special skill compared to 19% of females.

Savant skills are far more common amongst individuals on the autism spectrum than amongst other groups. Leo Kanner, who first described and named autism, noted the 'islets of ability' exhibited by many of these individuals, and found outstanding skills at follow-up in 6 of his 11 original cases, mainly in music and rote memory. Although data are scarce, estimates suggest that savant skills may be more than ten times more common in individuals with autism than in groups without, either with or without intellectual disability. For example, Hill's survey in the late 1970s of more than 100 institutions for individuals with intellectual disability suggested a prevalence of savant skills of ~0.06%. A population-based twin study in the United Kingdom asked parents of over 6000 8-year-olds if their children were unusually good at maths, music, art, or memory – better than children much older. In this study, parents identified 3–6% of children as unusually talented in each of these areas, with memory being the most, and art the least, commonly endorsed.

Splinter skills have also been reported in genetic conditions including Smith–Magenis syndrome (maths, memory), Prader–Willi syndrome (memory, visuospatial), and Williams syndrome (memory, music). Musical skills, and absolute pitch, may be more common in congenitally blind individuals. Savant skills have been speculatively linked to synaesthesia: Daniel Tammet reports that each positive integer up to 10 000 has its own unique shape, color, texture and feel for him, and that his synaesthesia allows him to 'see' the results of complex

calculations, and to sense whether a number is a prime, without conscious effort.

What Is the Source of Savant Talent?

The study of savant skills was transformed, from fascinating case studies to rigorous group studies, by London-based psychologists Neil O'Connor and Beate Hermelin in the 1980s. Some of their groundbreaking empirical work is discussed in Hermelin's book, *Bright Splinters of the Mind*. O'Connor and Hermelin showed that well-designed experiments were possible with individuals previously considered 'untestable,' and their studies of, for example, error patterns and reaction times in calendrical calculators showed that these skills were no mere trick of memory, and reflected (implicit) mastery of complex rules and regularities. These studies did not support early speculations that savant skills were rooted in, for example, eidetic imagery.

Because of the strong association between savant skills and autism, many theories of the former take as their starting point cognitive theories of autism. Indeed, 'islets of ability' and an uneven profile across the subtests of standard IQ assessments are very typical in autism. So what aspect of autism might explain this predisposition to narrow areas of talent?

Autism spectrum disorders (ASDs) are diagnosed on the basis of deficits in social interaction, communication and the presence of rigid and repetitive activities and interests. These different facets of ASD have aroused a number of explanatory theories. The social and communication difficulties, for example, have been hypothesized to result from problems representing the mental states (e.g., beliefs) of others and possibly of self – resulting in a sort of 'mindblindness.' Might mindblindness foster talent? Might time, or even brain capacity, normally spent on social interaction be rededicated in savants to the service of special skill? This notion has popular appeal, and indeed genius is often cited as an excuse for social gaucheness. Conversely, typically developing children and adults might be considered 'social savants,' remembering as they do, for example, thousands of faces without difficulty. There is, however, little evidence to support a causal link between mindblindness and savant skills – development of savant skills typically aids rather than compromises further social development, and neuroimaging studies to date have not found evidence for rededication of normally social brain systems for savant skill execution. While a certain social distance, and the pursuit of skill for own pleasure versus popular approval, may contribute to originality of vision, mindblindness appears unlikely to be the facet of ASD predisposing to savant skills.

Nonsocial difficulties in ASD appear to fit a pattern of 'executive dysfunction,' resembling in some ways the disorganization and lack of flexibility sometimes seen following acquired injury to the frontal lobes. Might this be the starting motor for talent? This appears, on the face of it, unlikely since difficulties in executive function are relatively nonspecific to ASD, and notable in a range of other conditions (e.g., ADHD) not associated with savant skills.

A third set of theories relate autism to superior featural processing, or 'eye for detail.' A tendency to notice and remember small details, often at the expense of the 'bigger picture,'

was first proposed by Uta Frith in her influential book *Autism: Explaining the Enigma*, in which she proposes that this 'weak central coherence' results in assets as well as deficits in autism. Superior featural processing is perhaps the best current cognitive explanation for the strong association between autism and savant skills. Laurent Mottron, has suggested that 'enhanced perceptual functioning' underlies savant skills, as reflected in perfect pitch, faultless drawing in perspective, and so on. Simon Baron-Cohen's 'hyper-systemizing' account takes as its starting point superior processing of detail. Francesca Happé has linked talent to detail-focus within and beyond autism; parent-reported talents were found to be more common in ordinary 8-year-olds with high levels of autistic-like eye for detail.

How Is the Savant Brain Different?

The scale and peculiarity of savant feats readily suggest a foundation in atypical brain function or structure. Somewhat surprisingly, studies utilizing neuroimaging as a window into the neural basis of savant skills are limited thus far. A case study by Boddaert and colleagues reported functional brain activity (using positron emission tomography (PET)) associated with calendar calculation in a relatively high functioning adult male with autism. During calendar calculation, as compared to rest, this savant activated the left hippocampus, left frontal cortex, and left middle temporal lobe, regions previously associated with memory – a key component to savant skill development. However, this study lacked a comparison group or even participant, partly due to the rarity of calendar calculation. This prevented conclusions regarding atypicality, in terms of both localization and degree, of the activation pattern during calendar calculation. A more recent study by Cowan and Frith used functional magnetic resonance imaging (fMRI) to investigate activation patterns during calendar calculation and mental calculation tasks for two higher functioning adult male calendar calculating savants with ASD. During the mental calculation task, these savants did not demonstrate atypical activation patterns. The calendar savants utilized the same regions as used by neurotypical adults when completing this task. Moreover, the savants activated overlapping parietal regions during both calendar calculation and mental calculation tasks, suggesting similar neural underpinnings for these tasks. These findings indicate that calendar savants do not rely on different networks to perform calculations; however, the use of functional neuroimaging to study the neural basis of savant skills has only just begun. The two studies completed thus far have studied calendar calculation only, making it hard to obtain a comparably skilled control group. Similarly proficient controls, or even participants who can perform better than chance when asked to give the day on which a certain date falls, are extremely rare, preventing direct comparisons of savants and controls on a calendar task. Future work is needed to extend this line of inquiry to include other skill domains.

To date, one study has utilized magnetoencephalography (MEG) to study neural correlates of savant skills in individuals with high functioning ASD. Within a group of seven savants with memory skills (mostly for time tables and maps), basic memory was assessed in the MEG environment using an

old-new paradigm for both novel shapes and pseudowords. Though the mnemonist savants did not outperform controls on these tasks, and in fact were outperformed by controls on the pseudoword task, there was some indication that savants used occipital regions (i.e., the visual system) instead of parietal regions, as controls did, during early components of the pseudoword task. These findings are reminiscent of earlier fMRI studies showing what amounts to inefficient reliance on visual regions during verbal tasks by (nonsavant) individuals with autism. Unfortunately, because this MEG study did not compare savants and nonsavants with autism, it is unclear whether the findings reflect autism, savant skills, or both. Moreover, localization of MEG signal was hampered by the lack of structural MRI scans for the savants.

Structural neuroimaging, including quantification of brain volumes, cortical thickness, and/or white matter tractography, has been used to assess the impact of expertise on the brain, such as short-term training to learn to juggle. The most robust effects have been demonstrated among London cab drivers, who undergo extensive training to learn the intricate and irregular layout of London's streets (the 'Knowledge'). Widely reported research by Eleanor McGuire and colleagues found that cab drivers who successfully completed this 3-year training had larger posterior hippocampi than did controls, and a driver's years of experience were positively correlated with posterior hippocampus size. Finally, retired taxi drivers exhibited hippocampus size more similar to controls, suggesting that brain changes underlying this expertise were maintained by ongoing practice.

Only one published study thus far has sought to apply these techniques to study the structural brain correlates of savant skills. Wallace and colleagues compared cortical thickness between a multiply talented (in art, calendar calculation, and memory) adult male savant with Asperger's syndrome and age- and verbal ability-matched neurotypical males. The savant volunteer demonstrated generally thinner cortex in frontal, temporal, and parietal regions, consistent with other studies of adults with ASD, and with the social and nonsocial deficits characteristic of these disorders. However, a small region of bilateral superior parietal cortex was thicker for the savant as compared to control males, intriguing given that this region has been implicated in visual-spatial functions, including drawing and calculation, two of his areas of expertise.

Though savant skills occur predominantly in the context of ASD, savant-like skills are also found in non-ASD populations, which may inform their neural foundations. For example, Brink described a case of left-sided brain injury from a gunshot wound after which mechanical skills emerged, despite persistent difficulties in relearning language and academic skills in reading, writing, and arithmetic. Kim Peek had agenesis of the corpus callosum as well as other brain abnormalities. While the disconnection of his left and right hemispheres may have played some part in his uncanny ability to read simultaneously two pages from an open book, what contribution, if any, it made to his mnemonic abilities is unclear. There are also suggestions that frontotemporal dementia (FTD) is associated with later onset of savant-like skills. Miller described five individuals who developed artistic skills, some of which were previously undocumented, concurrent with the onset and progression of FTD. Similar to savant artists with ASD, the images

produced tended to be detailed and realistic copies rather than abstract renderings. Consistent with savants more generally, these patients exhibited an intense focus and preoccupation with their skill domain; art, in this case. 'Paradoxical functional facilitation,' Kapur's term for enhanced behavioral functioning resulting from a neural insult, has been invoked to explain these findings. Miller speculates that increased interest and skill in art was the result of diminished inhibition of visual systems due to degeneration of anterior temporal and orbitofrontal cortices.

In a provocative account of the neural origins of savant skills, Snyder has suggested that each of us is capable of savant skills, but our complex conceptual cognition overwhelms and suppresses these skills. Savants with ASD, on the other hand, are suggested to have 'privileged access' to raw, unprocessed information that is not usually available to neurotypical individuals. Snyder and colleagues tested this model by applying transcranial magnetic stimulation (TMS) to the left frontotemporal cortex (based in part on the studies of FTD discussed above) on two drawing tests. Though the use of TMS did not result in systematic improvement of drawing ability, stylistic changes were noted for 4 of the 11 participants. Using a similar approach, Morrell and colleagues did not find skill enhancement on a wide variety of savant-related tasks after TMS. Based on these results, they suggest that instead of savant abilities lying dormant in us all, they are likely to be possible for a small segment of the neurotypical population, just as they are for individuals with developmental disabilities. Though TMS is a useful tool in the search for the neural underpinnings of savant skills, it has limitations. Interfering with key brain regions using TMS in adults to study savant skill ontogeny is not equivalent to the early development (often emerging during early to middle childhood) of these skills. Therefore, TMS studies of this sort may more closely approximate the cases of later savant skill onset, not the more predominant early onset cases, which invoke notions of experience-dependent plasticity of cortex given the continual learning and honing of skills during development.

Where Do Savant Skills Come From?

When considering talent development, genetic (e.g., heritability of skills) and environmental (e.g., practice) influences are often at the forefront of discussion. These issues have also been debated vigorously as they apply to savant skills; however, they have rarely undergone rigorous empirical scrutiny. One recent population-based twin study of over 6000 8-year-olds demonstrated that (parental) skill ratings in savant domains are highly heritable and are associated with nonsocial autistic traits, such as being detail focused, having special interests, or exhibiting an 'insistence on sameness.' Complementing these quantitative genetic findings is at least one molecular genetic study in which regions of chromosome 15 were associated with ratings on autism diagnostic inventory (a gold-standard parent interview measure of autism symptoms often used for diagnosis) items that assess savant skills, although an attempted replication of these findings failed. Surprisingly good skills in isolated domains have also been reported in genetic disorders, which may also inform genetic etiology. For example, there are reports

that people with Williams syndrome (deletion of a portion of chromosome 7) exhibit strong interest and abilities in music, while individuals Prader–Willi syndrome (disorder of chromosome 15) perform well on jigsaw puzzles and similar tasks.

There are an increasing number of studies addressing the heritability of savant-related skills; for example, family and twin studies converge in demonstrating the heritability of absolute pitch, a skill nearly universal among savant musicians. Moreover, the largest savant study to date found that relatives of savants were more likely than relatives of nonsavant individuals to exhibit talents and extreme narrow interests.

Recent advances in understanding the interplay between genes and environment render a simple nature–nurture dichotomy obsolete. Environmental factors, particularly education, training, and practice, are of enormous importance. However, whether practice alone can account for savant feats remains highly debated: many such skills seem to appear more or less out of the blue, with at least little overt rehearsal or preparation. While the now famous ‘10 000 h of practice’ may be sufficient for talent, it remains a key question why only some few individuals are motivated to develop such savant skills as calendrical calculation. Notably, in the study of London cab drivers, only around a third of those beginning their training in the knowledge completed the course – suggesting that practice interacts with preexisting individual differences in ability, personality or motivation.

In spite of our impressive and rapid technological advances in neuroscience and genetics, we have only begun to scratch the surface in better understanding the biological basis of savant skills.

Conclusions

Savants are common figures in popular fiction, fascinating for their extraordinary feats and helpful plot-devices in Hollywood. There can be a downside to such ‘positive’ publicity, with parents of children with autism being asked eagerly what

their child’s talent is, and the implicit suggestion that the value of the individual comes from his or her skill rather than being inherent to their status as a person. However, further research into the basis for savant skills may teach us much about how to appreciate a different mind in autism and other neurodevelopmental conditions. Recognizing potential, encouraging interests and passions, and raising awareness of the mysteries of the human mind may all be fostered by future studies of savant skills.

Glossary

Atypical or second-generation antipsychotics A more recently developed class of antipsychotic drugs that act as antagonists at both serotonin 5-HT_{2A} and dopamine D₂ receptors and carry a lower risk of motor side effects than the conventional antipsychotics.

Conventional, or typical, antipsychotics A class of antipsychotic medications first developed in the 1950s with high affinity for D₂ receptor that carry a high risk for sedation, motor and anticholinergic side effects, such as blurry vision and dry mouth.

Dopamine hypothesis of psychosis A model that attributes the psychotic symptoms of schizophrenia to a disturbed and hyperactive dopaminergic signal transduction in the mesolimbic pathway.

Endophenotypes Heritable intermediate phenotypes (neurophysiological, biochemical, endocrinological,

neuroanatomical, cognitive, or neuropsychological) associated with an illness but with a simpler genetic architecture than the illness phenotype.

Executive functions A defined collection cognitive functions involving higher order brain processes such as abstract thinking, planning, problem solving, and initiation/inhibition of appropriate/inappropriate actions.

Negative symptoms A group of symptoms observed in patients with schizophrenia that include social withdrawal, apathy (decreased motivation), poverty of speech, inability to experience pleasure (anhedonia), limited emotional expression, and attentional deficits.

Positive symptoms A group of symptoms present in patients with schizophrenia such as delusions, hallucinations, and disorganized thought and behavior.

Introduction

Personality disorders are pervasive chronic psychological disorders involving several areas of the personality. Patients suffering from these disorders experience severe disturbances to their characterological constitution and exhibit behavioral tendencies leading to considerable personal and social disruption in their lives. When the Axis II personality disorders were included in the third edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-III), they were grouped into three clusters. The first cluster (cluster A) includes the paranoid, schizoid, and schizotypal personality disorders. Features such as eccentricity and odd appearance are common among individuals suffering from this cluster. Before the inclusion of schizoid and schizotypal personality disorders in DSM-III, schizoid abnormalities were understood as attenuated manifestations of schizophrenia.

Schizoid Personality Disorder

The term schizoid was first introduced by Eugen Bleuler in 1908 to describe the concept of introversion, that is, the tendency to direct attention toward one's inner life and away from the external world. An extreme version of introversion is one of the main characteristics of schizoid personality disorder (SZPD). SZPD was initially considered the prototypic schizophrenia-related personality disorder, a role now largely assumed by schizotypal personality disorder (STPD). SZPD was broadly defined in the first two versions of the DSM, but was then divided in the DSM-III (APA, 1980) into the schizoid, avoidant, and schizotypal types of personality disorder.

Epidemiology and Genetic studies

Incidence and prevalence

SZPD is believed to be one of the rarest personality disorders because its prevalence in the general population is <1%. However, other studies have found its prevalence to be as high as 3.1% in the US population and even higher in substance-abusing and primary-care samples. Epidemiological studies of personality disorders suggest that SZPD is more prevalent among men than women, with a two-to-one sex ratio.

Genetic studies (twin and adoption studies/familial aggregation)

SZPD is more frequently observed in first-degree relatives of patients with schizophrenia, further supporting the notion of a shared genetic liability among individuals with SZPD and other schizophrenia-spectrum disorders. The heritability of SZPD has been estimated to be in the range of 28–29%, as revealed by twin studies in two independent Norwegian epidemiologic studies. However, a follow-up study that included more reliable measurements for the diagnosis of SZPD found higher heritability rates, ranging from 55 to 59%. In addition, environmental factors can influence very early neurodevelopmental processes. For example, prenatal exposure to famine has been associated with a twofold increase in the relative risk for SZPD.

Clinical Features and Diagnosis

SZPD patients have prominent defects in the ability to relate to others in a meaningful way. The first symptoms of SZPD,

Table 1 DSM-IV-TR diagnostic criteria for schizoid personality disorder

-
- (A) A pervasive pattern of detachment from social relationships and a restricted range of expression of emotions in interpersonal settings, beginning by early adulthood and present in a variety of contexts, as indicated by four (or more) of the following:
- (1) neither desires nor enjoys close relationships, including being part of a family
 - (2) almost always chooses solitary activities
 - (3) has little, if any, interest in having sexual experiences with another person
 - (4) takes pleasure in few, if any, activities
 - (5) lacks close friends or confidants other than first-degree relatives
 - (6) appears indifferent to the praise or criticism of others
 - (7) shows emotional coldness, detachment, or flattened affectivity.
- (B) Does not occur exclusively during the course of schizophrenia, a mood disorder with psychotic features, another psychotic disorder, or a pervasive developmental disorder and is not due to the direct physiological effects of a general medical condition.
-

manifested as early as childhood and adolescence, include underachievement in school, social isolation, and poor peer relationships, which mark them as 'different' and make them targets for teasing and bullying. [Table 1](#) summarizes the DSM-IV-TR criteria for the diagnosis of SZPD. The main characteristic of this personality disorder is the attenuated desire for relationships or the absence of it. This is manifested by extreme social isolation and limited interactions with peers, mostly first-degree relatives, which provide them with a sense of security and stability. In addition, the limited social interaction is typically characterized by emotional coldness and reduced expression of affect. SZPD individuals demonstrate a limited capacity to express either positive or negative emotions, manifested by an indifference to praise or criticism from others.

Patients with SZPD may display characteristics of apathy and amotivation, such as lack of goals and passive reaction to adverse circumstances, as well as inappropriate response to important life events. The lack of interest in social relations and extreme introversion often lead to engagement in solitary intellectual activities, such as computer games or puzzles. However, the pleasure experienced in these activities lasts only for a brief period, typically followed by a more pervasive period of anhedonia. For SZPD patients, modulating their emotional interaction with others is important and, when their personal space is violated, they experience emotional distress and an increased need to remain isolated and independent. In addition, these patients are usually sexually apathetic, although the majority of such individuals have a normal sex drive. Occupational functioning may be impaired, especially in cases where interpersonal involvement is required. However, SZPD individuals may do well when they work under conditions of social isolation.

Course and Prognosis

The onset of SZPD usually occurs in early childhood. While there are no well-established clinical data about the prognosis, SZPD individuals are believed to remain functional in the context of a restricted, well-defined environment. On the other hand, lifestyle changes in social settings, living arrangements,

or work environment can create additional stress that can complicate their prognosis. Like many of the personality disorders, SZPD is a long-lasting, but not necessarily lifelong, condition. Progression to schizophrenia might occur, usually in the second or third decade. However, the proportion of SZPD individuals who later develop schizophrenia is unknown. Furthermore, some investigators have found that premorbid SZPD is associated with specific dimensions of schizophrenic symptomatology, especially negative symptoms.

Differential Diagnosis and Comorbidity

SZPD shares common phenomenological features with other schizophrenia-spectrum disorders, such as reduced expression of affect and negative symptoms. However, in comparison with schizophrenia patients, schizoid individuals do not present with prominent psychotic symptoms. Another caveat is the difficulty, particularly in the early stages of the illness, in differentiating individuals with SZPD from those with pervasive developmental disorders, such as mild forms of autism. In contrast to these disorders, SZPD does not involve impairment in nonverbal communication or patterns of restricted interests and repetitive behaviors. However, the relationship between SZPD and autism, more particularly Asperger's syndrome, is a complex one and, as is the case with schizophrenia, it is likely that SZPD has been diagnosed in place of autistic spectrum disorder, rather than vice versa. Furthermore, although SZPD patients may suffer from associated depression, this personality disorder is not usually associated with guilt, hopelessness, helplessness, or low self-esteem.

SZPD also has certain features commonly observed in other personality disorders, occasionally making it difficult to distinguish it from these disorders. Phenomenological characteristics such as social isolation and constricted expression of affect are present in cluster A personality disorders. However, SZPD is distinguished from STPD by the lack of cognitive dysfunction and perceptual distortions; and from paranoid personality disorder by the lack of exaggerated suspiciousness and paranoid ideation. Individuals with SZPD and avoidant personality disorder share the characteristic of social isolation. However, the social avoidance in SZPD does not stem from fear of rejection but from genuine indifference to social relationships, pervasive detachment, and limited desire for social intimacy.

The diagnosis of SZPD should be made only when the traits exhibited by an individual are maladaptive and inflexible, and cause significant subjective distress or functional impairment. Moreover, it is crucial to explore the individual's cultural background as the interpersonal style of certain cultures may be erroneously labeled as schizoid. Additionally, immigrants from other countries or those who have moved from rural to metropolitan areas may initially react with emotional coldness, constricted affect, and limited interactions with their peers and be mistakenly perceived as cold, hostile, or indifferent.

SZPD and the Brain

Psychological test data

A study of 314 twins revealed that executive function deficits and personality disorders are significantly heritable. This study also found a 27% correlation attributable to heritable factors

between executive function deficits and schizoid characteristics, the lowest among the personality disorders that were tested. Executive functions were assessed in this study with the use of the Coolidge Personality and Neuropsychological Inventory, which contains items measuring decision-making difficulties, organizational impairments, poor planning, perseveration, and sequencing difficulties. The findings from this study provide some insight into why individuals diagnosed with SZPD frequently exhibit chronic difficulties with everyday decision making and selective attention, as well as deficits in inhibition, judgment, planning, and flexibility.

Biological test data

Psychophysiological studies

Eye movements In a recent study that examined the association between smooth pursuit eye-movement (SPEM) score and schizophrenia-spectrum personality symptoms, relatives of schizophrenic patients who experienced schizoid symptoms were compared to community-recruited subjects without family history of psychosis but with comparable schizoid scores. Eye tracking was significantly worse in those subjects with spectrum personality symptoms who had a biological relative with schizophrenia. Furthermore, schizoid symptoms explained 20% of the variance in the eye-tracking measure in relatives of schizophrenia patients.

P300 event-related potential Multiple studies have reported P300 amplitude reduction in schizophrenia and STPD. However, only one study assessed the P300 event-related potential in SZPD. This study did not find P300 to be reduced in individuals who had been diagnosed as schizoid in childhood.

Genetic risk factors

The *NcoI* restriction fragment length polymorphism (RFLP) (C to T transition) in exon 6 of the dopamine (DA) D₂ receptor gene has been associated with SZPD. The C allele predicts low density of the DA D₂ receptor; this variant is more prevalent in SZPD individuals. In addition, the A1 allele of the *TaqI* A1–A2 RFLP of the DA D₂ receptor gene has also been significantly associated with SZPD, predicting higher schizoid behavior. Interestingly, both the *TaqI* A1 and *NcoI* C alleles, which are present with increased frequency in SZPD patients, correlate with lower DA D₂ receptor density. A weak association between the variable number tandem repeat 10/10 genotype of the DA transporter gene and schizoid/avoidant behavior has been identified. Moreover, a functional deletion/insertion allelic variation associated with decreased expression of the serotonin transporter gene SLC6A4 was also found to restrict expression of schizoid traits in normal subjects and patients with affective disorders.

Treatment (Biological and Psychological)

In keeping with their excessive isolation and social withdrawal, individuals with SZPD rarely seek treatment. Such patients do not perceive the establishment of a therapeutic relationship with the treatment team as potentially beneficial. Thus, they are brought for treatment by others or may occasionally seek treatment for an associated problem, such as depression. As such, treatment reports of patients with SZPD have been

rare, and obtaining a substantial number of SZPD patients for a treatment study is a challenge in itself.

Psychological

Psychotherapy is the treatment of choice for personality disorders, and this is mainly concluded from two formal meta-analyses. The most recent meta-analysis reported a large to very large overall effect size for both psychodynamic treatments and cognitive-behavioral therapies. However, this meta-analysis included 22 studies of which 19 had patients exclusively from cluster B and/or C. The other three studies recruited patients from all three clusters and had a naturalistic design. Thus, clinical descriptions and research reports in psychotherapeutic treatment of SZPD patients are limited. Based as it is on expert advice, individual psychotherapy is the initial treatment of choice. The primary aim of the therapy should be the development of a strong therapeutic alliance. This might be facilitated by the avoidance of early interpretation or confrontation and by showing an interested and caring attitude toward addressing the possibility of underlying needs. The primary goal of therapy should be to increase the coping and interpersonal relationship skills of SZPD individuals and to make them more comfortable in social settings. Psychotherapy should also be focused on alleviating current pressing concerns or stressors in the individual's life.

Another beneficial approach in the psychotherapeutic treatment of SZPD is the incorporation of cognitive-behavioral techniques that encourage patients to gradually increase their social involvement. In addition, cognitive-restructuring exercises may be appropriate for those irrational thoughts that negatively influence the patient's behavior. Furthermore, SZPD patients who are able to complete individual therapy may have adequate minimal social skills and abilities to tolerate group therapy. In this alternative treatment modality, SZPD patients develop social and interpersonal skills, and improve their capability to relate and interact appropriately and meaningfully with other individuals.

Biological

The pharmacotherapy in SZPD is understudied, as there have been no long-term controlled clinical trials. In view of the limited clinical data, long-term psychopharmacological treatment should be avoided in SZPD patients without other comorbid conditions. Medication is generally useful only as a temporary aid for the relief of specific acute symptoms such as overwhelming anxiety, or as an effective treatment in SZPD individuals with comorbid conditions such as major depression. Many experts in the field recommend the use of atypical antipsychotics in SZPD, based on the fact that schizoid traits are similar to the negative symptoms of schizophrenia. More specifically, there are anecdotal reports that low doses of risperidone or olanzapine might constitute effective therapeutic options in the treatment of social deficits and blunted affect. Additionally, antidepressant medications might be effective in treating the rejection sensitivity and social anxiety of SZPD patients. Bupropion, an atypical antidepressant that inhibits norepinephrine and DA reuptake, has been reported to be effective for the anhedonia commonly experienced by these patients. Other available options include the selective serotonin reuptake inhibitors, tricyclic antidepressants, and monoamine oxidase

inhibitors. However, sufficient evidence is lacking to support the use of a specific antidepressant medication in SZPD. The administration of benzodiazepines for short periods might diminish the interpersonal and social anxiety of these patients.

Schizotypal Personality Disorder

STPD was first introduced in DSM-III (APA, 1980) as part of the 'odd, eccentric' cluster A along with schizoid and paranoid personality disorders. This disorder is characterized by eccentricities of behavior, cognitive, or perceptual distortions, as well as acute discomfort with, and reduced capacity for, close relationships. STPD is considered the prototypic schizophrenia-related personality disorder, sharing genetic, neurophysiological, structural, and functional neuroanatomic features with schizophrenia. Interestingly, in the International Statistical Classification of Diseases and Related Health Problems 10th Revision (ICD-10) by the World Health Organization, STPD is classified as a mental disorder associated with schizophrenia rather than as a personality disorder, in contrast to the DSM-IV classification.

Epidemiology and Genetic Studies

Incidence and prevalence

The prevalence of STPD is approximately 3% of the general population. However, this prevalence differs across different cultures, ranging from 0.6% in a Norwegian sample to 4.6% in a US sample population. Results from a recent large epidemiological survey in the United States showed a 3.9% lifetime prevalence of SZPD. Men (4.2%) have significantly higher prevalence rates than women (3.7%). Moreover, the phenomenology of STPD is gender dependent: male STPD individuals exhibit higher scores on measures of negative schizotypy compared to female STPD individuals. Conversely, female STPD individuals exhibit higher positive schizotypy scores than their male counterparts. Higher prevalence of STPD was present among individuals with lower incomes, as well as those who were separated, divorced, or widowed. Odds for SZPD are significantly higher among black women and lower among Asian men, but it still remains unclear if this is due to culture-specific environmental stressor/genotype interaction or to a relative lack of cultural sensitivity in the DSM diagnostic manual. Furthermore, STPD is associated with higher co-occurrence rates of Axis I and other Axis II disorders, including bipolar I and II disorders, social and specific phobias, lifetime generalized anxiety disorder, and posttraumatic stress disorder, as well as borderline and narcissistic personality disorders.

Genetic studies (twin and adoption studies/familial aggregation)

STPD is more frequently observed in first-degree siblings of patients with schizophrenia, further supporting the hypothesis of a genetic basis for STPD and a strong shared genetic liability with schizophrenia and other schizophrenia-spectrum diagnoses. The notion of a common genetic substrate for these disorders is further supported by findings of adoption, family, and linkage studies. Findings from a twin study suggest that positive-like and negative-like symptoms might represent two relatively independent heritable dimensions in STPD

patients. This study also showed that in STPD, and in other schizophrenia-spectrum disorders, genetic factors are responsible for the social and cognitive deficits (i.e., spectrum phenotype), as well as for the psychotic symptoms (i.e., psychotic phenotype), and might be transmitted independently. Additionally, the spectrum phenotype of STPD shares a stronger genetic liability with schizophrenia in comparison to the psychotic phenotype, further supporting the notion that specific dimensions of the STPD phenomenology might share a closer genetic relationship to schizophrenia and other schizophrenia-spectrum diagnoses.

Clinical Features and Diagnosis

The diagnosis of STPD is based on a constellation of signs and symptoms, as there is no laboratory test that can definitively indicate the presence of the disorder. STPD individuals have a pervasive pattern of deficits marked by discomfort with, and reduced capacity for, close relationships, as well as cognitive or perceptual distortions and eccentricities of behavior. The DSM-IV-TR criteria (Table 2) include odd beliefs or belief in magic that diverge from the social norms of the subjects' culture and usually exert a significant impact on their speech and appearance. Speech in this disorder is characterized by unusual or idiosyncratic phrasing as well as loose and vague construction, but without the more severe deficits, such as derailment or loosening of associations, observed in schizophrenia. A main clinical manifestation observed in STPD individuals is the idea of reference, where patients develop a belief or perception that irrelevant, unrelated, or innocuous phenomena in the world refer to them directly or have special personal significance. This should not be confused with delusions of reference, where the beliefs are held with significantly more conviction. Additionally, it is common for patients with STPD to experience perceptual alterations, such as hearing a voice whispering their name.

Table 2 DSM-IV-TR diagnostic criteria for schizotypal personality disorder

- (A) A pervasive pattern of social and interpersonal deficits marked by acute discomfort with, and reduced capacity for, close relationships as well as by cognitive or perceptual distortions and eccentricities of behavior, beginning by early adulthood and present in a variety of contexts, as indicated by five (or more) of the following:
 - (1) ideas of reference (excluding delusions of reference)
 - (2) odd beliefs or magical thinking that influences behavior and is inconsistent with subcultural norms (e.g., superstitiousness, belief in clairvoyance, telepathy, or 'sixth sense'; in children and adolescents, bizarre fantasies or preoccupations)
 - (3) unusual perceptual experiences, including bodily illusions
 - (4) odd thinking and speech (e.g., vague, circumstantial, metaphorical, overelaborate, or stereotyped)
 - (5) suspiciousness or paranoid ideation
 - (6) inappropriate or constricted affect
 - (7) behavior or appearance that is odd, eccentric, or peculiar
 - (8) lack of close friends or confidants other than first-degree relatives
 - (9) excessive social anxiety that does not diminish with familiarity and tends to be associated with paranoid fears rather than negative judgments about self
- (B) Does not occur exclusively during the course of schizophrenia, a mood disorder with psychotic features, another psychotic disorder, or a pervasive developmental disorder.

STPD individuals exhibit suspiciousness, which makes them extremely cautious about others' motives and intent. These individuals may also suffer from paranoid ideation, believing that they are being harassed or persecuted. Thus, their interaction with others is usually characterized as inappropriate, rigid, or constricted. This could also be related to their inability to express a full range of affects and interpersonal cuing or to relate appropriately to other people. While these patients often complain of a lack of relationships or of being isolated, their behavior suggests an attenuated desire and drive for intimate contacts. Their social relationship is usually restricted to their first-degree relatives as interaction with unfamiliar people or social situations leads to exaggerated levels of anxiety. This excessive social anxiety may not diminish with familiarity as it is usually associated with suspiciousness about others' motives. STPD individuals commonly demonstrate odd speech, excessive social anxiety, and suspiciousness, as well as the lack of empathy and pleasant emotions. These characteristics lead to prominent social deficits affecting the potential to interact with and relate to other people. A recent study found that young STPD subjects use the Internet for social interaction more frequently than normal controls. It could be further speculated that these youths might utilize the Internet for social interaction, as an environment that attenuates the interpersonal deficits in communication skills.

The first symptoms of STPD may be evident as early as childhood or adolescence. These symptoms differ from the typical clinical picture found in adults. Children or adolescents demonstrate poor peer relationships, pronounced social anxiety, underachievement in school, and a tendency toward solitary pursuit of activities. Additionally, symptoms that may be present during the developmental stages of childhood include bizarre fantasies, unusual use of language, odd thoughts, or hypersensitivity to criticism and correction. Children with these tendencies present with prominent social isolation and poor or disrupted interpersonal relations, which increase their risk for future development of more severe STPD psychopathology.

The clinical presentation and symptomatology of STPD can sometimes be confused with the abnormalities seen in patients with schizophrenia. However, the psychotic and cognitive-like symptoms observed in STPD, while pervasive and disturbing to the patient, almost never lead to prolonged functional impairment with multiple hospitalizations or long-term exposure to psychotropic medications, as in schizophrenia. Moreover, the cognitive deficits of STPD are usually milder and more circumscribed than those of schizophrenia. Occasionally, STPD individuals can develop transient psychotic episodes. These episodes are characterized as less pronounced or frequent than in schizophrenia. However, there are limited data to support the notion that STPD individuals develop brief psychosis. Additionally, experts in the field suggest that such individuals might be misdiagnosed as schizotypals though, in actuality, they meet the criteria for schizophrenia.

Course and Prognosis

The prognosis of STPD is variable and significantly related to the patient's maturity and to the integrity of his/her coping mechanisms. STPD is thought to be a premorbid personality of schizophrenia. Thus, a large proportion of young individuals,

ranging from 17 to 40%, meeting the criteria for the STPD diagnosis in cross-sectional studies, later develop the full spectrum of schizophrenia. Moreover, retrospective studies have demonstrated that a significant number of patients with schizophrenia exhibit schizoid and schizotypal traits before the onset of their illness. However, other authors have shown that patients who were diagnosed with schizophrenia actually met DSM criteria for STPD. Additionally, preliminary findings from ongoing studies show that subjects with more 'typical' STPD symptomatology rarely develop schizophrenia. Furthermore, published data suggest that the childhood personality of individuals who later develop STPD is totally distinct from those with schizophrenia. Interestingly, longitudinal studies have reported attenuation in the STPD symptomatology, or even significant remission rates with age. Currently, no conclusive evidence exists as to whether STPD is a necessary transitional stage of schizophrenia.

Differential Diagnosis and Comorbidity

STPD is the prototypic schizophrenia-spectrum disorder, which shares with schizophrenia common phenomenological features emerging from common spectrum-related risk factors. It has been speculated that STPD subjects have more developed compensatory mechanisms such as preservation of frontal integrity and function, as well as the capacity to recruit other related brain regions to compensate for dysfunctional areas during cognitive demands. Therefore, STPD individuals are more protected from the severe cognitive deterioration and social deficits of schizophrenia. Moreover, STPD lacks the severity of psychosis seen in patients with schizophrenia, and they are thus spared from multiple hospitalizations and long-term exposure to psychotropic medication. The differentiation between STPD, schizoid, and paranoid personality disorders is complicated by their shared phenomenological features. For example, both schizoid and STPD are characterized by a lack of close friendships. However, in SZPD this results from diminished pleasure or absence of pleasure from casual or intimate relationships. In contrast, the asociality observed in STPD individuals is secondary to suspiciousness, odd, bizarre behavior, and excessive social anxiety.

STPD and the Brain

Abnormalities in specific structural, psychophysiological, and neurocognitive tasks have been suggested as candidate biomarkers of STPD. These abnormalities are hypothesized as arising from alterations in brain frontal and fronto-parietal-temporal circuitry. Unfortunately, none of these abnormalities has yet proven sensitive or specific enough to implicate a clear etiology of STPD.

Psychological test data

STPD and schizophrenia patients exhibit similar neurocognitive impairments hypothesized as secondary to shared neurodevelopmental pathway abnormalities. However, the deficits in STPD are less severe and more circumscribed to specific cognitive areas compared with the more severe and diffuse ones observed in schizophrenia. For example, STPD individuals have been found to perform poorly on tests measuring

abstraction and executive function tasks such as the Wisconsin Card Sorting Test, Stroop Color Word Interference Test, and Trail Making Test B. A common component of all the above tasks is the engagement of working memory, a short-term type of memory that stores and manipulates information required to perform specific tasks. Multiple studies have demonstrated that working memory is subserved by the dorsolateral prefrontal cortex (DLPFC) dopaminergic system. Dysfunction in the DLPFC has been implicated in the neuropathology of clinical STPD populations, and working memory is believed to represent a core deficit in these populations. In a recent study, STPD patients performed significantly worse than healthy volunteers and patients with personality disorders unrelated to psychosis on tasks of working memory, episodic memory, and delayed recall. Working memory differences were the most significant determinants of differences in cognitive performance in the aforementioned comparison groups. Similarly, deficits in working memory have been demonstrated in nonclinical populations with high scores of negative or positive schizotypy scales.

Other cognitive domains in which STPD subjects show poor performance include selective attention and verbal learning, believed to be modulated by the fronto-striatal circuits and temporal cortex, respectively. Schizophrenic patients and individuals with high schizotypal personality features, as revealed by the schizotypal personality questionnaire, perform worse on attentive tasks, namely the sustained attention response to task. Furthermore, studies have also shown that STPD patients suffer from impairments in initial word list learning and multitrial memory learning tasks.

Biological test data

Neurochemical, functional, and structural studies

STPD subjects show neurochemical alterations similar to those observed in schizophrenia patients. In schizophrenia, augmented levels of homovanillic acid (HVA), a DA metabolite, correlated with severity of psychotic symptoms. Similarly, the plasma and cerebrospinal fluid (CSF) concentration of HVA is significantly increased in STPD individuals compared with healthy controls or patients with other personality disorders. Conversely, STPD patients with poor performance on neurocognitive tasks and/or deficit-like symptoms have low levels of plasma and CSF HVA concentration. Augmentation of DA neurotransmission by the administration of the indirect DA agonist amphetamine in STPD subjects improves their cognitive functions. However, this improvement is not accompanied in these patients by the appearance or exacerbation of psychotic-like symptoms, as observed in patients with schizophrenia. A possible explanation for this is that the amphetamine-induced increase of striatal dopaminergic neurotransmission observed in STPD is significantly lower compared to that in schizophrenia during illness exacerbation. This is consistent with reports of reduced striatal volume, especially in the caudate and putamen in STPD, when compared to patients with schizophrenia. Moreover, STPD patients do not suffer from the significant volume reductions in the medial dorsal nucleus of the thalamus found in schizophrenia patients. The medial dorsal nucleus receives its main input from the prefrontal cortex (PFC) and limbic system and then projects to the prefrontal association cortex. Thus, it has a crucial role in attention, planning, organization, abstract

thinking, multitasking, and active memory. Importantly, reductions in the medial dorsal nucleus of the thalamus in schizophrenia are accompanied by smaller volumes in the PFC, a finding not observed in STPD. Other brain areas with consistently attenuated volumes in schizophrenia but not in STPD include middle temporal regions such as the amygdala and the hippocampus.

The reduction of the frontal lobe gray matter is less prominent in STPD than in schizophrenia, leading to significantly less cognitive and social deterioration in STPD subjects compared to schizophrenic patients. A recent study that assessed the cortical gray/white matter volumes in a large sample of unmedicated schizophrenia-spectrum patients and healthy controls showed that the observed frontal reduction in STPD was only about 50% of that found in schizophrenia and did not differ statistically from the healthy control group. Additionally, there is evidence to support the notion that STPD individuals are capable of recruiting different PFC areas as a compensatory mechanism during cognitive tasks, a finding not observed in schizophrenia.

Psychophysiological studies

Subjects with schizophrenia-spectrum personality disorder exhibit deficits in information processing. This could be secondary to an inability to filter out irrelevant information in the early stages of processing so that attention can be focused on the more salient features of the environment. It is possible to examine this inhibitory phenomenon by using psychophysiological paradigms.

Prepulse inhibition Prepulse inhibition (PPI) of the acoustic startle response refers to a reduction in the magnitude of the blink reflex component of the startle response to a strong auditory stimulus if this is preceded by a weak stimulus. PPI is considered a measure of 'sensorimotor gating,' whereby prepulses reduce the effect of subsequent sensory stimuli to protect the brain from sensory overload. Deficient PPI is a reliable feature of neuropsychiatric disorders such as schizophrenia, where reduced gating is thought to be one possible neurobiological mechanism underlying some basic cognitive abnormalities associated with this disorder. Reduced PPI was also found to be present in asymptomatic first-degree siblings of schizophrenic individuals, as well as in schizophrenia-spectrum personality disorder patients. Moreover, PPI levels are significantly correlated in STPD subjects with a general schizotypy score, reflecting a general proneness or vulnerability to psychosis.

Smooth pursuit eye movement SPEM measures visual tracking of smoothly moving targets, such as a pendulum. The psychophysiological study of eye movements, particularly the antisaccade task, has been proposed as a candidate endophenotype for schizophrenia. This is a result of SPEM deficits being evident in the majority of patients with chronic schizophrenia when compared with controls. Additionally, SPEM impairment is also significantly more marked in relatives of probands with schizophrenia and STPD individuals. Volunteers who were selected on the basis of poor eye-tracking accuracy had a greater prevalence of STPD diagnosis than the control group with high eye-tracking accuracy. In addition, deficits during the eye-movements task have been observed in

nonclinical populations such as adult, healthy volunteers with a high degree of schizotypy. STPD patients with positive-like symptoms are likely to show elevated error rates on standard antisaccade tasks in comparison to healthy normal controls. Additionally, a recent study showed that SPEM deficits were predicted solely by the criterion of social isolation, with low accuracy trackers also reporting reduced desire for social contact. These findings support the notion of impaired SPEM in relation to negative-symptom schizotypy. However, other studies have failed to demonstrate differences in antisaccade error rates between STPD with predominantly negative-like symptoms and normal individuals. Based on this, it remains unclear whether impaired SPEM is specific to negative versus positive symptoms or instead reflects the entire schizotypal syndrome. Nevertheless, SPEM deficits are found in both STPD and schizophrenia patients, further supporting the notion of impaired SPEM as an endophenotype for schizophrenia-spectrum disorders.

P300 event-related potential P300 amplitude has been proposed as an endophenotype for the study of psychosis as multiple publications have reported P300 amplitude reductions in patients with schizophrenia. STPD individuals demonstrate similar deficits; however, these findings are less consistent than in schizophrenics. Similar reductions in auditory P300 amplitudes and delayed P300 latencies are exhibited by nonclinical populations scoring high in schizotypy as measured by the Schizotypal Personality Questionnaire.

P50 event-related potential P50 is another type of event-related potential task that assesses attention and early information processing. Impairments in P50 wave suppression have been identified as vulnerability markers for the sensory gating deficits observed not only in patients with schizophrenia, but also in their first-degree relatives, further supporting the notion of P50 as a candidate endophenotype for schizophrenia-spectrum disorders. Compared with healthy volunteers, STPD subjects show less suppression of the P50 event-related potential to the second of a pair of click stimuli, indicating a failure of sensory gating at a relatively early stage of information processing. Healthy volunteers with higher schizotypal characteristics, as assessed by the schizotypal personality questionnaire, had lower P50 suppression than subjects with a low schizotypal score.

Genetic risk factors

There is now abundant evidence that catechol-O-methyltransferase (COMT) has a critical impact on dopaminergic transmission. Certain variations of COMT, a candidate gene for the modulation of performance in PFC-mediated cognitive tasks, have been hypothesized as playing a role in the phenomenology of STPD. A polymorphism in the COMT gene, leading to an amino acid substitution valine (Val) to methionine (Met), results in the Met/Met variant. Patients with this variant exhibit 40% less enzymatic activity than Val/Val individuals. There is an extended literature on recent functional magnetic resonance imaging (fMRI) findings showing that, relative to Met-loading subjects, Val homozygotes underperform in PFC-related tasks and/or have prefrontal hyperactivation. Recent studies have shown that these subjects have deficient gating and early information processing as evidenced by deficient PPI. Consequently, it has been suggested that the Val allele is

associated with less efficient information processing and increased prefrontal neuronal 'noise.' Recent studies have shown that STPD subjects with the Val/Val genotype exhibited worse performance on executive functioning and PFC-dependent memory tasks independent of clinical status. These findings were replicated in a recent study in which the STPD subjects with higher Val loading showed not only worse cognitive performance, but also more severe negative schizotypy. These Val-dependent cognitive and early information processing deficits were found to be improved by compounds such as tolcapone, a selective inhibitor of the brain COMT enzyme, resulting in DA neurotransmission enhancement in the PFC and simultaneous improvement in gating and working memory deficits. Another recent study has pointed to other genes, such as the proline dehydrogenase (PRODH), which might be an important determinant of the continuum from normality to psychosis and the genetics of schizophrenia-related traits. Healthy individuals who displayed the markers for the psychosis variant risk factor presented with gating and verbal memory deficits, as well as higher anxiety and schizotypal personality traits.

Treatment (Biological and Psychological)

In STPD, treatment could be beneficial, leading to measurable gains, especially in mildly affected individuals. However, the majority of these individuals are not able to alter their ingrained ways of perceiving or interpreting reality. The lack of a social support structure might prevent most STPD subjects from initiating any type of treatment. Notably, compared to schizophrenia, the severity of psychopathology is milder in STPD patients and a significant portion will maintain, despite their oddities, an adequate functioning level in occupational, social, and interpersonal environments.

Psychological

As with SZPD, only a limited number of studies have assessed the psychotherapeutic treatment of SZPD patients, and most of the evidence is based on expert opinion. The principles of therapy in STPD patients do not differ from those in patients with SZPD. However, individuals with STPD distort reality to a more significant degree and usually demonstrate peculiar patterns of thinking and behavior, such as involvement in cults and strange religious practices. Therapists must keep a neutral position and should not be judgmental about these beliefs or activities. In addition, STPD patients often report feelings of being 'different,' usually because of their belief in magic or delusional thinking. A warm, supportive, and client-centered environment should be established with initial rapport, as these individuals lack an adequate social support system and usually avoid most social interactions due to extreme social anxiety. Significant emphasis should be given to the acquisition of social skills, as competence in the fundamentals of social interactions may be beneficial. While individual therapy is the preferred modality at the onset of therapy in these patients, it may be appropriate to consider group therapy as treatment advances in order to enhance social and interpersonal skills.

Biological

The number of pharmacological treatment trials in STPD is significantly higher in comparison to SZPD. However, all the

clinical trials of STPD have to date typically included subjects with borderline or mixed personality disorders. The phenomenological similarity of the psychotic-like symptoms (e.g., magical thinking, suspiciousness, and ideas of reference) of STPD individuals with the psychosis of chronic schizophrenia has led to the notion that treatment with antipsychotic medications will ameliorate and improve these symptoms. The first studies that examined the beneficial effect of antipsychotic medications suffered from design flaws such as lack of homogeneity (i.e., inclusion of patients with other personality disorders besides STPD) and lack of randomization. Despite these drawbacks, these studies have been able to demonstrate a reduction of psychotic-like symptoms in STPD patients following administration of first-generation antipsychotics. For example, in a mixed sample of patients with schizotypal and borderline personality disorders, thiothixene led to a more prominent improvement of psychotic symptoms in STPD patients compared to those with borderline diagnosis. Additionally, compared with placebo, haloperidol has been shown to improve positive-like STPD symptoms. However, these findings were not replicated in subsequent trials of haloperidol in STPD.

More recently, the effectiveness of second-generation antipsychotic treatment has also been demonstrated in STPD. More specifically, a randomized, small-scale study showed that, compared to placebo, risperidone reduced the positive, negative and general score of the positive and negative syndrome scale (PANSS) in these patients. Interestingly, this effect was more significant for doses in the range of 1 mg day^{-1} or even smaller. The authors concluded that this might be secondary to better tolerability and less exacerbation of somatization-like symptoms in treated patients. This success in the improvement of psychotic-like symptoms is not observed in the case of depressive symptoms, where there is poor effectiveness of medications. For example, risperidone failed to demonstrate a reduction of depressive symptoms in STPD patients. However, a recent open-label study with a flexible olanzapine dose demonstrated significant improvement in psychotic-like symptoms, depression, and overall functioning scores in a small group of patients, most of whom had STPD that was comorbid with borderline personality disorder.

Also, the use of antidepressant medications has failed to show a significant improvement of mood or psychoticism in STPD patients without comorbid borderline personality disorder. More specifically, an open trial of fluoxetine in patients with borderline personality disorders and STPD showed significant improvement in psychotic symptoms; however, the results were not analyzed with respect to diagnosis. Another clinical trial of fluoxetine demonstrated improvement in impulsive aggression in a mixed sample of patients with personality disorders. However, these results were not presented separately by cluster.

Early phenomenological studies have reported that STPD shares similar cognitive deficits with other schizophrenia-spectrum disorders. Studies have shown that amphetamine reduces these cognitive deficits. Specifically, the use of this drug leads to attenuation of errors on working memory and verbal learning tasks in STPD subjects. This is attributed to the enhancement of the dopaminergic system by amphetamine, as hypodopaminergic neurotransmission is an important determinant of the cognitive deficits in schizophrenia-spectrum

illnesses. More specifically, amphetamine indirectly activates the D_1 receptors in the frontal cortex, which are known to modulate visuospatial working memory performance. The use of escalating doses of another DA agonist, pergolide, with preferential activity at D_1 receptors for 2 weeks has shown to improve working memory performance in STPD subjects, without any clinical worsening. The increased risk for valvular heart disease induced by pergolide has restricted the use of this agent in the management of STPD patients. Another pharmacologic compound with a high ratio of D_1/D_2 activity is dihydrexidine. In a recent study, the administration of this agent failed to improve cognitive deficits of patients with schizophrenia; however, the beneficial effect of this compound on cognition may be detected with more sensitivity in STPD patients whose deficits are usually less severe and more readily reversible than in patients with schizophrenia. Additionally, compared to schizophrenia patients, STPD individuals do not experience worsening of psychotic-like symptoms after the administration of dopaminergic agonists. It has been speculated that STPD patients share with schizophrenia patients the cortical hypodopaminergic, but not the subcortical hyperdopaminergic neurotransmission.

Norepinephrine has also been found to play a significant role in cognitive functions such as working memory and attention. More specifically, norepinephrine increases the signal-to-noise ratio in the PFC during the processing of sensory stimuli, enhances long-term memory consolidation in the amygdala and hippocampus, and modulates cognitive flexibility for insight-based problem solving. Guanfacine is an agonist that acts on the norepinephrine α -2a postsynaptic receptors of the PFC. This compound has the potential to be an effective treatment for the cognitive deficits in the schizophrenia-spectrum disorders. Indeed, a recent, placebo-controlled, double-blind study showed that guanfacine improved performance in context processing (though not in verbal or visuospatial episodic memory tasks) in STPD individuals, but not in patients with other personality disorders. This selective enhancement of context processing but not episodic memory further suggests that working memory deficits may in fact underlie the range of cognitive deficits within the schizophrenia-spectrum disorders.

Summary

Schizoid and schizotypal personality disorders are included in the odd and eccentric cluster A personality disorders. SZPD is characterized by a restricted range of emotional expression in interpersonal settings and excessive detachment from social relationships, while STPD is characterized by pervasive patterns of social and interpersonal deficits marked by a reduced capacity for close relationships as well as by cognitive or perceptual distortions and eccentricities of behavior. Research has supported heritability for both disorders and higher prevalence in biological relatives of schizophrenics. STPD is highly prevalent in the general population and is associated with the co-occurrence of Axis I and other Axis II disorders. SZPD is less common than STPD or other personality disorders. It is still unclear whether a proportion of SZPD individuals progress to schizophrenia or whether STPD is the premorbid personality of

schizophrenia or a necessary transitional stage of schizophrenia. Cognitive deficits in schizotypal individuals are similar to those for patients with schizophrenia, but less severe and more circumscribed to specific cognitive areas. Thus, STPD is considered the prototypic schizophrenia-related personality disorder, sharing genetic, neurophysiological, structural, and functional neuroanatomic features with schizophrenia. Moreover, schizotypal features can be quantitatively measured at the general population level by using self-rated schizotypal personality traits. Thus, both schizotypy and STPD might serve as promising endophenotypes for schizophrenia. Schizoid and schizotypal individuals usually seek treatment for a concomitant Axis I disorder. Psychotherapy is the initial treatment of choice for SZPD, and the primary goal of therapy is to increase coping and interpersonal relationship skills. Limited clinical trials in STPD support the notion that these patients might benefit from the addition of antipsychotic medication. However, pharmacotherapy in both personality disorders is understudied, and additional long-term controlled clinical trials are needed.

Glossary

Delusion A strongly held erroneous belief that does not change in the face of contradictory evidence or information.

Hallucination A sensation without an external object or precept. Hallucinations can be in any sensory modality.

Negative symptoms The absence or diminution of cognitions, feelings, or behaviors.

Paranoia The belief that others are currently planning to harm, injure, or mistreat the person usually without evidence.

Positive symptoms Thoughts, sensory experiences, and behaviors that are usually in excess of normality and not found in persons without the disorder.

Prognosis The outcome or conclusion of the disorder; future direction and course.

Psychosis A loss of contact with reality.

Recovery A broad concept that implies that the person has achieved some degree of improvement in symptoms and community and social functioning.

Social cognition The way a person thinks about, perceives, and interprets social events and others.

Introduction

Schizophrenia is considered one of the most severe and debilitating psychiatric disorders. Persons with schizophrenia report symptoms that include delusional beliefs, unusual sensory experiences, disorganized speech and behaviors, and apathy, emotional flattening, and indifference. Schizophrenia is also characterized by impairments in social functioning, including difficulty establishing and maintaining interpersonal relationships, problems working or fulfilling other instrumental roles (e.g., student, homemaker, employee), and difficulties caring for oneself (e.g., poor grooming and hygiene). Many individuals with the illness depend on others to meet their daily living needs. For example, estimates from studies in Europe and the United States suggest that between 25% and 60% of persons with schizophrenia live with relatives, and an even higher percentage rely heavily on relatives for daily care. Individuals without family support typically rely on mental health, residential, and case management services to get their basic needs met. In the worst case scenario, persons with schizophrenia who have insufficient contact with relatives and who fall between the cracks of the social service delivery system end up in hospitals, jail, or become victimized or homeless. About 25% of all inpatient hospital beds are for the treatment of schizophrenia and it has been estimated that the cost of treating schizophrenia is over 63 billion per year in the United States. The burden of schizophrenia places the disorder as one of the top ten most disabling conditions in the world in terms of illness-adjusted life years. One of the largest costs is the lack of productivity over the lifetime, as unemployment rates are near 75%. Sadly, even with optimal treatment, many continue to experience substantial impairments throughout most of their lives.

Brief History of Schizophrenia

The exact origins of schizophrenia are difficult to determine, but it is believed schizophrenia has been present in various

forms for centuries, with historical reports going back to Ancient Egypt. Many persons with psychosis were believed to be possessed or acting under the influence of malevolent gods or spirits. John Haslam, the resident apothecary at Bedlam Hospital (London, UK), offered the first detailed description of schizophrenia on a patient named James Tilley Matthews, who developed paranoid delusions around 1810. Matthews believed that a gang of London area criminals skilled in 'pneumatic chemistry' were torturing and manipulating him using a device called an air loom. In the 1880s, the German Psychiatrist Emil Kraepelin suggested that schizophrenia, or what he called 'dementia praecox,' was a distinct mental disorder, not a form of manic depression, thus solidifying its place as a formal mental condition. In 1911, the Swiss psychiatrist Eugen Bleuler first coined the term 'schizophrenia' which means split mind. Bleuler believed that schizophrenia was a group of different disorders, thus referring to them as 'the schizophrenias.'

Prevalence and Gender Differences

Worldwide, schizophrenia affects more than 50 million persons. In the United States, it is estimated that 2.2 million persons have schizophrenia. The lifetime prevalence rate for developing schizophrenia is about 1% for the general population. The prevalence rate of schizophrenia is believed to be remarkably stable (ranging between 0.5% and 1.0%) across a wide range of different populations and cultures. There has been little difference in the rates of schizophrenia according to gender, race, religion, or level of industrialization. However, there is evidence that schizophrenia is more heavily concentrated in urban areas of industrialized countries, and in fact persons from developing or third world countries may have a better prognosis and course of illness.

Schizophrenia can develop at any age, but is most common between the ages of 16 and 30. The peak age of onset is 20 for men and 24 for women. Childhood-onset schizophrenia (in children <10 years old) is considered rare and

controversial at present. There are persons, most often women, who show signs of schizophrenia after the age of 40, which is believed to be exacerbated by falling estrogen levels in menopause (schizophrenia after the age of 40 is often called late-onset schizophrenia). There are about 1.5–2 times as many men with schizophrenia than women and men tend to have more severe cases and less functional recovery over time. Women tend to spend less time in hospitals, have fewer negative symptoms, demonstrate less cognitive impairment, and have better social competence and social functioning than men with the illness.

Onset, Course, and Prognosis

In general, the onset of schizophrenia can be described as either gradual or acute. The gradual onset of schizophrenia can take place over many months or years, and it may be difficult for family members and others to clearly distinguish onset of the illness. Many persons enter a prodromal phase in which symptoms become increasingly apparent and more severe over time. As persons develop the condition, they may lose interest in friends, jobs, and school. Other common prodromal symptoms include odd beliefs, magical thinking, and paranoia. The prodromal phase then evolves into the active phase of the disorder, and for persons who are experiencing their first break this can be a frightening and confusing time. In other cases, the symptoms develop acutely over a period of a few weeks with dramatic and easily observed changes occurring over this time. Generally, though, once schizophrenia has developed, the illness usually continues to be present at varying degrees of severity throughout most of the person's life. Over the lifetime, schizophrenia is usually an episodic illness with periods of acute symptom exacerbation (i.e., relapse) requiring more intensive, often inpatient, treatment interspersed by periods of higher functioning between episodes (i.e., remission). Prognosis is better for persons with primarily positive symptoms, females, and persons with a later onset of symptoms. A poorer prognosis is found for males, persons with early onset of symptoms, and persons with persistent negative and cognitive symptoms. Recently, there has been an emphasis on recovery which consists of a reduction in symptoms, subjective improvement in quality of life, and improved social, community, and interpersonal functioning. In fact, longitudinal studies which follow clients for over 20 years have reported that between 21% and 57% of persons with schizophrenia showed periodic episodes of recovery.

Clinical Symptoms and Diagnosis

The formal diagnostic criteria for schizophrenia can be found in the *Diagnostic and Statistical Manual for Mental Disorders*, 4th edn., text revision (DSM-IV-TR). The criteria for schizophrenia are as follows (Table 1).

In recent research, the individual symptoms of schizophrenia are generally classified as either positive or negative. *Positive symptoms* refer to thoughts, sensory experiences, and behaviors that are usually in excess of normality and not found in persons without the disorder. Positive symptoms include

Table 1 Summary of DSM-IV-TR criteria for the diagnosis of schizophrenia

-
- | | |
|----|---|
| A. | Presence of at least two or the following characteristic symptoms in the active phase for at least 1 month: |
| 1. | Delusions |
| 2. | Hallucinations |
| 3. | Disorganized speech (e.g., frequent derailment or incoherence) |
| 4. | Grossly disorganized or catatonic behavior |
| 5. | Negative symptoms (i.e., affect flattening, alogia, or avolition) |
| B. | <i>Social/occupational dysfunction</i> : For a significant proportion of the time from the onset of the disturbance, one or more areas of functioning, such as work, interpersonal relations, or self-care, is markedly below the level achieved prior to the onset |
| C. | <i>Duration</i> : Continuous signs of the disturbance persist for at least 6 months. This 6-month period must include at least 1 month of symptoms that meet criterion A |
| D. | <i>Schizoaffective and mood disorders exclusion</i> : Schizoaffective disorder and mood disorder with psychotic features have been ruled out |
| E. | <i>Substance/general medical condition exclusion</i> : The disturbance is not due to the direct effects of a substance or a general medical condition |
-

hallucinations (e.g., hearing voices, seeing visions), delusions (e.g., a strongly held belief that is maintained despite contradictory evidence), and bizarre, disorganized behavior (e.g., maintaining a peculiar posture for no apparent reason, wearing multiple layers of clothes, mumbling or talking to oneself). Persecutory delusions (i.e., belief that some entity, group, or person has clear on-going or future intentions to harm the person) or grandiose delusions (i.e., belief that the person is very important, famous, or has special powers or abilities) are the most common types of delusion found in schizophrenia. More bizarre delusions include thought stealing, thought broadcasting, and thought insertion. About 75% of persons with schizophrenia report hallucinations. Auditory hallucinations are the most common form of hallucinations and are frequently derogatory, negative, or abusive although some can be benevolent, comforting, and kind. Many persons with schizophrenia develop a close relationship with their voices. Auditory hallucinations can range from inaudible sounds (buzzing sounds, noises, muffled speech) or clearly perceived voices of either gender and can occur intermittently or on a continuous basis. Visual hallucinations are less common and are found in about 10–15% of persons with schizophrenia. Olfactory and tactile hallucinations can be present, but are considered rare. Disorganization includes problems in language, emotion, and behavior that are perceived as strange and bizarre by others. Persons with the disorder may display emotional expressions that are either too intense or out of context for the situation (e.g., laughing at a funeral). Their speech may be incoherent, tangential, or circumstantial (e.g., speech that is difficult to follow or understand), and their behavior may be strange or bizarre (e.g., wearing multiple layers of clothing, yelling at others on the street, mumbling, or talking to oneself). *Negative symptoms*, on the other hand, refer to the absence or diminution of cognitions, feelings, or behaviors which are ordinarily present in persons without the illness. Common negative symptoms include blunted or flattened affect (e.g., diminished facial expressiveness), poverty of speech (i.e., diminished verbal communication), anhedonia (i.e., inability to experience

pleasure), apathy, psychomotor retardation (e.g., slow rate of speech), and physical inertia. Long-term, persistent negative symptoms (e.g., deficit syndrome) are considered a poor prognostic indicator and are linked to impaired social functioning, poorer clinical outcomes, and greater brain and cognitive impairments. Once a diagnosis of schizophrenia is made, it is often useful to determine if a particular subtype of the disorder is present. Common subtypes include paranoid, disorganized, catatonic, undifferentiated, or residual schizophrenia.

Associated Symptoms

Although neurocognitive deficits are not part of the diagnostic criteria for schizophrenia, they are regarded by many researchers and clinicians to be a core feature of the disorder. Research in this area has consistently documented stable, often severe neurocognitive deficits across multiple domains, including verbal memory, visual memory, working memory, executive function, attention, verbal fluency, processing speed, and motor speed. Individuals with schizophrenia often perform below the 5th percentile compared to the normal population on neuropsychological tasks. While a small percentage of individuals (about 10%) with schizophrenia do not display these impairments (e.g., normal functioning schizophrenia), it is likely that these individuals still show significant impairment relative to their premorbid cognitive abilities. High-risk children who have a parent with schizophrenia tend to show attentional, language, and motor abnormalities early in development (around the age of 2 at the earliest), and these deficits may predict the development of schizophrenia as adults. Finally, first-degree, unaffected relatives of a person with schizophrenia tend to show problems in smooth pursuit eye tracking (tracking a moving object with their eyes) and other cognitive abilities, reflecting the genetic aspects of the condition.

In addition to cognitive deficits, it has become apparent that impairments in social cognition (defined as the way we perceive, interpret, and understand social information) are also found in schizophrenia. Deficits in emotion and social cue perception, problems inferring the intentions and motivations of others (theory of mind), and impairments in social knowledge and schemata have all been found in schizophrenia. Persons with schizophrenia have severe problems recognizing facial expression of emotion, and this deficit is more pronounced than in any other psychiatric disorder. Persons with persecutory delusions tend to exhibit an attributional style in which they tend to blame others rather than situations for negative events (personalizing attributional style).

Other symptoms associated with schizophrenia include high rates of substance abuse, medication noncompliance, and emotional distress. Substance abuse is problematic as many drugs of abuse can mimic or produce psychosis. Amphetamines, marijuana, LSD, and alcohol are the most commonly used substances, and about 70% or more of persons with schizophrenia smoke cigarettes. Approximately 50% of all persons with schizophrenia have a lifetime history of substance use disorder. Persons with schizophrenia have a two to three times higher rate of cannabis abuse, and a heavy use of marijuana in adolescence (before the age of 18) can increase risk of schizophrenia by as much as six times. Medication noncompliance is also a problem in schizophrenia. Studies estimate that about 75% of persons with schizophrenia do not take their medication

as prescribed. Persons may discontinue medications due to the presence of side effects, cost, a lack of insight into their condition, daily hassle, or stigma from others. Recent research has found that persons with schizophrenia report higher levels of depression, anxiety, and suicidal ideation. It is estimated that 40–50% of persons with schizophrenia report significant levels of depression or anxiety in addition to schizophrenia. Sadly, about 10% of these persons commit suicide, and suicide risk is 10–50 times higher if depression is present, if there is a history of prior suicide attempts, and in the weeks immediately preceding and/or following hospitalization.

Etiological Theories

Genetics

Schizophrenia is a complex disorder with a number of interrelated causes, with many stemming back to prenatal development. There are hundreds of theories about the causes and potential mechanisms of schizophrenia, each with varied levels of research support. There has been considerable interest in genetic factors involved in schizophrenia due to findings that a person's risk for developing schizophrenia is higher if a first-degree relative (parents, siblings, and children) has the condition. Children born from two parents with schizophrenia have an estimated 46% greater risk for developing the disorder themselves (1% lifetime risk in the general population). Twin studies have proven useful in understanding genetic factors in schizophrenia. Studies examining rates of schizophrenia among monozygotic (MZ; 100% genetic similarity) and dizygotic (DZ; 50% genetic similarity) twins show pairwise concordance rates of 28% and 6%, respectively. In MZ twins, the one who is discordant (i.e., does not have the disorder) for schizophrenia has a 17% chance of having children who develop the disorder even though they themselves are healthy. Twins who are reared apart still have an elevated risk for developing schizophrenia above that accounted for shared environmental factors. Adoption studies conducted in Scandinavia show a rate of schizophrenia of about 16% if one of the biological parents has schizophrenia. Environmental factors such as communication deviance (i.e., incomprehensible speech) and stressful family events in combination with a genetic predisposition led to the highest risk for developing schizophrenia in adoption studies. Despite the clear role of genetics and family history in schizophrenia, the genetic relationship is modest at best and schizophrenia is considered a polygenetic construct. In fact, it is possible that there may be different types of schizophrenia each with their own profile of genetic abnormalities. Current research has focused on several chromosomes such as 6, 8, 13, and 22, but research to identify a specific genetic locus has proved largely disappointing. Chromosome 22 is of particular interest as it contains the COMT (catechol-*o*-methyltransferase) gene that metabolizes dopamine. Persons with a particular type of COMT genetic profile (valine/valine allele type) are at an increased risk for developing schizophrenia.

Brain Pathology and Impairments

Schizophrenia is largely considered a brain disorder, so it is not surprising to find a number of cerebral impairments in persons

with the disorder (see associated symptoms above). The brain pathology found in schizophrenia appears to predate the condition and represents a developmental process subject to genetic and environmental triggers. In terms of brain structure, people with schizophrenia are apt to have abnormally reduced cortical gray matter (3% smaller brain volume on average) and larger cerebral ventricles. The frontal lobes seem to be implicated in schizophrenia with a reduction in both total gray and white matter volume in this area. Notably, the frontal lobes are presumed to be the neural substrate of planning, motivation, working memory, goal-directed activities, and the capacity to inhibit impulses. Coincidentally, schizophrenia is characterized by poor problem-solving, apathy, and disorganized behavior. Thus, these frontal lobe anomalies may underlie some aspects of schizophrenic symptomatology. Researchers have also found abnormalities in the temporal lobe, parietal lobe, thalamus, amygdala, basal ganglia, and hippocampus. Functions attributed to the temporal lobes are varied, and include auditory processing, language, and memory. Schizophrenia is often characterized by auditory hallucinations, disorganized language, and impaired memory, which reflect temporal lobe function. This suggestion is supported, albeit weakly, with some research revealing an association between temporal lobe volumes and severity of positive symptoms.

Although the etiology of structural brain impairments has not been clearly determined, they appear to be present at the time of initial symptom onset. The combination of brain pathology and cognitive deficits in high-risk children and the lack of glial scarring in the brain itself might suggest that cerebral anomalies precede symptom onset. Thus, schizophrenia may be a neurodevelopmental process. However, it is still possible that over time some further deterioration in cerebral integrity may occur, implying a progressive etiology.

Regarding functional abnormalities, many of the same regions implicated in structural imaging studies appear to manifest abnormal activation patterns. In particular, the prefrontal lobe structures demonstrate considerable hypoactivation in people with schizophrenia, especially when they perform tasks requiring working memory, vigilance, or concentration. This 'hypofrontality' is one of the most consistent findings in schizophrenia.

These structural and functional anomalies seem to correspond with abnormalities at the cellular level. In particular, schizophrenia is associated with disordered arrangements of neurons, and this ultimately is reflected by abnormal distribution and orientation of neurons within the six cortical layers. This is found most consistently in the hippocampus. Research has also suggested that there are fewer neurons in the thalamus, which may lead to sensory overload and the inability to screen out irrelevant information. Problems in cellular organization may suggest some problem in neuron migration, synaptic pruning, or preprogrammed cell death. Taken together, these findings imply that frontal and temporal lobe regions possess abnormal interconnectivity, as evidenced by anomalous neuronal branching and distribution during the second trimester and first few years of life. This type of disorganization again suggests a developmental process.

Neurochemical Deficits

Dysfunction in neurotransmitters, in particular, dopamine, has been important in both the etiology and treatment of

schizophrenia. In fact, the dopamine hypothesis of schizophrenia was promulgated over 50 years ago based on the effect of early antipsychotic medications, such as chlorpromazine, which block dopamine receptors (dopamine antagonists). According to this model, excessive levels of dopamine activity yielded positive symptoms given that dopamine affects how much salience we give to internal and external stimuli. Further support for the role of dopamine in psychosis comes from evidence that amphetamines can induce a psychotic state, and if dopamine agonists are given to a person with schizophrenia, psychosis will ensue. Over the years, a modified dopamine hypothesis has been proposed based on inconsistent evidence for dopamine abnormalities in schizophrenia. In this model, subcortical dopamine (mesolimbic and nigrostriatal; primarily D2, D3, and D4 receptors) circuits interact synergistically with frontal cortical dopamine systems (mesocortical; primarily D1 and D5 receptors) to yield excessive subcortical dopamine activity and insufficient dopamine activation in the frontal cortex. The nature of this abnormal activation seems broad, as presynaptic storage, release, and reuptake of dopamine, but current research suggests that the dopamine receptors are supersensitive. In fact, higher numbers of D2 dopamine receptors have been found in medication naïve patients before taking antipsychotic medications. Notably, excess subcortical dopamine activity corresponds with severity of positive symptoms while a lack of dopamine activity is believed to correspond to deficits in working memory, impaired cognition, and negative symptoms.

The second major neurotransmitter of interest is glutamate. Glutamate is a diffusely distributed neurotransmitter which generally acts to increase arousal, and is localized in the prefrontal cortex and hippocampus. In schizophrenia, however, glutamate tends to have a diminished presence (reduced NMDA receptor activity), and this correlates with severity of negative symptoms and is affected by excess dopamine activity. Moreover, glutamate antagonists, such as ketamine and PCP, tend to exacerbate psychotic symptoms.

Environmental and Life Events

Given the brain impairments found in schizophrenia, it has been argued that certain prenatal, perinatal, and postnatal events could trigger the condition. Research conducted in Finland in the 1950s noted a slightly higher risk (8%) for developing schizophrenia among mothers who were infected with the influenza virus in the second trimester. The second trimester (around the 5 month of gestation in particular) is considered a crucial time period for brain development and maturation, and influenza might lead to some type of abnormal autoimmune response that impairs brain development. Since this early finding it has been shown that a number of other infections or obstetrical problems enhance risk, albeit slightly, for schizophrenia. Diabetes, *rh* incompatibility, placental or uterine abnormalities, low birth weight, advanced parental age at conception (fathers greater than 45 years of age) and hypoxia during delivery have been associated with schizophrenia.

Although stressful life events alone are not the 'cause' of schizophrenia, some theories hypothesize that negative life events may play an important role in the course of schizophrenia. The stress-vulnerability model assumes that stressors can impinge on the biological vulnerability of schizophrenia to

exacerbate symptoms. *Stressors* include traumatic events such as being the victim of violence and assault, poor family interactions, poverty, and being a member of a minority group.

Schizophrenia can be affected by stressful events and interactions between the individual and family. Although families do not cause schizophrenia, it has repeatedly been found that critical attitudes and high levels of emotional over-involvement (expressed emotion, EE) on the part of the relatives toward the individual with schizophrenia are strong predictors of the likelihood that persons with schizophrenia will relapse and be rehospitalized. Family EE seems to act as a stressor, increasing the vulnerability of persons with schizophrenia to relapse.

Due to the severity of the disorder, many persons with schizophrenia live in poverty (schizophrenia is often more concentrated in urban areas). Persons with schizophrenia might gradually drift into lower socioeconomic classes (SES) as symptom severity and functional impairment increases, but this has not been consistently supported. However, it is also possible that persons with schizophrenia are born into poverty and get worse due to their lack of resources and care. Being a member of a minority/immigrant group may also increase the risk for developing schizophrenia or being hospitalized. Minority individuals may experience high levels of racism and discrimination, which can lead to higher levels of stress and physiological arousal. In terms of psychosis, there has been a link between the amount of perceived racism and paranoid ideation among African-Americans. In addition, certain ethnic and migratory groups such as second-generation Afro-Caribbeans living in the United Kingdom, Dutch Antillean and Surinamese immigrants in Holland, Finnish, Eastern and Southern European first- and second-generation immigrants in Sweden, and African-Americans in the United States have shown higher rates of schizophrenia.

Finally, people with schizophrenia are much more likely to be the victims of violence, criminal acts, and sexual/physical abuse. Rates of childhood sexual or physical abuse range from 30 to 50% (based on self-reports) and similar rates have been reported for criminal victimization. Exposure to traumatic events may lead to the development of posttraumatic stress disorder (PTSD) in persons with schizophrenia. The presence of PTSD in persons with schizophrenia has been found to worsen the course of the disorder and complicate treatment. The prevalence of PTSD among people with schizophrenia and other severe mental illnesses ranges from 29% to 43%, which are greater than the general population rate of about 10%.

Treatment of Schizophrenia

The treatment of schizophrenia is complex and requires a multidisciplinary team of psychiatrists, psychologists, social workers, and case managers. Due to the many problems (symptoms, medication issues, social functioning) associated with the condition, the ideal treatment is multifaceted. In general, the most common avenue of treatment is the use of antipsychotic medications, but there are also a number of psychological approaches that are of benefit. Even with optimal medication management, a person with schizophrenia often has reduced social and occupational functioning and residual symptoms. No treatment is considered 100% effective. Treatment can be

offered in inpatient or outpatient settings depending on the severity of symptoms. Psychological approaches are best when the person has been stabilized on medications.

Medical Treatment

Antipsychotic medications are the first line of treatment for schizophrenia in order to reduce the active symptoms of the disorder. There are two main classifications of antipsychotic medications: (1) first-generation (typicals) or (2) second-generation (atypicals). First-generation medications, such as Haldol, have been shown to be efficacious in reducing the positive symptoms of the disorder and have a long history of clinical use. The first antipsychotic used en masse for schizophrenia was chlorpromazine (Thorazine), which was developed in the 1950s and was largely responsible for the deinstitutionalization movement in the 1960s. However, effectiveness of chlorpromazine and other first-generation drugs is tempered by the side-effect profiles of these medications (sedation, fatigue, dry mouth, motor side effects, memory impairment), which are largely responsible for their waning use in current treatment. These side effects also lead to high rates of noncompliance, and some clients receive injectable medications which last longer than traditional pills. First-generation antipsychotics block D2 dopamine receptors (dopamine receptor antagonists) in the temporal and frontal lobe dopamine circuits, and this mechanism of action is believed to lead to their antipsychotic effect. Since the blockade of dopamine receptors also occurs in the nigrostriatal pathway, these medications also lead to an array of extrapyramidal symptoms (EPS). EPS symptoms include motor abnormalities such as dystonia (painful muscle contractions/spasms), akathisia (restlessness, pacing, inability to sit still), and medication-induced Parkinson symptoms (fine tremors, rigidity, gait problems, slowed cognition). Long-term administration of these first-generation medications can lead to the development of a serious medical condition called tardive dyskinesia (TD). TD consists of involuntary hyperkinetic movements of the face, tongue, limbs, fingers, and trunk. TD is considered irreversible and cannot be accurately predicted, but can be reduced by switching to an atypical antipsychotic medication with less dopamine D2 receptor antagonism or using the minimal effective dosage.

In the 1990s, atypical antipsychotics such as Clozaril were developed with promise of improved treatment for schizophrenia with greater efficacy and fewer side effects. As a general rule, atypical medications such as risperidol, ziprasidone, and aripiprazole are less potent antagonists of the D2 receptor system (less potential for EPS) and affect several neurotransmitter systems such as serotonin (5-HT_{2A/2C}), norepinephrine, acetylcholine, and glutamate (NMDA receptors). These medications tend to activate other dopamine receptors such as the D1, D3, D4, and D5 receptors in the brain as compared to a nonspecific blockage of D2 receptors found in first-generation medications. Thus, these drugs are more specific in terms of their effect on the dopamine system. It is now recommended that atypical medications be considered the first line of treatment for schizophrenia due to a lower risk for EPS in these medications. However, atypicals do have their share of potential side effects such as sedation, weight gain, abnormal heart activity (QT interval slowing),

and diabetes. It was hoped that atypical medications, due to their impact on different neurotransmitters, would also improve cognition, but results have been generally disappointing in recent years.

Psychological Treatments

There are a number of psychological treatments for schizophrenia, but only those that have some degree of research support (e.g., evidence-based treatments) are considered appropriate. Behavioral treatments have fared well in research; many efficacious treatments involve behavioral or modeling components. Some of the more common therapies will be presented here.

Behavioral interventions using reinforcement and punishment to reduce hallucinations and delusions have the longest history, but the use of a token economy system has shown the most effectiveness. Token economies are program or hospital level treatments based on the reinforcement of adaptive behaviors using tokens (most often points, checks, etc.) that can be cashed in for privileges or tangible items. For example, if a person attends group therapy they earn ten points. Points are accumulated to obtain some item or goal that is desirable for the client. When implemented correctly, these are very effective. However, these programs are costly and require substantial training and fidelity along with administrative support to work in real-world settings.

Social skills training (SST) is aimed at improving the social functioning and competence of persons with schizophrenia. Persons with schizophrenia have consistently been found to have poorer social skills than persons with other psychiatric disorders. SST provides instruction on conversation skills such as how to begin, maintain, and end conversations, express emotions appropriately, and resolve interpersonal conflict. Each social skill is broken down into different units such as verbal, paralinguistic, and nonverbal components. To facilitate learning, SST involves didactic teaching, rehearsal, role-playing, corrective feedback, and modeling of appropriate social and communication skills, usually in a group setting. To reinforce gains made in the group session, participants are asked to continue to develop and practice these skills outside of the group sessions, which may improve the generalization of new skills into the real world. SST does improve specific social skills, but evidence for improved symptoms and community functioning or preventing relapse is less consistent.

Behavioral family therapy (BFT) is based on teaching adaptive coping skills to ameliorate the deleterious effects of stress on schizophrenia (i.e., EE). The treatment works to reduce negative, hostile, and overly critical communication patterns found in families. There is a clear link between EE and higher rates of relapse. BFT emphasizes psychoeducation about the symptoms and causes of schizophrenia, communication exercises, and group problem-solving activities. BFT can be conducted with a single family unit or with multiple families. BFT has shown to lower relapse rates from about 60% to 30%.

Cognitive-behavioral therapy (CBT) has seen a tremendous increase in popularity since the 1990s as a treatment for schizophrenia, and it can be argued that CBT has the most research support of any treatment. The most common applications of CBT are in the treatment of delusions, hallucinations, and negative symptoms, which allows a very specific treatment

focus. CBT assumes that psychotic symptoms develop from information processing biases in attention, appraisal, attribution, and belief formation. CBT for schizophrenia grew out of the work of Aaron Beck in his seminal work on depression. Delusions and hallucinations are modified by challenging the evidence for a person's beliefs. Cognitive restructuring, behavioral experimentation, teaching and practicing coping skills, generating alternative attributions for events, and behavioral activation are common techniques. Although CBT has tremendous promise, there remains a lack of dissemination and implementation in the United States. However, in the United Kingdom, CBT is considered a front-line treatment offered to all persons with schizophrenia.

Other treatments of note include: (1) assertive case management (ACT), (2) cognitive remediation, and (3) supported employment. ACT teams provide intensive support and medication services to clients in their homes, and the idea is to meet the clients where they are, whether in the home or on the street. Medications are delivered and administered to clients to increase compliance rates. Cognitive remediation targets the neuropsychological and cognitive impairments found in schizophrenia. Repeated cognitive exercises and computer games are used to improve attention, memory, visual processing, and problem solving. It is believed that improving basic cognitive ability will lead to better social and community functioning. Given the high rates of unemployed in schizophrenia, supported employment programs provide training to clients prior to and during employment. Clients are taught the basics of their job, how to interact with others, and how to manage stress and symptoms. Supported employment works best when the client is placed in a job and then trained (rather than trained and then placed later).

Conclusions

Schizophrenia is a chronic psychiatric condition that affects over 50 million persons worldwide and is characterized by positive symptoms (hallucinations, delusions), negative symptoms (social withdrawal, flat affect, apathy), and impairments in cognitive (executive functioning, memory) social-cognitive (emotion perception), and social functioning. There is no consensus on the etiology of schizophrenia, but there appear to be both biological and environmental factors involved in the development, course, and outcome of the disorder. In terms of treatment, antipsychotic medications are considered the first line of treatment and show efficacy in reducing symptoms, especially positive symptoms. However, adherence rates to medications are low, even with the widespread use of newer atypical medications. Psychosocial treatments such as CBT have led to further improvement in functioning or a reduction in symptoms that do not respond to medication therapy. The combination of medication and psychosocial treatments leads to the best outcome and has provided a renewed hope for recovery for those persons with the condition.

Selective Mutism

M M Nieves, F Mesa, and D C Beidel, University of Central Florida, Orlando, FL, USA

© 2012 Elsevier Inc. All rights reserved.

Glossary

Contingency management Behavioral intervention that involves the structured provision of rewards for certain behaviors. The value of performing each behavior is clearly specified in advance.

Exposure Exposure is a procedure used in behavior therapy than involves, under therapist-controlled conditions, placing individuals in contact with an object, event, or situation that they fear.

Selective mutism A consistent failure to speak in specific social situations (in which there is an expectation for speaking, e.g., at school) despite speaking in other situations.

Shaping Shaping is a process by which an individual's behavior is reinforced to achieve a predetermined status.

Systematic desensitization A form of behavior therapy that combines the use of gradual exposure and relaxation skills to approach more anxiety-provoking situations.

The term selective mutism (SM) used to describe the failure to speak in social settings has undergone an evolution over the past 130 years. The condition was first described by Adolf Kussmaul in 1877, who labeled it *aphasia voluntaria*. The use of this term conceptualized this disorder as one in which children *voluntarily* withheld speech. This label was later changed (in 1934), when the term *elective mutism* was proposed by Swiss child psychiatrist Moritz Tramer. Still, the term implied that children with SM elected or chose to remain quiet in social settings. Whereas the current *International Classification of Diseases – Tenth Edition* has retained the term *elective mutism*, other diagnostic schemas such as the Diagnostic and Statistical Manual of Mental Disorders – Fourth Edition Text Revision (DSM-IV-TR) changed the term from *elective* to *selective* in an effort to avoid previous conceptualizations of the behavior as inherently volitional (i.e., the child actively refusing to talk). Thus, whereas the ICD-10 continues to conceptualize SM as a withholding of speech in social settings, the change in wording from 'elective' (voluntarily deciding not to speak) to 'selective' was an effort to remove the connotation that children with this disorder were deliberately oppositional and replace it with the connotation that it was the situation, and not the child, that was responsible for the lack of speech. Despite the change in term in the DSM, the controversy regarding the presence of oppositional behavior in at least a subgroup of children with SM remains.

Diagnosis

According to the DSM-IV-TR, SM is defined "as consistent failure to speak in specific social situations (in which speech is expected, e.g., at school) despite speaking in other situations" (p. 125). The most common presentation of SM is a child who speaks freely (and often loudly) when at home in the company of parents or siblings. However, when other individuals (often including grandparents) come to the home, the child 'clams up' refusing to speak, often refusing to make eye contact and sometimes hiding in another part of the house. Similarly, a child with SM who speaks at home will refuse to speak in any environment outside of the home, even if in the

presence of parents, if there are other people who might overhear the conversation. At these times, parents often report personal frustration or embarrassment because adults are speaking to their child and the child stares back but does not respond. Parents fear that this refusal to speak will be perceived as 'rude' by other adults and parents quickly respond for the child. Although this negates parental distress, it also allows children to escape from what is perceived to be an uncomfortable situation, and perhaps sets up a pattern of continued avoidance of verbal communication (see section 'Etiology'). In school, when parents might not be available, children will often turn to a classmate to verbally communicate their needs to a teacher.

The use of the phrase 'verbal communication' in the above paragraph is a deliberate choice on our part. Often, nonmental health professionals interpret a 'failure to speak' as a failure to communicate. In fact, children with SM are often able to communicate quite effectively through nonverbal means. Gestures, pointing, nodding, writing, and even using email are some the means that children with SM use to communicate their needs. Therefore, these children can express themselves even without the use of verbal communication.

Simple failure to speak in situations where speech is accepted is not sufficient for a diagnosis of SM. This failure to speak must interfere with educational/academic achievement or with social communication. In many instances, children with SM do have difficulty in school. Although most children with SM appear to learn, it is often difficult for teachers to determine the child's academic achievement. Children refuse to read aloud making it difficult to assess their reading skill. Similarly, because they refuse to speak, they do not answer questions in class or ask the teacher for help, leading to distress on the part of the child and frustration on the part of school personnel.

In addition to the need for SM to result in distress or functional impairment, the diagnostic criteria require that the duration of the disturbance must be at least 1 month and not limited to the first month of school. Indeed, social reticence in novel situations is common and often occurs, even among children who do not have SM. Therefore, it is important to allow children to become familiar and comfortable in new situations before raising concern about limited speech in

these settings. Even if children remain in the same school, the start of a new school year, with a new teacher, a new classroom, new school subjects, and perhaps even new classmates, may create sufficient novelty and elicit temporary distress. Thus, there is a need to allow any child to adjust to new surroundings prior to determining the existence of SM.

Interestingly, the refusal to speak does not always interfere with the children's ability to establish friendships. Following the diagnostic subgrouping used for social phobia, Cunningham, McHolm, and Boyle examined the social skills and social relationships of children with either specific SM (e.g., did not speak to teachers but spoke to friends at school) or generalized SM (e.g., spoke only to parents at home). Despite their subtype designation, children with SM had similar scores on parent-rated measures of social phobia, generalized anxiety, and obsessive-compulsive disorder (OCD) symptoms. Furthermore, parental and teacher reports revealed that children in both SM groups had significantly poorer verbal and nonverbal social skills when compared to controls. Despite this, children with SM did not see themselves as less accepted by peers. Therefore, even though adults perceive significant psychopathology among children with SM, this condition may not always seriously impact children's ability to interact with peers.

The diagnostic criteria require that the failure to speak is not due to a lack of knowledge of, or comfort with, the spoken language required in the social situation. Therefore, a diagnosis of SM must be cautiously applied when evaluating children who have recently moved from another country, and/or for whom the language spoken at school (or in other settings) is not their first language. In such cases, it is important to determine if the same pattern of behavior existed prior to the move to a new country or culture. Similarly, SM is not diagnosed if the lack of speech is part of a larger communication disorder such as stuttering or only occurs as part of other disorders such as pervasive developmental disorder, schizophrenia, or another psychotic disorder.

Epidemiology

SM typically begins between 3 and 5 years of age. Yet, even though refusal to speak occurs at such a young age, the determination that the child has a psychological disorder does not necessarily occur until the child enters situations where failure to speak is problematic – such as formal schooling. Since children speak at home, parents may not initially view the behavior as problematic. Thus, there is often a considerable lag between initial failure to speak and referral to a mental health specialist. The delay from onset to identification and diagnosis holds out the possibility of entrenchment of the mutism behavior and has implications for treatment and service delivery. Specifically, intervention for children with SM is intensive and extensive. Therefore, earlier identification could lead to earlier intervention thereby shortening intervention length and perhaps preventing or limiting functional impairment.

Relationship to Social Anxiety Disorder and Shyness

Although it is possible that SM could exist in conjunction with many other disorders, children with SM most often exhibit an

anxious affect, show social avoidance, and are very often comorbid with social phobia, with rates ranging from 61 to 97% of children with SM also meeting criteria for social phobia, depending on the particular characteristics of the sample, leading some researchers to propose that SM may not be a separate disorder but a severe and developmentally appropriate variant of social phobia.

By conceptualizing failure to speak as a behavioral avoidance strategy designed to eliminate distress, it is possible to examine the idea that SM represents a developmentally appropriate and/or severe variant of social phobia. To date, most of the research has addressed the issue of severity and has compared children with SM and comorbid social phobia to children with social phobia alone. In the following review, we will refer to children with SM and comorbid social phobia simply as children with SM. In one of the initial investigations, Manassis and her colleagues found that children with social phobia and children with SM scored similarly on a number of standardized measures of general anxiety and social anxiety. In our research clinic, children with SM were rated by parents and observers as more socially distressed than children with social phobia alone. However, in our clinic, the groups were indistinguishable in terms of self-report measures assessing social anxiety, trait anxiety, and general fears.

Furthermore, research data suggests that children with SM are not anxious in general. Rather, their anxiety is restricted to social situations and social conversation. For example, children with SM self-reported significantly higher social anxiety than children with other anxiety disorders and controls. However, children with other anxiety disorders reported greater overall anxiety than children with SM and controls. Thus, children with SM are not just overly anxious – rather their anxiety appears to be specific to social situations. Overall, the data suggest that there may be a special relationship between social phobia and SM, although not all researchers are in full agreement. Alternatively, it may be that as a result of their behavioral avoidance, children with SM may underreport anxiety symptoms.

Oppositionality

As noted above, a number of children with severe social phobia symptoms do respond to verbal communication by others. In an effort to identify factors that might differentiate children with SM from other children who have social phobia, a number of clinicians have pointed to refusal to speak as evidence of an oppositional behavior style. Overall, there is minimal evidence for the presence of significant externalizing disorders, such as conduct disorder or oppositional defiant disorder in children with SM although they sometimes display oppositional symptoms/behaviors. However, this type of behavior (e.g., refusing to engage with an anxious object, situation, or event) also exists among children, and even adults, with other types of anxiety disorders. Thus, the presence of oppositional behavior, whether it is refusal to leave a parent (as in the case of separation anxiety disorder) or refusal to speak (as in the case of SM), may indicate the presence of severe anxiety and not oppositional defiant disorder. The distinction between the presence of oppositional behaviors and oppositional defiant

disorder is important to emphasize, as many parents often hear the work 'oppositional' and conclude that the therapist is labeling their child as being deliberately oppositional rather than understanding anxious emotionality as the probable basis for the behavior.

Etiology

There is no single identified etiology for SM. As with many other conditions, it is likely that biological, psychological, and environmental factors play a role either singularly or in various combinations. There is a strong family history of social phobia, avoidant personality disorder, taciturnity (minimal speech), shyness, and SM among the first-degree relatives of children with SM. These results, further supported by numerous clinical observations, indicate that a genetic predisposition must be considered. However, it is important to note that when disorders 'run in families,' mechanisms such as vicarious conditioning and information transfer may be as important as genetics.

A number of investigations have examined the presence of neurological deficits, neurodevelopmental delays, language abilities, and auditory processing deficits among children with SM. In many instances, research data suggest a significantly higher presence of speech/language abnormalities among children with SM when compared to children with no disorder. There are two important caveats to keep in mind. First, even though much of the research finds a significantly higher rate of speech/language deficits among children with SM, the rates of abnormalities do not exceed 50% of the sample, suggesting that the deficits that might exist do not account for a substantial number of cases of SM. Second, there are different abnormalities reported in different studies and the findings are not consistent, discounting the idea that there is a consistent abnormality that accounts for a substantial number of cases of SM.

Traumatic experiences have been suggested as an etiological factor, but data from controlled empirical trials do not support this hypothesis. However, as noted above, parents may be deliberately or inadvertently contributing to the onset and/or maintenance of this disorder in one of two ways. First, as noted above, a number of parents of children with SM also have social phobia, avoidant personality disorder, SM or exhibit minimal speech in social encounters. Thus, these parents may model anxious behaviors and/or limited speech in social encounters and children may learn to imitate this pattern of behavior.

Parents and teachers, among others, often reinforce nonresponse to social overtures by (1) continuously asking the child to 'please answer,' setting up a contest of wills (which the child will always win) or (2) answering for the child. Behaviors such as these often have the opposite effect on children with SM. That is, parental attention to 'not talking' often strengthens the child's lack of speech. For example, clinically, it has been our experience that when the child will not answer an adult, the child is encouraged to whisper the response to the parent, who will respond for the child. This strategy allows the child to get what he or she might need but also the attention that the child receives sets up a pattern of reinforcement for not speaking. Teachers and classmates often participate in

reinforcing silent behavior. In particular, classmates are often used by the child to request permission to go to the bathroom, ask a question, etc. In such cases, there is little motivation for the child to speak, as there are alternative ways of getting what the child needs/desires. In order for therapy to be efficacious, all relevant parties must be trained to discontinue reinforcement of nonspeaking and reinforce the child for any attempts at speaking (see section 'Treatment').

Assessment

Exemplary assessment of SM requires that clinicians draw information from various sources. Given the clinical symptomatology of the disorder, the child is often unable to provide an adequate description of their experiences. Therefore, information shared by the parent is essential to the assessment of SM. The Anxiety Disorders Interview Schedule for Children and Parents is a semistructured clinical interview that gathers information pertaining to SM, as well as other anxiety and psychiatric disorders. Items of the ADIS-C/P assess DSM-IV diagnostic criteria as well as vital features such as symptom history, age of onset, and situations in which the child displays mutism. Furthermore, the ADIS-C/P allows for severity ratings to be assigned to each diagnosis. Although it is unlikely that children will verbally respond to the interview questions, we have found that oftentimes, they respond in nonverbal fashion, giving a 'thumbs up or thumbs down' for 'yes' or 'no' and using the feelings thermometer included in the ADIS-C/P to allow children to point to their estimated level of distress.

Another method through which a parent may relay information is the SM Questionnaire (SMQ), a 17-item parent report measure. The SMQ consists of items that assess for speaking behavior in three general situations: at school, at home or with family, and in public. Parents rate each behavior on a 4-point Likert-type scale that ranges from 0 (never) to 3 (always); thus, lower scores on the SMQ represent fewer instances of speech from the child. The SMQ has demonstrated excellent internal reliability and consistency and convergent validity with the ADIS-C/P clinical severity ratings. Additional studies replicate the strong psychometric properties of the SMQ and support its incremental validity when used with other measures of child anxiety.

Although it is difficult to interact directly due to the mutism, behavioral observation remains a useful approach to examining first-hand the nature of impairment (i.e., whether or not the child engages in nonverbal communication). Moreover, examining the specific situations, people, and events that are associated with each child's specific refusal/inability to speak will allow parents and therapists to identify characteristics that elicit or maintain the lack of speech in certain settings.

The developmental history is a critical consideration when evaluating SM. Potential neurological deficits should be considered to rule out other conditions that may better explain language difficulties and delay. Additionally, a thorough speech and language assessment could identify potential speech problems that may be contributing to SM. This may be particularly important if parents report articulation or fluency difficulties that are observed when the child is at home. Audio-taped samples of 'normal' speech with family members

may be used to determine fluency, semantics, phonetics, and expressive syntax. By identifying potential difficulties in the child's speech, assessors may begin to ascertain and address the factors influencing mutism across other situations.

Because schoolteachers typically have extensive interactions with their students, they are important sources of information in the assessment of SM. Schoolteachers may provide descriptions of verbal and other communicative behaviors in school settings. They furthermore may identify peers/classmates to whom the child speaks and who may assist at later points of the intervention. Schoolteachers may also provide descriptions of the situations in which the child is most or least likely to verbalize and may report on the success of previous intervention attempts.

Treatment

Within the past 15 years, several reviews have summarized the efficacy of psychosocial and pharmacological interventions to treat SM. The treatment literature for SM is relatively small, with many studies having methodological weaknesses (i.e., lack of comparison groups). Currently, most investigations consist of single case studies. Thus, the need for larger randomized controlled trials is evident but may be limited by the relatively rare nature of this disorder. The literature on treatment includes a broad range of modalities, including play therapy, family therapy, behavior therapy, cognitive-behavior therapy (CBT), and multimodal interventions. However, critical reviews of the extant literature conclude that behavioral interventions offer the most robust evidence for efficacy. Newer CBT approaches also have support for their effectiveness, including a web-based CBT program for children with SM.

Behavioral interventions for SM include exposure-based practices such as systematic desensitization, shaping and stimulus fading, self-modeling, social skills training, and parent-based contingency management. Systematic desensitization traditionally involves the use of gradual exposure and relaxation skills to approach more anxiety-provoking situations. The therapist also assists the child in developing a fear hierarchy so that the feared speaking situations are targeted in order of difficulty. There is evidence that systematic desensitization is effective in increasing speech with peers and teachers and reducing anxiety related to speaking. However, systematic desensitization and relaxation techniques may work better for older youth, with younger children benefitting more from *in vivo* exposure, due to difficulty with imaginal exercises. Similarly, cognitive techniques used in CBT (i.e., cognitive restructuring, coping plans) may be more effective for older youth with SM relative to younger children.

Contingency management techniques involve positive reinforcement for nonverbal communication (i.e., pointing, nodding) and eventually verbal communication through shaping, where approximations of the target behavior (i.e., mouth-ing words, whispering) are reinforced. Once contingency management is implemented successfully, stimulus fading interventions can be used by rewarding speech after gradually increasing (i.e., fading in) the number of people and places to which the child is exposed. It can be helpful to begin shaping and fading procedures with a friend or family member to

whom the child already speaks before adding unfamiliar people to the group. With parent-focused techniques, therapists can also train parents to continue with contingency management in scenarios encountered regularly (i.e., restaurants). Although there is support in the literature for both contingency management and stimulus fading, follow-up studies are needed to confirm if gains made in treatment are sustained after the reinforcement is ceased.

Self-modeling is an effective and convenient technique to increase speech. Self-modeling involves creating and playing video and/or audiotapes repeatedly of the child speaking. It is expected that the child habituates to hearing their voice in settings where they previously remained silent. It is important to note that sometimes children refuse to record their own voices. In addition, if not done correctly, listening to a recording of their voice could make the child's anxiety worse. Thus, this procedure should be done under the guidance of a mental health clinician.

Since children with SM may begin to avoid social interaction with peers at an early age, positive interactions may be thwarted by the lack of appropriate skills to initiate and maintain friendships. Social skills training may be used to facilitate speech in instances when the child has anxiety related to peer interaction. In a randomized trial comparing children with social phobia (without SM) who received fluoxetine alone and those who received a combination of medication and social skills training, deficits in social skill remained for children who received the medication alone, despite reporting a decrease in anxiety related to social situations. Because children with SM most likely suffer from social phobia, these data suggest that children with SM may have similar positive outcomes with the inclusion of social skill training.

Many approaches in treating youth with SM combine behavioral procedures, thus limiting the ability to identify the efficacy of any one treatment component. When exposure-based practices and parental contingency management practices were compared, exposure-based practices were superior at increasing words spoken audibly and daily in public situations. Empirical support for differential effects of behavioral techniques may lead to increased gains and cost-effectiveness in treatment.

For more than a decade, researchers have been concerned about the considerable gap existing between the frequency with which physicians prescribe pharmacological treatments to children with SM and the limited empirical data supporting the prescribed medications. Currently, the majority of studies examining the efficacy of medication are single case studies, which limit the external validity of the findings. A review of the literature has examined the effectiveness of selective serotonin reuptake inhibitors (SSRIs), monoamine oxidase inhibitors, and depressants (i.e., nitrous oxide). Although there is some support for all three forms of medications mentioned, SSRIs (i.e., fluoxetine, paroxetine, sertraline, fluvoxamine, citalopram) appear most promising for youth diagnosed with SM. Medication is recommended only for those children who have a chronic condition and are unresponsive to other forms of treatment (i.e., psychosocial and behavioral). Researchers also note that youth treated with fluoxetine remain highly symptomatic once treatment ends and that side effects are common. Since the United States Food and Drug Administration placed 'black box' warnings on these medications to alert consumers

of the risk of suicidal thoughts or self-harm, clinicians and physicians must carefully monitor youth on SSRIs. Future research is needed to assess how youth with SM function once medication is discontinued.

Since SM may otherwise have an extensive treatment course, increasing awareness of SM to target school teachers, physicians, and parents, may increase the early identification and possibly improve treatment outcome. Since maintenance of the disorder may be highly influenced by the child's environment, a collaboration of efforts with parents, teachers, and the child's friends proves promising in reducing the cycle of reinforcement the child receives for not speaking. Overall, much more research is needed in many areas (i.e., longitudinal studies) to better conceptualize SM and identify the best modes of treatment.

Self-Defeating Behaviors

R C Curtis, Adelphi University and W.A. White Institute, New York, NY, USA

© 2012 Elsevier Inc. All rights reserved.

Glossary

Learned helplessness A failure to exert behaviors to avoid negative consequences when such behavior would be effective after experiencing uncontrollable outcomes.

Procrastination Procrastination is knowing that one needs to perform a task, but not motivating oneself to do it within a defined period of time.

Self-defeating behaviors Self-defeating behaviors are those that make more likely a consequence that the person tried to avoid. They lead to a lower reward/cost ratio than available through alternative behaviors.

Self-fulfilling prophecies Self-fulfilling prophecies are beliefs that individuals make happen by their actions, sometimes enlisting others to aid in making the predicted events come to pass.

Self-handicapping behavior The process whereby a person creates or chooses obstacles to behavior or a performance setting, for the purpose of protecting self-esteem in response to an esteem-threatening situation.

Self-regulatory behavior Self-regulatory behavior involves setting different goals, assessing progress toward goals, emotional reaction to progress or the lack thereof, and shifting resources toward either attaining or giving up goals.

Self-defeating behaviors are generally viewed as behaviors that enable people to maintain a particular view about themselves, but which lead to certain consequences the individuals would have preferred to avoid. Any behavior if overused can become self-defeating when people do not have a wide and flexible repertoire of responses to differing situations. A self-defeating behavior is any deliberate behavior that will likely have a negative effect on oneself or one's goals. Specifically, however, a self-defeating behavior is any behavior that leads to a lower reward/cost ratio than was available through an alternative behavior or behaviors. Self-defeating behaviors include choosing to suffer, self-handicapping, failure to achieve potential, fear of success, learned helplessness, procrastination, and impulsivity. A person may procrastinate in handing in an assignment, for example, in order to try and do a better job, but get a lower work evaluation due to the delay. Or a person may avoid a social situation out of fear of rejection when the primary motive is to make more friends.

Self-defeating behaviors are learned in a variety of ways, but usually they are initially adaptive in preventing greater suffering or in obtaining rewards in the situations in which they are originally learned. For example, parents may be less punitive if children are self-critical after doing something the parents do not like than if children do not derogate and punish themselves. Such self-critical behavior can subsequently become a self-defeating pattern. Self-defeating behaviors often occur as a consequence of situations that are uncontrollable. For example, if children are punished even when they believe they have behaved well, or if they are rewarded even when they have behaved poorly, they may gain the impression that their behavior does not matter. Then 'learned helplessness' is said to occur because the child feels that he or she is not in control of what is happening. On the other hand, persistence at tasks can become counterproductive when it prevents people from engaging in more valuable experiences or when it leads people to exhaust their resources in futile endeavors.

Baumeister and Scher (1988) identified three potential types of self-defeating behaviors: (1) primary self-destructiveness,

(2) trade-offs, and (3) counterproductive strategies. They found no evidence for primary or deliberate self-destructiveness among normal individuals. Trade-offs occur when people act to gain short-term benefits despite long-term costs – behaviors especially likely to occur when people are emotionally aroused and/or highly self-aware. For example, shy people may avoid social situations out of a fear of making a bad impression. Their avoidance of people may lead to a greater social exclusion in the future, resulting in their becoming even less confident. They trade the possibility of intimacy to avoid short-term rejection. Or, the cost of medical treatment may lead people to discontinue it when they do not perceive symptom relief. Failure to comply may exacerbate their condition in the long run. Counterproductive strategies involve misjudging one's capabilities or the realities of the situation. An example is choking under pressure. Here, one may carefully monitor performance in order to do one's best, but the monitoring itself may lead to more anxiety and a poorer performance.

Self-defeating behaviors may follow from rejection and exclusion. Although prosocial acts would help individuals to be accepted by a group, several studies have shown that the rejection leads people to be less prosocial and more aggressive, further reducing their chances of acceptance. Narcissistic people also engage in more self-defeating behaviors, but this relationship is often mediated by impulsivity and lack of self-control. Sometimes, it is also related to grandiosity, as in the case of gambling.

Maladaptive Cognitive Schemas

'Maladaptive cognitive schemas' are considered by many psychotherapists to be related to all self-defeating behaviors. Maladaptive schemas may be that others are not reliably available to provide support or protection, that one will inevitably fail or be inferior to one's peers, that something bad will happen at any moment, and that one should surrender one's needs or emotions to avoid anger or rejection from others.

Maladaptive beliefs are more likely to persist if people provide explanations for them. Some maladaptive thinking patterns are selective abstraction, overgeneralization, dichotomous or black-white thinking, maximization and minimization, and personalization.

Self-Fulfilling Prophecies

In many situations, people use their preconceived beliefs to guide their behavior. These behaviors may in turn influence others to act in ways that confirm the initial beliefs. This phenomenon, in which belief creates reality, is known by several names such as self-fulfilling prophecy, expectancy confirmation, and behavioral confirmation. Teachers who were led to expect that certain students (actually selected randomly) would 'spurt' during the school year acted in ways that created a self-fulfilling prophecy so that the actual performance of these students improved as measured eight months later.

Self-defeating behaviors often simply reflect these self-fulfilling prophecies or expectancy-confirmation processes. If we think that we are not good at a particular task, we do not try our best, and then we perform more poorly than if we had thought that we could excel. People also often internalize the expectations held by others as to their gender, race, or social class and then engage in behaviors to confirm others' prophecies. If such expectations are negative, then they are self-defeating. For example, when people were led to believe, through deception, that another person disliked them, they sat further away, engaged in less eye contact, and disagreed more than people who were led to believe that the other person liked them. Research has also investigated people who are 'rejection sensitive,' people who expect others to reject them. Women who are rejection sensitive are more hostile to their partners and thus elicit the rejection they expect. They do not simply choose partners who are more rejecting.

People who expect something bad to happen may not only make it more likely to happen, but may also do something else that is unpleasant to themselves, or they may choose to suffer. Sometimes people appear to 'choose to suffer' in an effort to improve (magically) their outcomes in some other situation. Such behavior may stem from an unrealistic extension of the work ethic. Research has shown that people expecting an unpleasant event are more likely to choose to engage in another unpleasant activity during the waiting period if they change their beliefs about themselves, such as thinking either that they are brave or that they deserve to suffer. If they change their beliefs about the situation, such as thinking it would not be so bad after all, they are less likely to engage in an unpleasant activity during the waiting period. People who 'choose to suffer' also expect to score higher on a subsequent task. They appear to believe that if they chose to suffer, they were likely to be rewarded. People have also been found to choose to suffer after failing tests. In one experiment, participants who were led to fail five tests shocked themselves more than participants who were led to fail only two tests.

Studies of masochistic-like behavior have been conducted mostly with animals. Dogs that were given a mild shock before feeding eventually gave indications of welcoming the unpleasant experience. Human infants who were given a needle prick

followed by feeding also appeared to show a pleasurable anticipation. Cats that learned to depress a switch for shock and food continued to press the switch when the food was no longer forthcoming. These studies suggest that pain accompanied by pleasure might be sought after for itself. In other research, rats learned to escape shock in a starting box. Then the shocks in the starting box were extinguished, but some rats got shocks in the alleyway. These rats continued to run to the alleyway, whereas rats that did not receive shocks there did not. These and other studies demonstrated that if there was an expectation of something unpleasant, animals and humans appeared to prefer having control over the advent of the unpleasant experience.

Self-fulfilling prophecies have also been referred to as 'vicious circles.' For example, if one feels unloved, unsafe, and unvalued, one develops a basic anxiety that inhibits spontaneity and leads one to adopt defensive strategies, such as avoiding other people or close relationships. This, in turn, leads to feelings of being unloved.

Fear of Success

Fear of success was an idea essential to Freud's concept of the Oedipal conflict. Freud noticed that some people appeared to have difficulty in achieving more success than their parents. He hypothesized that these parents were competitive with their children and that the children failed to achieve their potential in order to protect the parents' fragile ego, although both parties were usually unaware of these feelings and behaviors. Other psychoanalysts and clinical psychologists have noted the difficulty that children, including grown children, experience when leaving their parents. For example, a child may develop a school phobia. Something bad may have happened at school or the child may have a fear about what might happen to the parent, such as anxiety or alcohol abuse, if the child is not at home. A grown child may also worry about what will happen to a parent, for example depression, if he or she is not around to take care of the parent. This sort of fear of success has been called 'neurotic fear of success' and deals with a personality characteristic.

Research from a social-psychological perspective examines the conditions under which most people will act in ways to avoid success. Research in the 1960s and 1970s in the United States examined stories about what men and women who were first in their classes at medical and law school might have experienced. Although people wrote about positive consequences for men, the consequences for the women were often disastrous. These results were interpreted as reflecting social views about what happens to women who outperform men in areas where men have traditionally achieved greater success. This type of fear of success is known as 'feminine fear of success.' Subsequent research demonstrated that people avoid success, not surprisingly, in areas where success might indicate to themselves or others an undesirable personality characteristic.

Experimental research indicated that when participants achieved greater success than they had expected, and were then given a chance to change some answers, they changed right answers to wrong ones, appearing to make their

performance, although not necessarily consciously, more consistent with their previous expectations. Such research appears to confirm the notion that people often prefer consistency in expectations over unexpected success. When women were tested in the presence of men and blacks in the presence of whites, it was found that they had lower expectations of their performance than when tested in the presence of others of their own group. As discussed earlier, when people have low expectations regarding their performance, their performance is poorer than when they hold high expectations. Therefore, the performance of women was poorer in the presence of men than when they were alone or when they were in the presence of other women, and the performance of blacks was poorer in the presence of whites or even when they thought that their scores were to be compared with those of whites.

The personality trait of fear of success is called 'neurotic fear of success.' Parents of children who are high in fear of success intrude more in their children's activities – preempting, criticizing, and preventing independence. Success fearers are characterized by low or unstable self-esteem, and a preoccupation with evaluation and competition. Fear of success is also highly correlated with a fear of failure. In research regarding achievement motivation, these motives have been referred to as motives to avoid success and motives to avoid failure. Individual success in work or athletic achievement situations can have negative consequences for achievement in affiliation situations. For people who are motivated to avoid both types of experiences, achievement may be most sought after when it will provide the group with success. Success fearers can tolerate success when it contributes to the success of others and they need not fear retaliation or rejection. In athletics, this is sometimes the position of the 'choke' player. Here, the person avoids failure, but also avoids the anxiety of other people for whom his or her being more successful than they were might present a problem – real or imagined. At one college, all the best 'choke' players identified by three coaches were found to be high in fear of success.

Learned Helplessness

The learned helplessness hypotheses evolved from work in animal laboratories, where it was observed that dogs that were first subjected to inescapable shock did not attempt to escape shock when they were given the opportunity in a later condition. When outcomes are not related to behaviors but are independent, this sense of helplessness apparently develops. This can occur with unavoidable punishment or when rewards are given regardless of actions. This may, at times, occur with people who are very smart or attractive. Further research revealed that punishment contingent on responses also produced helplessness. A later distinction was made between personal and universal helplessness. Personal helplessness refers to the perception that events can be controlled by the actions of others but not by one's own. Universal helplessness refers to the perception of events as being beyond anyone's control. Personal helplessness occurs when a person has a low sense of self-efficacy, while universal helplessness occurs when a person has low outcome expectancies. When people feel helpless, they start to believe that nothing they do will improve their situation and so they do not try.

Learned helplessness is related to people's beliefs about control over life events, known as 'locus of control.' Some people feel personally responsible for the things that happen to them. These people are labeled 'internals.' Others feel that their outcomes in life are determined by forces that are beyond their control (e.g., fate, luck, and other people). These people are labeled 'externals.' People who are internally controlled are more likely to attribute their failures to a lack of effort and their successes to effort and ability. Obviously, most people fall between the two extremes, forming a continuous distribution of locus of control beliefs. Externals tend to exhibit less persistence at tasks. They are less likely to seek feedback and thus they may have more inaccurate self-assessments. Internality is positively related to a willingness to delay rewards in order to maximize them. Internals, especially if they are male, have a greater likelihood of achievement.

Self-Handicapping Behaviors

Self-handicapping behavior refers to the process whereby a person creates or chooses obstacles to behavior or a performance setting, for the purpose of protecting self-esteem in an esteem-threatening situation. In other words, the choice enhances the opportunity to excuse failure while accepting credit for success. Self-handicapping can occur when people receive positive information that they feel may be unwarranted. In order to protect a positive view of themselves, people may engage in some sort of excuse-making in advance in order to protect a positive, but precarious, self-view or self-esteem. Self-handicapping involves engaging in a behavior that is known to hurt performance, such as getting too little sleep, using a harmful substance, not studying, or not working hard. A person may choose a task so easy that success is meaningless or so difficult that success is unlikely. Success and failure in such situations do not provide information about one's comparative ability.

In the original research regarding self-handicapping, Berglas and Jones students were told they had performed exceedingly well on a test made up of questions that were impossible to answer questions, in one of the experimental conditions. They had 'succeeded' without knowing why or how. In the other condition, the problems had been soluble. The students were all expected to take a parallel form of the test after they took either a performance-inhibiting or performance-enhancing drug. The students who had been in the condition where the problems were insoluble were more likely to take the performance-inhibiting drug. The authors reasoned that if the students performed poorly, they could maintain their precarious view that they were brilliant and that the drug lowered their performance the second time. Subsequent work showed that the text-anxious and hypochondrical participants reported more symptoms during an evaluative task than did similar participants who informed that symptoms could not serve as an excuse for poor performance. Type A personality types were more likely to choose an inhibiting drug after receiving failure feedback on a task that was unrelated to their performance in comparison with Type As, who received the contingent success feedback and Type Bs who received either contingent success or noncontingent failure feedback. More

self-handicapping occurs in public conditions where others will also know what has happened, unlike in private conditions, but the phenomenon is not limited to conditions where others' views are a concern. The conditions that lead to self-handicapping also lead to the avoidance of evaluative information that is highly diagnostic of abilities. Self-handicapping appears to occur mostly among depressed individuals with an exaggerated perception of control.

Self-handicapping is correlated with low self-esteem, neuroticism, narcissism, perfectionism, elevated evaluative concerns, lower grade-point averages, increased substance abuse, and depression among depressed people who have exaggerated perceptions of control. Self-handicappers are high in public self-consciousness, social anxiety, other-directedness, depression, and are less agreeable, conscientious, extraverted and less open to experience. Although anxiety is a factor related to self-handicapping, anxiety can have additional effects. Self-handicapping appears to be related to a self-aggrandizing attribution style more than to self-presentational concerns. Those who are afraid of being seen as impostors also handicap more. Men are more likely to engage in active behavioral forms of self-handicapping, such as withdrawal of effort, taking drugs or alcohol, or listening to distracting music than women. Research regarding self-handicapping has been conducted cross-culturally with diverse groups, including Asians and Lebanese.

Excuse-making is related to self-handicapping. Excuses will protect one's image if certain principles are followed: First, excuses must be consistent with social conventions. For example, blaming others has significant social costs. Second, excuse-making should be ambiguous. Excuses do not work if they are found to be inconsistent with certain facts. Third, an excuse should not be used often enough for a personality label to apply such as alcoholic, depressed, or procrastinator. Fourth, an excuse maker may have to choose between negating responsibility for an act and negating the wrongfulness of an act. The excuse maker may take responsibility but provide a justification for the act, to reduce the perception of wrongfulness.

Taking responsibility for a failure or for a negative event, including self-blame, can have obvious benefits. The person can then assess how to handle situations differently in the future. For example, it can be adaptive for victims to blame their behaviors for their experience, although it is not adaptive to blame personality traits that are not modifiable.

Procrastination

Procrastination is knowing that one needs to perform a task, but not motivating oneself to do it within the defined period of time. People who procrastinate have a more diffuse sense of identity than people who begin and complete tasks promptly. The beginning of difficult and unpleasant tasks is delayed. Anxiety from fear of failure or fear of success affects the beginning of a project, whereas perfectionism affects the completion of a task. Once procrastinators begin a task, they make more errors. Those who procrastinate in making decisions are systematic in requiring more information about choices and have not been found to be more distracted. However, they

are less tolerant of uncertainty. Overall, procrastination has been found to be positively correlated with a large number of variables: fear of failure, depression, guilt, anxiety, evening proneness, rebelliousness, indecision, irrational cognitions, public self-consciousness, perfectionism, parental criticism, and parental performance expectations. Not surprisingly, procrastination is also related to cheating and plagiarism. It is negatively correlated with optimism, confident feelings of control over one's life, dominance, self-esteem, global life satisfaction, and intrinsic motivation. Putting off a task can engender a self-destructive cycle. Although putting off the task enables people to avoid anxiety temporarily, by delaying they set themselves up for even stronger negative emotions when forced to confront the task, and for self-blame afterwards.

Low conscientiousness is related to procrastination and ability to delay gratification. High conscientiousness, however, can lead to persistence and irrational commitment in order to save face. High achievement strivers who are high in conscientiousness may escalate commitment to a losing proposition.

Perfectionism

The most common definition used for perfectionism is the tendency to establish excessively high personal standards of performance. Maladaptive perfectionism is associated with depression, stress, obsessive-compulsive disorder, eating disorders, and suicide. Research has shown that perfectionism itself is multifaceted and requires distinctions to be made between self-oriented perfectionism (i.e., high self-standards and motivation), and two interpersonal dimensions described as other-oriented perfectionism and socially prescribed perfectionism. Other-oriented perfectionists tend to have unrealistically high standards for others, whereas socially prescribed perfectionists believe that others are imposing perfectionistic demands on the self (i.e., my family expects me to be perfect). A distinction must also be made between people who need to be perfect and people who need to appear perfect. People who wish to appear perfect engage in self-promotion and do not display or disclose imperfections.

The avoidance of verbal disclosures of any perceived personal imperfections can lead to an avoidant interpersonal style. Perfectionists who are concerned about negative evaluation are less verbally expressive in social situations. This is in keeping with research that suggests that perfectionists who are concerned about social evaluation tend to be anxious. Social perfectionists demonstrate high levels of emotional control and social sensitivity. Emotional control is the ability to regulate displays of emotionality, and social sensitivity involves the skill to understand verbal messages from others. Maladaptive perfectionism is related to parents who are psychologically controlling, harsh, or critical.

Failures in Self-Regulation

Many behaviors are failures to self-regulate, such as overeating and other substance abuse, gambling, impulsive behaviors, and physical aggression. There appear to be limits to the extent to which people can expend energy to engage in self-control.

Self-regulatory behavior includes setting different goals, assessing progress toward goals, emotional reaction to progress or the lack thereof, and shifting resources toward either attaining or giving up goals. People appear to be able to tolerate failures to the extent that goals do not threaten survival or survival of the meaning system including their theories of themselves, others, and the world. When failure has a larger meaning, depression and/or anxiety often result. For others, attempts to control the uncontrollable can lead to high blood pressure and coronary illness.

The inability to delay gratification is one type of regulation failure. Delaying gratification requires sacrificing immediate rewards for distant but greater ones in the future. To delay gratification, a person must direct his or her attention away from the immediate lure and focus on the positive consequences of the distal pursuit. Too much self-control, however, can lead to problems in experiencing pleasure, depression, or anorexia. The self-control needed to overcome impulses and operate successfully may well be a limited resource, like energy. People who exert self-control over a variety of impulse-related behaviors, such as dieting and quitting smoking, subsequently have impairment of self-control. Self-control may get depleted.

One type of regulation failure is emotional self-absorption or excessive self-focus. Self-focus can be beneficial to self-regulation when the comparison to a standard is temporary and accompanied by high expectations. When this happens, people bring their behavior in line with the high standard. However, prolonged self-focus is self-defeating. It is counter-productive when people allocate limited conscious attention to their emotions, and leads to impairment of performance. Poor performers have more frequent 'off-task' thinking and misdirect attention toward emotional control rather than motivational control. Choking under pressure is an example of a behavior when people give too much attention to internal processes. If people are too self-focused, they may also fail to assess others' emotions accurately. They may fail to help others out or may actually hurt others.

Self-regulation requires ways of coping with threat and anxiety. Defenses can lessen the perception of threat and its ensuing emotional impact. Defenses include rationalization, intellectualization, humor, sublimation, projection, repression, idealization/devaluation of others, dissociation, and denial. Defenses that distort reality, such as projection and denial, are more self-defeating in the long run than those that do not, such as rationalization and sublimation.

As there are limits to how much information people can keep in consciousness at any given moment, people in threatening situations often cope by focusing on details and not seeing the larger picture or by concentrating on the whole situation without sufficient attention to particular details. Although this type of regulation has the advantage of maintaining conscious functioning and control without paralysis, information that is not attended to may be crucial. Memory is also limited and people may tend to forget unpleasant memories ('repressors') or to forget pleasant experiences (depressives). When people are not aware of their emotions, physical symptoms, and illness may result. Cognitions that are emotionally informed are preferable to cognitions that are disconnected from feelings. Awareness of emotions, even unpleasant ones, has advantages. College freshmen who write down their

feelings, for example, make fewer visits to the doctor. People who felt ill after listening to others speak of their experiences in a concentration camp had fewer physical symptoms and visits to a physician in the next year than people who reported not feeling that bad during and after the experience.

Self-Defeating Personality

A scale to measure self-defeating personality has been developed. Those who score high on this scale identify with a victim position. Self-defeating personality has been found to be related to memories of rejecting and nonsupportive parents and to a memory of an over-involved parent in men. Those with this personality style report their families to have been less cohesive. They report more ambivalent and avoidant histories of their mothers and men report more histories of avoidant fathers. The men say that their home environment discouraged expressiveness, lacked achievement orientation, and provided no moral or religious emphasis. People who score high on this scale are more depressed and have more suicidal ideation, especially females. They score lower in self-esteem and have more negative views of themselves, the world, and the future. With lower ego strength and more of an external locus of control, they have less adaptive coping strategies and engage in more denial, mental disengagement, alcohol, and drug use. They also have greater career indecisiveness, and self-defeating women have greater choice anxiety and less need for self-knowledge. These women are less argumentative and less assertive, with thoughts that inhibit them from making assertive statements. Those with self-defeating personalities score higher on social dependence, but the women also score higher on autonomy, suggesting that threats to their independence may be a source of depression as well. In relationships, women who have self-defeating personality describe their style of loving as game playing and being less romantically involved. Once in a relationship, both men and women with self-defeating personalities feel more dependent, jealous and more desperate to maintain the relationship. Women report more difficulty in dating. Those with self-defeating personalities report less self-reinforcement, and less pleasure and enjoyment from individual and social activities. Sexually abused persons are more likely to have self-defeating personalities but people in physically abusive relationships are no more likely to have this personality style.

Scores on the self-defeating personality scale are correlated with scores on a self-handicapping scale. A scale to measure chronic self-destructiveness was also developed. However, it is not a good measure of self-defeating behaviors, and is most useful as a measure of impulsive and self-centered behavior. Those high in chronic self-destructiveness feel more hopeless and are more involved in risky behaviors, such as cheating, aggressive and illegal behaviors, alcohol, and drug use. The self-destructive men, however, are less likely to engage in high risk sports.

Insecure Attachment Styles

Most of the behaviors studied by psychologists under the rubric of 'self-defeating behaviors' are related to achievement

situations. Self-defeating interpersonal behaviors are often more elusive and harder to investigate, unless they have reached the degree of severity to be labeled as a 'Psychiatric Disorder or Personality Disorder.' Recently, however, many psychologists have investigated the role of attachment styles that affect friendship formation and romantic relationships. Individuals who are confident that others will befriend them are considered 'secure' in their attachment style, while those who expect rejection are labeled 'fearful,' those who devalue others and relationships with them are considered to be 'dismissive.' Those who value relationships with others highly and tend to idealize others, and depend on them for their self-esteem are referred to as 'preoccupied.' Such attachment styles are measured in numerous ways, but these styles are predictive of many variables in life, with secure individuals engaging in fewer behaviors that are considered self-defeating and less likely to score high on the self-defeating personality scale. They are less likely to be rejected by others, to engage in infidelity, etc. These attachment styles begin as ways of coping with early relationships in life and often persist throughout the lifespan, although they can be altered by positive relationships, including psychotherapy.

Selective Attention and Memory

Considerable knowledge in psychology and psychiatry are needed to fully understand self-defeating behaviors. An examination of defensive styles and ways of coping is necessary in order to understand the ways in which people deal with threatening situations – and then repeat these successful responses in situations where these responses are no longer the most advantageous ones required. Self-defeating behaviors often involve self-deception. People tend to defend themselves against threats by focusing on the whole picture at the expense of details or on details at the expense of the whole picture. In other words, they selectively attend and inattend, and selectively remember and forget, experiences. Much perception and forgetting is thus self-defeating to some extent, although perhaps allowing a titration of information into consciousness, so that conscious decision-making and processing can continue to occur and prevent deterioration into paralysis or insanity. What might appear to be self-defeating may actually serve to preserve life itself or preserve the meaning-making system. Although not feeling emotions is self-defeating in many regards, it is helpful in other ways. Without understanding a human being as a whole, it is difficult to say with certainty what defeats the self.

Difference from Psychiatric Disorders

All clinical disorders could be considered as forms of self-defeating behaviors. The term 'self-defeating behaviors' is a more general term, however, that could apply to people who would not be considered as having a psychiatric disorder or a personality disorder. They may simply talk too much or too little, disclose too much or too little, or behave in numerous other ways that other people do not like. Many psychologists object to a disease model being applied to behaviors and

prefer terms such as 'problems in living,' 'maladaptive behaviors,' or even 'self-defeating behaviors' to all such difficulties. Most psychologists and psychiatrists consider psychiatric and personality disorders as more serious in nature, however, than the behaviors referred to here as self-defeating, unless such actions become chronic. These more serious disturbances are measured by such tests as the Minnesota Multiphasic Personality Inventory (MMPI) and the Millon Multiaxial Clinical Inventory (MMCI). Self-defeating behaviors can also be distinguished from self-destructive, self-injurious behaviors, and physical self-harm, which refer to cutting, burning, or mutilating oneself. They are also distinguished from substance abuse.

A specific category, 'self-defeating personality disorder,' was considered briefly by the American Psychiatric Association, drawn largely from characteristics that had been noted as masochistic by clinicians since the time of Freud. The criteria for the proposed self-defeating personality disorder, however, overlapped too much with those for dysthymic disorder (depression) and other personality disorders, such as dependent personality, borderline personality, and avoidant personality. Furthermore, feminists were concerned that women who were abused might get labeled as having a personality disorder that brought on abuse, thus leading to victims of abuse being blamed. Therefore, such a personality disorder was only included provisionally in the Diagnostic and Statistical Manual of the American Psychiatric Association and then deleted. This category was described as a pervasive pattern of self-defeating behavior, which begins by early adulthood and presents in a variety of contexts. The person may often avoid or undermine pleasurable experiences, be drawn to situations or relationships, in which he or she will suffer, and prevent others from helping him or her, as indicated by at least five of the following: (1) chooses people and situations that lead to failure, disappointment, or mistreatment when better options are available; (2) rejects or renders ineffective the attempts of others to help him or her; (3) responds with depression, guilt, or a behavior that produces pain, following positive personal events; (4) incites angry or rejecting responses from others and then feels hurt, defeated, or humiliated; (5) rejects opportunities for pleasure, or is reluctant to acknowledge enjoying himself or herself; (6) fails to accomplish tasks crucial to his or her personal objectives despite demonstrated ability to do so; (7) is uninterested in or rejects people who consistently treat him or her well; (8) engages in excessive self-sacrifice that is unsolicited by the intended recipients of the sacrifice.

Treatment

All forms of psychotherapy are designed to treat some form of what might be called self-defeating behavior. The major theoretical orientations of psychotherapy are cognitive-behavioral, psychoanalytic, and experiential or affect-focused. When people are frightened of situations, that is, when they are phobic or have panic attacks, behavioral treatments are usually the most effective. When people have unrealistic thoughts, cognitive treatments have been shown to help with catastrophization, discounting, and exaggeration of beliefs. When people are not clear as to what the problem entails, a treatment involving talking and ascertaining feelings that are not necessarily

conscious may be appropriate. For example, psychoanalysis has been oriented especially toward understanding if fears of hurting parents or other loved ones interfere with achieving personal goals, such as the fear of leaving a loved one all alone, being more successful than a parent, or not fulfilling loved ones' desires to impress other people. At some level, self-defeating behaviors avoid aversive affects such as anxiety, grief, or anger, hence the effectiveness of affect-focused treatments. Lack of motivation, anxiety, mood disorders, and unrealistic thinking are also treated with medication in combination with psychotherapy. Personality disorders, including the following types – obsessive-compulsive, schizoid, paranoid, histrionic, borderline, dependent, and narcissistic – often take longer to treat than problems such as depression and anxiety not accompanied by a personality disorder.

The Challenge of Treatment

Self-defeating behaviors often represent behaviors learned in one situation that are repeated in a new situation where they do not work. It is possible, however, that what may appear to be self-defeating to an observer may in fact act to avoid a further deterioration in a person vulnerable to extreme depression, paralysis, or a loss of sanity. Given the complexity of human beings, there are ways in which what appears to be self-defeating undoubtedly feels self-enhancing – if we are able to enter the other person's subjective experience. The reader is referred to the broader topic of the self. Herein lies the challenge of the treatment.

Self-Efficacy

M W Gallagher, University of Kansas, Lawrence, KS, USA

© 2012 Elsevier Inc. All rights reserved.

Glossary

Agency A broader term that encompasses multiple psychological theories that emphasize the role of the individual in determining outcomes.

Mastery experiences The achievement of valued goals, which are proposed to be the most effective means of developing self-efficacy beliefs.

Mediator The mechanism by which an intervention or psychological factor influences an outcome.

Self-efficacy is proposed to be a crucial mediator of clinical interventions.

Meta-analysis A method of reviewing research literature that allows for the systematic integration of the results of numerous studies.

Optimism The generalized belief that positive outcomes will occur frequently in the future.

Self-efficacy The belief that an individual can execute the actions necessary to achieve a valued goal.

Introduction

Self-efficacy is defined as people's domain-specific perceptions of their ability to perform the actions necessary to achieve desired outcomes. The concept of self-efficacy was first proposed by Albert Bandura in 1977 in an attempt to provide a unified theory of behavior change. Bandura suggested that the effects of psychological treatments on behavioral change are mediated by self-efficacy beliefs. Importantly, the mediation of treatment outcomes via changes in the level and strength of self-efficacy beliefs is proposed to be universal across treatment modalities. The development of self-efficacy theory was therefore a critical development in the field of psychology because, to the extent that empirical evidence supports Bandura's hypotheses, self-efficacy theory provides a compelling and parsimonious explanation of how and why behavior can change. The lasting impact of self-efficacy is clearly demonstrated by the extraordinary amount of citations that the original 1977 manuscript has accumulated (more than 10 000 as of December, 2009), and the broad impact that self-efficacy theory has had on the various subdisciplines of psychology.

Defining Self-Efficacy

Self-efficacy has been a vibrant area of research for more than three decades, but there has often been confusion about exactly what self-efficacy beliefs are and what they are not. Before discussing the benefits of self-efficacy beliefs, it is therefore important to clearly identify what self-efficacy beliefs are and to clearly distinguish between how self-efficacy and similar theories describe human behavior.

Self-efficacy beliefs are defined as people's perceptions of their capability to execute the actions necessary to achieve a desired goal. Self-efficacy is not a perception of whether one *will* perform these actions or whether one *will* necessarily achieve the desired outcomes, but an evaluation of whether one *can* perform the necessary actions.

Self-efficacy beliefs are not a stable personality trait, but rather represent an evaluation of perceived capacity in relation to specific contexts or goals. Some researchers have proposed

using measures of generalized self-efficacy, but the extent to which these measures demonstrate incremental utility beyond the domain-specific measures has been inconsistent, and Bandura has consistently argued for the focus of research to be on domain-specific evaluations of self-efficacy.

Self-efficacy beliefs do not necessarily reflect an individual's intention or motivation to pursue a particular goal. It is possible to feel extremely efficacious for a goal or task that one cares little about or to feel ineffective about extremely important goals. It is in the pursuit of the most valued goals, however, that self-efficacy beliefs become the most important and have the most impact on eventual outcomes.

Finally, self-efficacy beliefs are not merely the evaluations of fine motor abilities, but are the evaluations of whether people believe they can execute behaviors when necessary. It is clear from this discussion of the form and function of self-efficacy beliefs that self-efficacy theory shares much with other popular psychological theories.

Control

One of the theories most often discussed in relation to self-efficacy theory is Julian Rotter's Locus of Control theory. The primary theoretical distinction between Locus of Control theory and self-efficacy theory is that Locus of Control theory focuses on perceptions of whether responses are contingent upon personal behavior or external circumstances whereas Bandura's theory focuses on perceptions of whether individuals can execute the actions necessary to produce successful outcomes. Self-efficacy beliefs therefore presume some degree of internal locus of control for particular tasks/outcomes.

Optimism

Another relevant theory of positive expectancies is the optimism model developed by Charles Carver and Michael Scheier. Their theory defines optimism as a generalized expectation that positive outcomes in the future will be common and undesired outcomes will be rare. They have found optimism to be a stable trait that is consistently associated with improved psychological and physical well-being. Optimism is measured in global

terms and is posited to produce effects by impacting the way in which individuals think about and pursue goals, and how they react to adversity when pursuing their goals. The two primary distinctions between the optimism and self-efficacy theories are that (1) optimism is conceptualized as a global evaluation of outcome expectancies, and (2) self-efficacy explicitly focuses on the individual as the agent of action whereas optimism is more ambiguous about how or why necessary actions may be accomplished.

Trait Agency

Another important distinction is between Bandura's theory of self-efficacy and other theories of human agency that focus on more global or generalized perceptions of agency. Numerous theories (e.g., Rick Snyder's theory of hope) have articulated alternative theories of human agency that focus on more generalized perceptions of human agency. As previously mentioned, Bandura has always focused on domain and state-specific evaluations of agency in the form of self-efficacy beliefs and has consistently argued that these more global assessments are not as useful. Nevertheless, there is extensive research examining Snyder's hope theory and other theories of agency that suggest that dispositional agency beliefs may also be important predictors of behavior and outcomes. The relative utility of trait agency beliefs and state/domain-specific self-efficacy beliefs in predicting human behavior and outcomes remains unclear.

Self-Efficacy and Social Cognitive Theory

An improved understanding of self-efficacy theory can be obtained by considering the broader social cognitive theory developed by Bandura. Social cognitive theory provides a model of understanding human emotion, behavior, cognition, and motivation that emphasizes how as humans we actively interact with and help shape our environment, rather than be passively controlled by it. Briefly stated, the basic premises of social cognitive theory are as follows.

Our environment, our behavior, and personal factors such as cognitive (i.e., self-efficacy beliefs) or emotional/biological events interact with and jointly determine one another in what is referred to as 'triadic reciprocal determinism.' Social cognitive theory therefore suggests that each of these three areas is shaped by and helps shape the other two. The relative influence of these factors is thought to vary according to the situation, and the relative speed with which these three factors may influence one another can also vary.

Our perceptions of ourselves and our personalities are social constructions that are constantly revised as a result of our interactions with others. These perceptions are therefore never static and can often vary depending upon the context in which we are in.

Humans have evolved to have the cognitive capacity to develop internal models of our experiences that allow us to visualize potential courses of action and to communicate these possibilities to others. We are also capable of reflecting upon our own thought, feelings, and actions, and these self-referential abilities provide the foundation for self-regulation.

We are capable of regulating our behavior in the pursuit of goals. The attainment of goals is a fundamental motivator for human behavior and our expectations regarding our ability to achieve our goals are crucial determinants of our behavior.

Social cognitive theory also provides the foundation for understanding how self-efficacy beliefs are developed over the course of a lifetime. As children, we develop the capacity to understand cause and effect relationships, which provide the foundation for understanding how our actions can influence our environment. Families play a crucial role in fostering this sense of agency by providing an environment that is responsive to the child's actions and needs. The development of self-efficacy beliefs is further cultivated as children enter school and are presented with new opportunities to explore their environment and to develop an improved understanding of their capacities. Peer relationships gradually become more and more important determinants of efficacy beliefs as children develop relationships that help form their identity. Our self-efficacy beliefs then continue to evolve with age as we incorporate information from the various sources of self-efficacy beliefs.

Sources of Self-Efficacy

Research has identified five mechanisms by which self-efficacy beliefs can be developed: mastery experiences, modeling/vicarious experiences, imagined experiences, social persuasion, and somatic/emotional cues. These five mechanisms vary in terms of their effectiveness, and individuals tend to use a combination of the various methods as they pursue their goals.

Mastery experiences are the most effective method of developing self-efficacy beliefs. The successful attainment of meaningful goals has a powerful effect on self-efficacy beliefs if people attribute the success to their own actions. This is particularly true when individuals are required to persevere despite serious obstacle as the experience of success following adversity can have a profound effect on individuals' confidence. For example, if an employee receives positive evaluations from her/his boss and believes those positive evaluations reflect her/his actions at work, then she/he is likely to develop stronger self-efficacy beliefs regarding her/his job performance. Similarly, experiences of failure that are attributed to personal actions can have negative effects of self-efficacy beliefs.

Modeling, or witnessing the mastery experiences of others, is another effective way of developing self-efficacy beliefs. Although it is generally not as effective at developing self-efficacy beliefs as achieving personal success, witnessing other people achieve success and persevere despite obstacles can help inspire people to believe more in their own capabilities and to maintain a strong sense of self-efficacy when faced with difficult circumstances. Modeling can be especially effective when individuals share an identification with an individual or group that embodies success (e.g., having a Nobel Prize winning mother). Vicarious experiences of success can also be particularly powerful when we encounter a task that we are unfamiliar with as we often develop our performance expectations on the basis of observing the successes and failures of other individuals.

Imagined experiences are another effective way of developing self-efficacy beliefs. By visualizing ourselves or others

performing successfully, we can gradually influence our expectations for our own behavior and ultimately help determine the likelihood of successfully obtaining our goals. This process is perhaps most commonly discussed in the context of athletic performances (e.g., golfers visualizing themselves sinking an important putt or basketball players visualizing themselves hitting a crucial free throw) but is also commonly used in clinical interventions that target self-efficacy beliefs (e.g., exposure treatments for specific phobias), and this process can be applied to any domain of performance. Although these imagined successes can often increase self-efficacy beliefs, they are rarely as effective as actual experiences of success.

Social persuasion is a fourth mechanism by which self-efficacy beliefs can be developed. Just as witnessing or imagining the success or failure of others can influence self-efficacy beliefs, the encouragement or discouragement of others can help shape our beliefs about our capabilities. The extent to which social persuasion is effective varies according to numerous social factors such as the closeness of the relationship and the perceived trustworthiness of the source. Although not necessary to develop self-efficacy beliefs, the presence of a trusted friend or family member providing encouragement can often be a crucial factor in helping people to develop and maintain self-efficacy beliefs in the face of obstacles.

The last method of influencing self-efficacy beliefs is on the basis of somatic/emotional cues. This is the least effective method of promoting self-efficacy beliefs, but can still play an important role in many situations. The extent to which individuals are emotionally/physiologically aroused can have minor effects on the level and strength of self-efficacy beliefs. When people are experiencing pain, fatigue, or unpleasant levels of physiological arousal, they are more likely to question their abilities than when they are in a rested or relaxed state. Interestingly, by helping to shape our perceptions of perceived threats, self-efficacy beliefs can help promote more adaptive levels of physiological arousal, which can in turn serve to help improve or maintain higher levels of self-efficacy beliefs.

The core idea running through each of these five methods is that success, particularly when it occurs after overcoming obstacles, promotes further success. This is true both for personal success and the success of other individuals. Although self-efficacy theory is primarily focused on perceptions of personal agency, the theory does not suggest that we operate in a vacuum. Rather, the success, failures, and encouragements of those around us are proposed to be crucial mechanisms in the development of adaptive levels of self-efficacy. In this way, self-efficacy theory suggests that the promotion of individual's success can have a cascade of positive effects both for that individual and those around them.

Mechanisms of Self-Efficacy

Bandura has also identified four mechanisms by which self-efficacy beliefs exert their influence. As with the sources of self-efficacy beliefs, these mechanisms work in concert to help people more effectively pursue their goals.

First, self-efficacy beliefs determine cognition by helping to shape the goals that individuals identify, the strategies individuals identify to pursue their goals, and the thoughts they

experience as they pursue these goals. Individuals with higher levels of self-efficacy beliefs are more likely to seek out challenges that allow them to continue to develop their skills and are more likely to believe that they are capable of overcoming these challenges.

Self-efficacy beliefs also help determine individual's motivation and willingness to persevere in the face of obstacles. Affirming thoughts can be a crucial factor in determining whether individuals persevere when the going gets tough.

Self-efficacy beliefs are a crucial determinant of behavior. For example, phobic individuals are more likely to physically approach feared stimuli if they perceive themselves to be capable of managing the potential threat.

Finally, self-efficacy influences the experience of emotion directly by shaping how we appraise events and indirectly by facilitating the achievement of valued goals, which in turn promotes a positive effect. Individuals with higher levels of self-efficacy are less likely to experience anxiety as a result of perceiving uncertain situations as threatening and are more likely to experience relaxation as a result of their confidence in their ability to cope with difficult situations.

Adaptive Benefits of Self-Efficacy Beliefs

As previously mentioned, the benefits of self-efficacy have been extensively studied in a variety of contexts over the past three decades. The rationale for why self-efficacy beliefs promote positive outcomes is perfectly captured in the classic children's story *The Little Engine That Could*. In this story, the little engine is able to succeed where all other engines have failed by resolutely maintaining a strong sense of efficacy. This confidence is exemplified by the 'I think I can, I think I can' mantra that the engine repeats to help motivate himself to persevere despite all the obstacles that he encounters.

Self-efficacy theory suggests that this confidence in one's abilities is one of the most crucial determinants of success. People inevitably encounter obstacles when pursuing goals and these obstacles provide crucial junctures at which people can become discouraged and give up on their goals or remain motivated, persist despite the obstacles, and ultimately achieve the desired outcomes. Self-efficacy beliefs are proposed to be the crucial psychological characteristic that allows people to persevere in such situations. Furthermore, individuals with higher levels of self-efficacy perceive these challenges as exciting opportunities to test and improve their abilities rather than frightening situations that need to be avoided. Self-efficacy beliefs therefore provide individuals with the motivation to continually challenge themselves, develop new skills, and further solidify their confidence in the ability to perform the actions necessary to achieve their goals.

Classic Self-Efficacy Anecdotes

The value of a persistent sense of self-efficacy has been famously demonstrated by many of the most accomplished artists, musicians, authors, scientists, and inventors. Many of the most famous and successful members of various professions did not achieve instant fame or success, but rather persisted through years of rejection, failure, or uncertain outcomes. The ability to persist

through these setbacks is often what distinguishes these elite performers from individuals who do not achieve such success.

The following are examples.

The Beatles were arguably the most successful rock band of all time, but their initial efforts to obtain a recording contract met with little success. Following their initial audition with Decca Records, the Beatles were told that 'guitar groups are on their way out' and that 'the Beatles have no future in show business.' The Beatles are now estimated to have sold more than 1 billion records since their inception.

Michael Jordan is now widely considered to be the best basketball player of all time, yet he failed to make the cut when he first tried out for the varsity basketball team during his sophomore year of high school. Rather than giving up, Jordan practiced even harder, made the varsity squad the following year, and eventually won six NBA championships.

Despite painting nearly 900 paintings during his lifetime, Vincent van Gogh sold only one of his paintings during his life. He is now widely considered to be one of the greatest painters in history and had a remarkable impact on the development of modern art.

J. K. Rowling's Harry Potter series of children's novels is one of the most successful book franchises of all time, with more than 400 million copies sold in more than 60 languages. Yet when J. K. Rowling submitted her first Harry Potter manuscript she was rejected by a dozen publishing houses before finding a small London publishing house that was willing to take a chance on her. Despite living in poverty at the time, Rowling stuck with her dream of becoming a successful writer and is now one of the most successful writers in history.

Lance Armstrong is one of the most successful cyclists of all time. With seven consecutive Tour de France victories, he has had one of the most distinguished careers in the history of the sport. Yet when Lance Armstrong began his career, he did not meet with immediate success. In Lance's first race, the San Sebastian Classic, he not only did not win the race, but he finished dead last in the field of 111 cyclists. He persevered despite this setback and is now considered to be one of the greatest cyclists of all time.

Thomas Edison was told by his teachers that he was 'addled' and not smart enough to learn anything. Edison famously made 1000 unsuccessful attempts before successfully inventing the light bulb. When Edison was famously asked by a reporter "How did it feel to fail 1,000 times?," Edison is said to have replied, "I didn't fail 1,000 times. The light bulb was an invention with 1,000 steps."

Robert Sternberg received a C in his introduction to psychology class in college. He was told by his psychology professor that "there was a famous Sternberg in psychology and it was obvious there would not be another." Decades later, he became a tenured professor at Yale University and was elected President of the American Psychological Association.

These stories share a common theme. In various fields, many of the most successful individuals do not succeed immediately. Rather, what has defined the careers of many icons is an extraordinary willingness to fail and ability to persevere through the early setbacks. Self-efficacy theory suggests that it is these individuals' unwavering belief in their abilities to perform the actions necessary to achieve their goals (i.e., self-efficacy) that confers this resilience and ultimately determines their success.

Empirical Evidence

In addition to these fascinating stories demonstrating the immense value of a resolute sense of self-efficacy, there is now more than three decades of empirical research demonstrating the adaptive benefits of self-efficacy beliefs in a wide variety of contexts.

Some of the earliest research examining the benefits of high levels of self-efficacy was in relation to mental health and mental illness and this remains a vibrant area of research today. In particular, the benefits of self-efficacy beliefs have been extensively studied in relation to the development and treatment of anxiety disorders. Self-efficacy beliefs are thought to be critical factors in determining how individuals exercise control, appraise threats, manage feelings of anxiety, and whether individuals engage in avoidant behavior. Specifically, when people believe they can manage threatening situations, they do not fear those situations and do not resort to maladaptive coping techniques. Evidence of the importance of self-efficacy beliefs comes from studies indicating that self-efficacy beliefs are negatively correlated with anxiety in children and adults, and studies suggesting that self-efficacy beliefs are a better predictor than anticipatory anxiety of avoidant behavior in individuals suffering from anxiety disorders.

The benefits of self-efficacy beliefs in academic contexts have also been examined extensively. Academic self-efficacy beliefs are proposed to influence academic success by helping students to more effectively identify academic and career options, to more efficiently harness their natural talents, and to persevere through academic setbacks. Meta-analytic reviews of the academic self-efficacy literature have supported these hypotheses and have demonstrated that academic self-efficacy beliefs are crucial determinants of who excels in academic contexts. What is particularly interesting about this research is that the effects of positive evaluations of personal agency have been shown to predict academic performance many years later. This research suggests that instilling high levels of self-efficacy beliefs in young children could have profound effects on the course of their education.

A third area in which the benefits of self-efficacy beliefs are often examined is in work contexts. Self-efficacy beliefs have been proposed to influence the performance of individual workers and the success of the companies in which they work by helping workers to more effectively and efficiently complete their required tasks. A meta-analytic review of more than 100 studies in the self-efficacy and work literature has been conducted and the results of this review have demonstrated that self-efficacy beliefs predict superior performance in professional contexts. These results suggest that by developing supportive environments that promote early successes and the development of professional self-efficacy beliefs, companies could improve not only the job satisfaction of their employees but also their own overall performance.

These are just a few of the many areas in which self-efficacy beliefs have been evaluated and demonstrated to promote positive outcomes. The common thread throughout all of this research is that self-efficacy beliefs appear to be an importance predictor of behavior and performance, regardless of the specific context. What is perhaps most remarkable is that empirical research has demonstrated that self-efficacy beliefs

are sometimes better predictors of future behavior than past behavior. There are few other psychological theories or constructs of which that same claim can be made.

Self-Efficacy Interventions

In the original 1977 publication that provided the first overview of self-efficacy theory, self-efficacy beliefs were proposed to be crucial mechanisms or mediators of behavior change in the treatment of psychological disorders. Early self-efficacy research tested this idea within the context of the treatment of anxiety disorders and found promising support. Specifically, Bandura and colleagues demonstrated that changes in self-efficacy beliefs over the course of treatment predicted individuals' willingness to confront the objects of their phobias, which in turn predicted symptom improvement. These early studies provide promising evidence that interventions designed to target self-efficacy beliefs may provide an effective means of treating various psychological disorders. Subsequent research has examined the utility of self-efficacy focused interventions for the treatment of obesity, substance abuse, depression, and many other conditions. This research has consistently demonstrated that targeting self-efficacy beliefs can often provide clinicians with an effective means of promoting behavior change, even in cases when previous treatments have failed.

Perhaps, the most striking example of an intervention that was developed on the basis of self-efficacy theory comes from recent self-efficacy based interventions that were delivered via television in Mexico and other countries. These interventions targeted crucial issues such as condom use, literacy rates, and women's rights in many communities in which these issues are not often given much attention. Bandura consulted with the producers of telenovelas (i.e., soap operas) to adapt the scripts in order to boost self-efficacy levels of viewers by providing positive models of agentic action. Follow-up studies demonstrated that individuals in communities in which these self-efficacy telenovelas were shown were significantly more likely to enroll in literacy programs and to practice safer sex practices after watching these videos. These interventions provide compelling evidence that the benefits of self-efficacy beliefs are universal and are not just limited to laboratory settings. This process also perfectly captures the worldview of self-efficacy theory in that the empirically supported practices of developing self-efficacy beliefs were applied to empower individuals across the world by elevating their levels of self-efficacy.

The Agentic Worldview of Self-Efficacy Theory

Self-efficacy theory emphasizes the importance of the individual and the individual's perceptions of his/her personal capabilities as key determinants of successful outcomes. Self-efficacy theory, and the broader social cognitive theory in which self-efficacy is encompassed, therefore clearly endorses a democratic ideal that suggests that all individuals are competent and capable of being successful, provided they have the opportunities and self-efficacy necessary to pursue their goals. Self-efficacy theory explicitly focuses on how individuals and communities can be empowered with a sense of agency that

will facilitate goal attainment. This is important as self-efficacy theory does not presume that individuals who are currently successful are inherently better than those who are not as successful. Rather, self-efficacy theory would suggest that individuals who are currently struggling may not have been provided with opportunities to obtain mastery experiences or modeling necessary to develop high levels of self-efficacy. Self-efficacy theory therefore suggests that it is the responsibility of the government and society to provide everyone with sufficient opportunities to engage in mastery experiences, receive positive social persuasion, and witness positively reinforcing models that will engender a strong sense of self-efficacy.

It is worth noting, however, that self-efficacy theory does not suggest that positive self-efficacy beliefs are the only causes of important outcomes. Rather, as previously discussed, self-efficacy theory is rooted in a theory of triadic reciprocal determinism in which there is a constant interplay between personal factors (i.e., self-efficacy beliefs), behavior, and environmental factors. Self-efficacy theory emphasizes the relative importance of personal factors, but acknowledges that behavioral and environmental factors have profound effects on outcomes. This theory of triadic reciprocal determinism therefore further reinforces the idea that if the effects of the environment are consistent (i.e., an even playing field for all), then self-efficacy beliefs will take on an even greater role in determining human behavior, and ultimately shaping outcomes.

It is also important to note that self-efficacy theory does not advocate a Pollyannaish world view in which positive expectancies for the future are the sole determinant of future outcomes. There has been a recent backlash against positive thinking among many members of the popular press. Books such as Barbara Ehrenreich's *Bright-Sided: How the Relentless Promotion of Positive Thinking Has Undermined America* have argued that an excessive emphasis on and belief in the benefits of positive thinking has had a detrimental effect on the lives of many individuals and the society as a whole. There is much to be said about identifying the potential pitfalls of naively optimistic worldviews or self-help programs that suggest that positive thinking provides almost magical benefits. However, it is important for researchers, clinicians, and the public to recognize the distinction between these less scientific theories of positive thinking and empirically based theories such as self-efficacy. Self-efficacy beliefs are in no way proposed to be a panacea for all of the ills of the world nor are self-efficacy beliefs proposed to be the only psychological factor that may determine important life outcomes. Rather, self-efficacy theory proposes a more measured worldview in which opportunities to experience or witness success may promote positive evaluations of one's capacities to succeed in the future which in turn increases the likelihood of subsequent positive outcomes.

Impact of Self-Efficacy Theory on Psychology

The agentic worldview of self-efficacy theory is particularly interesting when considering the historical context in which self-efficacy theory was developed. Bandura received his doctorate from Iowa University in the early 1950s, a time in which psychoanalytic and behavioral perspectives still dominated much of psychology. Bandura's theory of self-efficacy provided

an important contrast to these models that emphasized how external forces or intrapsychic forces that individuals were unaware of ultimately shaped behavior. Bandura's theory and research on self-efficacy helped to shift the course of psychology by emphasizing two factors that had previously been minimized. First, he emphasized the role of personal agency in opposition to deterministic behaviorist theories espoused by psychologists such as John Watson and B. F. Skinner. Second, he emphasized the role of cognition as a vital mediator in treatments that produced behavioral change. By emphasizing how cognition moderated the influence of external events, and mediated the effects of interventions, Bandura helped to usher in the cognitive revolution that followed under the leadership of Aaron Beck, Albert Ellis, and many others. Self-efficacy theory therefore played an important role in the history of psychology as it helped to shape the trajectory of the field by assigning agency to the individual and emphasizing the importance of cognition.

Future Directions

Research to date has clearly demonstrated the adaptive benefits of self-efficacy beliefs in numerous contexts. Self-efficacy theory nevertheless remains a vibrant area of psychological research as researchers are now attempting to develop a more sophisticated understanding of exactly how positive evaluations of personal agency may promote positive outcomes. In particular, three areas of self-efficacy research appear to be particularly promising areas for future research.

The first promising area for future research is the exploration of self-efficacy as a mechanism or mediator of change in psychotherapy. In Bandura's original 1977 article, self-efficacy beliefs were proposed as a crucial mechanism of change. Early self-efficacy research provided promising support for this hypothesis. In particular, research examining the treatment of anxiety disorders, specifically phobias, provided promising evidence that self-efficacy beliefs were in fact a crucial mechanism of psychotherapy. Unfortunately, subsequent research has failed to adequately build on these early promising findings and the extent to which self-efficacy beliefs fully or partially mediate the effects of psychotherapy remains unclear. There has been a recent resurgence in interest, however, in the mechanisms of change of empirically supported treatments, and researchers are once again proposing self-efficacy as a crucial mechanism of change in the treatment of psychological disorders, particularly anxiety disorders. What is now needed is more sophisticated longitudinal research using the recently developed and improved quantitative methods of examining mechanisms of change. This research will be difficult to conduct, but is crucial for advancing our understanding of the function self-efficacy beliefs play in empirically supported treatments of psychological disorders.

A second promising area for future research is the examination of the concept of collective efficacy. As the name obviously implies, self-efficacy research has traditionally focused on the adaptive benefits of a personal sense of agency. More recently, however, Bandura and other self-efficacy researchers have begun to explore the potential utility of extending the individual focus of self-efficacy to the level of groups or

communities in order to evaluate collective efficacy. Collective efficacy is defined as the perception of a group that they can successfully work together to accomplish valued goals. Initial research examining the construct of collective efficacy has demonstrated that the construct may have promise. Higher levels of collective efficacy have been shown to predict satisfaction in marriages, academic achievement in kids, and team athletic performance. Nevertheless, more research is needed to determine exactly how collective efficacy should be defined, how it should be measured, and whether it consistently promotes superior performance.

A third important area for future research will be examining the incremental validity of trait theories of agency in relation to traditional, domain-specific self-efficacy constructs. As previously mentioned, despite the initial focus on domain-specific measurement, numerous researchers have expanded upon the agentic core of self-efficacy theory in order to examine the utility of global or trait levels of agency/self-efficacy. As expected, this research has generally demonstrated that trait self-efficacy is an important predictor of behavior and positive outcomes. The problem with much of this research, however, is that traditional measures of domain-specific self-efficacy beliefs have rarely been measured in conjunction with trait measures of self-efficacy. The extent to which the global self-efficacy construct/scales help improve our understanding or prediction of human behavior beyond the predictions of traditional self-efficacy measures is therefore unclear.

Summary

Self-efficacy theory was presented in 1977 as an ambitious attempt to provide a unifying theory of behavior change. Although the extent to which the theory is truly unifying and comprehensive remains open to debate, there can be no doubt that the development of self-efficacy theory has had an extraordinary effect on the course of psychology. In fact, it could be argued that few psychological theories have had more of an impact worldwide than self-efficacy theory.

Self-Esteem

D R Kille and J V Wood, University of Waterloo, Waterloo, ON, Canada

© 2012 Elsevier Inc. All rights reserved.

Glossary

Domain-specific self-esteem Self-regard referring to a particular area of one's life (e.g., athletic self-esteem).

Implicit self-esteem A relatively automatic, nonconscious, self-evaluation. This term is also used to refer to measures of self-esteem that do not require self-report and whose purpose is not transparent.

Self-esteem A person's global evaluation of the self.

State self-esteem Transient assessment of self-worth that is relatively malleable.

Trait self-esteem One's dispositional, overall evaluation of the self that is fairly stable across situations.

Self-Esteem Defined

Self-esteem refers to one's overall evaluation of oneself – the extent to which one values and prizes the self. Self-esteem need not reflect objective reality. Instead, self-esteem is one's subjective evaluation of the self. A person who is overly critical of himself or herself may have a more negative self-evaluation (and thus lower self-esteem) than someone else who, by objective standards, is less competent. Although people with high self-esteem (HSEs) have more favorable self-views than their low self-esteem (LSE) counterparts, LSEs do not necessarily view themselves negatively. Most LSEs evaluate themselves positively, just less positively than do HSEs, or have ambivalent attitudes toward the self. Relatively few LSEs actually dislike themselves.

Self-esteem can refer to either trait or state self-esteem. Trait self-esteem refers to global evaluations about the self that are relatively stable and enduring. This type of self-esteem is highly resistant to change, with test–retest correlations over a 16-year period reaching as high as 0.72 in one investigation. Stability of this construct is comparable to other personality traits, and is particularly stable in later adulthood. State self-esteem, in contrast, refers to self-evaluations that occur on a moment-to-moment basis. Such temporary evaluations are more fragile and malleable than trait self-esteem. For example, a person whose trait self-esteem is high may have low state self-esteem after being refused for a date. Self-esteem also can be conceptualized as global or domain-specific, with the former referring to one's overall self-view and the latter referring to one's self-view in a specific domain, such as academics or appearance. As an example, whereas one's global self-esteem might not decrease after losing a tennis match, one's athletic self-esteem would likely suffer.

People differ not only in terms of their levels of trait self-esteem (e.g., high vs. low), but also in terms of how much their self-esteem varies around their own average level. Kernis and his colleagues demonstrated the importance of such within-person fluctuations of self-esteem. People whose self-esteem is relatively stable enjoy better mental health outcomes, such as less depression, than people whose self-esteem is unstable, even when their initial levels of self-esteem are controlled. It seems that it is beneficial not to simply have a positive self-evaluation, but to have a consistent self-evaluation.

Within the last two decades, self-esteem has also been examined as an implicit evaluation of the self. Implicit self-esteem is usually assessed by social-cognitive measures such as the implicit association task (IAT), whose purpose is not transparent to respondents. Such measures are thought to tap into evaluations of the self that the individual may not be aware of or be able to articulate, and are less vulnerable to social desirability concerns than self-report measures. Research shows that implicit self-esteem can predict a variety of behaviors, particularly when explicit self-esteem is incongruent with implicit. For example, participants with high explicit, but low implicit, self-esteem have been shown to act more defensively (e.g., derogating an outgroup member) than participants high in both implicit and explicit self-esteem. The remainder of this entry will concern explicit self-esteem at the conscious level.

Perspectives on Self-Esteem

As Jonathon Brown has noted, researchers have traditionally emphasized one of two self-esteem models. The cognitive perspective emphasizes the judgmental and 'bottom up' component of self-appraisals. Cognitive models stress that domain-specific self-evaluations (e.g., "I am a good chess player") combine to produce either high or low global self-esteem. Several positive self-evaluations in specific domains lead to high global self-esteem. In contrast, affective models emphasize the 'feelings' part of self-regard (e.g., "I feel happy with myself generally") – feelings that are thought to develop early in life from general perceptions of others' acceptance and love. How we feel about ourselves can then influence in a 'top down' fashion how we evaluate our specific qualities. For example, if we have mixed or negative feelings about ourselves, we are more likely to evaluate our competence in a given domain unfavorably. It seems likely that both the affective and cognitive models have merit – that overall feelings about the self influence specific evaluations (the affective view) and that domain-specific evaluations influence global feelings of self-worth (i.e., the cognitive view) – especially when those specific evaluations are highly personally relevant.

Why does self-esteem exist? Several theories have emerged regarding the function of self-esteem. From the perspective of Mark Leary's sociometer theory, self-esteem is a barometer

of one's relational value to others. When a person feels that she is valued by others, her self-esteem is high. Taking quite a different view of self-esteem, theorists associated with Terror Management Theory hypothesize that self-esteem develops to ward off the fear and anxiety that arises due to people's knowledge of their own mortality (for a discussion on this view of self-esteem, see Pyszczynski et al., 2004). Another view of self-esteem, outlined in self-determination theory, makes a distinction between true and contingent self-esteem. Whereas contingent self-esteem is reliant on meeting external standards, true self-esteem is noncontingent on achievement or on reaching others' standards, resulting in a genuine, more stable sense of self-worth. True self-esteem, from this perspective, is thought to arise from pursuing the three fundamental needs of autonomy, relatedness, and competence.

Cultural differences have been observed in the self-esteem literature, with East Asian participants typically reporting lower levels of global self-esteem than their Western counterparts. Some researchers have argued that cultural values in the East, such as modesty, constrain responses on explicit self-esteem scales. Indeed, implicit measures of self-regard reveal fewer cultural differences than do explicit measures. However, when participants complete anonymous measures of self-regard, which presumably reduce modesty concerns, East Asian participants again rate themselves less positively than Western participants. The exact nature of the cultural differences in self-esteem continues to be debated.

Measurement

Given that self-esteem has been defined in various ways – trait versus state, global versus domain-specific – it is not surprising that there exist multiple measures of self-esteem. For instance, researchers who conceptualize self-esteem as a global self-evaluation would see little utility in asking domain-specific questions. On the other hand, researchers who are interested in increasing academic self-esteem through an intervention would be wise to use a domain-specific measure of self-esteem because it is unlikely that a short intervention would boost one's global feelings about the self.

By far, the most commonly used scale is the Rosenberg Self-Esteem Scale (1965). This ten-item scale assesses participants' overall impression of the self and contains items such as, "On the whole I am satisfied with myself" and "I feel I do not have much to be proud of" (reverse scored). The scale has been shown to have high internal consistency, high test-retest reliability, as well as convergent and discriminant validity. However, it is likely that the Rosenberg, like all self-report measures of self-esteem, is contaminated to some extent by social desirability concerns, inasmuch as it is socially desirable to have HSE. Another frequently used measure of self-esteem is the Fleming and Courtney Self-Esteem Scale (1984), a revision of the Janis-Field Feelings of Inadequacy Scale (1959). This scale has 33 items that tap into global feelings of self-adequacy, as well as self-esteem in the domains of social confidence, school abilities, physical appearance, and physical ability. As with the Rosenberg, participants respond on a Likert scale, answering questions such as "How often do you dislike yourself?" Other commonly used scales include the Texas Social Behavior

Inventory and the Coopersmith Self-Esteem Inventory (for a detailed review, see Blascovich and Tomaka 1991).

Each scale reflects a different theoretical conceptualization of self-esteem. The Rosenberg taps into general feelings of self-regard rather than self-esteem in specific domains. Hence, it captures the 'affective' view of self-esteem identified by Brown better than the cognitive or 'bottom up' view. In multidimensional scales, such as the Fleming and Courtney scale discussed above, researchers are more interested in a 'self-esteem profile' rather than a single global self-esteem score. Multidimensional scales, which measure self-evaluations in several domains, are more appropriate than global scales when investigators are interested in specific components of the self-concept. For example, researchers who are interested in increasing academic self-esteem through an intervention would be wise to use a domain-specific measure of self-esteem, because it is unlikely that a targeted, short intervention would boost one's global feelings about the self. Conceptualizing self-esteem as unidimensional, in contrast, the Coopersmith assesses self-esteem in various domains and then sums across domains to form a single measure of self-worth. This practice has been criticized, because it fails to acknowledge that people differ in the importance they place on different domains. As William James recognized long ago, proficiency in some domains matter a great deal to one's self-esteem, whereas proficiency in others matter not at all. For example, athletics are more important to an athlete's overall self-esteem than to a statistician's. Harter and her colleagues advocated assessing self-esteem in line with James' observation – namely by asking questions about self-regard in a variety of domains as well as the perceived importance of success in each domain. Most self-esteem research conducted by social psychologists assesses general feelings of self-worth, rather than unweighted summed scores of domain-specific regard.

Several scales have been developed specifically for use with children. The most commonly used is the Piers-Harris Children's Self-Concept Scale (1984). Children respond 'yes' or 'no' as to whether various statements apply to them (e.g., "I am dumb at most things"). The scale contains subscales to assess domains such as popularity, happiness, and intelligence. Another measure, the Self-Perception Profile for Children (Harter 1985), uses pictorial representations and is therefore less dependent on children's verbal abilities.

Although most self-esteem scales have focused on trait self-esteem, some measures tap into how participants feel about themselves at the moment of measurement. Heatherton and Polivy's (1991) scale was developed specifically to assess state self-esteem, and taps into the domains of performance, social, and appearance self-esteem (e.g., "I am pleased with my appearance right now."). McFarland and Ross (1982) developed a measure that is often adapted to assess current feelings of self-worth, using bipolar adjectives such as 'accepted-rejected.'

Self-Esteem and Responses to Failure

By far, the topic that has received the most attention by self-esteem researchers within social psychology has been self-esteem differences in response to failure. In the typical experiment, HSEs and LSEs (often selected from the top third and bottom third, respectively, of the distribution of

self-esteem scores) engage in some task purportedly measuring an intellectual or social skill. Participants are randomly assigned to receive bogus failure feedback, or, in a comparison condition, either neutral, success, or no feedback. Then measures are administered that typically tap into one or more of the following: affective reactions, 'cognitive' reactions, or the use of 'self-enhancement' strategies.

On measures of affect, results consistently indicate that LSEs are more devastated than HSEs by failure. LSEs report more anxiety and distress than HSEs, and more than LSEs in neutral or success conditions. In success conditions, LSEs and HSEs appear to be equally happy after succeeding. For a long time, such results led self-esteem researchers to believe that the key to understanding how self-esteem is maintained lies in LSEs' and HSEs' different reactions to negative events. Recent research, however, suggests that LSEs and HSEs *do* differ after success (albeit less than they do after failure): LSEs are more anxious than HSEs after succeeding, and LSEs can even be more anxious after success than in neutral conditions. These results, as well as evidence that LSEs savor positive moods less than HSEs, suggest that self-esteem differences in reactions to positive events may, like reactions to negative events, serve to perpetuate self-esteem differences.

'Cognitive' measures inquire about reactions such as participants' attributions for the feedback and their judgments of the validity of the (bogus) test they completed. HSEs, to a greater extent than LSEs, tend to make self-serving attributions – blaming failure on an invalid test, for example, and success on their skills. HSEs also tend to believe that failure feedback is less valid than LSEs do. Such results have been interpreted as evidence for 'self-verification' motives. According to Swann's self-verification theory, people are motivated to maintain their self-views because stable self-views make the world more orderly and predictable. When HSEs encounter negative feedback, they may dismiss it, so as to preserve their HSE. Likewise, LSEs may doubt or minimize success feedback to preserve their LSE.

Alternatively, such cognitive measures may be interpreted as a means of self-enhancement for HSEs; attributing failure to an invalid test may help them restore their wounded pride. Some measures are designed to capture precisely such tendencies. 'Self-enhancement' measures afford participants an opportunity to 'self-enhance' – to maintain or boost their self-esteem in some way. For example, participants may be presented with a measure that asks them to rate themselves relative to someone else, to seek positive or negative information about other people, to stereotype others, to focus on their own favorable attributes, and the like. Over and over again, HSEs have been found to engage in more self-enhancing strategies than LSEs. After failure, HSEs self-aggrandize, derogate others, choose to see negative information about others, engage in stereotyping, and so forth. It is widely believed that such strategies help HSEs to maintain their HSE.

Self-Esteem-Related Motives: Self-Enhancement, Self-Verification, and Self-Protection

Why do LSEs and HSEs differ in their reactions to failure? For some time it was believed that LSEs may simply lack the motive to self-enhance. Now the consensus seems to be that both LSEs

and HSEs are motivated to feel good about themselves, but that LSEs are constrained by their self-beliefs; they cannot as readily claim or defend a positive view of themselves, so are wary of entertaining overly positive self-views. Also constraining LSEs may be self-verification motives; their motives to feel good about themselves are opposed by motives to maintain a stable self-view.

In addition, the motive to feel good about oneself may differ somewhat between LSEs and HSEs. A useful distinction has been offered between self-enhancement and self-protection: Whereas self-enhancement involves striving for or enhancing positive self-views, self-protection involves avoiding or minimizing negative self-views. Baumeister et al. (1989) proposed that HSEs focus on self-enhancement – taking risks to draw attention to their skills and talents – whereas LSEs focus on self-protection – seeking to *avoid* drawing attention to their deficiencies. This view of HSEs as risk-taking and self-enhancing, and of LSEs as cautious and self-protective, is supported by research on decision making, achievement, social comparison, and interpersonal behaviors, as will be described later.

Extensive debate has surrounded the question of whether self-verification or self-enhancement/self-protection motives are more important determinants of human behavior. Many social psychologists regard the motive to self-enhance as paramount, and as guiding almost all facets of life. Yet self-verification researchers have amassed substantial evidence that, contrary to the view that people engage in unbridled self-enhancement, LSE people do resist overly positive information about themselves and even seek information that confirms their relatively negative self-views. Probably the safest conclusion is that both self-verification and self-enhancement/self-protection motives operate for most people, with the predominance of each motive varying with person and situation.

Development Across the Lifespan

There is a growing consensus as to how self-esteem develops and evolves throughout the life span. Using meta-analytic techniques to analyze a large number of self-esteem studies, Trzesniewski, Robins, and their colleagues have determined that although self-esteem, on average, may wax and wane across the life-span, rank-ordered self-esteem remains fairly stable. For example, individuals who have LSE compared to their peers during adolescence are likely to have relatively LSE in later adulthood, even though their personal self-esteem may have increased.

During early childhood, self-esteem tends to be quite high, perhaps due to children's egocentric style of thinking. As childhood continues, self-esteem gradually decreases – a decrease that corresponds to developments in the cognitive system. Children begin to represent the self in a more complex fashion as they start to incorporate external feedback and information about their standing relative to their peers. Self-esteem continues to diminish through adolescence, which likely reflects the myriad of biopsychosocial changes in the adolescent's life. Concerns about 'fitting in,' hormonal changes, as well as further cognitive development (e.g., thinking about the self abstractly) all contribute to relative uncertainty about the self's worth during adolescence.

With adulthood, increases in self-esteem are evident. During this stage of life, several important milestones occur, such as forming and maintaining stable long-term relationships, becoming a parent, and attaining and establishing career goals. Self-esteem tends to slowly increase across adulthood until the mid to late sixties, at which point it reaches its apogee. Although less data exist on self-esteem in old age, the available evidence points to marked declines in self-esteem. This decline has been attributed to the many changes that are inevitable in older age, such as the loss of mobility, autonomy, cognitive ability, close friends, and spouses.

Finally, gender differences in self-esteem are small but consistently reported. Namely, although both males and females follow a similar developmental pattern, during early adulthood, boys tend to report having higher self-esteem than girls. This gap remains until old age, at which point it is reduced or erased.

Some of the predictable changes in self-esteem over the life span are likely due to changes in reference groups. For example, although self-esteem tends to be relatively low around the ages of 12–13, an important predictor of self-esteem at this age is whether or not the adolescent attends a new school – and thus encounters a new group of peers. When Grade Seven is marked by a transition to a new school, self-esteem in seventh-grade students is lower than that of seventh-grade students who attend a K-8 school. Also highlighting the importance of reference group for self-esteem, when children with learning disabilities are mainstreamed, and hence have nonlearning-disabled classmates more available as comparison targets, they report lower self-competence than when they attend classes only with others who have learning disabilities. Experimental studies have also underscored the importance of social comparisons on self-regard. For example, in one study, the self-esteem of job applicants was lower when a competing applicant was unkempt and disorganized than when the other applicant appeared tidy and orderly.

Self-Esteem and Other Personality Dimensions

Studies that have examined self-esteem in relation to other personality variables have consistently found that self-esteem is negatively correlated with neuroticism, which is viewed as one of the five basic personality traits (the 'Big Five'). This association is not surprising, given that LSE is associated with general negative affectivity, which is a central component of the neurotic personality trait. Extraversion, another Big Five personality trait, is associated with HSE. This association is less robust than that of LSE and neuroticism. More specifically, correlations of -0.50 or stronger are typically reported between neuroticism and self-esteem, whereas correlations between self-esteem and extraversion tend to fall within the 0.30 – 0.50 range. A weaker, but significant correlation is typically found between self-esteem and conscientiousness (e.g., $r = 0.20$ – 0.43). The other two personality traits of the Big Five, openness and agreeableness, are only weakly associated with self-esteem (e.g., typical r s = 0.19 and 0.16 , respectively). Attachment style is also reliably correlated with self-esteem, such that people with a secure style of adult attachment tend to have HSE. Conversely, insecure attachment styles are associated with LSE. The association between self-esteem and attachment style (as well as

neuroticism and extraversion) has been replicated across a diverse range of cultures.

Another facet of the self that is linked to self-esteem is self-concept clarity. HSEs' self-views are more internally consistent, stable, and confidently held than those of LSEs. Perhaps due to deficient self-concept clarity, research suggests that LSEs' self-views are more susceptible than HSEs' to external self-relevant feedback, which may, for example, encourage conformity.

Why are several personality traits linked with self-esteem? From the perspective of sociometer theory, the self-esteem – personality links do not imply that self-esteem causes the observed differences between HSEs and LSEs. Instead, the underlying cause of both LSE and associated personality variables may be low perceived relational value. When people feel that their relational capital is low, self-esteem will also be low; in addition to experiencing LSE, feeling relationally undervalued may also cause a person to develop an insecure style of attachment, or a neurotic personality (for a review, see [Leary and MacDonald, 2003](#)). This argument is buttressed by evidence linking LSE with rejection sensitivity and fear of negative evaluation.

Emotions and Psychopathology

Self-esteem is associated not only with certain personality traits, but also with emotional disposition, as well as some forms of psychopathology. When self-reported mood has been factor analyzed, two independent factors consistently emerge. Positive affect reflects a tendency to experience enjoyable mood states (e.g., pride, joy), whereas negative affect reflects a tendency to experience undesirable mood states (e.g., shame, sadness). These two factors, positive and negative affect, are highly associated with HSE and LSE, respectively. In one study, the strength of the association between self-esteem and positive affect was 0.47 , whereas the strength of the association between self-esteem and negative affect was -0.54 . Compared to HSEs, LSEs report more guilt, hostility, anger, proneness to embarrassment, and jealousy. Further, LSEs are less motivated to repair negative moods than HSEs, despite being equally knowledgeable about mood-enhancing strategies. And whereas HSEs tend to actively savor positive mood states, LSEs are less likely to do so.

LSE is often linked with depressive symptoms, and in fact, some theorists believe that unfavorable self-evaluations are the root cause of depression. More specifically, certain theories of depression place LSE as a primary etiological factor, and in the Diagnostic and Statistical Manual of Mental Disorders, 'feelings of worthlessness' is a symptom of a major depressive episode. Correlations between self-esteem and depressive symptoms have been reported to range from -0.53 to -0.74 . In a recently reported longitudinal study that included participants of diverse ages, LSE at Time One was associated with higher levels of depressive symptoms across a 9-year period. This association was found at all ages, and the reverse association was not found; depressive symptoms did not predict future (low) self-esteem (see Orth et al., 2009, for more detail). Anxiety disorders are also (negatively) associated with self-esteem, but to a lesser degree than is depression (with correlations between -0.31 and -0.45 reported in the literature).

Eating disorders are thought to be influenced by self-esteem as well. This association is not surprising, given that eating disorders involve an unrealistically negative view of the self. Bulimia Nervosa in particular seems to afflict LSE women to a greater degree than HSE women. A study of adolescent patients found that the association between LSE and eating disorders was mediated by depressive symptoms. That is, LSE was related to depressive symptoms, which in turn predicted maladaptive eating patterns (see Courtney et al., 2008, for full details).

Links have been reported between LSE and substance use and abuse, although there is substantial disagreement regarding this link. Whereas women alcoholics have lower self-esteem than nonalcoholic women (and alcoholic men), alcohol consumption in men is more complex. Some studies show positive, negative, or no link between alcohol consumption and self-esteem for male participants. In terms of drug use, the results are also varied. Initial drug use has been found to negatively correlate with self-esteem, although other evidence points to HSE leading to risky behavior in adolescence, including activities such as drug use. Further, longitudinal evidence reveals that although LSE may be associated with initial drug experimentation, continued use may actually boost self-esteem. Thus, although there may be an association between self-esteem and substance use, this association is complex and additional factors need to be considered.

Self-Esteem and Other Real Life Outcomes

Humanist theories, talk shows, and popular wisdom alike have long held that LSE is at the root of many social problems. From substance abuse to poor school achievement, LSE has been viewed as causing several deleterious outcomes. Indeed, the California Task Force to Promote Self-Esteem and Social Responsibility was initiated in the belief that boosting self-esteem would remedy societal ills of all kinds. However, increasing self-esteem may not be the cure-all for social ailments. Roy Baumeister and his associates reviewed evidence concerning self-esteem and real-life outcomes, including academic achievement, professional success, delinquency, and substance abuse. They drew two main conclusions. First, the associations between self-esteem and many outcomes are weak or nonexistent. For example, these authors concluded that academic achievement, success in the workplace, and leadership quality were virtually uncorrelated with self-esteem (although some weak positive associations were reported). Further, Baumeister and colleagues' review made clear that certain links between self-esteem and outcomes such as smoking, engaging in early sexual activity, and antisocial behavior, previously thought to be associated with LSE, have mixed empirical support (at best). Only a few differences between HSEs and LSEs seem to exist beyond the laboratory. For example, HSEs appear to show a stronger tendency toward in-group favoritism, and persist longer in the face of failure.

Baumeister and colleagues' second main conclusion is that, where associations involving self-esteem do exist, HSE does not necessarily cause such outcomes, so boosting self-esteem may not help. It may be just as likely that the causal direction is reversed – that some positive outcomes, such as overall happiness, cause increases in self-esteem. Additionally, both

self-esteem and positive outcomes may be caused by a third variable, such as strong interpersonal bonds producing both HSE and happiness, for example.

The 'Dark Side' of HSE

One ongoing debate in the literature surrounds the 'dark side' of HSE. Jean Twenge and colleagues have argued that attempts to increase self-esteem, such as the California Task Force mentioned above, alongside greater emphasis on individualism, may be leading toward more narcissism in Western society. These researchers argue that the rates of narcissism, or the tendency to aggrandize one's self-worth, have steadily increased since the 1980s – thus leading Twenge to dub recent generations as 'Generation Me.' Other researchers have questioned whether narcissism has actually increased, and contradictory findings exist (e.g., see Trzesniewski et al., 2008; but also Twenge and Foster, 2010).

Another potential harm linked to HSE involves aggression. According to popular wisdom, delinquency and aggression are associated with LSE. Contrary to this view, Baumeister and colleagues reviewed considerable evidence that people with LSE are *not* especially prone to aggression. In fact, these authors linked aggressive behaviors with high, not low, self-esteem. They reviewed evidence that people who have "favorable self-appraisals that may be inflated or ill-founded" (p. 5) are prone to aggression when anyone or anything calls into question their positive self-evaluations. Some self-esteem researchers may take issue, however, with how Baumeister et al. included in the HSE category those who are arrogant, conceited, or whose self-views may be 'inflated or ill-founded.' Thus, Baumeister et al.'s review of the 'dark side' of HSE may depict a construct closer to narcissism than to self-esteem. Indeed, in one study by Baumeister and colleagues, the combination of HSE and high narcissism produced the highest levels of aggression toward a confederate who provided a negative evaluation of the participant. HSE with low levels of narcissism did not produce the same degree of aggressive behavior.

Relationship Functioning and Self-Esteem

HSEs report themselves as being higher in popularity, more socially skilled, and as having larger networks of friends than LSEs. Although HSEs may inflate self-reports of social capital due to self-enhancement motives, empirical evidence suggests that HSEs generally do make better relationship partners. This evidence concerns all relationship phases, from relationship initiation to established unions.

In terms of relationship formation, HSEs' tendencies to self-enhance and LSEs' tendency to self-protect are evident in their initiation strategies. One study found that HSE men were more likely than LSE men to make direct overtures to potential romantic partners. Whereas HSE participants introduced themselves, for example, LSE participants reported more passive strategies, such as waiting for the other person to approach them.

In a related vein, it has been shown that LSEs are highly vigilant to rejection cues when interacting with a new person. This focus on rejection may overshadow positive overtures, and

in fact, LSEs tend to underestimate how much a new acquaintance likes them. Interestingly, LSEs are not ill-equipped to detect acceptance cues. Instead, Stinson and Cameron and their colleagues have found that although LSEs do not seem to notice or report acceptance cues when the overtures are directed at themselves, they do detect such cues if directed toward another person.

Another way that self-esteem can influence relationship initiation is through self-disclosure. We tend to like those who disclose information to us, and we tend to disclose information to those we like. This association holds because self-disclosure acts as a sign of intimacy, a necessary ingredient for developing (and established) relationships. In general, LSEs report that they disclose less information than HSE individuals, a finding confirmed by studies that use objective judges to rate self-disclosure. When one interaction partner is concerned with self-protection, as LSEs tend to be, they reveal little about their opinions or feelings. LSEs' interaction partners are then apt to report that they found the interaction awkward and boring, and that they like the LSE person less. Self-protectively refraining from self-disclosure, then, can bring about precisely the reaction LSEs fear: rejection.

In developed relationships, compared to HSEs, LSEs tend to experience more ups and downs, and less relational satisfaction. Longitudinal studies of relationship partners have revealed that HSEs start out with higher levels of relational satisfaction than LSEs, and experience increases in satisfaction over time. LSEs, in contrast, are more likely to show decrements in satisfaction as relationships go on.

According to the 'risk regulation model' of interpersonal functioning put forth by Sandra Murray and John Holmes, relationship partners must balance the goal of connecting with their partner against the goal of protecting the self from the sting of rejection. Connection can bring joy, increase intimacy, and heighten commitment, but it also increases the pain that rejection would bring. How do people decide, then, whether to seek connection or to protect themselves against possible rejection? According to the risk regulation model, perceived regard, or the extent to which people feel that their partners value them, is an important determinant of whether people pursue connection or protection goals. That is, the more people think their partners value them, the more likely they are to let go of self-protection goals and to pursue connection goals. As detailed above, LSEs are concerned with self-protection during initial social interactions, and perhaps unsurprisingly, this concern extends to long-term relationships as well.

Through multiple studies, the risk regulation model has garnered empirical support, often underscoring undesirable outcomes for LSEs and their partners. LSEs typically underestimate how much their partners love them, and instead, seem to assume that their partners question their worth in the same way they themselves do. Another problematic tendency for LSEs is that, as in relationship initiation, they interpret neutral or ambiguous cues in a less than benign manner. LSEs are quick to infer personal rejection when their partner is in a bad mood. HSEs, in contrast, are more likely to make favorable attributions for ambiguous partner behaviors, which can increase trust and relationship quality.

Inevitably, though, all relationships face threats or setbacks. Differences in how HSEs and LSEs deal with such threats has

proven informative. When the fear of rejection is warranted, LSEs self-protect by defensively drawing away from the partner. Intuitively, this may seem like a smart strategy; after all, it hurts much more to be rejected by a close other than by a distant other. However, when they are concerned about rejection, LSEs not only draw away from the partner, they also derogate their partners' value and behave less positively toward the partner. How do HSEs respond to potential rejection? Instead of creating distance between the self and partner, HSEs attach greater value to the partner, and feel more loved – a response that leads to positive interpersonal outcomes.

Summary

Self-esteem has received an abundance of research attention, both in pursuit of understanding the nature of self-esteem per se, and in relation to other variables that are important in life. Indeed, at the time of publication, a search of 'self-esteem' in the database PsychINFO reveals well over 65 000 results! Self-esteem refers to an evaluation of the self and has been conceptualized as a stable trait and as a state – a moment-to-moment evaluation. A large body of evidence makes clear that LSEs (at the trait level) respond less adaptively than HSEs when faced with failure and that LSEs behave in a more self-protective manner than HSEs, who are more likely to self-enhance. Several lines of research suggest that LSE is associated with undesirable personality traits, such as neuroticism, and proneness to guilt and shame, as well as with certain types of psychopathology, such as depression and anxiety. Also reviewed was evidence that HSE is not highly associated with positive outcomes such as superior academic performance, or successful task performance in the lab or workplace. Aggression in response to 'wounded pride' might be specific to HSEs (particularly those with high levels of narcissism). Research has made clear that interpersonal relationships of HSEs and LSEs differ in meaningful ways. Whereas HSEs draw closer to their partners in response to relational threat, LSEs distance the self from the partner. Although it is tempting to conclude that LSE causes negative outcomes and HSE causes positive outcomes, it is important to recall that most studies of self-esteem simply measure this construct. Thus, causal conclusions cannot be drawn. One prominent theory of self-esteem has proposed that both self-esteem and related outcomes are both caused by perceived relational value. Although much is already known about self-esteem, many questions remain unanswered. Self-esteem will undoubtedly continue to hold the imagination of researchers, the popular press, and the general public.

Glossary

Binomial effect size display (BESD) A standardized procedure for the display of an effect size correlation of any magnitude, where row and column totals are set at 100; its purpose is to clarify the practical importance of the obtained correlation.

Correlation (r) An index of the closeness of a relationship between variables.

Effect size The magnitude of the research results, such as the size of the relationship between an independent variable (e.g., treatment vs. placebo) and a dependent variable (e.g., degree of improvement).

Experimenter expectancy effect An experimenter-related artifact that results when the hypothesis held by the experimenter leads unintentionally to behavior toward the participants that, in turn, increases the likelihood that the hypothesis will be confirmed.

Meta-analysis The use of quantitative and graphical methods to summarize the results of a group of similar studies.

Placebo A substance without any pharmacological benefit given as a pseudomedicine to a control group.

Introduction

Self-fulfilling prophecy is a concept used in the social and behavioral sciences to refer to the idea that one person's or one group's expectations for the behavior of others can quite unintentionally help to bring about the behavior expected of those others. The sociologist, Robert K. Merton, helped to bring this concept into the mainstream of the social sciences and gave it a now classic example from the discipline of economics. If, for some reason, people who have deposited their money in a particular bank come to believe that the bank will fail, they may well rush out to withdraw their money from that bank, thereby causing the up-until-now solvent bank to fail. In the area of international relations, social psychologist Gordon Allport believed that a self-fulfilling prophecy can be the cause of war. If one nation (A) believes that another nation (B) is arming itself in anticipation of going to war against nation A, then nation A will arm itself in self-defense, signaling hostile intent to nation B, which will then arm itself in self-defense, and so on until an actual war may occur based on initially unfounded observations. The expectation of the need for war may have contributed to the onset of that war.

In the medical sciences, Henry K. Beecher compared the effects of morphine to the effects of placebo. The beneficial effects of morphine in reducing pain were greater when investigators were aware of whether they were administering the morphine or the placebo. When the investigator did not know when was the morphine or when was the placebo being administered, then the morphine was no more effective than the placebo. Apparently, the knowledge that they were getting the real thing was somehow communicated to the participants who were administered the morphine, leading to their deriving greater benefits from it than were obtained by morphine-receiving participants whose investigators did not know whether the real thing had been administered to the participant.

Perhaps the most famous example of a self-fulfilling prophecy in the early days of modern experimental psychology is the

case of Clever Hans. Hans was a well-known horse who, in the early years of the twentieth century, amazed even sophisticated scientific observers by multiplying and dividing numbers in his head, and tapping out the answers with his hoof. Hans could do a great deal more including spelling, reading, and solving problems of musical harmony. Hans's owner, Mr. von Osten, a German mathematics teacher, unlike the owners of other clever animals of the time, did not profit financially from his horse's talents, and it seemed unlikely that he had any fraudulent intent. He was quite willing to let others question Hans even in his absence so that cues from the owner could be ruled out as the reason for the horse's abilities. In a brilliant series of experiments, Oskar Pfungst discovered that Hans could answer questions accurately only if the questioners themselves knew the answer and were visible to the horse during his foot-tapping of the answer. Finally, it was discovered that whenever people asked Hans a question, they leaned forward very slightly, the better to see Hans's hoof. That, it turned out, was the unintentional signal for Hans to begin tapping. Then, as Hans approached the number of hoof-taps representing the correct answer, the questioners would typically show a tiny head movement. That almost imperceptible cue was the signal for Hans to stop tapping, and Hans was right again. The questioner, by expecting Hans to stop at the right answer, was actually 'telling' Hans the right answer and thereby fulfilling his own prophecy. Pfungst did not learn all of this so easily. It took a long and elegant series of experiments to learn the secret of Hans's success. Pfungst summarized eloquently the difficulties in discovering Hans's talents. He and others had been misled too long by, to paraphrase, 'looking for, in the pupil, what should have been sought in the teacher.'

The four important examples of self-fulfilling prophecies drawn from the domains of economics, international relations, medicine, and experimental psychology, help us define and clarify the concept, but they do not by themselves establish the generality or the replicability of the effects of a self-fulfilling prophecy. To establish that generality and that replicability requires a series of randomized experiments, that is, a series

of studies in which the causal nature of the prophecy, or interpersonal expectancy, can be firmly established. In what follows, the evidence from a few of these randomized experiments is reported.

Some Early Experiments

Human Research Participants

In the first of the studies using human subjects, ten students of psychology, both undergraduate and graduate, served as the experimenters. All were enrolled in an advanced course in experimental psychology and were already involved in conducting research. Each student-experimenter was assigned as his or her research participants about 20 students of introductory psychology. The procedure was for the experimenters to show a series of ten photographs of people's faces to each of their participants individually. Participants were to rate the degree of success or failure shown in the face of each person pictured in the photos. Each face could be rated as any value from -10 to $+10$, with -10 meaning extreme failure and $+10$ meaning extreme success. The ten photos had been selected so that, on the average, they would be seen as neither successful nor unsuccessful, but quite neutral, with an average numerical score of zero.

All ten experimenters were given identical instructions on how to administer the task to their participants and were given identical instructions to read to them. They were cautioned not to deviate from these instructions. The purpose of their participation, it was explained to all experimenters, was to see how well they could duplicate experimental results which were already well established. Half of the experimenters, who had been randomly selected, were told that the 'well-established' finding was such that their participants should rate the photos as of successful people (ratings of $+5$), and half of the experimenters, who had been randomly selected, were told that their participants should rate the photos as being of unsuccessful people (ratings of -5). Results showed that experimenters who had been led to expect higher photo ratings obtained higher photo ratings than did experimenters who had been led to expect lower photo ratings. Subsequent studies tended to obtain generally similar results.

Animal Research Subjects

Pfungst's work with Clever Hans had suggested the possibility of experimenter expectancy effects with animal subjects. In addition, Bertrand Russell, in 1927, had noted this possibility, adding that animal subjects take on the national character of the experimenter. As he put it: "Animals studied by Americans rush about frantically, with an incredible display of hustle and pep, and at last achieve the desired result by chance. Animals observed by Germans sit still and think, and at last evolve the solution out of their inner consciousness."

But it was not only the work of Pfungst and Russell that led to the test of the generality of experimenter expectancy effects by working with animal subjects. It was also the reaction of researchers who themselves worked with animal subjects. That reaction was: "Well of course you'd find expectancy effects and other artifacts when you work with humans; that's why we work with rats."

A class in experimental psychology had been performing experiments with human participants for most of a semester. Now they were asked to perform one more experiment, the last in the course, and the first using animal subjects. The experimenters were told of studies that had shown that maze-brightness and maze-dullness could be developed in strains of rats by successive inbreeding of the well and the poorly performing maze-runners. Sixty laboratory rats were equally divided among the 12 experimenters. Half of the experimenters, chosen at random, were told that their rats were maze-bright, while the other half, chosen at random, were told that their rats were maze-dull. The animal's task was to learn to run to the darker of the two arms of an elevated T maze. The two arms of the maze, one white and one gray, were interchangeable; and the 'correct' or rewarded arm was equally often on the right as on the left. Whenever animals ran to the correct side, they obtained a food reward. Each rat was given ten trials each day for 5 days to learn that the darker side of the maze was the one that led to the food.

Beginning with the first day and continuing on through the experiment, animals that were believed to be better performers became better performers. Animals that were believed to be bright showed a daily improvement in their performance, while those believed to be dull improved only on the third day and then showed a worsening of performance. Sometimes, an animal refused to budge from the starting position. This happened 11% of the time among the allegedly bright rats, but among the allegedly dull rats, it happened 29% of the time. When animals did respond and correctly so, those believed to be brighter ran faster to the rewarded side of the maze than did even the correctly responding rats that were believed to be dull.

When the experiment was over, all experimenters made ratings of their rats and of their own attitudes and behavior vis-à-vis their animals. Those experimenters who had been led to expect better performance viewed their animals as brighter, more pleasant, and more likable. These same experimenters felt more relaxed in their contacts with the animals and described their behavior toward them as more pleasant, friendly, enthusiastic, and less talkative. They also stated that they handled their rats more and also more gently than did the experimenters who were expecting poor performance.

The next experiment with animal subjects also used rats, this time using not mazes but Skinner boxes in which there was a food dispenser and a small bar that could be depressed by the rat and would sometimes lead to a bit of food from the food dispenser. Because the experimenters (39) outnumbered the subjects (14), experimenters worked in teams of two or three. Once again, about half of the experimenters, selected at random, were led to believe that their subjects had been specially bred for excellence of performance. The experimenters who had been randomly assigned the remaining rats were led to believe that their animals were genetically inferior.

The learning required of the animals in this experiment was more complex than that required in the maze learning study. This time the rats had to learn in sequence and over a period of a full academic quarter the following behaviors: to run to the food dispenser whenever a clicking sound occurred; to press the bar for a food reward; to learn that the feeder could be turned off and that sometimes it did not pay to press the bar; to learn new responses with only the clicking sound as a

reinforcer (rather than the food); to bar-press only in the presence of a light and not in the absence of the light; and, finally, to pull on a loop which was followed by a light which informed the animal that a bar-press would be followed by a bit of food.

At the end of the experiment, the performance of the animals that were believed to be superior *was* superior to that of the animals that were believed to be inferior, and the difference in learning favored the allegedly brighter rats in all five of the laboratory sections in which the experiment was conducted.

Just as in the maze learning experiment, the experimenters of this study were asked to rate their animals and their own attitudes and behaviors toward them. Once again those experimenters who had expected excellence of performance judged their animals to be brighter, more pleasant, and more likable. They also described their own behavior as more pleasant, friendly, enthusiastic, and less talkative, and they felt that they tended to watch their animals more closely, to handle them more, and to talk to them less.

The absolute amount of handling of animals in this Skinner box experiment was considerably less than the handling of animals in the maze learning experiment. Nonetheless, those experimenters who believed their animals to be Skinner box bright handled them relatively more, or said they did, than did experimenters who believed their animals to be dull. The extra handling of animals believed to be brighter may have contributed in both experiments to the superior learning shown by these animals.

In addition to the differences in handling reported by the experimenters of the Skinner Box study as a function of their beliefs about their subjects, there were differences in the reported intentness of their observation of their animals. Animals believed to be brighter were watched more carefully, and a more careful observation of the rat's Skinner box behavior may very well have led to more rapid and appropriate reinforcement of the desired response. Thus, a closer observation, perhaps due to the belief that there would be more promising responses to be seen, may have made more effective teachers of the experimenters who had been led to expect good performance.

Teacher Expectation Effects

If rats became brighter when expected to, then it would not be far-fetched to think that children might become brighter when expected to by their teachers. Indeed, psychologist Kenneth Clark had for years been saying that teachers' expectations could be very important determinants of their students' intellectual performance.

The Pygmalion Experiment

All of the children in the study were administered a nonverbal test of intelligence, which was disguised as a test that would predict intellectual 'blooming.' The test was labeled as 'The Harvard Test of Inflected Acquisition.' There were 18 classrooms in the school, 3 at each of the 6 grade levels. Within each grade level, the three classrooms were composed of children with above average ability, average ability, and below

average ability, respectively. Within each of the 18 classrooms, ~20% of the children were chosen at random to form the experimental group. Each teacher was given the names of the children from his or her class who were in the experimental condition. The teacher was told that these children had scored on the 'Test of Inflected Acquisition' such that they would show surprising gains in intellectual competence during the next 8 months of school. The only difference between the experimental group children and the control group children, then, was in the mind of the teacher.

At the end of the school year, 8 months later, all the children were retested with the same test of intelligence. Considering the school as a whole, the children from whom the teachers had been led to expect greater intellectual gain showed a greater intellectual gain than did the children of the control group.

An Unexpected Finding

At the time the Pygmalion experiment was conducted, there was already considerable evidence that interpersonal self-fulfilling prophecies could occur, at least in laboratory settings. It should not then have come as such a great surprise that teachers' expectations might affect pupils' intellectual development. For those well acquainted with the prior research, the surprise value was, in fact, not all so great. There was, however, a surprise in the Pygmalion research. For this surprise, there was no great prior probability, at least not in terms of many formal research studies.

At the end of the school year of the Pygmalion study, all teachers were asked to describe the classroom behavior of their pupils. Those children in whom intellectual growth was expected were described as having a better chance of becoming successful in the future and as more interesting, curious, and happy. There was a tendency, too, for these children to be seen as more appealing, adjusted, and affectionate and as less in need of social approval. In short, the children in whom intellectual growth was expected became more intellectually alive and autonomous, or at least were so perceived by their teachers.

But we already know that the children of the experimental group gained more intellectually, so that perhaps it was the fact of such gaining that accounted for the more favorable ratings of these children's behavior and aptitude. But a great many of the control group children also gained in IQ during the course of the year. We might expect that those who gained more intellectually among these undesignated children would also be rated more favorably by their teachers. Such was not the case. The more the control group children gained in IQ, the more they were regarded as *less* well-adjusted, as *less* interesting, and as *less* affectionate.

From these results it would seem that when children who are expected to grow intellectually do so, they are benefited in other ways as well. When children who are not specifically expected to develop intellectually do so, they seem either to show accompanying undesirable behavior or at least are perceived by their teachers as showing such undesirable behavior. If children are to show intellectual gain, it seems to be better for their real or perceived intellectual vitality, and for their real or perceived mental health, if their teacher has been expecting

them to grow intellectually. It appears worthwhile to investigate further the proposition that there may be hazards to unpredicted intellectual growth.

The Meta-Analytic Evidence for the Self-Fulfilling Prophecy

Meta-analysis is the rapidly developing area of data analysis in which the entire body of research literature on a given question is summarized quantitatively.

Table 1 summarizes eight meta-analyses of the literature on interpersonal expectancy effects (self-fulfilling prophecies), with each meta-analysis conducted on a different domain of the research. For each domain, the table shows the mean effect size (r) and gives an example of the type of study included in each domain. The effect size r can be interpreted as the correlation, r , between (a) experimental versus control group status (e.g., coded 1 or 0) and (b) the outcome score (say, gain in performance). In an updated meta-analysis of 479 studies conducted nearly 20 years later, the average effect size r was 0.30. The correlation r indicates the strength of the relationship between two variables, for example, (a) the randomly assigned expectation for another's behavior and (b) the subsequent occurrence of that behavior. A correlation (r) of 0.00 indicates no relationship at all between the two variables (a) and (b); an r of +1.00 means a perfect positive correlation between (a) and (b) (the higher the score on (a), the higher the score on (b)); an r of -1.00 means a perfect negative correlation between (a) and (b) (the higher the score on (a), the lower the score on (b)). More on the interpretation of the correlation, r , of any particular magnitude, is discussed shortly.

Meta-analyses are also available for just the effects of interpersonal expectations on pupils' IQ test performance. Both

Stephen Raudenbush and Mary Lee Smith each found significant overall effects of interpersonal expectations on students' IQ. The mean effect size reported by Mary Lee Smith in units of r was 0.08. (The term 'significant' in referring to the results of these meta-analyses is a technical term meaning approximately that there is less than a 1-in-20 chance (i.e., a probability (p) of 1/20 or 0.05) that the results would have been obtained if the true size of the effect had really been an r of 0.00. The statistical significance of a particular correlation depends on the size of r and the size of the sample being studied. The larger the r and the larger the sample on which it is based, the more 'significant' is the result. There are many ways to compute the statistical significance of any effect size (e.g., r), and one of the most common is called the t test.)

Stephen Raudenbush's more recent meta-analysis was designed to investigate the relationship between the credibility of the expectancy induction and the magnitude of the teacher expectancy effect on pupil IQ. He reasoned that inductions of expectations in teachers would be credible only to the extent that teachers did not already know the children and, thus, had not already established expectations on the basis of their direct experience. As he had predicted, he found dramatic differences in effect sizes as a function of how long teachers had known pupils before the induction of the expectation.

Table 2 shows the magnitude of teacher expectancy effects on their pupils' intellectual performance for four levels of prior acquaintance: <1 week, 1 week, 2 weeks, and 3 or more weeks. There was a very strong linear trend such that the longer teachers were acquainted with their pupils before the induction of the expectation for superior performance, the smaller was the effect of teachers' expectations, exactly as Raudenbush had predicted.

It seems clear, then, based on the meta-analytic evidence, as well as on the evidence provided by the original *Pygmalion* experiment, that the educational self-fulfilling prophecy has now been well established – and as Merton noted some 40 years later – that is the first step in the scientific study of any phenomenon.

Table 1 Magnitude of interpersonal expectancy (self-fulfilling prophecy) effects in eight research domains

Domain	Mean effect size r	Example of type of study
Laboratory interviews	0.07	Effects of sensory restriction
Reaction time	0.08	Latency of word association
Learning and ability	0.26	IQ test scores; verbal conditioning
Person perception	0.27	Perception of others' success
Inkblot tests	0.39	Ratio of animal to human Rorschach responses
Everyday situations	0.40	Symbol learning; athletic performance
Psychophysical judgments	0.46	Ability to discriminate tones
Animal learning	0.65	Learning in mazes and Skinner boxes
Weighted mean ^a	0.33	
Unweighted mean	0.35	
Median	0.33

^aWeighting is by the number of studies in each domain.

The Practical Importance of Experimental Effects

For the eight experiments in **Table 2** in which teachers' expectations could most credibly be created, those in which teachers

Table 2 Stephen Raudenbush's meta-analysis showing teacher expectancy effects as a function of length of prior teacher–pupil acquaintance

	Number of weeks of prior acquaintance			
	0	1	2	3(+)
Mean r	0.24	0.18	0.05	-0.05
k of studies	5	3	3	8
Contrast weights (λ)	+3	+1	-1	-3

$t_{\text{contrast}}^a = 3.77$, $df = 15$, $p = 0.00093$, $r_{\text{contrast}} = 0.70$

$t_{\text{grand mean}}^b = 3.39$, $df = 15$, $p = 0.0020$, $r = 0.66$

$t_{\text{alerting}}^c = 10.53$, $df = 2$, $p = 0.0045$, $r_{\text{alerting}} = 0.99$

^aTests linear trend of 19 effect sizes over length of acquaintance.

^bTests mean of four effect sizes for overall effect of teacher expectancy.

^cTests linear trend of four mean r s over length of acquaintance.

knew their pupils 1 week or less, the median effect size was an r of 0.14, or $r^2 = 0.02$. These effect size estimates of r , and, especially, r^2 (called the proportion of variance accounted for), suffer from a common problem, the tendency to underestimate the practical importance of the effects of behavioral or biomedical interventions. This tendency to underestimate the importance of effects occurs not only among experienced behavioral researchers but among experienced statisticians as well. Accordingly, an intuitively appealing general purpose effect size display was proposed, the interpretation of which is far more transparent: the binomial effect size display (BESD). The question addressed by the BESD is: What is the effect on the success rate (e.g., survival rate, cure rate, improvement rate, selection rate, etc.) of the institution of a new treatment procedure? It, therefore, displays the change in outcome attributable to the new treatment procedure. Table 3 illustrates the BESD for the median effect size under discussion ($r = 0.14$) and for the median effect size for just those studies that Raudenbush reported in which teachers had already known their pupils for 2 weeks ($r = 0.04$).

It seems clear from Table 3 that a treatment that changes success rates (e.g., survival) from 43% to 57% or even from 48% to 52% is of substantial practical importance. Death rates are dramatic but so are failure rates, rejection rates, and error rates. To use the BESD, we compute the effect size r for our experimental effect. Adding the quantity $r/2$ to 0.50 gives the experimental group's success rate. Subtracting the quantity $r/2$ from 0.50 gives the control group's success rate. When effect sizes are displayed as a BESD, there emerges a better picture of the real-world importance of any treatment effect. Even so 'small' an effect as one accounting for nearly 0% of the variance, the BESD shows, has practical implications to a degree that most behavioral researchers and most statisticians find surprising. If it seems far-fetched to consider important those effects improving the rate of favorable outcomes from 48% to 52%, it should be noted that major drug studies have been interrupted and discontinued because the effect size, which was of just that magnitude, was regarded as so important that it seemed unethical to deprive the placebo control patients of the benefits of the drugs in preventing heart attacks. The drugs were propranolol in one case and aspirin in another.

The 10-Arrow Model

For many years, the central question in the study of interpersonal expectancy effects was whether there was any such thing.

Table 3 Binomial effect size displays (BESD) for r s of 0.14 and 0.04 that account for 'only' 2% and '0%' of the variance, respectively

Example of a treatment result				
Effect size	Condition	Alive	Dead	Σ
$r = 0.14$ ($r^2 = 0.02$)	Treatment	57	43	100
	Control	43	57	100
	Σ	100	100	200
$r = 0.04$ ($r^2 = 0.00$)	Treatment	52	48	100
	Control	48	52	100
	Σ	100	100	200

The meta-analytic evidence has answered that question sufficiently (e.g., $p < 1/10^{175}$, (i.e., 1 chance in 1 followed by 175 zeros), mean $r = 0.30$, based on the full number of 479 studies) so that simple additional replications will add little new knowledge. The central questions in the study of interpersonal expectancy effects have changed so that now the more interesting questions include the specification of the variables that (a) moderate expectancy effects and (b) mediate expectancy effects. Moderator variables are preexisting variables such as sex, age, and personality that are associated with the magnitude of interpersonal expectancy effects; mediating variables refer to the behaviors by which expectations are communicated. The basic elements of the 10-arrow model designed to clarify the study of interpersonal expectancy effects are (a) distal independent variables (e.g., stable attributes of the expecter and the expectee), (b) proximal independent variables (the expectancy), (c) mediating variables, (d) proximal dependent variables (e.g., outcome measures such as achievement on tests, etc.), and (e) distal-dependent variables (longer-term outcome variables). A useful feature of this model is that the ten arrows of the model represent the types of relationships that can be examined in research on interpersonal expectancy effects (see Figure 1).

For our purpose here, it will be enough to mention only the two links relevant to the topic of mediation: the B-C and C-D arrows. B-C relationships describe the effect the expectancy has on the expecter's behavior, the relationships most often investigated in research on mediation. Equally important to understanding mediation, however, are the C-D relationships between the expecter's behavior and outcome variables. Research bearing on the B-C link tells us which behaviors are induced by a given expectancy, but research bearing on the C-D link assures us that these behaviors affect the expectee so as to create a self-fulfilling prophecy. As is evident, the two types of relationships address different questions, making the B-C/C-D distinction critical.

The Four-Factor 'Theory'

On the basis of the first 30 or so published studies relevant to mediation, a four-factor 'theory' of the mediation of teacher expectancy effects was proposed. The 'theory' describes four major groupings of teacher behaviors hypothesized to be involved in mediation. The first factor, *climate*, refers to the warmer socioemotional climate that teachers tend to create for high-expectancy students, a warmth that can be communicated both verbally and nonverbally. The *input* factor refers to the tendency for teachers to teach more material to their 'special' students. The *output* factor refers to the tendency for teachers to give their 'special' students greater opportunities for responding. Finally, the *feedback* factor refers to the tendency for teachers to give more differentiated feedback to their 'special,' high-expectancy students. By differentiated, we mean that the feedback will be contingent on the correctness or incorrectness of the student's response and that the content of the feedback will tend to be directly related to what the student has said.

Subsequent meta-analyses were designed to summarize the many studies examining either the B-C or C-D links (or both) and to come up with a quantitative estimate of the importance

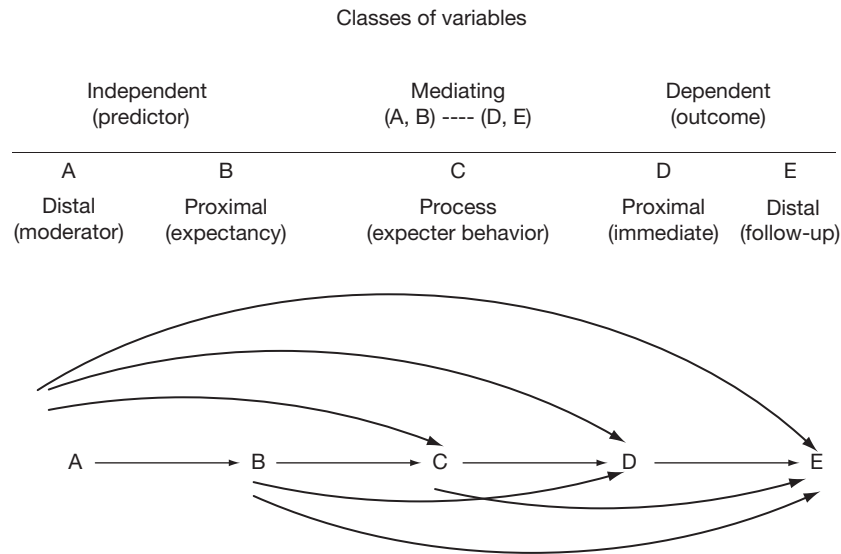

Figure 1 Model for the study of interpersonal expectancy effects.

Table 4 Summary of four factors in the mediation of teacher expectancy effects

Factor	Brief summary of the evidence
<i>Central factors</i>	
1. Climate (affect)	Teachers appear to create a warmer socioemotional climate for their 'special' students. This warmth appears to be at least partially communicated by nonverbal cues
2. Input (effort)	Teachers appear to teach more material and more difficult material to their 'special' students
<i>Additional factors</i>	
3. Output	Teachers appear to give their 'special' students greater opportunities for responding. These opportunities are offered both verbally and nonverbally (e.g., giving a student more time in which to answer a teacher's question)
4. Feedback	Teachers appear to give their 'special' students more differentiated feedback, both verbal and nonverbal, as to how these students have been performing

of each of the four factors in the mediation of interpersonal expectancy effects.

Table 4 summarizes the qualitative evidence for each of the four factors based on the meta-analyses, and **Table 5** gives the average magnitude of the role of each factor separately for the B–C and C–D links. While all four factors received ample support in terms of statistical significance, the magnitudes of the effects for the *climate* and *input* factors were especially impressive. Teachers appear to teach more and to teach it more warmly to students for whom they have more favorable expectations.

From these results, one cannot infer that if one selects warmer and more material-presenting teachers, school children will learn more. One also cannot infer from these results that training teachers to be warmer and more material-presenting

will lead to improved learning on the part of their students. The results do suggest, however, that conducting the research required to determine the benefits of selection and training for *climate* (or affect), *input* (or effort), *output*, and *feedback* may well yield substantial benefits both for science and for society.

Beyond Classrooms and Laboratories

The covert communication mediating one person's expectation for the behavior of another occurs well beyond the confines of the classroom or the cubicles of our laboratories. A meta-analysis of 13 Pygmalion studies conducted in work organizations found a mean overall effect size r of 0.38. In terms of the BESD, a mean effect size r of that magnitude is associated with improving a success rate from 31% to 69%. Larger effects of interpersonal expectations were found when workers' initial levels of performance were low. Larger effects were also found when the experiments were conducted in military rather than in business settings.

Several studies have investigated the effects of judges' beliefs about the guilt of the defendant on the way in which judges deliver their instructions to jurors (i.e., the B–C links described earlier), and the way in which these instructions influence jurors in how they decide on the defendant's guilt (i.e., the C–D link described earlier). In a meta-analysis of four studies, the median effect size r was 0.14, combined $p = 0.0006$, (i.e., 6 in 10 000). In terms of the BESD, the obtained median effect size r is associated with a change in the rate of findings of guilty from 43% to 57% as a function of being instructed by a judge who believes a defendant to be guilty rather than not guilty. It should be added as a methodological note that the defendant the judge believed to be guilty versus not guilty was not the same defendant whose case the jurors were trying to decide. Jurors saw a videotaped trial with defendant A but were given their instructions via videotape by a judge who was actually instructing a different jury with a different defendant, B.

Table 5 Meta-analytically derived average correlations indexing the effect sizes of the four-factor theory

Factor	Correlation between expectation and expecter's behavior (B–C link)	Correlation between behavior of expecter and response of expectee (C–D link)	Mean correlation
1. Climate (affect)	0.23	0.36	0.30
2. Input (effort)	0.26	0.28	0.27
3. Output	0.18	0.16	0.17
4. Feedback	0.13	0.08	0.10

Source: Harris MJ and Rosenthal R (1986) Four factors in the mediation of teacher expectancy effects. In: Feldman RS (ed.) *The Social Psychology of Education*, pp. 91–114. New York, NY: Cambridge University Press.

Note: All correlations are significantly greater than zero at $p < 0.002$, that is, <2 times in a thousand.

The correlation between the magnitudes of the average B–C and C–D links is 0.88.

There have been few randomized experiments in which health care workers' expectations have been raised for the health outcomes of their patients. One such study was conducted in a nursing home context; it was found that raising caretakers' expectations led to a reduction in the depression levels of the residents.

Not all of the relevant research on covert communication has been directly in the context of the mediation of interpersonal expectancy effects. For example, some recent work on what has been called 'thin slices of nonverbal behavior' has dealt with the tone of voice that primary care physicians and surgeons use when talking with their patients. Clinicians who had never been sued were compared with those who had been sued at least twice. Surgeons who were more bossy in tone of voice, and primary care physicians who seemed to care less about their patients, judging from their tone of voice, were those more likely to be sued. A good deal earlier it had been found that physicians' tone of voice in talking about patients was substantially correlated with physicians' success rates in getting alcoholic patients to enter treatment.

Of special interest to those who teach and are evaluated at the end of the term by their students is the research showing just how easy it is to predict how students will evaluate their instructor's overall effectiveness at the end of the term. All it takes is showing 30 s of a videotape of instructors' teaching behavior, with the sound turned off, to undergraduate raters of nonverbal behavior. Nonverbal warmth, enthusiasm, likability, etc. as rated by these undergraduate raters predicts the subsequent overall effectiveness ratings made by our students with $r = 0.76$; a replication study in a high school rather than a college setting yielded $r = 0.68$. In further studies, when the 30 s of silent videotape was reduced to 6 s, predictive accuracy decreased but remained remarkably high: $r = 0.71$ for college teachers, $r = 0.31$ for high school teachers.

These studies turned out not to be aberrant. In a meta-analysis of 38 independent studies using thin slices of behavior (5 min or less), considerable accuracy of predictions of various objective outcomes were found in the areas of social and clinical psychology, with an overall mean effect size r of about 0.40. Perhaps most surprising was the result that accuracy did not increase as exposure length was increased from 30 s to 5 min; nor did it increase for a series of studies based on quite thick slices of behavior covering spans of hours and even days.

Conclusion

Some processes of covert communication in classrooms, clinics, and courtrooms, and in the cubicles of corporations and of laboratories have been described. The primary emphasis has been on processes in which the expectation of one person (a teacher, a health care provider, a judge, an executive, or an experimenter), for the behavior of another person (a pupil, a patient, a juror, an employee, or a research participant), has come to serve as a self-fulfilling prophecy. The behavior expected actually came to pass *because* the expecter expected it.

That causal conclusion can be drawn because of the hundreds of randomized experiments that have been conducted, reported, and summarized quantitatively. However, there is still much that is not known. It is not known precisely what changes in the expecter's verbal and nonverbal behavior are brought about by changed expectations nor is it known precisely what elements of these changes are causal in bringing about the behavior changes seen in expectees.

As more is learned about various processes of covert communication, more is learned about what it is we do *not* yet know. But that should not be discouraging; it just shows the normal progress of the science of human behavior.

Glossary

Action plans The 'if-then' links between environmental stimuli and the desired behavioral outcome. Action plans specify when, where, and how one will strive to obtain that chosen goal.

Behavior change processes Processes including motivational stages (strengthening motivation and developing new behavioral goals), action stages (adoption and maintenance of the new behavior), and relapse stages (returning to old behavioral habits). Transition from stage to stage is a function of self-regulatory processes.

Behavioral intention or goal Intentions are self-instructions to perform particular behaviors

or to obtain a certain outcome. Proximal goals (or intentions) indicate how hard an individual is willing to try to perform the target behavior or pursue the outcome. Goal setting includes processes of selecting behaviors, capturing the motivational factors.

Self-efficacy Beliefs about the ability to attain goals regardless of challenges, and internal or external barriers, arising during the goal pursuit.

Self-regulation Processes of management of thoughts, attention, emotion, and impulses. Self-regulation has an ultimate aim of reaching goals in an efficient way.

Introduction

Self-regulation is a volitional process of managing one's own thoughts, feelings, impulses, and reactions aiming at goal attainment. Simple and direct processes translate into a complex function, regulating intentional behavior. Self-regulation takes place when information about the current state is used to manage this state. According to major theoretical models of self-regulation, achieving self-regulatory efficiency is a function of balance between planning, initiating, and maintaining behavior patterns oriented toward achieving realistic goals. The withdrawal of engagement should follow if the goal becomes unattainable. Self-regulation is a cyclical process. Thus, monitoring and memory processes are crucial to the efficiency of self-regulation. Fixed patterns of behavior are ineffective as people need to constantly adjust to changing conditions.

As a result of natural selection, self-regulation in humans appears to be greater than among other species. It may be assumed that self-regulation is one of the qualities specific to the human species. Self-regulation research derives from several competing areas. Most of the conceptualizations, however, share the same basic assumptions. For example, theory and research clearly point to the fact that most of the behavior is goal-oriented. In this context, self-regulation is understood as a process of controlling responses in order to achieve a desired end state.

Self-regulation skills may have a function of attention and emotion control. Attention regulation deals with the ability to organize incoming stimuli in order to maintain a calm state of mind, delay gratification, tolerate change, and create the cognitive and behavioral response to selected stimuli exclusively. Processes of attention regulation depend on central nervous system characteristics and abilities of the brain to transform sensory data into organized neural impulses, which also suggests that attention regulation might be a relatively stable

characteristic of an individual. Attention self-regulation enables the individual to attend to relevant (voluntarily selected) environmental stimuli and to reduce the interference by irrelevant stimuli. Another aspect of regulatory skills portrays the ability to regulate and selectively attend to information that originates from within, for example negative emotions. Self-regulation of emotions is defined as modification of subjective experience of emotions in such a way as to optimize some personal goals. Thus, low self-regulation of negative emotions results in inability to stop experiencing negative emotions, rumination, preoccupation with current emotions, and difficulties with disengagement from their current emotional state.

In adopting a desired behavior, individuals first form a goal and then attempt to execute the action. Goals serve as self-incentives and guides to behaviors. A distinction can be made between distal goals and proximal goals. The latter regulate the amount of invested effort and guide action. Intentions, as defined in other social cognitive theories, are more similar to proximal goals than to distal goals. Terms such as 'I intend to' or 'I aim to' reflect goals, with all major theories agreeing that goals or intentions should be as specific as possible in order to facilitate subsequent action. In any case, goals (or intentions) are seen as direct and sometimes sufficient predictors of behavior. People tend to focus on multiple goals. These goals may compete or produce synergistic effects. Either achieving or failure in achieving a goal results in emotional and motivational consequences. Thus, attention and emotion self-regulation, goal setting, goal attainment, and affect are closely related to each other.

The science of intentional behavior and self-regulation often accentuates processes of planning. People formulate conditional plans of taking specific action in response to particular circumstances. Contrary to unconditional goals, conditional planning assumes that behavior is triggered with regard to specific conditions. In general, action planning is an extension

of an intention as it includes specific situation parameters and a sequence of action. Action plans specify when, where, and how the intention will be implemented. A different way of planning is the anticipation of barriers and generation of strategies to overcome them. This has been called coping planning. People may imagine scenarios that hinder them in performing their intended behavior, and they develop one or more plans to cope with such a challenging situation. Coping planning might be a self-regulatory strategy which augments the effects of action planning, partly because it implies action planning. After people contemplate the when, where, and how of an action, they imagine possible barriers and generate coping strategies.

Self-monitoring is an umbrella term for the self-regulatory processes enabling an individual to detect the discrepancies between the goals and actual behaviors. Self-regulation systems should allow for detecting discrepancies, varying in terms of the size and relevance. In general, the sensitivity to errors varies intra- and interindividually. The self-monitoring processes of high sensitivity promote fast response to discrepancies, prompt action before the discrepancies are too large, and precisely detect even small differences between the goals and behaviors.

One of the fundamental concepts connected to research on self-regulation is metacognition. Metacognition is known as the 'cognition of cognition,' a process in which an individual consciously monitors and controls their cognitive functions. Metacognition processes derive information about the cognition through the monitoring process. At the same time, metacognition informs cognition with the control process. We are thus able to reflect on our own cognitive processes and exert conscious control upon them. One of the facets of metacognition is the metacognitive knowledge, a construct strictly related to the monitoring function. Metacognitive knowledge is organized in a declarative belief system including models for cognitive processes such as language or memory. Metacognitive knowledge includes information regarding ongoing tasks, applied strategies, and selected goals, in the context of the environmental changes. This type of knowledge develops continually, through conscious observations on outcomes of our own actions, undertaken in different situations.

Leading Theories of Self-Regulation

There have been many conceptualizations modeling the underlying mechanisms of self-regulatory processes. Five major theories are discussed in this section. We start with the model of self-regulation by Carver and Scheier, and briefly summarize Baumeister's strength model, social cognitive theory by Bandura, Kuhl's theory of personality systems interaction, and Strack and Deutsch's reflective-impulsive model of self-regulation.

Carver's and Scheier's Self-Regulation Model

According to Carver and Scheier's model of self-regulation, human behavior is oriented toward reducing the perceived difference between the desired end state and the current situation. The process begins with a comparison between the desired state and the perceived present state. If the desired

standard is not met, an individual begins to take action in order to change the current situation to the point when subsequent 'adequacy tests' eventually show that the desired goal has been reached.

The perception of a goal being distant intensifies efforts undertaken in order to reach it. Consequently, when the perceived discrepancy between the current situation and one's goals is a continuing state, a modification of the desired end result may be initiated as a function of time and experience. That is to say, failure in achieving success results in the restriction of a person's goal. The process of abandoning a goal or developing a new one is referred to as limited disengagement.

According to Carver and Scheier, self-regulation acts as a negative feedback system reducing the discrepancies between current and desired states. The person's assessment of the current situation is the input and the person's behavior the output of the feedback system. One of the core ideas of the model is that the perceived pace at which a person approaches his or her goals has affective consequences. When the rate of progress toward the desired end state is greater than expected, positive affect is induced. A slower pace results in negative affective reactions. Emotional changes result from a variable rate of progress while constant rate does not evoke emotional changes.

Carver and Scheier assumed that both our goals and behavior are organized hierarchically. At lower levels, our goals are concrete and practical and they gradually become more abstract and conceptual toward the higher levels. People focus on an ideal self which then translates to corresponding principles. As a response, adequate behavior is being triggered. According to this theory, the attainment of high-level goals is only possible when the lower level behaviors are performed antecedently. Moreover, the success in reaching high-level goals is a function of the consistency between goals at antecedent levels. Emmons performed a rather sensible summary of the concept stating that "The most adaptive form of self-regulatory behavior may be to select concrete, manageable goals that are linked to personally meaningful, higher order representations."

Some critique of the model states that Carver and Scheier's theory is limited solely to mechanisms of either maintaining or withdrawing efforts concerning selected goals. The theory doesn't account for the nuances of the initial process of goal setting; hence, to some degree it omits individual differences in the perceived importance attached to different goals. The process of goal attainment requires a broader theoretical perspective.

Personality Systems Interactions Approach to Self-Regulation

The core idea of Kuhl's personality systems interactions theory states that human motivation is controlled by regulatory systems organized in a hierarchical manner. Similar to other conceptualizations, Kuhl postulated the existence of specific processes that manage the initiation and maintenance of goal-oriented behavior. The processes are triggered in cases where automatic behavioral responses prove to be inadequate. One of the crucial self-regulatory processes is self-discrimination. It refers to the ability to distinguish one's own conceptions from other's beliefs, desires, and expectations. Self-regulation processes are present and effective when the intentional behavior

is self-related. Intentional behavior should at all times conform to current circumstances in order to adapt to changing situations. Using an internal-control pattern enables an individual to flexibly choose between maintaining a behavioral pattern and disengaging from his or her initial intentions. According to Kuhl's theory, adapting to ever changing demands is the very essence of self-regulation processes.

The model assumes that several regulatory systems work with each other to perform self-regulatory functions. Seven levels of regulation can be roughly divided into three basic categories from elementary sensations and intuitive behavior, through affective control, to sophisticated cognitive processes. Self-regulation is a product of an interaction between goal enactment and self-development. Goal enactment processes consist of abstract goal representations put into concrete actions by intuitive behavior. Self-development functions by way of including new experiences in a person's network of accumulated experience. Both systems are strongly related to a person's affect. In states of low positive affect, goal representations become accentuated while high positive affect puts emphasis on intuitive behavior. States of high negative affect elicit increased object recognition at the expense of extension memory. The opposite happens when negative affect is low; in those cases, the process focuses on extension memory.

Social Cognitive Theory

According to social cognitive theory (SCT), human motivation and action are extensively regulated by forethought. This anticipatory control mechanism involves expectations that might refer to outcomes of undertaking a specific action. The theory outlines a number of crucial factors that influence behavior. The crucial factors are perceived self-efficacy beliefs and outcome expectancies, which promote behavior change and behavior maintenance. Besides these two cognitions, SCT also includes goals, perceived impediments, and opportunity structures in the environment of the individual.

Outcome expectancies are the other core construct of SCT which are concerned with people's beliefs about the possible consequences of their actions. Outcome expectancies can be organized along 3D: (a) area of consequences, (b) positive or negative consequences, and (c) short-term or long-term consequences. The area may refer to physical (e.g., health-related), social (e.g., social response to behavior change, such as disapproval or acceptance), or self-evaluative consequences (e.g., such as being ashamed, being proud of oneself, or satisfied with oneself).

Perceived self-efficacy represents the confidence that one can employ the skills necessary to resist temptation, cope with stress, and mobilize one's resources required to meet the situational demands. Self-efficacious individuals believe in their own capabilities to perform specific actions required to attain a desired outcome. Self-efficacy beliefs represent self-regulatory cognitions that determine whether instrumental actions will be initiated, how much effort will be expended, and how long it will be sustained in the face of obstacles and failures. Persons with low self-efficacy harbor pessimistic thoughts about their likely accomplishments and personal development. Self-efficacy beliefs affect the amount of effort to change undesired behavior and the persistence to continue

striving in the face of barriers and setbacks. Self-efficacy may be of a general character (i.e., generalized beliefs about ability to cope with various barriers arising during the processes of goal pursuit) and behavior- or domain-specific (i.e., referring to condom use, physical activity, and academic achievements). Further, efficacy beliefs may be specific for stages of behavior change, that is, they may refer to barriers specific for forming intention, processes of initiation of behavior change, maintenance of desired behavior, and relapse prevention (or a reduction of the scale of relapse). Self-efficacy is based on different sources, such as an experience of personal mastery, observing a model who is successfully acting upon his or her intention, verbal persuasion by others (e.g., role models), and positive emotions.

Baumeister's Strength Model of Self-Regulation

In Roy Baumeister's strength model, self-control is regarded in analogy to a working muscle. According to the theory, self-regulation derives from a global resource which, when depleted, disenables an individual from continuing the self-regulation process. Just as a muscle requires energy in order to retain effort through a period of time, the self-regulatory processes draw strength from a specific supply that is limited in its nature. When facing demanding circumstances for the self-regulatory processes over a prolonged period of time, people develop a growing level of fatigue which leads to self-regulatory failure. In accordance to Baumeister's findings, performing continuing acts of self-control leads to a dropdown in performance of the subsequent self-control responses. Baumeister refers to this state of energy exhaustion as ego depletion. The model expands on the muscle analogy and claims that the self-control reservoir can be replenished through rest and relaxation.

The theory further suggests that the mentioned strength supply is used for various volitional processes, be it controlled processing, active choice, initiating behavior, or overriding automatic responses. A substantial part of self-regulation deals with resisting impulses, and thus it should be regarded within the same categories as motivation. One of the obvious dimensions of motivation is the strength aspect. According to the theory, if motivation can be placed on the strong-weak continuum, then self-regulation should also be regarded as operating in the same plane.

Reflective-Impulsive Model

Strack and Deutsch's model suggests a system of two parallel processes – the impulsive and reflective system – that regulate social behavior. The impulsive system is interpreted as a parallel, fast-paced, and partially automatic activation spread along content associations. Essentially, the impulsive system may be regarded as a basic memory system. Environmental circumstances are associated with corresponding activation patterns. The emergence of subsequent stimuli in spatial and temporal proximity forms stronger links. Such associations may also include behavioral and affective responses.

On the other hand, the reflective system is responsible for rule-based reasoning and symbol manipulation and is the primary resource for self-regulation. The reflective system is a

sophisticated process enabling the use of more complex and flexible relations which at the same time contribute to a decreased rate of processing and reduced stability.

According to RIM, in the process of managing our behavior, the two systems may interact, using different procedures. The reflective system drives behavior by conscious decisions based on probabilistic assumptions. The impulsive system administers behavior according to activation patterns, formed automatically on the basis of previous stimuli and associations. According to the reflective-impulsive model, self-regulation is a process of restraining impulses and changing behavioral responses with the impulsive and reflective systems working antagonistically. The reflective system's ability to influence impulsive reactions is a trait specific to the human species. Similar to Baumeister's theory, it is assumed that people have a limited supply of reflective energy and recurring acts of self-regulation lead to the depletion of the person's resources.

Measurement of Self-Regulation in the Context of Behavior

Assessment of self-regulation mirrors the underlying theory and the conceptualization of self-regulation constructs. For the models applying the approach favoring conscious self-regulation processes, the measurement covers cognitive strategies (specific for the theory), metacognitive strategies (if included in the theory), and respective cognitive and behavioral outcomes. The measurement may range from more global to domain- and situation-specific, referring to motivational and volitional components of self-regulation. Further, the measures cover environmental factors which may interfere or contribute to the pursuit of behavioral goals.

Usually, self-report questionnaires with standardized instructions and response forms are used. This form of assessment is a typical way of evaluating self-regulation in the context of health behaviors, academic achievements, or sport performance. Self-regulation in the context of academic achievements is also evaluated by means of observations of overt behaviors, think-aloud protocols, or interviews.

The example of measurement of self-regulation processes may be derived from recent developments in SCT. This theory suggests that the measurement of the key cognitions should refer to the particular task at hand, specific behavior, and barriers relevant for the target population. For example, if we want to explain adolescents' tobacco use, we should apply self-efficacy referring to refraining from smoking in those situations which increase the risk for obtaining a cigarette. If the aim is to predict diabetes management and the control over diabetes symptoms, then diabetes self-efficacy beliefs should be evaluated. The measure would cover the ability to deal with diabetes-related self-care in the context of the typical barriers that arise when an adolescent tries to integrate diabetes self-care into his or her daily routines. In general, self-efficacy is measured with items referring to respective behavior and expected barriers "I am confident that I can ... (perform an action) even if ... (a barrier)." Intentions are usually measured with items such as "I intend to do X within the next week (day, month, etc.)." In line with other theories, the level of specificity is adjustable. One could say "I intend to swim twice a week,

starting from tomorrow," or one could say "I intend to exercise more in the near future." The semantic structure of outcome expectancies is: "If ... (a behavior), then ... (consequences)." An example of a positive outcome expectancy is "If I exercise more frequently, I will become slim." An example of a negative one is "If I exercise more frequently, I will have less time for my favorite social activities."

As indicated above, researchers have also proposed that self-regulatory cognitions may be measured as more general, or that they should be measured as tailored to particular stages of behavior change. Applying general measures of self-regulatory cognitions may be particularly useful if the investigation aims at predicting a broad range of behavioral outcomes. Measuring stage-tailored behavior may be particularly useful if a target population is in a particular stage of behavior change (e.g., the intervention is applied to adolescents who have not initiated sex life, therefore they are in motivational stage in terms of condom use).

Self-Regulation in the Context of Academic Performance

Self-regulation is frequently applied to explain academic achievements from kindergarten to university education. Regardless of a myriad of research, so far, randomized controlled trials were very rarely conducted in the area of self-regulation and academic achievement; thus, any conclusions should be drawn with caution.

Self-regulated learning is considered one of the key outcomes of the educational process, besides the instruction of factual knowledge. The process of self-regulated learning includes the preaction phase, when a learner sets his or her goals. Applying self-motivation strategies facilitates goal achievement and accentuates personal responsibility. In the action phase, the learner may acquire control over internal resources (e.g., concentration) and master several self-regulatory strategies, including metacognitive strategies (planning and monitoring), resource management strategies (time and attention management) or external regulation strategies, such as support-seeking. Finally, the learner acquires strategies allowing him or her for the evaluation of his or her efforts and strategies enabling dealing with mistakes. Thus, goal attainment should be accompanied by self-reflection processes. Besides learning outcome (i.e., the acquired knowledge), the learning process always results in affective response.

Experimental studies indicate that teaching such self-regulation strategies during regular math classes resulted in a significant increase of motivation, higher overall use of self-regulation strategies, setting higher goals, and an increase of global self-regulation. Although the direct effects on math tests results are only marginally significant, those who participate in such training and show an improvement in their self-regulation skills have significantly better results of math tests at follow-ups. Studies using randomization and experimental design indicated that the type of teaching strategy (i.e., an instruction method) may influence not only students' achievements but also their use of self-regulation strategies such as self-monitoring and knowledge acquisition strategies, as well as their self-efficacy beliefs. When prompting self-regulation

development is considered as the main outcome, concept mapping strategy turns out to be significantly more effective than individual study methods.

Recent experimental research also indicated that using computer programs fostering self-regulation skills during mathematics learning may affect the results of learning. In particular, programs training metacognitive control (planning and monitoring) enhance use of control strategies. Such programs also lead to better knowledge acquisition. Further, experimental studies show that metacognitive prompting interventions for science, which include metacognitive skills training during the phases of forethought, performance, and self-reflection, resulted in higher academic achievements. Encouraging students to reflect on their observations and conclusions and prompting them to compare their results with the expectations of the scientific community promotes progress in students' content knowledge. Further, participating in metacognitive prompting interventions resulted in a reduction of making decisions based on authority. By contrast, an increase of the frequency of making decision based on evidence was observed.

As indicated, models of self-regulatory learning assume that the main results of self-regulatory learning include both learning outcomes (academic achievements) and affect or well-being outcomes. Theory of self-regulation assumes that intrinsic self-regulation is the most autonomous form of self-regulation (people freely chose an activity out of a sense of interest). It is assumed that intrinsic self-regulation is superior to the identified regulatory style (the individual recognizes and accepts the value and importance of a behavior and integrates the behavior into the self). Experimental research supports this hypothesis, showing that intrinsic self-regulation is related to children's well-being at school, and also to better academic performance over longer periods. Identified regulation is also a good predictor of academic achievements, but only a combination of high school grades and high identified self-regulation was predictive of better well-being.

Self-Regulation in the Context of Health Behavior Change

Self-regulatory cognitions influence behaviors in different health domains, such as adherence to medication, recovery from disease, and dealing with pain. Further, the role of self-regulation is frequently analyzed in the context of initiating health-promoting behaviors, such as physical activity and healthy nutrition, and ceasing health-compromising actions, such as cigarette smoking, illicit drug use, and unsafe sex practices.

Researchers analyzing the role of the self-regulation strategies in health behavior change frequently apply SCT, Carver and Scheier's control model, information-motivation-behavioral skill model by Fisher and Fisher, and theory of planned behavior. Recent taxonomy of health behavior change interventions assumes that conscious self-regulatory processes form the backbone of the behavior change. Abraham and Michie proposed a list of 26 theory-based health behavior change techniques, which are most frequently applied in the health behavior change intervention. The taxonomy includes such self-regulatory strategies as prompting self-monitoring of behavior, specific goal setting, using feedback on performance,

planning social support or social change, prompting self-talk, task grading, barrier identification, intention formation, analysis of behavior consequences, and analysis of behavior-health link.

Recent systematic reviews allow for a synthesis of the accumulating research evidence in the area of self-regulation and health behavior change. For example, an increase of physical activity is likely to be obtained if the interventions apply self-regulatory techniques focusing on strengthening self-efficacy beliefs and focus the participants on positive expected outcomes. Other systematic reviews suggest significant relationships between goal formation (and intention strength) and health behavior (such as physical activity) as well as significant associations between forming actions/coping plans and nutrition (in particular, moderate effects were observed for adoption of healthy diet, smaller effects are observed for a reduction of unhealthy nutrition habits).

The number of experimental studies on the effects of self-regulatory interventions on health behavior and health-related outcomes is impressive. There are, however, some serious limitations. Research rarely showed that behavior change is mediated by the change in self-regulation. Only a few studies indicated that the change in health behavior or health-related outcomes is indeed a function of a change in an application of self-regulation. For example, our study suggested that overweight and obese women who participate in a training prompting their abilities of planning significantly reduced their body weight, compared to controls who received a standard care. The effect of the intervention was completely mediated by an increase of the use of physical activity and nutrition planning. However, a vast majority of experimental research has not shown the mediating effect of a shift in self-regulation. Such a mediation effect is required if one wants to assume that the effects of self-regulation-enhancing interventions are indeed due to changes in self-regulation processes. A recent systematic review conducted in the context of addition behaviors points out that although self-regulatory interventions promoting behavior change result in a change of behavior or self-regulatory beliefs (such as self-efficacy), the evidence that the behavior change is actually mediated by a change in self-regulation is actually very weak. In sum, further research is pending, before stronger conclusions about the role of self-regulation may be drawn.

Experimental and longitudinal research explaining health behavior change also showed that the self-regulatory cognitions may operate in a specific order, or acquiring higher self-regulatory skills in one area may be a condition for the effective use of other self-regulatory skills. There is sufficient evidence to assume that strong intentions (proximal goals) are prerequisites for obtaining beneficial effects of planning strategy. Thus, self-regulatory training may first focus on forming realistic goals and strengthening the willingness to engage in those goals and then teach participants how to form effective action plans. Further, the effects of a prompting action planning intervention are moderated by the self-efficacy beliefs. For example, our studies indicated that participants of nutrition planning intervention who have strong baseline nutrition self-efficacy are able to change their nutrition more effectively than participants of the planning intervention who have weak baseline self-efficacy or suffer a decline in nutrition efficacy beliefs.

Thus, teaching planning self-regulatory skills should follow after the training which enhances self-efficacy. Systematic reviews suggest that the largest effects on self-efficacy may be expected, if the intervention includes feedback on past or other's performance.

Self-Regulation in the Context of Sport Performance

Basic rules of interventions aiming at the performance enhancement in sports are drawn from self-regulation theories. Professional and elite sport players are constantly confronted with strenuous training, competition, and evaluation, as well as a need to balance personal life and sport career demands. Thus, self-regulation may be considered a prerequisite to achieve progress in physical skills and in achieving elite status. Self-regulation strategies are usually acquired in the process called mental skills training. Mental skills training aims at helping athletes to attain optimal personal development, management of one's own psychological and physical states, achieving optimum of psychological functioning, and enhancing learning (of physical and mental skills) by means of activating self-regulatory processes.

It is assumed that the acquisition of four groups of mental skills by athletes and their coaches affects sport performance and athlete well-being. The first group, called foundation skills, includes: (1) training of productive thinking (management of thoughts in order to effectively prepare and respond to life events, training, and competition), (2) building up self-confidence (or self-efficacy), (3) increasing self-awareness of physical processes in athlete's body, (4) introspective and retrospective analysis and understanding of the interactions between thoughts, feelings, and behaviors. Performance self-regulatory skills refer to attentional focus and energy management. Personal development skills refer to regulatory abilities aiming at developing interpersonal competences. Finally, team skills deal with all self-regulation skills, which are used to building the leadership competencies, effective team communication, fostering team cohesion, and confidence.

There is a variety of mental skills-training components, but only four sets of self-regulatory techniques were investigated more thoroughly. The studies applied experimental design and focused on adolescents involved in sport training and on adult elite and nonelite athletes.

First technique refers to use of imagery or visuomotor behavioral representation. Imagery technique develops 'mental blueprints,' representing perfect behavioral responses in a specific situation. Imagery may include both physical and visual representation of a sequence of actions which will be implemented in a training situation or during a competition. An application of such technique aims at boosting self-confidence, attention control, reducing harmful effects of sub-optimal activation, and promoting visual search abilities. It also improves performance satisfaction and cohesion of sport performance.

Goal setting represents second crucial self-regulatory technique. This technique promotes speedy progress in physical skills training and thus prompts performance improvement. Athletes are taught to plan, set, focus on, evaluate, and manage their behavior in the perspective of the self-selected goals.

It is suggested to use goal setting systematically, as systematic use promotes better attention focus and results in increased efforts. Sport psychologists differentiate between outcome (e.g., winning the competition, not really controllable), performance (flexible, allowing to raise the levels of specific skills continually), and process goals (enabling athletes to focus on specific demands created by the current situation, the promotion of coping with the situation in a most effective way). Goal setting techniques are moderately related to the sport performance. Training goal setting (including individual and team goals) may be more useful in earlier stages of sport career.

Next self-regulatory technique, called self-talk, encompasses a range of self-regulatory skills of using verbal dialogue and evaluations in order to interpret and manage emotional states and perceptions. Self-talk also aims at giving oneself instructions or reinforcements. Self-talk may include positive thinking and positive reinterpretation, blocking distractions, and perspective talking. This technique is used more consistently and for longer time periods by elite athletes, compared to those in earlier stages of their career. It enhances skill acquisition and performance (e.g., precision of shooting). One of the main consequences of using self-talk is a reduction of anxiety and arousal during the competition, psyching oneself up during training or while competing in endurance sports, relaxing and calming down, managing confidence, and reinforcing oneself after an effortful trial.

The final component of mental training in sport refers to the relaxation techniques. These techniques are used to manage physical energy levels. Applying physical relaxation helps athletes to reduce somatic aspects of anxiety. Relaxation may include restricted emotional stimulation, inducing deep relaxation state prior to the competition. Such self-regulation strategies may enhance performance of fine motor tasks, requiring high precision. Cognitive relaxation techniques may help athletes to reach their individual optimal zones of arousal and mobilization, which in turn may affect sport performance.

Recent research indicated that the effective mental skill training should include a combination of self-regulatory skills. Randomized controlled trials showed that visuomotor behavior rehearsal combined with self-talk or a combination of goal setting with activation regulation techniques (relaxation) and self-talk may result in performance improvement in sports.

Self-Regulation and Coping Behaviors

Self-regulatory cognitions determine the ways individuals perceive and cope with stress and therefore they influence mental and physical health, as well as any behaviors at stress. According to Carver and Scheier's approach to self-regulation, coping behaviors reflect the self-regulatory efforts at the time of stress. The commonsense model of self-regulation, developed in the context of illness, assumes that perceptions related to illness may influence coping responses (i.e., coping aiming at emotion regulation and problem-solving coping). In turn, coping efforts predict emotional response and such behaviors as the use of external resources, management of one's own symptoms, and adherence to recommended behavior change.

A large body of evidence on the role of self-regulatory beliefs in predicting coping with stress refers to the effects of

self-efficacy. For example, self-efficacious individuals perceive stressful situations as challenging and controllable, which may reduce the negative impact of stress on health. SCT suggests that self-efficacy is a resource determining the way individuals cope with stress. In particular, efficacy beliefs facilitate the selection of active coping strategies, increase coping effectiveness, affect mental health directly, and buffer stress indirectly (reducing negative affect). Self-regulatory beliefs, such as self-efficacy are seen as a proximal determinant of physiological stress response, affecting levels of cortisol, catecholamines secretion, and immune system response. It is assumed that because self-regulatory cognitions determine that a stressful situation is perceived as manageable, the neuroendocrine and immune response to stress is reduced, and therefore a stressful situation becomes less harmful to physical and mental health. Systematic reviews indicate that a combination of specific coping strategies (low passive coping, such as wishful thinking, self-criticism, and social withdrawal), accompanied by high self-efficacy, is an important predictor of well-being among people with diseases inflicting chronic pain. Similar conclusions may be drawn from systematic reviews of research in the area of adaptation among patients with cancer. Those patients who use problem-focus coping and harbor high self-efficacy beliefs have better emotional adjustment.

Another construct which has been developed in the context of self-regulation theories and theories of coping with stress refers to proactive coping. This construct refers to processes of anticipation or detection of potential stressors and acting before the situation arises in order to reduce its negative impact. Aspinwall and Taylor suggested that proactive coping develops in several stages, such as resource accumulation (e.g., social support-seeking), recognition of potential stressors, initial appraisal, preliminary efforts to cope, and the use of feedback regarding the effects of one's own coping efforts.

Conclusions and Outlook

Self-regulation science of the last two decades offered a major development in self-regulation theories. Models assuming conscious self-regulation evolved into models encompassing both conscious and impulsive (automatic) processes. Although the area of self-regulation had drawn major attention and resulted in a large body of empirical evidence, the quality of this evidence varies, depending on the area of studies or a target behavior. Our review indicates that although thousands of studies analyzed the use of self-regulatory strategies in the context of behavior at school, students' well-being, and their academic achievement, the list of randomized controlled trials is very short. Thus, there is a need of high-quality trials showing the effectiveness and superiority of self-regulated

learning over standard treatment/control condition. The role of self-regulation in predicting health behavior change has been studied more thoroughly, applying lines of experimental trials. The research, however, provides a limited experimental evidence for the assumption that the change in specific self-regulatory skills (trained in the intervention) mediates the change of health behavior. Recent years brought major developments in the area of sport-related behaviors and interventions addressing self-regulatory skills, aiming at optimal behavior in training and competition. Although sport psychologists provided detailed self-regulation intervention protocols (which are pretty detailed, as compared to descriptions of health behavior change interventions), the effects of these protocols were rarely evaluated in randomized controlled trials. In sum, across analyzed domains, the evidence for the effectiveness of the interventions promoting self-regulation is weak. Longitudinal and experimental trials, accounting for mediating processes of change in self-regulatory skills, are necessary to advance science of self-regulation.

Self-Relaxation

J C Smith, Roosevelt University, Chicago, IL, USA

© 2012 Elsevier Inc. All rights reserved.

Glossary

Autogenic training A suggestion-based approach to relaxation and 'self-healing.' Beginning exercises focus on passively thinking physical relaxation-related phrases such as 'hands warm and heavy.'

Breathing exercises Relaxation exercises targeted to enhance deep, even, and slow breathing with enhanced use of the diaphragm.

Imagery Relaxation exercises that focus on passively engaging in nongoal directed fantasy involving a relaxing setting or activity.

Meditation Relaxation and focusing exercise that involves passively directing attention to a simple stimulus.

Mindfulness Relaxation and focusing exercise that involves passively attending to spontaneously emerging stimuli while avoiding judgment, analysis, or effortful mental processing.

Progressive muscle relaxation Relaxation exercise that involves tensing up and letting go of targeted skeletal muscle groups.

Relaxation response Diffuse nonspecific reduction in physiological arousal that is generally the opposite of the stress arousal response.

R-state Relaxation state, or empirically defined psychological states, associated with the practice of various approaches to relaxation.

Self-stressing The voluntary triggering or maintaining of stress arousal through stressed posture or position, tensing skeletal muscles, stressed breathing, stressed body focus, stressed emotion, or stressed attention.

Stretching Relaxation strategy central to Hatha yoga that involves slowly, smoothly, and gently engaging stretching and maintaining balanced stretched positions.

Yoga General term for a cluster of ancient religious, philosophical, and relaxation disciplines, most often associated with stretching and maintaining special postures and positions.

Relaxation is perhaps the most widely applied tool in stress management as well as in complementary and alternative medicine. Thousands of techniques have evolved over the millennia from religion, philosophy, medicine, and psychology. Controversies exist concerning whether all techniques have the same effect or whether different approaches work for different individuals and goals.

Relaxation as Reduced Arousal: The Relaxation Response

Walter Cannon and Hans Selye helped popularize the notion of stress as increased physiological arousal. Mediated largely by the brain's hypothalamus and the sympathetic nervous system, the stress arousal response automatically awakens and energizes the body for emergency action in what is traditionally termed the 'fight or flight response.' The fight or flight response is automatically integrative, adaptive, and helps us respond to emergencies. Its effect can be immediate and prolonged. However, prolonged activation has its costs, contributing to an increased propensity to display high levels of chronic stress arousal.

Stress arousal can make one more vulnerable to, less likely to recover quickly from, and more likely to suffer complications from a wide range of diseases. Put simply, intense and chronic activation of the stress response subjects the body to measurable wear and tear. Our organs were not meant to continue in a state of emergency readiness for long periods of

time without showing some wear and tear. Second, although brief stress can boost the body's immune system, too much stress interferes with immune functioning, making one more vulnerable to illness and less likely to heal and recover quickly. Wear and tear as well as impaired immune functioning are two important reasons why stress can be unhealthy.

Severe and prolonged stress can also have a detrimental effect on how well one performs the tasks of living. Eventually attention is reduced and one is likely to let important stimuli go unnoticed. Behavior is more rigid and less flexible; creativity is impaired (one can get 'stuck in a rut,' trying over and over the same unsuccessful coping strategies). Memory is impaired. Energy reserves are depleted and one is more likely to experience fatigue.

In the early 1970s, Harvard cardiologist Herbert Benson found that practitioners of transcendental meditation show a constellation of physiological changes suggesting deepened relaxation. These include the mirror opposite of the stress response – reduced heart rate, blood pressure, respiration rate, brain wave activity, and so on. Benson's research was not only partly responsible for increasing public and scientific interest in meditation, but he popularized a definition of relaxation as generalized reduced arousal, the 'relaxation response.' Any approach to relaxation, not just meditation, evokes the relaxation response and has the potential for protecting against over-stress and promoting stress recovery. Activity of the sympathetic nervous system, dominant during stress arousal, lessens whereas the parasympathetic nervous system (responsible for recovery and rest) becomes more dominant.

Neuropsychological Conceptualizations of Relaxation

Relaxation response definitions state that all approaches to relaxation should be equally effective as long as they evoke the relaxation response. Indeed, this is one reason why most stress clinics rely on one or two approaches. However, contemporary neurophysiological views of relaxation suggest that different approaches have quite different relaxation effects and work for different people. Self-stressing models (see below) place a bit more emphasis on neurophysiological variables whereas other models focus more on psychological states of mind, or 'R-States,' associated with relaxation (such as mindfulness, feeling rested). The author's research itself (Smith, 2006) suggests a surprising cornucopia of such psychological states, each reported during practice of relaxation. It is beyond the scope of this article to elaborate on these R-States. Briefly, they seem to sort into five categories: Withdrawal and Release (sleep, reported physical relaxation such as feeling heavy or warm, feeling far away); Basic Renewal (feeling peaceful, at ease, refreshed); Positive Energy (feeling energized, happy, love, optimism); Mindfulness (quiet mind aware, focused); and Transcendence (reverence, awe and wonder). When people practice a relaxation technique, they often experience many things (Figure 1).

Self-stressing and Relaxation

Today, most presentations of relaxation consider a variety of approaches, typically variations of yoga stretching, progressive muscle relaxation, breathing exercises, autogenic training, imagery/positive self-statements, and meditation/mindfulness. Such differentiation is no accident but an inevitable consequence of the very nature of psychological and physiological processes that underlie stress arousal (Smith, 2005). According to self-stressing theory, there are six ways by which we can trigger and sustain physiological stress arousal. Each form of 'self-stressing' suggests a corresponding family of relaxation technique (Smith, 2005).

Stressed posture and position: When confronted with stress, people often assume a variety of defensive or aggressive postures or positions (standing, crouching, bending over a

desk) for an extended time. This, combined with sustained immobility, can evoke skeletal muscle tension, joint stress, and reduced blood flow and contribute to tension, fatigue, and decreased energy. *Stretching approaches to relaxation such as hatha yoga are most associated with stressed posture and position.*

Stressed skeletal muscles: When threatened, one clenches, grips, and tightens skeletal muscles to prepare for attack or escape. When chronic, such tension can contribute to pain and fatigue. *Approaches involving tensing and letting go (progressive muscle relaxation) directly target stressed skeletal muscles.*

Stressed breathing: Under stress, one is more likely to breathe in a way that is shallow, uneven, and rapid, deploying greater use of the intercostal (ribcage) and trapezius (shoulder) muscles and less use of the diaphragm. *Breathing relaxation exercises, woven into many systems especially yoga, target relaxed breathing.*

Stressed body focus: Simply attending to and evoking thoughts and images about a specific body part or process can evoke related neurophysiological changes. An individual facing a threat may notice her rapidly beating heart or churning stomach. Attending to and thinking about these somatic reactions can aggravate them. *Autogenic suggestion approaches involve evoking thoughts and images about specific types of somatic relaxation ('Hands warm and heavy').*

Stressed emotion: We often motivate and energize ourselves for a stressful encounter with affect-arousing cognitions. We entertain fantasies and repeat words and self-statements that can evoke anxiety, anger, or depression. *Imagery and visualization approaches to relaxation involved evoking images and words associated with affective states conducive to relaxation.*

Stressed attention: When dealing with a threat, we actively and effortfully concentrate on attacking, defending, or running. In addition, we often direct our attention to multiple targets, including competing tasks (as in multitasking), a targeted task versus worried preoccupation, or self-stressing efforts (thinking how one is breathing, maintaining a stressed posture or position, thinking about relaxed fantasies or negative emotions, etc.) rather than the task at hand. *Meditation and mindfulness approaches involve calmly and simply attending to a single target stimulus, or the moment-to-moment flow of stimuli.*

In sum, self-stressing theory suggests that the world's diverse rainbow of relaxation strategies can be sorted into six universal family groups, stretching, tensing and letting go (progressive muscle relaxation), breathing exercises, autogenic exercises, imagery, and meditation/mindfulness. Approaches that do not fit neatly in one of these categories are combinations of approaches; for example, the graceful movements of tai-chi blend stretching, breathing, imagery, and meditation.

Self-stressing theory does not claim that one universal family group works only for one type of symptom, for example that progressive muscle relaxation works only for skeletal muscle tension. Instead, the associated self-stressing effect is an *initial effect*, part of the initial core rationale given to practitioners, and an initial procedural self-unstressing strategy. So a client may read that 'progressive muscle relaxation targets the

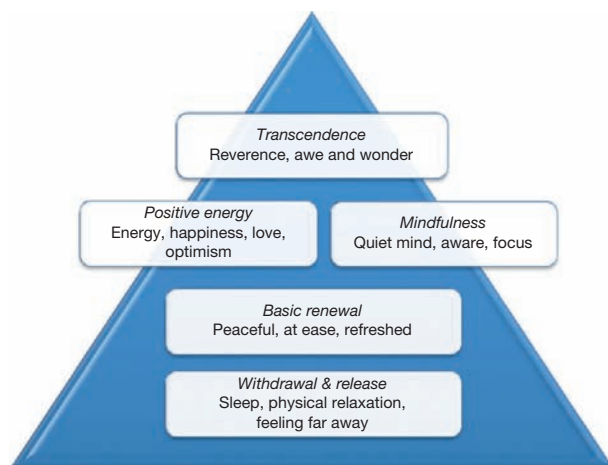

Figure 1 The dynamic pyramid of R-states.

muscles' (a typical rationale) and in the first session be instructed to 'focus on your shoulder muscles and let go' (a beginning procedural instruction focusing on skeletal muscles). Quickly, clients and practitioners discover that eventually *all universal family groups of relaxation can eventually address all components of self-stressing.*

Types of Relaxation

The relaxation practitioner has available thousands of techniques that evolved over several millennia. We have seen that according to the relaxation response perspective, all are interchangeable, as long as they evoke a general relaxation response. Contemporary theories of relaxation, organized under the rubrics of self-stressing and R-State theory, suggest that most approaches fall into one of six universal family groups. This is most clear for self-stressing theories of relaxation. Primarily physical family groups of stretching, progressive relaxation, and breathing exercises, initially targeted to stressed posture and position, muscle tension, and stressed tension. Cognitive family groups of autogenic self-suggestion, imagery and positive self-talk, and meditation/mindfulness target stressed body focus, stressed emotion, and stressed attention. Here we consider each universal family group. It is instructive to note that prior to the advent of relaxation science, advocates of each family group tended to view their approach as the only way to relax. Note that because breathing and stretching exercises share historical roots, we will consider them together.

Illustration of Yoga Stretching Exercise

Let both arms hang to each side. Slowly swing your right hand and arm up tracing a circle in the air to your side. Do this very slowly, smoothly, and gently, as if you were balancing a feather on your fingertips. Let your arm and hand move higher until it is pointing straight up into the sky. Continue attending to your hand and arm and you slowly, smoothly, and gently return it to your side.

Breathing and Yoga Stretching

The histories of breathing and yoga stretching (as well as meditation) are intertwined. Hinduism, one of the ancient religions of India, has incorporated a diverse assortment of yoga stretching, breathing, and meditation exercises for thousands of years. In the second century BC, such exercises were codified in the yoga aphorisms of Patanjali. Patanjali emphasized an eight-step path for cultivating a meditative state of mind conducive to spiritual insight. The steps included various initial ascetic practices, yoga postures and stretches, breathing relaxation exercises, and finally meditation. The easiest of meditative practices, often called concentrative meditation, involved withdrawing the senses from the troubling and distracting influence of external stimuli, memories, and so on, and concentrating on a single point.

Through the centuries, numerous divisions of Hindu thinking appeared, some emphasizing devotion to a theistic God and others an impersonal nontheistic absolute (the 'flow of energy everywhere,' 'consciousness and being'). This latter position, associated with the eighth century Indian philosopher Shankara, was eventually to form the basis of most Western

forms of Hinduism, yoga, and meditation, including transcendental meditation.

Many yogas

Yoga is primarily associated with exercises involving stretching and maintaining various postures (Smith, 2006). However, there are many approaches. There is no single yoga tradition. Over the past 5000 years, thousands of exercises and hundreds of systems have evolved. Indeed, someone who claims to 'practice yoga' has said very little about what she actually does; she might as well claim to 'practice fitness,' 'do holistic health,' or 'believe in moral living.' Some of the specific systems include hatha yoga, prana yoga, kundalini yoga, bhakti yoga, raja yoga, kriya yoga, and tantra yoga. Every year, a new yoga system emerges.

Some preliminary distinctions can be made. Hatha yoga focuses on stretching and maintaining specific postures (such as the famous 'lotus' cross-legged sitting position) and to some extent developing muscles; prana yoga focuses on breathing; kundalini yoga emphasizes chakra energy centers in the body, bhakti emphasizes prayer and worship, raja yoga focuses more on philosophical inquiry, kriya yoga tends to consider sources of energy, and tantra yoga is often associated with sexuality.

It should be noted that in the West simple stretching exercises can be traced back to Olympic athletes in ancient Greece. Such exercises, although sometimes similar to hatha yoga, have primarily been used to prepare for and recover from athletic activity. Other contemporary fitness routines, ranging from the Alexander technique to Pilates, incorporate some form of stretching.

Many breathing exercises

As we have noted, prana yoga focuses primarily on breathing exercises. It is an approach over 5000 years old and has generated thousands of specific breathing exercises.

Breathing exercises are almost always deployed as a part of another technique. One popular Western approach is Lamaze, a natural childbirth method. Breathing exercises vary considerably, and include active yoga stretches, active diaphragmatic breathing, and passive approaches. Generally, the goal of breathing exercises is to foster diaphragmatic breathing and a pace that is slow and even. One initially learns to breathe deeply, then breathing becomes effortless and shallow as training progresses and relaxation deepens throughout weeks and months of practice.

Illustration of Breathing Exercise

Gently take a deep breath. Pause. And slowly exhale, slowly letting the air flow through your lips, as if you were blowing on a candle flame. Attend to the flow of breath. Notice how it quietly moves in through your nostrils, and down into your lungs. Follow the flow of breath in and out.

Tense-Let Go Exercises (Progressive Muscle Relaxation or PMR)

Variations of Edmund Jacobson's progressive muscle relaxation is perhaps the most widely used professional approach to relaxation in America. For years it has dominated textbooks

and relaxation research and, even now we see the term 'progressive relaxation' used interchangeably (and incorrectly) with relaxation.

Jacobson's approach involved training subjects to detect and recognize increasingly subtle levels of muscle tension and remain relaxed throughout the day. In each session, a client would focus on a body part, for example, the hand, generate as small an amount of tension as possible and let go. Jacobson felt it was very important to avoid suggestive patter, fearing it might introduce what he felt were the confounding effects of hypnotic suggestion (ironically, some hypnosis scholars consider Jacobson's approach to be a form of hypnosis). Clients would be taught to relax two or three muscle groups per 60-min session, eventually covering 50 groups for the entire body. Training required 50 or more sessions that could last from 3 months to a year.

Overt PMR

Jacobson's minimal method was cumbersome and not widely used. In 1958, Joseph Wolpe introduced the first abbreviated version of progressive relaxation. Earlier, Wolpe had found that a conditioned fear reaction in cats could be eliminated by evoking a response incompatible with fear concurrently with a feared stimulus. Progressive relaxation could work as such a 'reciprocal inhibitor' and became a part of Wolpe's well-known desensitization treatments.

The abbreviated approach of Wolpe and others involves overtly creating a considerable level of relaxation starting in the first session. One effortfully 'tenses up' for about 5–10 s and then 'lets go' attending to the release of tension for 30 or so seconds. Often up to 16 muscle groups, rather than one to three, are separately targeted in each session. As training progresses, muscle groups are combined until eventually one can simply detect and relax tension without first overtly creating tension.

Covert PMR

Covert PMR involves letting go of muscle tension without first tensing up. Often it is presented as an advanced lesson, after weeks of training in overt PMR. Occasionally, covert PMR is introduced alone, without prior practice in overt PMR, and often combined with autogenic training. One focuses on letting go.

In the most abbreviated format, termed conditioned relaxation and cue-controlled relaxation, one simply thinks a relaxing cue word, such as 'relaxed' or 'calm,' immediately after practicing progressive relaxation. In time, thinking the cue itself is sufficient to evoke relaxation.

Illustration of Overt Progressive Muscle Relaxation

Quietly attend to your right hand. Tense up the muscles in your right hand now. Keep the rest of your body relaxed. Notice the tension grow in your right hand. And let go. Let the tension flow away. Notice the sensations of relaxation. Can you tell the difference between how your hand feels now and how it felt when you were tensing it?

Autogenic Training

Autogenic training is a popular European approach to relaxation, one that has had modest impact in North America. Its roots can be traced to hypnosis of nearly a century ago. At the

onset of the twentieth century, Johannes Schultz made use of the notion that hypnotic suggestions involving physical sensations related to relaxation can often evoke relaxation, for example, by simply and calmly stating 'your hands are warm.' Importantly, he was convinced that hypnosis was not something imposed upon a patient by a domineering hypnotist, but an inner ability patients permitted to unfold.

In the 1920s and 1930s, Schultz introduced autogenic training, a relaxation-based system of therapy based a somewhat overstated notion of 'self-generated' (autogenic) healing. This version has been popularized by Linden. Central to this idea is that the brain has powerful self-healing potential.

Standard and organ-specific exercises

Traditional autogenic training is a highly structured sequential program. It begins with six 'standard exercises' that involve mentally repeating verbal formulae or suggestive phrases targeted to the following somatic sensations:

- Heaviness,
- Warmth,
- Cardiac regulation (slowly, evenly beating heart),
- Respiration (relaxed breathing),
- Abdominal warmth, and
- Cooling of the forehead.

Autogenic training places considerable emphasis on 'passive volition,' that is, repeating formulae passively, while maintaining complete indifference about the result. A beginning client might be instructed to let the phrase 'hands are warm ... hands are warm' repeat in his or her mind, quietly attending to the repeating words much as one might attend to the slow repetition of an echo. After mastering beginning warmth and heaviness exercises, a client progresses to phrases targeted to the heart ('heartbeat strong and even'), respiration ('it breathes me'), abdominal warmth ('warmth radiates from my stomach'), and forehead ('forehead cool and calm').

Many traditional relaxation traditions have elements that resemble autogenic suggestion. One type of zen meditation involves focusing on abdominal warmth. Kundalini yoga involves meditating on presumed chakra 'energy centers,' which loosely correspond to autogenic standard exercises. Some forms of Christian prayer involve attending to feelings of loving warmth radiating from the heart.

Once the standard exercises are mastered, a variety of special exercises may be introduced. 'Organ-specific formulae' tailor the standard exercises to the particular needs of the patient. For example, a backache patient may use the phrase 'My back is warm,' a headache patient, 'My forehead is cool,' and so on. 'Intentional formulae' are phrases targeted to behavioral change objectives ('I will study more, drink less.')

Illustration of Autogenic Standard Exercise

Gently let these words float through your mind: 'Hand and arms, warm and heavy. Hand and arms, warm and heavy.' There is no need to deliberately try to conjure up these feelings. Just let the words float through your mind.

Autogenic 'meditation'

More advanced exercises incorporate various forms of 'meditative' imagery. One begins with an imagery preparation exercise that involves attending to vague retinal sensations that spontaneously occur with eyes closed in relaxation. Such sensations might include faint and formless clouds of light, spots, and so on. Once a trainee can sustain attention on such phenomena, he or she graduates to increasingly challenging images, including colors, then simple shapes (square, circle) and concrete objects (chairs, vases) until they can be produced and modulated on demand. The most advanced images include abstract constructs (truth, justice, friendship), emotional states, and other people. Eventually, exercises are directed toward seeking 'answers from the unconscious,' that is, asking questions ('What is the source of my frustration') and passively waiting for a spontaneous answer to emerge in the form of a change in image (an answer spontaneously appearing on an imagined blackboard or TV screen).

Today, autogenic training more or less in full form is popular in Europe and Canada whereas highly abbreviated forms (usually targeting 'warmth and heaviness') prevail in the United States. In addition, abbreviated variations have emerged with highly specific suggestions targeted, for example, to individual cancer tumors, the immune system, and so on.

Imagery and Relaxing Self-talk

Imagery involves creating in one's mind a passive relaxing setting or activity, often accompanied by the repetition of relaxing words or self-statements. Imagery has scientific roots in both hypnosis and autogenic training, and antecedents in nineteenth century religious and self-help cults and in many Eastern and Western religious traditions. Images often form an important part of hypnotic induction. Advanced autogenic exercises incorporate a graduated series of simple and complex images. It should be noted that yoga and meditation traditions have their own imagery exercises, although these are rarely employed in the West.

Many forms of imagery do not have relaxation as a goal. Active and discursive imagery is often used in psychotherapeutic traditions as diverse as psychoanalysis and behavior therapy. For example, a psychodynamic therapist might instruct a client to engage in 'free association.' Here, a word or topic ('Your dream about a domineering old bear') is selected that is salient to a therapy session. Then the client, with eyes closed, lets thoughts and images spontaneously emerge without any censorship, modification, or selection. During this activity, he or she shares to the therapist whatever thoughts arise.

Behavior therapists might use a different type of 'coping imagery.' Here imagery is a mental rehearsal of confronting and coping with a stressor, including possible setbacks. A client suffering fear of public speaking might visualize approaching a podium, taking a few deep breaths, opening lecture notes, repeating the supporting phrase 'one step at a time, I can do it,' beginning the speech, perhaps forgetting a point, coping by successfully checking notes, resuming, and successfully completing the speech. It should be emphasized, that coping imagery does not involve visualizing just the successful outcome. Although self-help books and programs often offer a

strategy of visualizing success ('Imagine yourself rich ... successful ... in love ... powerful ... etc.'), such imagery simply does not work.

Relaxation imagery involves creating a cognitive or mental representation of a real or hypothetical relaxing setting or activity, perhaps supplemented by relaxing self-statements. Unlike therapeutic imagery, it involves a minimum of thought activity and effort, greater sustained focus, and some indirect intention to evoke positive states of mind. Most forms of relaxation imagery can be divided into three categories: sense, narrative, and insight imagery. This text emphasizes sense and insight imagery.

Sense imagery involves passively attending to sense stimulation without engaging in an activity. One might imagine a beach and attend to the waves, sky, sounds of birds, and so on. Again, all senses are involved. Narrative imagery involves attending to a simple and somewhat plotless relaxing story, for example, walking through the woods, floating through the air, riding a horse, and so on. One attends to simple relaxing sensations (sights, sounds, feelings, smells) that arise while completing a relaxing activity. Insight imagery has as its objective evoking deeper understanding or appreciation of a topic or question.

Illustration of an Imagery Exercise (Sense Imagery)

Enjoy a fantasy about a pleasing vacation spot on the beach. Involve all of your senses. What do you see? The blue sky above? The green trees? The clear blue water? What do you hear? Perhaps the gentle rustle of trees, or the splashing of waves. What do you feel touching your skin? Perhaps the warm sun or cool breeze. And what relaxing fragrances are there? The clean scent of water? Flowers?

Meditation and Mindfulness

Health professionals who use meditation teach either concentrative meditation (sometimes termed focused attention meditation), which involves restricting attention to a simple stimulus, or mindfulness (open monitoring) meditation which involves nonjudgementally attending to all stimuli.

Concentrative meditation

Concentrative meditation is most often traced to ancient Hinduism and Tibetan Buddhism. Three general types of concentrative meditation that have appeared through the years: meditations of the body (focusing on relaxing body feelings, rocking, breathing), meditations of the mind (meditation on a thought syllable or mantra, meditation on an internal visual image), and meditation on an external stimulus (a repetitive sound or continuous visual image).

Mindfulness meditation

Mindfulness meditation (also called Zazen, just sitting, or Vipassana) traces its roots to Buddhism. Buddhism gave birth to Zen, one of the most popular approaches to meditation in Japan, and to some extent the West. Around 500 BC, Buddhism emerged as a reform offshoot of Hinduism. Buddha taught that existence is permeated with suffering caused by self-centered thought. Selfish thought can be destroyed by following an 'eightfold path' of right motivation and conduct eventually culminating in a passive focusing exercise, meditation.

In the sixth century, Buddhism was carried to China and appeared 600 years later in Japan as Zen. Unlike concentrative meditation, Zen involves calmly attending to the flow of all stimuli, not a continuous single stimulus. One does so without thought, judgment, or analysis. This is typically called mindfulness meditation. Today health professionals outside of the Buddhist tradition teach simple mindfulness awareness techniques, often in combination with stretching, breathing, and other concentrative meditation techniques.

Historically, at least seven methods have been used to teach meditation: (1) meditation (concentrative or mindfulness) alone, without pre-session warmup; (2) meditation (concentrative or mindfulness) with either yoga stretching or breathing or both as warmup; (3) meditation (concentrative or mindfulness; with or without breathing or stretching warmup) gradually increasing in length (over the course of several weeks) from 10 to 25 min; (4) graduated mindfulness, beginning with simple physical sensations, progressing to awareness of other sensory input, and ending with awareness of all sense input; (5) mindfulness with concentrative meditation as warmup; (6) mindfulness after several weeks of training in concentrative meditation; and (7) multi-technique concentrative/mindfulness meditation in which several approaches are taught and the client selects which works best. Trainers of mindfulness and meditation rarely mention (and may not be aware) of such diversity of approaches.

Illustration of a Meditation Exercise

Let the word 'one' easily float through your mind, over and over. There is no need to force it to repeat at any speed or volume. Just let the word gently repeat again and again. All you need to do is attend to the word 'one.' Whenever your mind wanders, gently return to attending to the word 'one' as it repeats over and over.

The Uses of Relaxation

Self-relaxation (as well as casual and assisted approaches) has been applied in a variety of goals, including enhancing sleep, alleviating unwanted states, achieving states that may be desired, and exploring the possibilities beyond everyday frustrations and joys. In more formal terms, these are the sleep-related, negative, positive, and transcendent goals of relaxation.

Sleep-Related Goals of Relaxation

People untrained in professional deep relaxation often think relaxation is sleep. Indeed, combating insomnia as well as enhancing sleep and mastering the skill of 'catnapping' or 'power napping' can be important preliminary goals of relaxation. Treatments that incorporate relaxation are used as a way of preparing for sleep.

The Negative Goals of Relaxation: Stress Management/Healing

Chronic stress arousal can contribute to a wide range of physical disorders as well as psychological distress. Traditionally, relaxation has been used in stress management and healing. Both are

negative goals in that they involve reducing or minimizing something one does not want, a negative. To summarize:

1. Relaxation has demonstrated potential for relieving the destructive wear and tear of severe and chronic stress arousal on specific body systems and organs as well as on the immune system.
2. Relaxation has demonstrated potential for speeding healing and recovery from nonchronic conditions. For example, the wounds of relaxed people heal more quickly.
3. Relaxation has demonstrated potential for reducing serious complications of chronic conditions. For example, individuals with AIDS or diabetes do better.
4. Relaxation has demonstrated potential for reducing the destructive impact of stress on functioning (attention, flexibility, memory, energy).

The Positive Practical Goals of Relaxation: Health and Energy/Calm Control

The negative goals of relaxation involve getting rid of something one does not want. The positive goals involving getting what one wants. The goal of health and energy seeks to maintain health and resistance to disease, and increase energy reserves and stamina. Those who use relaxation as a tool for enhancing health and energy have acquired a healthy habit, not unlike good diet, exercise, sleep, and proper hygiene. For them, the practice of relaxation limits extremes of stress arousal, enhances routine recovery from the stressors of daily living, and helps support a positive frame of mind. Energy is enhanced by limiting unnecessarily draining stress and worry, enabling the body to recover from sustained discursive effort, and opening sources of energy by enhancing breathing and cardiac functions.

The goal of calm control involves sustaining attention on a chosen task, ignoring external distraction, and coping with diverting impulses and desires to do something else. Calm control is required to finish one's homework, resist the craving to smoke a cigarette (or eat an extra cookie), or stay on a job in spite of boredom or fatigue. This can be differentiated from self-control, the management of internal emotions and desires; calm control has the additional feature of sustaining attention on a desired course of action, and returning to this course of action after internal or external distraction.

The Positive Expressive Goals of Relaxation: Spontaneous Enjoyment/Creativity and Insight

Relaxation becomes an expressive activity when it is done because it is fun or meaningful, and does not necessarily have any immediate pragmatic use. The simplest expressive goal is spontaneous enjoyment, practicing a relaxation exercise because it is fun or because it contributes to the unstructured, unplanned, and spontaneous enjoyment of another fun activity. Any of the six families can be presented in the spirit of play and pleasure. PMR and yoga become dance. Imagery becomes storytelling. Meditation becomes an adventure, and so on. Furthermore, one can deliberately introduce relaxation before a pleasurable activity, for example, by practicing breathing exercises before dancing, or meditating before a concert.

The goal of creativity and insight involves nurturing an expressive source of ideas. Of course, creativity and insight may be required for highly pragmatic goals, for example, deciding on a job, a term paper topic, a new business strategy, a course of action in a crisis, or even a proper gift for a friend. However, the act of brainstorming, of actually generating potential ideas, involves temporarily putting aside pragmatic concerns and freely entertaining all ideas, good and bad, sane and silly. To this end, relaxation can very much enhance creativity and insight.

The Transcendent Goals of Relaxation: God-Based Spirituality/Meditation and Mindfulness

Transcendent goals involve going beyond one's everyday wants, both negative and positive. Self-directed concerns are minimized. God-based or theistic spirituality focuses on celebrating and relating to a theistic entity, one's God or Higher Power. This may or may not be in the context of organized religion. The goal of transcendent meditation/mindfulness is the cultivation of calm and focused awareness and action in the world as it is, undistracted by irrelevant personal

concerns or biases. For God-based spirituality, one transcends self-centered negative and positive motivations and expectations in service of God or one's Higher Powers; for meditation/mindfulness, one transcends such distracting personal motivations and expectations in order to see and act in the world as it really is.

Semantic Memory

H E Schendan, Plymouth University, Plymouth, UK

© 2012 Elsevier Inc. All rights reserved.

Glossary

Amygdala It is responsible for processing of emotion (e.g., fear, disgust, happiness).

Association areas These are regions of the neocortex beyond the primary sensory processing cortex and cortical areas processing information before the primary motor cortex. Unimodal association areas surround primary sensory and primary motor areas, and multimodal association areas lie beyond these, that is, in between unimodal sensorimotor association areas.

Cingulate cortex It lies immediately superior to the corpus callosum, which is the white matter axonal fiber bundle that connects the cerebral hemispheres. Cingulate cortex is included in the limbic system implicated in emotion and motivation and continues posteriorly as the parahippocampal gyrus in the temporal lobe, which provides input to the hippocampus, consistent with a role in episodic memory.

Embodied (grounded) cognition This is a long-standing framework for cognitive science that proposes that processing of modal information (i.e., sensory, motor action, and mental state) has a necessary role in cognition, including semantic memory. Largely neglected until recently, this framework opposes the standard framework of cognition that states that an amodal symbol system exists apart from the modal systems and represents meaning in semantic memory. Embodied (grounded) cognition accounts vary according to whether embodied (grounded) cognition alone can explain all knowledge or embodied knowledge represents concepts alongside an amodal system. The latter hybrid frameworks vary further according to how much embodied and amodal systems each contribute to cognition.

Frontal lobe It extends from the anterior-most part of the brain to the central sulcus where the primary motor cortex ends. The frontal lobe contains motor areas and lateral and medial prefrontal regions and anterior cingulate regions implicated in cognitive control, working memory, and selective attention.

Lexicon This is the set of all words and expressions in a language (i.e., the vocabulary).

Linguistic This refers to perceptual cues (i.e., words) and actions involved in natural language, including semantics, grammar, and phonetics.

Mental state This is a state of brain activity related to introspection, that is, a state accompanied by a subjective quality of conscious experience (or qualia, e.g., feeling a headache, taste of food, your experience of the colors in a rainbow). Mirror neuron circuits, in which neurons involved in manipulating objects are also involved in perceiving another animate agent perform that action, may underlie social simulations for embodied cognition.

Occipital lobe It is the most posterior part of the neocortex. It includes the primary visual area (V1) in striate cortex and

extrastriate visual cortex that lies anterior to V1, as well as association areas that are object-sensitive, responding more strongly to intact images of objects than scrambled versions with no coherent object structure. This lobe is retinotopically organized such that adjacent neurons receive input from nearby parts of the visual field (and corresponding retinal location). Neurons adjacent but displaced laterally from each other across the cortex represent adjacent but likewise displaced visual field (and retinal) locations. Consequently, this cortex effectively represents an orderly image of light hitting the retina, though distorted to magnify central over peripheral retina. Extrastriate visual areas contribute to semantic memory based on an embodied cognition account.

Parietal lobe This lies in the dorsal posterior part of the cerebral cortex. It includes the angular gyrus region in the lateral inferior part (Brodmann's area [BA] 39; areas PGa and PGp) and the supramarginal gyrus (BA 40) that have been implicated in semantic processing in response to written and spoken words. This angular gyrus region extends posteriorly into the anterior occipital lobe.

Priming This refers to a phenomenon in which experience with a stimulus (referred to as the prime) affects the response to another stimulus (referred to as the target). Priming is typically attributed to implicit (nonconscious) memory. The relationship between the prime and target can be perceptual (i.e., both have the same or similar sensory features or properties, e.g., the words 'dog' and 'dog'), conceptual (i.e., both have the same meaning, e.g., the word 'dog' and a picture of a dog, or hearing and reading the word 'dog'), or semantic (i.e., both have associatively or categorically related meanings, e.g., the words 'nurse' and 'doctor' are associated concepts). Priming usually facilitates processing of the target, making task performance faster and more accurate but can be detrimental in some cases.

Semantic memory Semantic memory or knowledge refers to conceptual information about the meaning of words, objects, people, scenes, and facts. This meaningful information is not consciously related to specific, personally experienced events of episodes. However, concepts are formed by abstracting or generalizing across multiple individual experiences. For example, the meaning of a dog is not about a single personal event with a dog but rather the meaning of the dog category (dog-ness) is generalized across features common to many instances of dogs.

Spreading activation The process of how activation can move from one concept (or node) to another in a semantic (or associative or neural or connectionist) network. Each link between two concepts has a weight that determines how much a concept can activate the other linked concept. Concepts can be directly linked to each other and indirectly linked to each other through one or more other concepts. The combination of weights

and how directly linked concepts are determines how far activation of one concept spreads to other linked concepts. Through this process, activation spreads to related concepts in the network.

Temporal lobe It is a ventrally located region of the neocortex that includes association areas for visual processing, primary and association areas for auditory

processing, and multimodal association areas. The anterior temporal lobe has been proposed to be an amodal hub for semantic memory. The medial temporal lobe includes the hippocampus and the surrounding cortex of the parahippocampal region, which is composed of perirhinal cortex, parahippocampal gyrus, and entorhinal cortex, and may also represent semantic memory.

Semantic Memory Is One Type of Memory

Semantic memory is conscious long-term memory for meaning, understanding, and conceptual facts about the world. Semantic memory is one of the two main varieties of explicit, conscious, long-term memory, which is memory that can be retrieved into conscious awareness after a long delay (from several seconds to years). Endel Tulving in 1972 (building upon a distinction between two primary forms of memory by Reiff and Scheers in 1959) distinguished between semantic and episodic memory. Episodic memory refers to stored representations for personally experienced episodes from one's life within a particular spatiotemporal context (e.g., dinner in Berkeley in January this year). Semantic memory refers to stored representations for meaningful facts or world knowledge, regardless of the spatiotemporal context in which the information was acquired and without information about personal experiences surrounding learning of the information (e.g., the concept 'dinner' but not a particular dining experience), and is necessary for language. Crucially, while episodic memory involves awareness of a feeling of having personally experienced an event or item, regardless of meaning (i.e., an item could be a nonsensical figure like abstract art and so has no meaning but has been experienced before as on multiple museum visits), semantic memory involves awareness of meaning unaccompanied by a feeling of familiarity of having previously experienced the event or item or remembering the place and time of the personal learning experience(s). For example, using semantic memory, you know what a dog is and can read the word 'dog' and be aware of the meaning of this concept, but you do not remember where and when you first learned about a dog or even necessarily subsequent personal experiences with dogs that went into building your concept of what a dog is. Even without a feeling of personal experience, you know what a dog is when you see, hear, or read about a dog. Thus, you have semantic memory for meaning, regardless of a feeling of familiarity or recollection of the personal experiences that had originated from the concept.

Language, Concepts, Categories, and Semantic Networks

Hierarchical Model

Ideas about semantic memory developed from attempts to explain how human language communicates concepts. While computer scientists proposed semantic nets for translating natural language as early as 1956, the term 'semantic memory' emerged in psychology in early models of human knowledge about word

concepts circa 1969. Collins and Quillian viewed semantic memory as a hierarchical network of relations among concepts. A concept refers to meaning, which is stored in semantic memory. Language enables an arbitrary symbol, such as a stream of sounds comprising a word (e.g., 'dog'), to be associated with the memory representation of the meaning of the symbol (i.e., the semantic memory of a dog). As described in concept learning research, a concept is a mental representation that places an object, event, or idea into a category. Semantic memory can thus be said to be the store of mental representations of categories. In their original formulation of the organization of semantic memory, Collins and Quillian assumed that categories are organized hierarchically, and defining features compose each category. For example, an animal has skin, moves, eats, and breathes. In 1976, Eleanor Rosch proposed different levels of categories. For example, song and field sparrows are subordinate categories of the more general category of sparrow, which is a basic-level category, along with eagle and cardinal of the superordinate-level category of birds, and, at a still more general level, birds and fish are animals. Collins and Quillian's theory predicts that the response time to classify whether a feature belongs to a category depends upon how many nodes or levels of the hierarchy must be traversed to do the task, which was confirmed experimentally.

Feature Overlap

Smith and colleagues modified this basic framework to suggest that the meaning of a concept is a set of features, as opposed to a single node. Further, defining features are essential (e.g., robins have red breasts), whereas characteristic features are merely typical of a concept (e.g., robins are wild, bipedal, have wings, perch in trees). Consistent with this feature overlap model, people rate robins and sparrows as more typical birds than ducks and geese, and robins and sparrow are rated as more similar to each other than the other birds. However, there may be no defining features; as noted by the philosopher Wittgenstein in 1953, there is no feature that all games share. Also, feature overlap models compare features to decide the concept, but evidence indicates that other kinds of knowledge are relevant. For example, while a butterfly is readily categorized as an insect, subjects instructed to generate members of the insect category infrequently mention a butterfly. Such problems motivated alternative theories that continue to be debated and tested. The main competing theories can be grouped into those that propose that categories depend upon a prototype representation, which is an average of all examples, or many representations composed of each of the exemplars (or instances) of the category (e.g., each example of a dog experienced), referred to as prototype versus exemplar theories, respectively.

Spreading Activation

Most current theories organize concepts and categories as nodes in a network. Nodes connect to one another via a semantic link, thereby associating together related concepts or categories. The length of the link in a semantic network model varies with the relatedness and associations between concepts. For example, car, truck, and bus may be connected directly via short links, and each of these connects to fire engine via a longer link. Nodes can be connected directly or indirectly via links to other nodes. For example, apple may connect directly to red and connect indirectly to fire engine through the red node. As in the earlier Collins and Quillian model, the properties of a concept/category can be connected to its node. Semantic network theories propose that activation spreads from one node to another along the links between them, allowing for even indirectly linked concepts to activate one another. Semantic networks can easily explain retrieval of meaning. For example, when thinking about apples, one might activate the concept of red, which might trigger one to think about fire engines, stoplights, or bricks.

The semantic network approach has the advantages over other theories of predictive power (perhaps too much so that it becomes unfalsifiable, according to some critics) and being readily modeled using neurocomputational methods (i.e., connectionist or parallel distributed processing models, as described by Rumelhart and McClelland). A node can be modeled as a neuronal cell, and the dendrites (input) and axons (output) that interconnect neurons to each other are modeled as links between nodes. Neural network models incorporate recurrent and feedback connections that are well-known principles of neocortical organization. A node in a semantic network has a level of activation representing the probability that the neuron will fire, thereby potentially activating a connected neuron sufficiently that it also fires. Activation in one node could thereby spread to other nodes connected to it directly or eventually indirectly. Semantic memory is acquired using learning rules (e.g., hebbian plasticity) that determine network connectivity by modifying how strongly neurons connect to each other based on experience. Contemporary neural network models have more biological realism.

Compound Cue

Compound cue models propose that semantic memory operates like other types of memory. For example, in the case of episodic recognition, memory is an interconnected feature set representing the item (i.e., its meaning), its learning context, and its relation with other such feature sets. Recognition cues are held in mind briefly to probe the feature sets, producing a familiarity signal sent to a decision process, enabling a decision that the stimulus is old or new. Likewise, in the types of priming (implicit memory) tasks used to assess semantic memory, additional cues are relevant beyond those used for recognition. For example, in the lexical decision task people decide faster whether a letter string is a real word (or not, e.g., xutkifq) when the target word (e.g., doctor) is preceded by a word that is related (e.g., nurse) than unrelated (e.g., butter). Prime and target are both cues that together constitute a third type of association besides the associations between target and context

plus target and other feature sets, which are available for recognition. Compound cue theory attributes faster performance for prime and target pairs that are related to the greater number of shared associates between them than for unrelated pairs.

Knowledge and Generic Memory Encompass Semantic and Nonsemantic Memory

The common label, semantic memory, may not be the most appropriate but rather the term generic memory (suggested by D. L. Hintzman) or knowledge (suggested here) can include nonsemantic information about perceptual form and motor action-related processing. Consider that, in general, knowledge is what you know (e.g., that dogs bark, your house number, the capital of France, the color of spinach, the shape of a cat, as well as their meanings). Linguistic stimuli (i.e., words) activate meaning, but objects, scenes, and people are also meaningful. To activate meaning, the perceptual features of the stimulus must be matched to stored memory of these sensory-based features. For example, to categorize a dog, its perceived shape or other identifying perceptual attribute(s) (e.g., a bark) must match successfully to memory for the perceptual form associated with the dog category. Likewise, to activate the meaning of a word, the word form being currently perceived must match memory for the perceptual form of that word. Thus, semantic memory depends upon nonsemantic memory for perceptual form to mediate between the perceived cue and its meaning. In addition, activation of nonsemantic memory can also activate associated nonsemantic information about the stimulus, as when observing a dog and becoming aware of its meaning and associated perceptual (e.g., its color, sound, smell), motor (e.g., its movements), emotional (e.g., fear), or mental state information.

Like semantic memory, nonsemantic knowledge is distinct from episodic memory. For example, patients with visual object agnosia are slow and make errors categorizing common objects when visually presented (e.g., seeing a dog but being unable to name or describe it meaningfully as a dog). However, these patients can tell that they saw the object before, demonstrating episodic memory. Moreover, all forms of visual object agnosia involve some impaired perceptual processing, even associative (i.e., semantic) subtypes; a knowledge system for the perceptual form of an object is required in order to know also about its meaning. In most theories, this perceptual matching stage must, to some extent, succeed in order for semantic memory to become active. Substantial parallel and interactive processing between perceptual form and meaning can occur. Thus, activating meaning always requires matching memory to the perceptual form of the referent, be it a word, object, face, or place.

Knowledge, Priming, and Awareness

Semantic memory and nonsemantic (perceptual and motor) knowledge are nonepisodic, and aspects of these memories may be conscious, while others lie outside of awareness. Conscious semantic memory is primarily the variety of explicit memory that has been distinguished from episodic memory.

After all, clearly, one can become aware of a concept in a semantic network, as when you are aware that you know what a word means. However, one is not necessarily conscious of activating the nodes or links in the network itself that lead to awareness of meaning or aware of the processes that match a perceptual form to its nonsemantic memory. Nonetheless, these nonconscious processes can lead ultimately to awareness of the shape, color, category, and meaning of the object.

By contrast, nonconscious implicit memory is thought to include nonsemantic memory as well as situations in which semantic memory activates nonconsciously. Implicit memory is typically probed by repeating information. In such priming paradigms, the item (e.g., doctor) or a version of it (a picture of a doctor) or a related item (e.g., nurse) is presented for study, as in the lexical decision task used commonly to assess semantic memory. Then, following a delay, the target item (doctor) is presented again in the memory test phase. Relative to unrepeated (i.e., new) items, repeated items exhibit faster and more accurate performance, as well as different brain response characteristics. Repetition priming (i.e., doctor–doctor), conceptual priming (i.e., a picture of, and then the word for, doctor), and semantic priming (i.e., nurse–doctor) are varieties of implicit (nonconscious) memory. It is important to note, however, that evidence is accumulating that consciousness is not the critical factor distinguishing varieties of learning and memory. Instead, the computational and decision demands of the task, and how these recruit different brain structures, are primary.

Standard Theory of the Semantic Memory System

Research has focused on how meaningful (semantic) representations are organized, leaving nonsemantic knowledge organization relatively less understood. Multiple memory systems theory distinguishes between a semantic memory system and a nonsemantic perceptual representation system that can be matched to a currently perceived stimulus, for example, to determine what an object is, such as a dog, based on its perceived shape. This distinction of memory systems theory essentially reflects its adoption of the standard theory of meaning that proposes that conceptual knowledge resides in a single amodal system with a uniform architecture and exists separate from modal sensorimotor systems.

Anterior Temporal Lobe Stores Amodal Meaning

Multiple memory systems theory (e.g., Elizabeth Warrington in 1979) adopted the distinction between semantic and episodic memory and added the proposal that different brain systems support each type. In particular, while episodic memory depends upon the medial temporal lobe (MTL), semantic memory depends upon association areas of neocortex that lie outside primary sensorimotor areas and outside the MTL. Studies of patients with semantic memory problems indicate that an amodal system may reside in the anterior temporal lobe (ATL). The ATL is considered to be the best candidate for an amodal hub for meaning based on convergent evidence from patients with semantic memory problems and its anatomical connectivity. The ATL lies next to limbic system structures, including the amygdala and the orbitofrontal cortex, which

have been implicated in emotion, reward, and motivation processing, thereby enabling associations among these abilities and sensorimotor and linguistic aspects of concepts. Further, the ATL lies next to the anterior MTL system for episodic memory, which is thought to contribute to learning conceptual knowledge gradually over multiple experiences, as when many personal experiences with a variety of dogs gradually result in a concept of the dog category. Hub theories do not equate amodal with cross-modal (i.e., picture and word modalities), emphasizing that a cross-modal (or multimodal) region that integrates information from multiple sensory and/or motor regions may not perform the true amodal function required of a semantic hub. For example, the angular gyrus performs multimodal sensory integration but may not function as a semantic system for linguistic purposes.

However, it is unclear what exactly is the difference between amodal and cross-modal/multimodal, and this distinction will be critical for determining the anatomical locus of an amodal hub for meaning that abstracts across stimulus form. Consider that any region that integrates information, (a) across sensory modalities, (b) multiple sensory plus motor or linguistic information, or (c) any of these plus emotion or mental state information, would meet the definitions of multimodal, cross-modal, and amodal (i.e., a similar pattern of neural activity is activated by more than one type of physical stimulus or type of response in the case of motor output). Moreover, alternative views about the organization of semantic memory, including those that posit no amodal hub, can accommodate the anatomical definition offered for the amodal semantic hub (i.e., integrates sensorimotor and emotion/reward information).

Further, anatomical evidence suggests that the ATL may not be amodal (or fully multimodal) or a domain-general semantic hub. Some evidence suggests that the ATL stores knowledge about a unique item (e.g., an individual person, a famous landmark). This may be particularly necessary for socially relevant knowledge, as social information necessarily involves two or more unique persons. Consider also that the hippocampus receives nonspatial (or object) information computed along the ventral visual pathway from the perirhinal cortex in the MTL and spatial information from the dorsal visual pathway via the parahippocampal gyrus in the MTL, and both perirhinal and parahippocampal areas lie adjacent to and receive input from the associative cortex in the ATL. It is unclear why information in the MTL would be modal (e.g., spatial vs. object), whereas the adjacent ATL that feeds into it would be amodal, as the standard theory of semantic memory suggests. If the ATL is amodal, then why would segregated, modal nonspatial, and spatial inputs be sent into the MTL, which lies at a more advanced stage of hierarchical processing from the ATL? Modal segregation is difficult to reconcile with a definition of semantic memory organization that requires an amodal semantic hub where both spatial and nonspatial (object) information must be combined. Further, other types of sensorimotor, emotion, and reward inputs also send segregated inputs into the MTL via the ATL.

Medial Temporal Lobe, Episodic Memory, and Meaning

Perhaps the brain structure that shows the most amodal (or multimodal) properties is the MTL. The MTL shows highly sensory-invariant response properties. For example, MTL

neurons respond to single individuals (e.g., Jennifer Aniston), regardless of the form of the stimulus (i.e., varieties of pictures, names), showing seemingly complete invariance, and have been suggested to represent meaning in long-term semantic memory. Further, MTL structures have been proposed to construct representations of integrated multimodal percepts that are sensitive to semantic variables.

Spared new learning of knowledge in amnesia suggests that the MTL is necessary not only for episodic memory but also for semantic memory. However, this idea is hard to reconcile with the substantial evidence dissociating episodic and semantic memory. For example, patients with developmental amnesia in which the MTL is dysfunctional from childhood have impaired episodic memory but remarkably spared semantic memory. Some evidence suggests that MTL amnesics can acquire some new explicit knowledge, but this is limited in amount and generalization and attributable to the remaining spared MTL structures, clearly so in some cases and possibly in others. Whether new explicit knowledge learning is spared in amnesia remains controversial in part due to the inherent difficulties of the lesion approach involving human patients; controlled, targeted lesions cannot be done in humans and so residual sparing of critical structures is hard to rule out. Overall, the evidence suggests that knowledge can be acquired using primarily cortical mechanisms but only through substantial repeated exposure. Episodic encoding processes of the MTL accelerate knowledge learning by integrating across multiple episodes in a way that also facilitates generalization and abstraction of knowledge. This is consistent with evidence that episodic and semantic memory are interlinked. Episodic and semantic memory systems have substantial mutual interdependence during encoding and retrieval.

Semantic Memory Includes Embodied (Grounded) Knowledge

Neuroscience largely invalidates the strong form of the standard theory. All current views about the organization of knowledge incorporate an embodied (or grounded) cognition framework that says that knowledge depends upon multiple modality-specific systems, including those for sensorimotor properties in perceptual systems based on the senses (e.g., vision) and action systems for motor planning as well as emotion and mental states. For example, different modal knowledge systems in the extrastriate occipitotemporal cortex support face, word, and object knowledge. Different parts of each system can vary in the perceptual-specificity of the representation. Some knowledge is more specific for the shape, orientation, or other physical property (e.g., visually specific object knowledge) and others less so. The latter knowledge is more abstract from perceptual form) showing, for example, more invariance across changes in physical properties between experiences (e.g., an object from different viewpoints) or cross-/multi-modal activation patterns as when stimuli with the same associated meaning (i.e., a picture, sound, and word for dog) produce similar patterns of performance or brain activity. By an embodied account, a brain area can be both nonsemantic (e.g., sensorimotor), supporting, for example, both perceptual processing and perceptual memory, and semantic, supporting human symbolic abilities. Hybrid

theories suggest that one or more separate amodal system(s) act as hub(s) or convergence zone(s) that interact reciprocally with embodied knowledge systems.

A key argument against embodied cognition is that so-called abstract words, such as truth and freedom, are unrelated to sensorimotor processes. The main counterargument is that internal states, such as metacognition and emotion, are also stored as knowledge, and introspective states provide information that is central to representing abstract concepts. Unfortunately, relatively little is known about abstract concepts even though they play central roles in human cognition, as most research has focused on concrete concepts.

Brain Basis of Knowledge

Word Meaning

Mental lexicon

How words activate meaning has been a central question in language and semantic memory studies. The mental lexicon stores word information, including meanings (i.e., semantic memory for words), syntax, and perceptual word forms. Most studies focused on speech comprehension, with early accounts (e.g., by Levelt) positing a processing sequence from word sounds to syntax and finally to concepts in semantic memory. Due to the importance of sequential processing for language theory and the fact that language comprehension is rapid, with all word identification achieved even before sentences end, the timing of semantic activation with words has been of greater interest than anatomy. Consequently, most neuroscience studies of semantics from words measured electromagnetic potentials that have high temporal resolution that is lacking in anatomical methods like functional magnetic resonance imaging (fMRI), which instead has been used to locate the brain regions.

Linguistic N400 to words

Most studies of language and semantic memory focus on the linguistic N400, which is a scalp-recorded, negative electrical potential, peaking around 400 ms, that varies with semantic processing between 300 and 500 ms in response to written words and spoken words for which the onset is slightly earlier. The N400 indexes a multimodal, relatively abstract knowledge system for word meaning. This system is sensitive to ongoing context, constructive, and processes semantic information over an extended time period and across multiple brain regions. Thus, the meaning of a word is extracted within about 300 ms of processing. However, some lexical processing, including semantics, has been argued recently to occur before the N400 since ERPs to words between 200 and 300 ms seem sensitive to lexical processes.

Anatomy of word concepts

The N400 in response to words indexes activity in the ATL and the superior temporal gyrus, which are considered storage sites, and the ventrolateral prefrontal cortex (VLPFC), which supports efficient retrieval and encoding of this semantic knowledge. Electromagnetic potential and fMRI findings were combined to infer these neural generators. However, fMRI findings alone suggest that a more extensive, left-lateralized network (i.e., more activity in the left cerebral hemisphere) activates semantic memory in response to written and spoken words. The temporal lobe

regions recruited extend (a) posteriorly into the modal visual association cortex implicated in category-specific semantic deficits and semantic dementia and may store object knowledge specifying perceptual and conceptual attributes and support multimodal integration, and (b) medially into the parahippocampal region of the MTL, implicating it as an interfacing region between the more lateral temporal cortex and the episodic memory system in the hippocampus of the MTL. Notably, the left superior temporal gyrus region implicated in language comprehension problems of Wernicke's aphasia is mainly the modal auditory cortex for speech perception and has not been implicated in word meaning, though the most ventral part may contribute to processing abstract concepts. Nearby, in the lateral inferior parietal lobe, an angular gyrus region is greatly expanded in humans, receives multimodal inputs, and may support the conceptual retrieval, integration, and fluent combination processes critical for understanding discourse. While these regions are on the lateral surface, other regions lie medially. Specifically, the posterior cingulate region includes the retrosplenial cortex, which connects directly and bidirectionally with the MTL system for episodic memory and may promote episodic and semantic memory interactions. This cingulate region has been implicated in visuospatial, mental imagery, and simulation functions of both memory systems. In the frontal lobe, dorsomedial parts (BA 8) may support internally guiding semantic memory retrieval, while ventromedial parts support the emotional significance of concepts.

Semantic (default mode) network for words

Intriguingly, the lateral temporal lobe regions, the angular gyrus, posterior cingulate, and medial prefrontal regions of this proposed semantic memory network for words (i.e., all word meaning regions except VLPFC) are all key components of the default mode network (Figure 1(a) and 1(b)). This network activates in an anticorrelated manner with an active task network, which essentially includes the rest of the neocortex (Figure 1(c)). The active task network activates more than the default mode network during tasks demanding greater selective attention, working memory, and executive functions. By contrast, the default mode network activates more than the active task network in many language studies, episodic memory tasks (for which the MTL also activates), and rest (i.e., when minimally engaged with a task). The default mode network is affected earlier and more than other brain systems in Alzheimer's disease patients who develop progressively severe problems encoding new long-term episodic memory and retrieving knowledge. The default mode network may thus have a greater role in semantic memory, consistent with proposals that this network supports mental imagery or simulation processes that creatively synthesize, integrate, and associate multimodal information, especially episodic memory from the MTL, across past experiences. These functions would be crucial for constructing sequential, higher-order concepts from multiple life episodes, such as generalizing across numerous restaurant visit to construct a framework to comprehend the next such visit. Such a knowledge representation is known as a schema. Multiple schemas can combine to predict and anticipate how the next such visit will unfold over time. Such a sequential knowledge representation is known as a script. However, it is unclear whether default mode network regions are sufficient to support all aspects of meaning, as such studies

Figure 1 Brain systems for knowledge. (a) Rendering of the left lateral neocortex (Montreal Neurological Institute individual canonical brain, SPM99) showing the lateral inferior posterior parietal regions, including the angular gyrus, and superior temporal gyrus parts of the default state network implicated in semantic memory for words. (b) Sagittal slice through the medial cortex showing the medial areas that form most of the default state network implicated in semantic memory for words. (c) Rendering as in a, except showing the right lateral neocortex and parts of the active task network implicated in knowledge about visually presented objects during a categorization task. (d) The negative event-related potential called the N3 complex in response to visually presented known objects (from an experiment like that in c). *Note*, a and c were computed based on data from an experiment described in Schendan and Stern (2008), results in a are from the contrast of old > new objects (uncorrected $p < 0.001$) on an episodic recognition task; results in c are from the contrast of unusual > canonical views of known visual objects (e.g., dog) on a categorization task (uncorrected $p < 0.05$). Results in b were computed from the contrast of control > mental rotation (uncorrected $p < 0.05$) based on data from Schendan and Stern (2007). Results in d are based on an ERP version of that used for fMRI in c; the N3 is more negative for unusual than canonical views of known visual objects for which knowledge is more challenging to activate.

focused on words. After all, other regions in the active task network as well as the VLPFC are implicated in semantic memory and contribute important processes to knowledge encoding and retrieval and to mental imagery. For example, script knowledge evoked by linguistic and nonlinguistic (e.g., picture) sequences involves active task network regions that interact with basal ganglia structures implicated in sequential processing and implicit learning more than the default mode network.

Multiple Knowledge Systems

Nonlinguistic knowledge

The focus on semantic memory to words has left meaning in response to nonlinguistic stimuli relatively less well understood. Most work with nonlinguistic stimuli used pictures, revealing visual object knowledge. This knowledge is the most important to study in order to explain human cognition. After all, vision is our dominant sensory modality, and objects are the focus of visual processing and attention. Research on visual object knowledge is also necessary to define the neural underpinnings of semantic memory from neural circuits to systems. Such research enables direct links between human

and nonhuman animals not afforded by word studies. After all, nonhuman animals have at best only very limited linguistic capacity, precluding studies with words. Further, nonhuman animal work must be incorporated into semantic memory theory because most neuroscience questions cannot be addressed in humans for ethical reasons.

Object N3 complex

In response to a visually presented object, an N400-like scalp electrical potential, the N3 complex (aka N300, N350, N390), indexes neurophysiological processes between 200 and 500 ms involved in acquiring categorical knowledge, retrieving knowledge and implicit memory about objects, and making cognitive decisions based on object knowledge (Figure 1(d)). The N3 complex peaks around 350 ms, differs in scalp distribution from the N400 (i.e., the N3 has a frontal maximum and can become positive over occipitotemporal locations, whereas the N400 is centroparietal), and cognitive manipulations affect it earlier, around 200 ms, than the N400. The earlier time course of the N3 relative to the N400 suggests that the arbitrary relationship between a word and its meaning takes longer to activate than the (nonarbitrary) association between a perceived object and its meaning; note, the shape and other physical properties are part of its meaning by an embodied cognition account. The N3 complex indexes a modal knowledge system from more visually specific to more abstract or invariant representations stored in extrastriate occipital and ventral temporal cortex. Crucial evidence that the processes underlying the N3 complex are part of a semantic memory system is that the N3 is sensitive to similar contextual, memory, and conceptual manipulations as the linguistic N400. For example, semantic priming, that is, preceding an item by a semantically related item (e.g., doctor preceded by nurse), reduces both brain potentials and response time. The different scalp distributions of the N3 and N400 indicate multiple, modality-specific knowledge systems. This is due to recruitment of the occipitotemporal cortex involved in storing object knowledge (N3) versus anterior and superior temporal regions involved in storing word knowledge (N400). The VLPFC has a general role in semantic memory, however, controlling posterior cortical processes for both object and word knowledge to accomplish task-relevant goals and for decision-making (e.g., categorization). Notably, faces also evoke a functionally similar frontal N400-like potential. In sum, functionally similar but somewhat anatomically distinct semantic memory systems support knowledge about words, faces, and other objects.

Anatomy of object knowledge

Multiple knowledge systems are consistent with the functionally localized, hierarchical organization of the neocortex. From posterior to anterior areas along the ventral stream, stimulus selectivity becomes increasingly complex from more elementary, local features and greater visual-specificity to higher-order global shapes and combinations of features and increasing visual object constancy (i.e., similar responses despite changes in orientation, size, or other visual properties). Human occipitotemporal cortex is necessary for normal behavior on wide-ranging object cognition tasks. Patients with occipitotemporal damage have visual object agnosia: impaired perceiving, categorizing, and recognizing of visual objects with the pattern of deficits varying with

the locus of damage. Occipitotemporal areas are retinotopic (adjacent) and object-sensitive (i.e., responding more strongly to intact images of objects than scrambled versions with no coherent object structure). However, recent evidence suggests that object-sensitivity, object perception, and invariant object knowledge continue into the MTL, including the hippocampus. Extended object processing and memory from the occipital into the MTL accords with embodied cognition but not the standard theory of an amodal system.

Domains of knowledge

Multiple knowledge systems are consistent with embodied cognition and an alternative, but not incompatible, idea that object domain primarily constrains conceptual knowledge organization. Distributed domain-specific theories propose that evolutionary history influences development, which thereby determines object domain. Convergent findings suggest that the domains are living animate (e.g., mammals), living inanimate (e.g., trees), conspecifics (e.g., humans), and tools. For example, a brain-damaged patient can display category-specific semantic problems with multimodal input, implicating abstract representations of conceptual knowledge. Both picture-naming and verbal questions about objects can be impaired for living animate objects (e.g., animals) but spared for nonanimals. Even so, the patients can also have problems with nonsemantic, visual structural processing and knowledge. These and other findings motivated other multiple semantic system accounts to distinguish instead between nonliving things, animals, and fruits/vegetables. They propose that visual motion and functional information are more important for knowing about nonliving things, and other kinds of sensory information are more important for knowing about living things, of which fruits/vegetables depend more on color and taste information (than animals do). Notably, a domain account need not imply that semantic memory is modular. Instead, current ideas emphasize that domain-specific neural networks are distributed across multiple cortical regions. Each domain of knowledge can be further subdivided according to the sensorimotor, affect, and mental state processes posited in embodied cognition theories, enabling a rapprochement between theories. A central idea in hybrid accounts is that sensory processing within a specific domain (e.g., how a conspecific human looks based on visual processing) will be connected (e.g., via links in the semantic network) to other processes (e.g., how a conspecific human also sounds, emotes, or acts based on auditory, affective, or motor processing, respectively). Overall, findings converge on the idea that knowledge is organized across multiple cortical systems, contrary to the standard theory of meaning incorporated in multiple memory systems theory, but debates continue over the organizational principles governing the divisions (embodiment, domains, sensory-functional).

Frontal Lobe Controls Knowledge Encoding and Retrieval

The VLPFC controls encoding of mappings between knowledge stored in posterior areas and decision processes in frontal areas and subsequent retrieval. The human lateral prefrontal cortex (PFC) is organized functionally along a gradient from abstract decision and action planning processes in more rostral

parts (e.g., VLPFC) to increasingly more concrete response-related processes in more caudal parts (e.g., premotor cortex (PM)). This prefrontal system maintains patterns of activity for various types of information (e.g., linguistic, visuospatial, object, rules) in functionally distinct neural populations. Each influences (controls) other areas to accomplish a mental or overt action. For example, to decide the category of a visual object, dorsolateral PFC (DLPFC) and PM accumulate and compare visual evidence obtained from the occipitotemporal cortex to compute a decision according to a rule that determines the choice, which involves more rostral frontopolar (BA 10) areas. In the parietal lobe, the intraparietal sulcus (IPS) also accumulates evidence, consistent with its strong bidirectional connections with some decision-making regions. The VLPFC has an important role in disambiguating knowledge, as when multiple interpretations of the input result from initial processing (e.g., ambiguous figures, impoverished percepts, multiple alternative meanings or knowledge types are competing), and it interacts reciprocally with DLPFC and PM to recruit working memory resources to resolve uncertainty.

Simulation, Mental Imagery, and Semantic Memory

Embodied cognition theories propose mental imagery, particularly automatic simulation varieties, as a core mechanism for deep conceptual processing, rather than language with which semantic memory has been commonly allied. For example, hearing the word dog automatically simulates the sensorimotor, affect, and/or mental state associated with experiences of dogs (e.g., what they look like, how they move, feel, etc.). The idea is that embodied processes encoded into the knowledge system during the initial experience are later recapitulated via cortical network simulation mechanisms in response to the original stimulus (e.g., seeing a dog) or associated stimuli (e.g., the word, dog). The human capacity for symbolic cognition arises from interactions between simulation in the cortical knowledge network and linguistic processing. By this view, nonhumans lack symbolic cognition insofar as they lack linguistic processes, even though nonhuman animals have simulation abilities like those in humans by virtue of common cortical architectures for sensorimotor, emotion, and mental state processes.

However, mental imagery research has primarily investigated not automatic imagery but rather strategic mental imagery. Such studies, moreover, mainly use recently trained stimuli for which episodic memory (not semantic memory) likely dominates processing. For example, people are trained to memorize a few pictures until they can visualize them mentally with clear vivid detail. Later, while trying to visualize these pictures (i.e., strategically), they answer questions about them that require accurate mental images, such as whether a specific object part falls within a location of a grid on a computer screen. Consequently, little is known about mental imagery that is evoked automatically when semantic memory is activated. What is known comes mostly from studies of embodied cognition and two neuroimaging studies comparing episodic and semantic memory sources. The latter evidence implicates similar structures for imagery from episodic and semantic memory, including visual association areas, the amygdala,

which supports emotional processing, the MTL, and parts of the active task and default mode networks. Notably, the right VLPFC is activated more during mental imagery based on episodic than semantic memory. This is consistent with the possibility that most prior mental imagery studies reveal how strategic mental imagery from episodic memory works, which depends more on the frontal lobe, but not necessarily automatic mental simulation (imagery) from semantic memory.

Summary

Semantic and nonsemantic perceptual and motor memory systems store knowledge based on experience with the world independent from episodic memory about the originating personal experiences. Initial studies aimed to solve how language communicates concepts, inspiring cognitive models describing hierarchies of concepts composed of sets of overlapping features, semantic networks that operate by activation spreading along links between concepts, or memory decisions based on cues to conceptual associations. Meaning may be embodied in sensorimotor, emotion, and mental state information processing but also may be organized by domain in multiple semantic systems and may include an amodal hub in the anterior temporal lobe. While words activate meaning between 300 and 500 ms, knowledge evoked by nonlinguistic objects (for which the perceptual form may convey aspects of meaning, according to embodied cognition theory) starts earlier by 200 ms. Anticorrelated active task and default mode networks may support different aspects of meaning, while the lateral prefrontal cortex controls semantic memory retrieval and encoding. Conceptual processing depends critically upon automatic mental imagery simulating information processing in these brain networks, which, in humans, interacts with language to accomplish symbolic reasoning functions.

Sensation Seeking

J H Patton, Baylor University, Waco, TX, USA

© 2012 Elsevier Inc. All rights reserved.

Glossary

Boredom susceptibility An aversion to repetitive experience, routine work, or predictable people with a reaction of restless discontent when unavoidably exposed to such experience.

Disinhibition The need to seek release in uninhibited social activities with or without the aid of alcohol or other drugs.

Experience seeking Seeking of novel experiences through travel, music, art, and a spontaneous, nonconforming lifestyle with similarly inclined persons.

Impulsivity A personality trait characterized by a tendency to act quickly and without sufficient forethought or planning regarding the consequences of the action.

Sensation seeking A trait defined by the seeking of varied, novel, complex, and intense sensations and experiences, and the willingness to take physical, social, legal, and financial risks for the sake of such experience.

Thrill and adventure seeking A desire to engage in physical activities involving elements of speed, danger, novelty, and defiance of gravity (e.g., parachuting, scuba diving).

The trait of sensation seeking (SS), as measured by the sensation seeking scale (SSS), a self-report questionnaire, takes its definition from more than 40 years of research conducted by Marvin Zuckerman and his colleagues in the area of extroversion and optimal arousal or stimulation level. SS, as originally conceptualized by Professor Zuckerman, described only the 'sheer quantity and intensity' of external stimulation sought by an individual. Subsequent factor analytical work revealed that a more precise definition of SS would include the need for varied, novel, and complex stimulation as well as respect for the domains in which the stimulation was sought: socially acceptable or unacceptable venues. Therefore, a more contemporary definition of SS is that 'Sensation seeking is a trait defined by the *seeking* of varied, novel, complex, and intense sensations and experiences, and the willingness to take physical, social, *legal*, and *financial* risks for the sake of such experience.' According to Zuckerman, activities such as skydiving, scuba diving, and driving fast, as well as being more likely to drink ethanol, try recreational drugs, and perhaps sleep with strangers and gamble are common among sensation seekers. The main focus of sensation seeking is not merely the risk per se but the quest for novelty, change, and excitement. As we shall see, the drive to seek sensation is fundamental, but the venue for seeking stimulation can be very plastic and environmentally dependent.

believes that SS is related to reproductive success. He reasons that in order for animals to survive they must command enough territory to sustain them and engage in mate selection and reproduction. When resources become scarce in one area, animals must have the willingness to explore new territories in search of new sources of sustenance. Indeed, the animal that may have explored novel territory before resources became scarce would have a selective advantage since more resources would be available in times of stress. The same logic applies when it comes to mating; those animals most willing to explore the possibilities of finding new and different mates would more likely succeed in producing more offspring. However, those animals that expose themselves to excessive risk in search of resources or potential mates would be more likely to meet with misfortune and therefore are likely to pass fewer copies of their genes into future generations. Therefore, it is always a tradeoff between SS in the service of reproductive success and danger to the individual organism which might reduce his or her fitness or remove him or her from the gene pool altogether. In Zuckerman's view, SS is an instinctive drive in the service of reproductive success. Zuckerman sees humans, given their history of dispersal throughout the world, as a species who are aggressive sensation seekers. If we had not been willing to move into new territory and to seek mates outside our family groupings, we would simply not have come to dominate the earth in such a short time span.

Theoretical and Historical Background for SS

Evolutionary Underpinnings of SS

Zuckerman's early work draws heavily on evolutionary theory and comparative psychology to reach the conclusion that there is considerable variation in animals' levels of exploration, approaching novel stimuli, and levels of risky play. Zuckerman asserts that the tendency to engage in these activities is, to a large extent, biologically determined for any one individual. There is now confirming evidence that SS is a stable heritable personality trait with an h^2 of ~ 0.60 . Given the range of heritability of personality traits from somewhere in the 0.30 range to a high of near 0.80, SS is one of the traits that is most heavily influenced by inheritance, genetics. Zuckerman

Inhibition and Arousal

Zuckerman's theory depends heavily upon Pavlov's work. Pavlov claimed that organisms differ in terms of the type of nervous system they possess. He conceived of two nervous system types, one, a weak nervous system, prone to nervousness and shyness, while the other was a strong, gregarious type. For Pavlov, seeking environmental stimulation is to overcome inhibitions to the contrary. Seeking out stimulation in the face of physical or social danger requires disinhibition of protective tendencies. Some organisms seem to find it very difficult to overcome the anxiety barriers generated by social or physical danger. Other organisms seem willing to 'tread where angels

fear to go.' Cattell and Hans Eysenck have termed the tendency toward being disinhibited in social situations as 'extroversion,' one pole of the continuum of an introversion-extroversion personality dimension. Introverts are individuals who shy away from environmental interaction, while extroverts do exactly the opposite. Eysenck has repeatedly noted the relatedness of his theory of extroversion to theories of arousal and the physiological underpinnings thereof. Research indicates that SS is very probably a major component or corollary of Eysenck's extroversion.

Another corollary of SS relates to the level of arousal. Since the end of the nineteenth century, investigators and theorists have been interested in what constitutes an optimal level of stimulation for individuals. Each of us can recall situations from our own experience where a stimulus at a certain level may be pleasurable, yet when experienced at a different, often more intense level, the stimulus becomes aversive or even painful. Think of music. When your favorite music is experienced through headphones at 50–60 dB, it may be stimulating or soothing depending on the character of the music. Additionally, one's attention to the music at this level may drift away to other topics or issues. One can either focus on the music or let it drift in and out of the background while one accomplishes another task. However, when the volume begins to increase, attention shifts exclusively to the music and it produces higher levels of arousal until around 80–90 dB the music is most difficult to ignore and is quite arousing. At this level, for some people, the music may begin to resemble noise and at higher levels it becomes aversive and at still higher levels certainly painful. Organisms exposed to high levels of noise may appear very aroused and motivated as they attempt to avoid the aversive nature of the stimulus. Freud observed that stimulus intensity can drive internal 'cerebral excitement' or arousal.

Citing the work of Wundt, Freud, Yerkes & Dodson, Hebb, and Duffy as background, Zuckerman reached the conclusion that there is for each individual an optimal range of stimulus contact, intensity, and novelty that is most pleasurable or most conducive to better learning or performance. In this view, individuals seek stimulation to maintain an optimal level of arousal so as to maximize their comfort and pleasure. It is also clear that different levels of arousal may affect performance such as learning efficiency and motor performance. Interestingly, the level of arousal necessary for optimal learning and performance may vary as a function of the difficulty of the task to be learned or performed. As task difficulty escalates, less-intense stimulation is necessary for optimal learning and performance. Duffy studied several indices of physiological arousal, including EEG, as measures of mental effort. She observed that individuals vary in task arousal due to either genetic or environmental factors and that these differences reflect their personality or temperament.

Over the last quarter of the twentieth century and into the first decade of this century, personality theorists have come to understand that the well-defined personality traits are heavily influenced by heredity and genetics. The study of personality theory has become known as evolutionary psychology for just this reason. One early advocate of biologically based temperament, in the 1940s, was Hans Eysenck. He defined personality along three dimensions: introversion versus extroversion, neuroticism or emotional instability versus stability, and psychoticism or

tough-mindedness and antisocial tendencies versus socialized humaneness. The first two dimensions have been much better investigated than the third. In the 1960s, Eysenck proposed that extroverts have a higher optimal level of stimulation than do introverts. Capitalizing on an increased understanding of how cortical arousal is achieved, Eysenck linked his theorizing to differential levels of sensitivity of the brainstem reticular activating system (RAS). The RAS is responsible for modulating the level of cortical arousal, among other things, through a feedback loop system. Stimulation can impact the system from the senses or from the 'emotional brain' or limbic system. We now know that this system also includes the frontal cortex and that input from brainstem loci near the pons influences frontal lobe function via dopamine (DA) and serotonin inputs. There is also reciprocal looping between the frontal cortex and the amygdale that enhances our ability to modulate our arousal. Our ability to make decisions, or favor different levels of stimulatory activity, we now understand, is largely controlled by this complex system.

In the late 1960s, Eysenck began to increasingly emphasize the role of genetics for personality theory. Taking the animal literature as a point of departure, Eysenck observed that selective breeding could produce individuals of very different temperaments. He reasoned that human personality traits such as extroversion, and perhaps more narrow traits such as impulsivity or SS, might have a common or correlated genetic underpinning. Eysenck had a significant influence on Zuckerman who studied with Eysenck during an early period in his career when he was moving away from research on sensory deprivation and beginning to consider temperaments as a field of inquiry. The fact that genetics makes a significant contribution to personality development is a view shared by many psychologists today, and also researchers such as David Buss, who have come to provide significant research support for the position that both genetics and environmental influences are important, and in many cases at least equal, contributors to the stable patterns of behavioral tendency we call personality traits.

SS is clearly related to Eysenck's extroversion variable in his global theory of personality. It is also related to the surgency factor of the popular 'Big Five' global personality theory. Researchers such as Barratt, Revelle, and others have also found it related to more specific subfactor personality traits such as impulsivity, and it has also been linked to certain forms of psychopathology such as alcoholism and attention deficit disorder.

Measuring SS and Characterizing Sensation Seekers

The Sensation-Seeking Scale

Zuckerman's theory postulates that there are individuals in our midst who differ in terms of the stimulation they need to effectively negotiate the environment. In order to categorize individuals, Zuckerman developed the SSS. Form V, the latest version of the SSS, is a 40-item paper-and-pencil forced-choice questionnaire (more recently, a true-false version is also available and is often used). Items on the SSS separate into four factors:

1. *Thrill and adventure seeking (TAS)*. Items reflecting a desire to engage in physical activities involving elements of speed, danger, novelty, and defiance of gravity (e.g., parachuting, scuba diving).

2. *Experience seeking* (ES). Items reflecting seeking novel experiences through travel, music, art, and a spontaneous nonconforming lifestyle with similarly inclined persons.
3. *Disinhibition* (Dis). Items describing the need to seek release in uninhibited social activities with or without the aid of alcohol.
4. *Boredom susceptibility* (BS). Items reflecting an aversion to repetitive experience, routine work, or predictable people with a reaction of restless discontent when unavoidably exposed to such experience.

The SSS provides an overall score and subscores for each of the factors. Factor, internal and retest reliability data indicate that the SSS is psychometrically sound, and it continues to be refined and used in research and clinical settings (a more recent version, VI, was developed for more specific uses). Form V scales are moderately intercorrelated, suggesting that they all tap different aspects of a more global factor. Three of the four scales show good cross-gender and cross-cultural replicability (TAS, ES, and Dis).

Because of its cross-cultural validity, the SSS has been translated from English into more than 15 other languages and special forms have been developed for children in several languages. The fact that the subscales intercorrelate and that they seem to hold up psychometrically and cross-culturally supports the assertion that there is very likely a biological underpinning to SS. It is important to recognize, however, that the SSS is a paper-and-pencil assessment rather than a behavioral test. Although scale scores correlate highly with SS behaviors, it is clear that individuals may not be honest on self-report assessments. The degree that respondents are not honest affects the test's reliability and validity. Additionally, and even though the SSS has been translated into a fair number of languages for use outside the United States, culture is an important determiner of what constitutes SS behaviors. Zuckerman himself, as his work progressed, attempted to discriminate between culturally acceptable and unacceptable SS behaviors. The definition of what ultimately is acceptable and unacceptable is a cultural assessment. Even within the United States, there are differences in acceptability of specific behaviors based on race, culture, religion, social class, gender, geography, and many other demographic variables. Zuckerman himself recognizes and writes about the fact that young males who have a high imperative for SS may not have the diversity of avenues of expression available that would allow the most healthy choices or perhaps choices most valued by a different or dominant culture. Attitudes concerning particular high-risk behaviors change over time as well. A classic example is the changing attitude toward smoking where early in the last century no 'proper' woman would have smoked in public. While these issues do not render the SSS any less valuable in most contexts, recognition of these issues should provoke careful consideration of the use and interpretation of the assessment in any one case or study.

Characteristics of Sensation Seekers

Using data from self-report inventories of drug use along with SSS scores, researchers have found significant relationships between high scores on the SSS and drug use, including smoking (nicotine), ethanol, marijuana (hashish), amphetamines,

opiates, and psychedelic drugs. For many, tobacco is the first drug of abuse, and there has been a strong relationship between SSS scores and early smoking, one that has continued to remain strong in studies from the 1970s until today. More individuals with high SSS scores, members of both sexes, smoke and smoke earlier, and this relationship is found in data from many countries.

SS is also related to drinking ethanol in preadolescence and adolescence, and early high scores predict later ethanol use. Youngsters who use alcohol have higher SSS scores on average than those who do not but not as high as those who use other drugs, especially those who use drugs considered more harmful than marijuana. SS is correlated with early onset alcoholism which is defined by early onset and the presence of antisocial behavior combined with less anxiety. This is a difficult area because those who go on to be chronic alcohol and drug abusers have a tendency to display both anxiety and depression. SS may lead many youngsters to initially experiment with alcohol and drugs, and those who have issues with anxiety and depression seem more prone to adopt a longer lasting lifestyle choice to use these substances chronically and therefore become dependent. While drug use is related to all subscales and the total score, it is most clearly related to the Dis subscale.

Sensation seekers are also different in terms of their sexual experience, thrill seeking, and preference for complexity. Sexual experience in college students and sexual responsiveness, arousability, and frequency in young married women are related to the broad SS trait as measured by the SSS. Sensation seekers participate in a greater variety of heterosexual activities, with more partners. When it comes to thrill seeking, driving habits are a readily recognized outlet for thrill seeking expression. There is a very strong linear relationship between the speeds at which survey respondents reportedly drive on highways and all of the SSS scales. Sensation seekers have strong preferences for particular types of stimulation. High SS prefer complex as opposed to simple graphic designs when asked to rate designs. High SS people prefer spicy or sour foods and even prefer novel smiles versus familiar mundane ones.

High sensation seekers are more prone to volunteer for various types of unusual experiments and activities, including experiments in sensory deprivation, hypnosis, drug effects, encounter groups, and gambling instruction. Sensation seekers seem to have a continuing taste for novelty as well as intensity. Interestingly, in experiments that are boring or monotonous (e.g., sensory deprivation, meditation), sensation seekers are more likely to drop out early or seek additional stimulation. Notably, in experiments involving social interaction, sensation seekers seem to enjoy themselves, while low sensation seekers seem to experience anxiety, often withdraw, and report not liking the experience. Sensation seekers who volunteer for gambling experiments tend to bet more and at higher odds. Finally, sensation seekers who take scuba lessons tend to stay under longer and dive deeper on their first free dive than others. Groups such as volunteer salvage divers and volunteer fire fighters have even higher SS scores. The TAS subscale was predictive of how far female subjects would go in looking over an exposed parapet 16 stories high and has also predicted fear reactions in other phobia-evoking situations such as exposure to snakes. It is important to keep in mind that risk taking is not the end determinate of behavior in Zuckerman's system,

rather it is the need for stimulation. High sensation seekers generally tend to underestimate the risk in a situation compared to low sensation seekers as they seek stimulation. Given equal levels of risk appraisal, high sensation seekers anticipate more positive arousal, whereas low sensation seekers anticipate feelings of fear and/or anxiety.

SS has been correlated with other personality variables. Those who score high on the SSS also tend to score high on Eysenck's extroversion scale, although the correlation is modest and not all extroverts score high on SS. In fact, high SSS scores are more reflective of the 'impulsive' component of extroversion than the 'sociable' component. Sensation seekers tend to be nonconformists and risk takers guided more by their selfish interests than by societal convention or the needs and opinions of others. In persons with low SS scores, as activities get more risky, anxiety increases, while in high SS individuals, as risk increases, anxiety or fearfulness decreases. SS increases as a function of age until adolescence and then declines from the early 20s onward. Older persons tend to score lower on TAS and Dis. Males generally score higher than females especially on the Dis scale but also on TAS subscales, while scores on ES are similar.

The Place of SS in a Global Theory of Personality

The 'Big Five' personality structure has enjoyed decades of empirical support in the evolutionary psychology literature. It provides a structure for describing the most basic major (superfactor) dimensions of personality. The Big Five are (i) Extroversion or Surgency, (ii) Agreeableness, (iii) Conscientiousness, (iv) Emotional Stability, and (v) Culture or Intellect or Openness to Experience. Researchers such as Tupes, Christal, Catell, Costa, McCrae, Goldberg, and Hough have been major contributors to the initial elucidation of a set of stable primary temperaments and their subsequent combination into the five superfactors we now recognize as the Big Five. Evolutionary psychologists have found over decades of study that the Big Five model has held up across language domains, using both adjectival and questionnaire-type assessments, and across methods of analysis. Clearly, the Big Five structure is our most robust molar global description of personality. However, as Hough observes, on a more practical scale, while the Big Five may represent the superstructure of personality, it does not have the fine grain detail to adequately predict variation in constructs such as job success. Some evolutionary psychologists have criticized the Big Five noting that the combination of subfactorial traits underlying the five superfactors is sizable and complex. In any case, the first three factors of the Big Five seem the most stable. SS fits into Factor I (FI): Extroversion or Surgency. Some facets of FI include: talkative, extroverted, assertive, forward, daring, flamboyant, sociable, zestful, dominant, active, persistent, mischievous, confident, bold, uninhibited, flirtatious, explosive, adventurous, spontaneous, opportunistic, and exhibitionistic. These are easily recognizable correlates of SS.

Clearly, SS attributes load heavily on FI and this factor is one of the major descriptors of both human and likely nonhuman-animal personality. This is consistent with Zuckerman's assertion that SS is an important biologically relevant and determined personality trait or temperament. While SS and Extroversion or Surgency (FI) are not identical,

SS is a major component of FI and therefore important for inclusion in any dimensional theory of personality, no matter what the name a particular theorist assigns this factor. The factor, FI, is also stable across a number of investigational domains mentioned earlier. If this were not so, there would be considerable reason to doubt claims made for the biological relevance and determinism of this factor.

Biological Correlates of Sensation Seeking

Orienting Responses and Stimulus Seeking

As we navigate our environments on a daily basis, we are exposed to a stimulus array of great complexity. Some of these stimuli we recognize, in fact some we know quite well, and we may either choose to respond to them or ignore them depending on their meaning, context, and the situational demands. Others may be new and novel to us, and we have no experience with their meaning or predictive capabilities. These novel stimuli generate interest, and we attend to them, orient to them, producing what is called an orienting response (OR). If the initial stimulus is aversive, with greater than moderate intensity so as to be aversive or very intense, then organisms may wish to avoid that stimulus, the definition of a defensive reaction (DR).

The assumption is that sensation seekers have a higher drive, willingness, or curiosity to investigate moderately intense, novel, or complex stimuli. Therefore, sensation seekers should have stronger ORs to these stimuli. This is in fact what Zuckerman and others found when they compared subjects with various scores on the SSS for the strength of their OR. High SS subjects had larger galvanic skin responses in response to novel visual and auditory stimuli. Both high and low SS subjects habituated at the same rate to repeated stimuli, however. In fact, when several levels of sensory intensity are included in an experiment, the high SS subjects respond with a stronger OR to the moderately intense stimuli and with a DR to very intense stimuli, while low SS respond with DRs to both the moderate and highly intense stimuli. Further confirmation that OR is reflective of SS is the fact that young subjects have stronger ORs than older subjects, especially to moderately intense stimuli. OR strength has been related to psychopathology. Schizophrenics who are behaviorally inactive tend to display weak ORs. Stimuli in their environments do not seem to interest them while they are quiescent. These same schizophrenics typically score low on the SSS. However, schizophrenics who are more actively psychotic, as well as psychopaths, tend to display strong ORs. Additionally, extreme psychopaths have a tendency to give strong ORs to stimuli such as needle puncture and strong skin shock. These same stimuli would elicit strong DRs in normal people. Display of a strong OR to an intense stimulus is also a characteristic of high sensation seekers.

The definition of OR includes a component of physiological response in addition to a behavioral component. One type of physiological response can be recorded from ongoing brain, EEG activity, using scalp electrodes. When the brain perceives an external stimulus, it orchestrates the OR. In other words, any response to a stimulus is initially brain activity that may ultimately be manifested, or not, as overt behavior, an OR.

The brain's response, as elaborated in a disturbance of ongoing electrical activity, to an external stimulus is termed an average evoked response or evoked potential (AER). Monte Buchsbaum measured the amplitude of a certain component of the AER and plotted that amplitude as a function of the stimulus intensity that produced it. If increasing levels of stimulus intensity produce increasing amplitude of AER in an individual, then that individual is termed an 'augmentor.' This is similar to an increasingly intense OR to escalating stimulus intensity. Conversely, if increasing levels of stimulus intensity produce a reduction in AER amplitude, then the person is termed a 'reducer.' Again, obviously, this is similar to a DR. These differences are often most apparent at higher stimulus magnitudes. Augmentors are thought to be involved in stimulus intake, and stimulus seeking, while reducers are engaged in stimulus rejection. As you can see, there is a close parallel between augmenting and reducing and the OR versus DR continuum.

Buchsbaum and a number of colleagues, including Zuckerman, began to relate SS to the AER in the 1970s. In general, these studies have found that normal people who are augmentors tend to be high scorers on the SSS, that augmenting decreases with age, and that augmentors have low endorphin levels. Psychiatric patients who are augmentors tend to be manics (and their relatives), delinquents, heroin users, psychopaths, alcoholics, process schizophrenics, and to have low levels of the neurochemically important oxidative enzyme monoamine oxidase (MAO). Normal people who display a tendency to be reducers score low on the SSS and have higher levels of endorphins. Psychiatric patients who are reducers tend to be stimulant users, hospitalized reactive schizophrenics, insomniacs, and have high MAO levels. Of special note is the fact that manic patients are most often augmentors. Lithium, a standard treatment for bipolar affective disorder, prevents mania in many patients and may also reduce the number and severity of depressive swings common in this disorder. Lithium also has a tendency to reduce the augmenting pattern and seems most effective in those patients who are the most significant augmentors. Augmenting of the cortical evoked response seems to involve another postulated aspect of the biological makeup of sensation seekers: the capacity to seek stimuli and react to stimuli of high intensity without displaying a DR.

Neurobiology of SS

Catecholamine neurotransmitters, DA, and norepinephrine are long-recognized key regulators of important survival behaviors such as arousal, determining which stimuli are reinforcing control of movement and allocation of attention. MAO is a degrading enzyme in catecholamine systems that helps keep these neurotransmitters functioning within narrow limits, closely controlled by neuronal mechanisms, presumably because their particular functional levels are so important in regulating survival behavior. MAO assays have been instrumental in research in a number of fields searching for etiology of mental disorders including affective disorders and impulse control disorders. Over the last two decades, researchers have found MAO levels to be a reliable biological marker for a number of behavioral and personality traits.

Across a number of studies, from a diverse set of laboratories involving thousands of subjects, normal subjects who

score highly on the SSS tend to have lower levels of platelet MAO than low sensation seekers. For instance, low MAO subjects had a tendency to be heavy drinkers and more likely to be alcohol-dependent. In fact in males, low MAO is associated with type II alcoholism, which is defined as having an earlier age of onset and is associated with more antisocial behavior when intoxicated and a family history of alcoholism. In addition, people with low MAO were more likely to smoke tobacco and use marijuana. Recall the use of these three drugs, alcohol, tobacco, and marijuana, is heavily correlated with high scores on the SSS. Individuals with bipolar disorder tend to have lower levels of MAO, and these levels do not change in concert with their clinical state. In fact, their relatives have been found to have lower levels of MAO as well, a result many believe is indicative of a general predisposition for the disorder rather than a highly specific predictor of this particular disorder. The types of patients here described as having low MAO are also more likely to be augmentors. Not surprisingly, MAO research has not been confined to human subjects but has also been conducted in other primate species. Tested in a natural setting, rhesus macaques having low MAO were more active, social, and spent more time in play than those monkeys having higher levels of MAO regardless of sex. Those males with the lowest MAO were also the most aggressive, dominant, and sexually active. The parallel between the behavior of these macaques and extroversion and sociability in humans is unmistakable.

Recent research, in the last decade of the twentieth century and the first decade of the twenty-first century, indicates that perhaps the influence of MAO in SS is in DA pathways, both the striatal system and medial forebrain bundle system that projects from the nucleus accumbens to the ventral tegmental area and then to the frontal cortex. Evidence indicates that availability of DA D₂, ₃, & ₄ receptors in this system may be negatively correlated with SS. DA receptor genetics have now been firmly linked to SS as well as behaviors such as gambling, excessive drinking, and drug abuse, as well as personality traits such as impulsivity.

Numbers and characteristics of receptors as well as the functional capability of enzymes such as MAO are under both genetic and environmental influence in any one individual. A moderately low level of MAO, or reduced functional capacity of DA receptors, might occur in a person who is a sensation seeker, gregarious, an augmentor, and a social drinker who likes to party. However, this individual may live a relatively normal life if he or she has appropriate outlets for his or her SS behavior. Yet, a person with an even lower level of MAO or DA receptors, or one not having acceptable outlets for their SS behavior, may fall into a high-risk category, perhaps drinking to excess, using other drugs, and having a habit of driving while intoxicated and perhaps drug-related convictions along with a court-ordered psychiatric referral. Still lower levels of MAO, or decreased DA receptor availability, or more adverse life circumstances, might predispose one to become an outright alcoholic, drug addict, or have an incapacitating bipolar disorder. As MAO and/or DA receptor availability decreases behavior related to SS, more extreme SS increases in frequency. Clearly, SS seems related to neurochemical variables that are heavily influenced by genetics and also by early environmental experience.

Social Influences on the Expression of SS

We are all sensation seekers to some degree. However, most of us tend to express our SS tendencies through socially acceptable avenues. Many of the behaviors indicative of SS canvassed on Zuckerman's SSS on the TAS and the ES scales are reflective of the kinds of risk taking common to middle- and upper-class American people. Those two subscales, the TAS and ES, also show the greatest differences between British and American samples, indicating some cultural difference between the two populations. Cultural influences obviously have a heavy impact on the types of behaviors individuals choose to use as outlets to express the trait of SS.

Zuckerman feels that the more deviate the form of SS activity, vis-a-vis cultural norms, the more likely the behavior is the result of a biological imperative, driven by an extreme genetic component in that individual. Bungee jumping might be a good example as it is a culturally acceptable expression of SS that requires people of above average SS tendency to participate, but it is not deviate nor is it illegal. It is frightening as one is required to jump off some high object and no reasonable sober person would be without fear in such a circumstance. However, peer pressure or some other mechanism might be necessary to get some people who might not be such active sensation seekers to give it a try. In the last 10 years, 'reality' television programs have become very popular. One of the most challenging for participants is a program called 'Fear Factor.' On this program, participants are asked to do things that are known to produce fear or disgust, such as being placed in a clear plastic coffin for a brief period of time, a coffin filled with nonvenomous snakes, spiders, or large hissing cockroaches, allowing these animals to crawl all over them. The motivation to endure this frightening treatment is a substantive amount of money, tens of thousands of dollars. Yet, even for the promise of \$40 000 or \$50 000, many people simply cannot force themselves to complete some of the tasks. Their optimum level of arousal is exceeded, and many simply panic and decompose when pressured by a cocompetitor – which is obviously a great source of popularity among viewers who undoubtedly experience some level of vicarious excitement and arousal themselves from seeing others very excited or disintegrating into uncontrollable panic. Participating on 'Fear Factor' is a socially acceptable form of SS. Some other forms of SS that are culturally acceptable are sports such as mountain bike racing, rodeo, rock climbing, mountaineering, scuba diving, automobile or motorbike racing, and water skiing among others. Activities such as these might be termed forms of 'healthy' risk taking. They are risky, arousing, but not deviate or illegal.

In one of his most recent books, Zuckerman has an article entitled 'Prevention and Treatment of Unhealthy Risk-Taking Behavior.' We have already discussed multiple forms of unhealthy SS behavior from smoking to risky sexual behavior and polydrug use involving needles. How do people choose between healthy and unhealthy patterns of SS? This is especially critical if that person is not affluent and has limited or no avenue for socially acceptable but expensive forms of outlet for their drive to increase arousal. As Zuckerman states: "It is difficult to change a basic personality trait like sensation seeking." Zuckerman quickly thereafter asserts that it is entirely

possible to channel SS tendencies into risky sports or vocations such as fire fighting or police work. In fact, he provides the insight that while society condemns some forms of SS, it affirms other equally extreme forms practiced by public servants such as those who went into the Twin Towers or their rubble at considerable risk to save or recover others. These folks we anoint as heroes.

How do people get down these different paths? One simple answer is that availability and exposure are very important. Clinical experience tells us that it is very difficult to extinguish an SS behavior once it is established. Information, reasoning, and appeals to the imminence of negative consequences are almost always insufficient. Prevention is much preferred to treatment after a destructive pattern is established. Research shows that the full range of therapeutic interventions from pharmacological to established psychological methods such as cognitive-behavioral therapy must be applied to have any impact at all. Many who enter these programs drop out before completion and those who do complete may have changed their behavior for a while, but often relapse is very common, perhaps most common. The higher the indications are that an individual has a personality characterized by high SS and high impulsivity, the more dim the prognosis. One important covariate is testosterone level. As individuals age, testosterone levels often drop off to some degree. There is firm evidence, clinical and experimental, that testosterone levels interact with other biological determinants to produce higher levels of SS behavior. Prevention is key to avoiding maladaptive SS. Socializing at church or volunteer organizations, working a boring 9–5 job, and settling into a long-term monogamous relationship are not likely to work well after an individual has experienced the intense arousal of cocaine, gambling, or varied sexual experiences. Shifting to other societally acceptable risky behaviors such as extreme sports may or may not be within the grasp of individuals, and they may pose their own risk of dependency or injury.

What can be concluded from the research on prevention and treatment? The fact remains that it is difficult to modify to a great degree the genotypic influence and while we may understand some of the factors involved in the acquisition of SS preferences from within a range of environmental options, there is precious little practical advice for parents. It seems clear that one important way to deal with a child who might be a high sensation seeker is to channel that drive into socially acceptable methods of satisfaction where possible. In that regard, vigilance regarding what the child is doing and choice of peer groups is critical. Society clearly admires sensation seekers who advance the goals of society: fire fighters, astronauts, military jet pilots, explorers, and college and professional athletes, among others. Sadly, either because of personality structure, physical attributes, or opportunity, not everyone can channel their SS drive into one of these socially acceptable venues.

As we become more urban and civilized, we seem to have less tolerance for antisocial forms of SS. Until we find some accessible, affordable, alternatives for folks who crave stimulation, we are likely to have continued problems with the most extreme of sensation seekers among us who have not, by good fortune of early experience, affluence, and family circumstance, found acceptable outlets for their urgent drive to seek higher

levels of arousal. And even for those among us who by good fortune can live socially acceptable, even heroic, risk-taking lives, injury and death are constant shadows.

Conclusion: A Biosocial Model of SS

Zuckerman and his colleagues and collaborators have done a masterful job of outlining the parameters of a very important, impactful, personality trait – sensation seeking. As with many traits, the extremes would represent maladaptive behavior in most social contexts, and some middle point in the range would confer an evolutionary advantage for most of us, although points on either extreme might be more adaptive in selected circumstances. A genetic predisposition toward the extremes would be, predictably, fairly resistant to environmental modification, while those in the middle might come to be able to exercise their prerogative for SS with some flexibility and discernment. Those in the middle range would also find their expression more plastic to the environment both in terms of level and venues of expression. The malleability of this trait for those in the middle range of the distribution would only serve to make the trait more adaptive by allowing some modification to suit both the individual and the circumstances at hand.

Zuckerman and his colleagues then have compiled a sizable and remarkable literature outlining the nature of SS and its expression across a number of species, Zuckerman having published two books himself in the first decade of the twenty-first century. They have also made noteworthy progress in identifying physiological and neurochemical markers for this trait. They have firmly placed the trait into the general framework of personality trait structure accepted by most evolutionary psychologists and personality theorists. There is still work to be done regarding the specific nature of relationships with other traits, but the place of SS in empirically derived trait theory in personality is firmly established. Two major research issues remain. One would have the goal of understanding what environmental influences may most effectively modify the genotype one inherits for SS. A corollary topic would be what can be done therapeutically to redirect unhealthy SS behavior to more healthy alternatives and sustain those shifts over a

lifetime. Much work remains to be done here. A second research imperative is to more fully understand the neurobiology and genetics of this trait. This research is assured to continue with urgency as SS is so closely tied to both instances of heroism and tragedy of the human condition. Zuckerman, now Professor Emeritus, has stimulated two generations of behavioral and neural scientists with his keenly insightful outline of what has proved to be a key personality characteristic with a profound impact on both our daily individual happiness and our long-term species survival.

Glossary

Allocortex Regions of the cerebral cortex that have fewer cell layers than the neocortex, especially the olfactory cortex and the hippocampus. Also called *heterotypic cortex*. The phylogenetically older part of the cerebral cortex.

Amygdala An almond-shaped nucleus located deep within the medial temporal lobes of each side of the brain. This nucleus, which is part of the limbic system, plays a critical role in the processing and memory of emotional reactions.

Anterior olfactory nucleus A nucleus found behind the olfactory bulb and in front of the lateral piriform cortex and medial olfactory tubercle in a region known as the olfactory peduncle or retrobulbar area. The deep part of a sector of this nucleus comprises a thick ring of cells that surround the anterior limb of the anterior commissure.

Cortex A thin layer of gray matter on the surface of the cerebral hemisphere, folded into gyri with about two thirds of its area buried in fissures. It integrates higher mental functions, general movement, visceral functions, perception, and behavioral reactions.

Dynein arms Large multimeric proteins (600–800 kD) that comprise the outer microtubule doublets in the ciliary axoneme. These proteins are involved in ciliary activity that is dependent upon the decomposition of ATP into ADP and a free phosphate ion, thereby releasing energy.

Entorhinal cortex The entorhinal cortex is located at the rostral end of the temporal lobe and stretches dorsolaterally. It is usually divided into medial and lateral regions with three bands with distinct properties and connectivity running perpendicular across the whole area. A distinguishing characteristic of this cortex is the lack of cell bodies where layer IV should be; this layer is called the *lamina dissecans*. This cortex is important for memory and forms the main input into the hippocampus.

G-protein Any of a class of cell membrane proteins that function as intermediaries or transducers between receptors and intracellular elements such as enzymes (e.g., cyclic adenosine monophosphate or cAMP) or ion channels.

Mitral cell The major projection neuron of the olfactory bulb. The shape of its cell body resembles the head dress – mitre – of bishops in the Catholic church; hence its name. This cell sends primary dendrites into the olfactory bulb glomeruli, and axons to the primary olfactory cortex.

Secondary dendrites are found in the external plexiform layer of the bulb, where they receive inputs from a range of cells, including inhibitory inputs from granule cells.

Nasopharynx (also termed epipharynx) That part of the space behind the mouth (pharynx) located above the soft palate that is continuous with the nasal passages. The pharynx proper serves as a passage for food from the mouth to the esophagus and for air from the nose and mouth to the larynx.

Neocortex The outer layer of the brain of mammals. Also termed the neopallium or isocortex, the neocortex is made up of six layers, with layer VI being the innermost layer and layer I the outermost layer. It is involved in sensory, cognitive, and motor processes, including conscious thought and language.

Periglomerular cell The generic term for interneurons within the olfactory bulb that are located near olfactory bulb glomeruli, where the first synapses occur between the axons of incoming olfactory receptors and the dendrites of the major output neurons of the olfactory bulb, the mitral and tufted cells. Such cells modulate activity among glomeruli, with a number having processes that enter into glomeruli.

Pheromone A biological agent made up of one or at most a few chemicals said to uniquely and specifically elicit behavioral or endocrine responses among conspecifics. While such agents have been identified in insects and some other life forms, their existence in mammals is highly questionable.

Rostral migratory stream Also known as the rostral migratory pathway, this brain pathway is the route along which neuronal precursors that originate in the subventricular zone of the brain reach the olfactory bulb, where they differentiate into interneurons: namely, periglomerular and granule cells. Such neurogenesis continues into adulthood along this pathway.

Introduction

The sense of smell, termed olfaction, is ubiquitous in nature, being found in one form or another in nearly all air-, water-, and land-dwelling animals. Even bacteria and single cell organisms have mechanisms for sensing environmental chemicals. In our own species, this sense largely determines the flavor of foods and beverages and provides a means for detecting such environmental hazards as spoiled food, leaking natural gas, fire, toxic fumes, and polluted environments. Smell plays a significant role in social and sexual behavior, as evidenced by its role in the multi-billion dollar perfume and personal care products industries.

In this article, I review the anatomy and physiology of the human olfactory system, its presence in early life, and factors that alter its function in adulthood.

The Olfactory Receptors

An estimated 10–15% of the air that enters the human nose during inhalation reaches the olfactory epithelium, a pseudostriated neuroepithelium lining the roof of the nasal cavity. During chewing and swallowing, volatiles reach this epithelium from the rear of the mouth via the nasopharynx, a process

called retronasal olfactory stimulation. This epithelium contains 6–10 million receptor cells capable of detecting thousands of chemicals by G-protein-mediated receptors located on their thread-like cilia. Each cell extends 10–30 cilia up to one eighth of a millimeter in length. This results in an enormous surface area. In the human, for example, the surface area of the cilia is around 16 cm²; in the German shepherd dog, this surface area is ~5 times the surface area of the dog's body! A scanning electron photomicrograph of the surface of the olfactory epithelium with bordering respiratory epithelium is shown in **Figure 1**.

In 2004, the Nobel Prize in Physiology or Medicine was awarded to two scientists who identified the gene family responsible for the expression of the olfactory receptor proteins (hereafter termed simply olfactory receptors). In the human, around 450 types of functional receptors are expressed, in contrast to over a thousand in the mouse. This stands in stark contrast to the number of receptor types found in vision, that is, three types of cones and one type of rod. Interestingly, each of the 6–10 million human receptor cells expresses only one type of the ~450 receptors. However, a given receptor type responds to more than one odorant. The peripheral 'olfactory code' comprises set combinations of activity among receptors. For example, receptors a, b, c, d, g, k, n, w, r, and z may be

activated by odorant A, whereas receptors c, d, j, n, q, and r may be activated by odorant B. Note that receptors c, d, r, and n in this example are activated by both odorants, illustrating the concept that most receptor cells are 'generalists.'

The olfactory receptor cells are unique in a number of ways. First, they serve as both the receptor cell and the first order neuron, that is, first neuron in the chain of neurons that sends signals to the brain. Second, unlike the cilia in the surrounding respiratory epithelium, their cilia do not beat in unison and more or less waft in the mucus. This is because they lack the biochemical machinery, termed dynein arms, necessary for synchronized beating. Third, when damaged, the receptor cells can be replaced by stem cells located near the basement membrane, although such replacement is rarely perfect and damaged regions previously occupied by receptor cells are often replaced by other forms of epithelia. Fourth, these cells can be a direct conduit for the passage of viruses, bacteria, toxins and other exogenous agents from the nasal cavity into the brain. Indeed, it was discovered in the first half of the twentieth century that polio virus readily entered the brain via the olfactory receptor cells. This led to public health initiatives in Canada and elsewhere to chemically cauterize the olfactory region of school children in attempts to prevent contraction of polio.

When a sufficient number of odorant molecules bind to the receptors of a given receptor cell, an ion flux occurs across the cell membrane, generating an action potential that propagates along the length of the cell's axon. The long axon extends from the nasal cavity into the brain and, when depolarized, releases a chemical agent or neurotransmitter into the space between adjacent neurons, termed the synaptic cleft. The neurotransmitter release, if of sufficient magnitude, alters the activity of the cell or cells to which it is connected on the other side of the synaptic cleft, resulting in alterations in their ion flux and, in most cases, producing depolarization and an action potential.

Reproduced from Menco BPM and Morrison EE (2003) Morphology of the mammalian olfactory epithelium: Form, fine structure, function, and pathology. In: Doty RL (ed.) *Handbook of Olfaction and Gustation*, pp. 17–49. New York: Marcel Dekker, with permission from Marcel Dekker.

The Olfactory Bulbs

The olfactory bulbs are paired elongated structures found at the base of the brain. In humans, they are located roughly between the eyes. These structures are the sole recipients of the olfactory receptor axons, which first collect into bundles, termed 'fila,' before passing from the nasal cavity into the brain via small holes (foramina) in the cribriform plate of the ethmoid bone. The axons of the olfactory receptors ultimately make up the outermost layer of the olfactory bulb, the olfactory nerve layer. Each olfactory receptor cell axon then diverges from the bulb's olfactory nerve layer to penetrate a single olfactory glomerulus, a 50–200-μm spherical structure found in the second layer of the bulb, the glomerular layer. In young persons, the glomerular layer comprises thousands of glomeruli arranged in single or double layers. In older persons, this layer becomes less well defined, largely reflecting disappearance of glomeruli subsequent to death of the olfactory receptor neurons. The next layers of the bulb, in order, are the external plexiform layer, the mitral cell layer, the internal plexiform layer, and the granule cell layer (**Figure 2**).

A key element for understanding olfactory transduction is that each glomerulus receives axons only from olfactory

Figure 2 Schematic of the major cell types, layers, and interrelation of cells within the human olfactory bulb. Note excitatory influence of mitral cell axons on granule cell processes (+) and inhibitory influences of granule cell processes on secondary mitral cell dendrites (–). Modified from Alloway KD and Pritchard TC (2007) *Medical Neuroscience*, 2nd edn. Raleigh, NC: Hays Barton.

receptor cells that express the same type of receptor. Since these receptors are tuned to specific molecular features of odorants, the glomeruli are, in effect, functional units. The glomeruli are analogous, in principle, to other brain modules in which neurons with a similar function are grouped together, such as the 'barrels' of the somatosensory cortex or the 'columns' of the visual cortex. The information they receive, however, is complicated by the fact that, as noted earlier, a given olfactory receptor type can bind a range of molecules which share similar elements and a given odorant typically activates a number of receptors. Thus, the pattern of activation across receptors from information related to odor quality must be extracted by higher brain regions.

The main secondary neurons, the mitral and tufted cells, send their axons via the lateral olfactory tract to the olfactory cortex (see next section), whereas the periglomerular cells have localized projections confined to the bulb. The latter cells, along with the axonless granule cells found within the core of the bulb (Figure 2), serve to modulate the neural activity of the mitral and tufted cells. Periglomerular cell modulation presumably sharpens contrasts between adjacent glomerular modules, depending upon the nature of the stimuli. Granule cell modulation often reflects influences of centrifugal fibers from the hypothalamus and other brain structures, increasing or decreasing the sensitivity or gain control of the mitral and tufted cells, depending upon the biological needs of the organism. Like the receptor cells within the olfactory epithelium, granule cells and periglomerular cells are capable of being regenerated. Thus, subsets of these cells are continuously replaced by primordial cells that migrate along the rostral migratory stream from the subventricular region of the brain. Factors that alter this migration can influence the ability to smell.

There is evidence that the size of the olfactory bulbs relative to that of the brain correlates with how important olfaction is to the organism, although this relationship is not invariant. As a general rule, nocturnal and ground-dwelling species have

relatively larger olfactory bulbs than their diurnal and tree-living counterparts. The olfactory bulbs of bats that use echolocation to catch flying prey are typically smaller than the bulbs of fruit-eating bats.

The Olfactory Cortex

The primary olfactory cortex has been defined as cortical brain regions which receive the mitral and tufted cell axon projections. This includes the anterior olfactory nucleus, the piriform cortex, regions of the amygdala and periamygdaloid complex, and the rostral entorhinal cortex (Figure 3). The axonal projections from the bulb are primarily ipsilateral. Unlike other sensory systems, the output neurons project directly to cortex, albeit a simpler three-layered allocortex, without first synapsing in the thalamus. It has been suggested that this may help to explain strong associations between odors and memory, emotion, and endocrine function. The secondary olfactory cortex is defined as cortical regions receiving projections from the primary olfactory cortex. The structure most commonly termed secondary olfactory cortex in humans is the orbitofrontal cortex.

In humans, the *anterior olfactory nucleus* is a predominantly two-layered cortical-like structure with connections to the olfactory tract. It has an anterior segment located posterior to the olfactory bulb and a posterior segment within the anterior temporal lobe. Its functions are multiple, including reciprocal transfer of information from the bulb to the piriform cortex and relaying information between the left and right olfactory bulbs, as well as the left and right piriform cortices, largely via the anterior commissure.

The large three-layered *piriform cortex*, named for its pear-like shape, has frontal ('prepiriform') and posterior (temporal) components. This cortex reciprocally connects with a number of brain regions involved with behavior and emotion and is critical for processing basic olfactory information. It is involved

Figure 3 The anatomy of the human basal forebrain and medial temporal lobes, including the olfactory bulb, tract, and surrounding nonolfactory structures. DB, diagonal band; EC, entorhinal cortex; F-PIR, frontal piriform cortex; OB, olfactory bulb; OPT, optic tract; OT, olfactory tract; OTu, olfactory tubercle; T-PIR, temporal piriform cortex; UNC/AMY, uncus with amygdala situated beneath. with the learning and memory of odors, and encodes representations of odor quality, identity, familiarity, and hedonics. Another function of this brain region is that of multisensory integration. For example, piriform activity becomes elicited by visual stimuli after they are paired with a pleasant food odor. When food associated with the odor is eaten to satiety, this response is attenuated.

The almond-shaped *amygdala* is positioned deep within the medial temporal lobe. It is closely and reciprocally related to the hypothalamus, and is intimately associated with sympathetic nervous system activity and emotion, such as fear. Its connections with the ventral tegmental area, locus coeruleus, and laterodorsal tegmental nucleus influence the release of such neurotransmitters as dopamine, norepinephrine, and epinephrine. Recent neuroimaging studies suggest that the amygdala responds to the intensity of emotionally significant, that is, pleasant or unpleasant, odors.

The most caudal temporal lobe region that receives axonal projections from the olfactory bulb is the lateral entorhinal cortex. This six-layered cortex is a transitional cortex between the three-layered allocortex and the six-layered neocortex. This brain region has strong reciprocal connections with the piriform cortex. It preprocesses information entering the hippocampus and is intimately involved in learning and memory. In animals, conditioned odor-aversion learning is disrupted by lesions of the medial or lateral entorhinal cortex.

The *orbitofrontal cortex* is located in the posterior ventral region of the frontal cortex. This five-layered agranular neocortex receives projections from, and sends projections to, all

primary olfactory regions, including the amygdala, piriform cortex, and entorhinal cortex. In addition to these direct connections, the orbitofrontal cortex also reciprocally connects to a number of these structures via the dorsomedial nucleus of the thalamus. This cortical region has extensive connections with brain regions associated with vision, touch, taste, and visceral sensations, providing cross-modal integration and associative learning. In addition to integrating food-related and odor-guided behaviors, the orbitofrontal cortex is intimately associated with judgments of odor familiarity, intensity, hedonicity, and quality, and facilitates the perception of flavor sensations.

Development of Olfactory Perception

Both developmental and functional studies suggest that human and other mammalian fetuses can respond to odors in utero. In humans, the receptor cell axons are observed at 7 weeks gestation and cilia appear around 9 weeks, when the fetus weighs <3 g. Cilia numbers dramatically increase during weeks 10 and 11, along with G-proteins involved in stimulus transduction. By 11 weeks, mature looking ciliated receptors are observed at a time when the fetus weighs around 7 g. By 19 weeks, adult-like lamination of the olfactory bulb is apparent, including the presence of periglomerular cells. Olfactory marker protein, an index of functionality, is detected in human olfactory receptor neurons at 25–28 weeks. This protein is found in receptor neuron cell bodies and dendrites at 29–32 weeks and soon thereafter in the glomerular layer of the bulb.

The olfactory receptors develop in an intrauterine liquid environment rich with chemosensory stimuli. Such stimuli enter the amniotic fluid by means of the excreted urine, gut wastes, the mother's diet, and other constitutional sources. Much more fluid is inhaled than swallowed, implying receptor exposure to a wealth of odorous materials during later fetal life, particularly as the placental barrier becomes more permeable. Given that diffusion rates for odorants in amniotic fluid are similar to those in olfactory mucus, odor detection may actually be facilitated in the intrauterine environment.

Premature human infants reliably detect and discriminate among odorants by 29 weeks, and exhibit odor preferences by 31 weeks. Human newborns preferentially turn their head toward the odor of their mother's amniotic fluid when given a choice between that smell, the smell of amniotic fluid from an unfamiliar mother, and distilled water. Offspring of mothers exposed during pregnancy to anise in their diet are attracted to anise-spiked amniotic fluid, implying transfer of the flavor from the mother's diet into the amniotic fluid. The offspring of mothers who drank ethanol during pregnancy exhibit postnatal responses to ethanol odor, independent of whether abnormal development of the brain has occurred (e.g., Fetal Alcohol Syndrome). Prenatal ethanol exposure can influence odor preferences for alcohol years later and may, in some instances, increase the likelihood of alcohol abuse.

Conditioned aversive responses to odorants can also be learned in utero, although studies demonstrating this phenomenon have largely been performed in animals. Thus, offspring of pregnant mother rats who have been intentionally made sick following infusion of an odorant into the amniotic fluid show postnatal aversions to that specific odor.

Postnatally, olfaction is involved in the earliest infant–mother interactions. The mother’s nipple and surrounding areola area provide a rich assortment of maternal odors to the infant during lactation. In addition to secreting colostrum and milk from the lactiferous ducts (whose constituents are influenced by the mother’s diet, genetic constitution, and metabolism), the nipple is densely supplied with apocrine and sebaceous glands. The areola contains eccrine glands and enlarged sebaceous glands, including secretory prominences or protuberances that contain miniature mammary acini. Suckling babies rapidly learn to recognize their own mother’s odors and respond preferentially to them. This preference is learned within the first few days of the mother–child interaction, and increases as a function of the time the mother breastfeeds the infant.

Mammalian Pheromones

In the early 1930s, a German entomologist made the distinction, in insects, between hormones secreted within the body (‘endohormones’) and hormones excreted outside of the body (‘ectohormones’). The latter were divided into those agents acting within the species, such as sex attractants (termed homoiohormones) and those acting on other species, such as defense chemicals (termed alloiohormones). In the late 1950s, two investigators changed the term homoiohormone to that of pheromone, defining the latter as “substances which are secreted to the outside by an individual and received by a second individual of the same species, in which they release a specific reaction, for example, a definite behavior or a developmental process.” Soon thereafter a number of insect pheromones were chemically identified, most notably the primary sex attractant of the female silkworm moth, *Bombyx mori*.

In the 1960s and early 1970s, several prominent scientists suggested that pheromones are also present in mammals, including monkeys and humans. Claims were made that such agents mediated a host of behaviors and changes in endocrine state, such as territorial behaviors, sexual attraction, aggression, and acceleration of puberty. Although many studies have reported such pheromone-related effects, few such substances have been chemically identified and, even in these cases, the isolated agent or agents fall far short from being anything like an insect pheromone. Learning, novelty, bodily state, and other factors have been shown to be important in establishing the influences of most socially related chemicals on the behavior and physiology of mammals.

The most widely publicized claim for a human pheromone is the purported synchronization of the menstrual cycles of women who are close friends or roommates. The studies upon which this claim is based, however, have been thoroughly discredited on methodological and statistical grounds. Importantly, an evolutionary basis for such a phenomenon has been questioned. In most preindustrialized societies (which presumably are similar to societies associated with much of human evolution), pregnancy occurs in the early teenage years and there is little attempt to control fertility. Menstrual cycling, as seen in modern societies, was the exception rather than the rule. In an extensive study of the Dogon of Mali, a society where menstruating women are segregated at night in special

huts, no evidence for synchrony was found among those who habitually ate and worked together or who lived with a particular lineage of related males. Moreover, synchrony was not observed in any of the remaining cycling women, suggesting to the author of the study, Beverly Strassmann, that the “Popular belief in menstrual synchrony stems from a misperception about how far apart menstrual onsets should be for two women whose onsets are independent. Given a cycle length of 28 days (not the rule – but an example), the maximum that two women can be out of phase is 14 days. On average, the onsets will be 7 days apart. Fully half the time they should be even closer. Given that menstruation often lasts 5 days, it is not surprising that friends commonly experience overlapping menses, which is taken as personal confirmation of menstrual synchrony” (Strassmann, 1999: 128).

Another widely publicized claim for a human pheromone is that of 5 α -androst-16-en-3 α -one (androstenone), a steroid found in the blood, testes, seminal fluid, and fat of primarily male pigs. This agent, which purportedly influences sexual attraction and other social behaviors of humans, is the major cause of ‘boar taint,’ the bad taste of meat from boars who have not been castrated. Androstenone is found in human axillary secretions, as well as in the roots of numerous plants and vegetables such as parsnip and celery. While this agent has commercial value since it aids in the induction of lordosis – the mating stance of estrous sows – this effect is not invariant, does not occur in all sows, and is likely a result of conditioning, as numerous other sensory stimuli can similarly produce this phenomenon in sexually experienced sows.

Factors That Influence the Ability to Smell in Adulthood

The ability to smell in adulthood is influenced by age, sex, nutrition, health, smoking habits, air pollution, reproductive state, and a range of diseases and other factors. Olfactory sensitivity for some odorants, for example, is greater before than after a meal.

In general, women outperform men on a range of olfactory tests and retain normal smell function to a later age than do men (Figure 4). Decreased smell function is common in later life, with measurable decrements occurring in about half of those between 65 and 80 years of age and three quarters of those 80 years of age and older. Smell loss explains, in part, the disproportionate number of elderly persons who die in accidental natural gas poisonings and the reports of many elderly that food has little or no flavor. Decreased smell function can result in nutritional disturbances and, in rare instances, even death. Most food flavors, for example, chocolate, pizza, lime, meat sauce, strawberry, etc., depend upon stimulation of the olfactory receptors from the rear of the nasopharynx during deglutition. Taste buds mediate such sensations as sweet, sour, bitter, and salty.

The most common cause of smell loss seen in the clinic results from an upper respiratory infection. Usually, the infection is more severe than usual and damages the olfactory epithelium. Once the common symptoms of the cold, such as stuffiness and running nose, resolve, the individual discovers that food does not taste right and the smells are gone or diminished. Other common causes of smell loss seen in the

Figure 4 University of Pennsylvania Smell Identification Test (UPSIT) scores as a function of age and sex. clinic are chronic rhinosinusitis, which can lead to permanent neural damage of the olfactory epithelium, and head trauma. Blows to the head that result in rapid acceleration or deceleration of the brain relative to the skull can sever or damage the very thin olfactory fila as they course through the cribriform plate. A strange odor, likely representing either degeneration or attempts at regeneration of the receptor neurons, may be noticed for a few weeks or months after such an injury. Interestingly, olfactory dysfunction occurs more frequently from blows to the back of the head than to the front of the head, in part because frontal blows are cushioned to some degree by the collapse of the softer facial structures (e.g., the nose and sinuses).

Of particular interest to the clinician is the fact that olfactory dysfunction is among the first signs of Alzheimer's and Parkinson's disease. Indeed, in these disorders smell loss typically occurs several years before the onset of the classical disease signs. Such findings have led to the use of olfactory tests in helping to identify persons at the earliest disease stages and to differentiate between neurodegenerative diseases often confused with one another. For example, Alzheimer's disease is consistently associated with smell loss, whereas the major affective disorder, that is, depression, is not. Similarly, Parkinson's disease is associated with smell loss, whereas progressive supranuclear palsy and essential tremor disorders which are sometimes misdiagnosed as Parkinson's disease, have normal smell function.

Summary

The perception of odors begins when volatile molecules bind to specialized receptor proteins located high in the nose. Each of ~450 such receptors, expressed individually on

6–10 million receptor cells, respond to a range of odorant molecules. Activation of these receptors in combination encodes the initial information which is subsequently transformed in higher brain centers, beginning with the olfactory bulb, to produce the sensation of odor.

Multiple brain regions are involved in this process. The piriform cortex encodes higher-order representations of odor quality, identity, and familiarity, and is intimately associated with the learning and remembering of odors. The amygdala and entorhinal areas are thought to mediate the affective aspects of olfactory perception, and play an important role in olfactory learning and memory. The orbitofrontal cortex is involved in facilitating the appreciation of flavor sensations as well as other feeding-related and odor-guided behaviors.

Interestingly, the olfactory system is functional prior to birth, and neonates exhibit the ability to smell a wide range of environmental stimuli. In utero learning of the meaning of odors has been demonstrated in humans and other species, and such learning can influence behaviors directed toward odors after birth. In adulthood, a range of factors influence the ability to smell, including sex, age, and a wide range of medical conditions, including head trauma, upper respiratory infections, chronic rhinosinusitis, and such neurodegenerative diseases as Alzheimer's disease and Parkinson's disease. Olfactory testing is now employed to detect such disorders early in their development, as well as to differentiate between such diseases as (1) Alzheimer's disease and major affective disorder and (2) Parkinson's disease and progressive supranuclear palsy.

Glossary

Ageusia The complete loss of taste.

Dysgeusia An alteration or distortion in the perception of taste.

Hypogeusia A diminished sense of taste.

Mastication The process by which humans mechanically separate food molecules that dissociate in the presence of saliva and digestive enzymes.

Palatability The hedonic reward provided by foods or fluids that are agreeable to the 'palate' in regard to the homeostatic satisfaction of nutritional, water, or energy needs.

Taste buds Also referred to as taste receptors; any one of many peripheral taste organs distributed over the tongue and the roof of the oral cavity.

Taste, also known as gustation, is one of the five traditional senses and is a chemical sense by which the qualities and flavor of a substance are distinguished by the taste buds. Taste stimuli are detected by taste receptors, which are located on the tongue, mouth, and pharynx. In humans, five taste qualities have been identified, including sweet, salty, sour, bitter, and umami. Taste is different from flavor, which includes the olfactory, tactile, and thermal attributes of food in addition to taste. First, we review the significance of taste for humans and the five primary taste categories. Next, we examine the anatomical and physiological substrates in taste receptors. Then we describe the lifespan development of taste from *in utero* to elderly. Finally, we discuss common taste disorders and their effect on behavior.

Concepts of Taste

Significance of Taste

Why are humans equipped with the advanced capability of taste discrimination? The answer to this question is thought to lie in the evolutionary force of nature. The physiological mechanism of taste reception enables an organism to decipher different tastes, including those considered to be desirable, mediocre, or repulsive. Each flavor has a distinct taste and elicits a different response from the palate to the nervous system, which proves advantageous to the organism. For example, salty foods are useful in water retention, sweet flavors indicate a food source high in carbohydrates and calories, umami suggests protein-rich foods, while bitter flavors often are associated with food sources containing toxins that may prove poisonous to the organisms. Thus, it appears that taste reception was, at one point, important for the survival of an individual.

The idea that taste perception and discrimination is essential for energetic enrichment and nutritional preservation stems from the simplest of all organisms, the single-celled bacterium *Escherichia coli*. For example, if *E. coli* sense a baneful chemical, their whip-like appendages rotate and propel them away from such a stimulus, whereas the sensation of an advantageous chemical stimulus will prompt their movement toward the chemical. In regard to human behavior, our ability to

differentiate among various tastes permits individuals to digest the appropriate food source necessary for the required energy in active and dynamic organisms.

A combination of genetic inheritance and an individual's lifetime experiences and culture also contribute to taste perception and specific food preferences. For example, findings from a recent study revealed that variation in a taste receptor gene influences taste sensitivity of children and adults that can explain individual differences in taste preferences and food selection. In this study, researchers compared taste sensitivity and food-related behaviors across three genotypes of the TAS2R38 gene, which encodes a taste receptor responsive to bitter taste. Groups were classified according to the following genotypes: type AA had two bitter-insensitive sites (alleles), type PP had two bitter-sensitive alleles, and type AP had one of each. Findings indicate that children and mothers with a bitter-sensitive allele (type AP) on the TAS2R38 receptor gene were more sensitive to propylthiouracil as compared to children and mothers with two bitter-insensitive alleles or two bitter-sensitive alleles, suggesting some genetic influence on bitter taste sensitivity. In a study that examined the contributions of individual difference and culture, results demonstrated that infants and teenagers of African descent preferred significantly higher levels of sucrose when compared to similar aged Caucasians.

Four (or Five) Basic Tastes

Tastes are organized into five different categories; salty, sour, sweet, bitter, and the newly found umami which is a savory or meaty flavor. Enjoying different tastes has become a recreational activity for the average person such that eating foods pleasant to the palate is considered delectable. But on a more instinctual level, taste enables an individual to desire and enjoy the consumption of material that is in fact beneficial for life. The enjoyment or unpleasantness people experience when eating food differs between individuals and cultures; in other words, there is great variation between individuals, families, and cultures along the hedonic dimension. An individual's food preference may stem from multiple facets such as innate taste preference, acquired or learned food preference, or association of a specific taste to a certain memory.

Sodium is a necessary component for the maintenance of adequate electrolyte and water balance. Researchers believe that the perception of salty foods is derived from an ancestral need to maintain homeostatic equilibrium. The literature is decidedly mixed on the notion of salt acuity. Prior studies suggested that there were age-related changes in taste and odor sensitivity and/or preferences, yielding a more pronounced liking of salty foods in the elderly as compared to younger people. However, more recent experiments reveal that no differences exist between age groups in ratings of saltiness in chicken broth. Moreover, some research findings indicate that older individuals actually prefer less salty broth than do young adults.

Sour tastants are acids, often found in spoiled or unripe food. Infants make facial grimaces when sour tastants are ingested. Furthermore, one study found that infants ingested a smaller amount of mixed sour and sweet solution in comparison to a uniform sweet solution.

The hedonic 'sweet' taste signals high-calorie carbohydrates such as sugars, as well as nonnutritive synthetic sweeteners such as saccharin, which bind to the specific sweet taste receptors. Perhaps universally instilled in humans is the feeling of pleasure when eating something sweet. Many studies have shown that infants readily accept sweet tastes.

In contrast to a sweet taste, which evolved to detect a limited subset of nutrients, a bitter taste helps prevent the ingestion of numerous structurally distinct toxic compounds. The bitter taste is perceived by many to be unpleasant and sharp. Evolutionary biologists theorize that the bitter taste evolved in humans as a defense mechanism against toxins and poisons. This holds true regarding the taste of alkaloids, bitter almonds, and the like. Without prior repeated exposure to a bitter taste such as beer, coffee, or cabbage, most people regard these tastes as undesirable.

In humans, two L-amino acids known as monosodium glutamate (MSG) and aspartate generate the unique savory sensation known as umami. The relatively new umami taste was derived from Japanese soup. Generally, this taste triggers a pleasurable response in humans and thus encourages the intake of peptides and proteins. Proteins derived from food sources yielding a umami taste help to build muscle and organs, antibodies, and enzymes. Few studies have shown that human infants, when fed Japanese soup broth, regard umami taste in a similar manner to that of a sweet taste. In a cross-cultural study that compared hedonics of taste in the Japanese to that of Australians, findings revealed that the Japanese group demonstrated greater preferences for umami tastes. The Japanese people frequently cook with many foods containing the umami taste such as seaweed and nombu. As such, this difference can perhaps be attributed to a learned preference for umami tastes in the Japanese since they are far more accustomed to these tastes than Australians.

Anatomical and Physiological Substrates in Taste Receptors

Gustatory Receptors

Taste buds are clusters of taste receptor cells and are located in various places throughout the oral cavity, including the tongue,

palate, pharynx, and epiglottis. These taste receptors are specialized cells surrounded by nerve endings. The taste receptor cells within a bud are arranged such that their tips form a small taste pore, and through this pore microvilli from the taste cells extend. A single taste bud contains 50–100 taste cells. The number of taste buds varies (2000–10 000) from one individual to another, with the average human possessing approximately 5000–7500 taste buds. Distribution of the taste buds across the oral structures is uneven, with the largest concentration and density being located on the posterior tongue.

Taste buds tend to reside in clusters within the bumps of the tongue, called papillae. There are four types of papillae: (1) Filiform papillae are cone shaped and found all over the tongue. These papillae are mechanical and nongustatory and account for the tongue's rough and uneven surface – in their absence the tongue is pale and smooth. (2) Fungiform papillae are mushroom shaped and are located on the most anterior part of the tongue and generally contain one to several taste buds per papilla. These papillae appear as red spots on the tongue because they are richly supplied with blood vessels. (3) Foliate papillae are a series of folds along the sides of the tongue and are predominantly sensitive to sour tastes. (4) Circumvallate papillae are shaped like flat mounds surrounded by a trench and are found at the back of the tongue. Taste buds and papillae are more numerous in infants than adults. With advancing age, there is a gradual reduction in the number of papillae and the number of taste buds, at a rate of about 1% per year.

The lifespan of the taste cells within the taste buds is relatively short, approximately 10–14 days, although some cells have a much shorter and others a much longer life span. During this process, dying cells are continuously being replaced by new taste cells, such that cells at a variety of different developmental stages are present within a single taste bud. The lifespan of the cells is short due principally to the damaging effects of temperatures, textures, and size of foods; however, the taste bud itself will not die unless significantly damaged. If it is damaged, however, it will have to wait for a nerve to innervate the tissue.

Pathways to the Brain

Taste cells contain gustducin, or receptor molecules, which convert taste stimuli into nerve impulses. Three nerves are responsible for transmitting information from these impulses: nervus intermedius, part of the facial nerve (chorda tympani branch) which innervates the receptors of the anterior two-thirds of the tongue; the glossopharyngeal nerve which innervates the posterior one-third and part of the pharynx; and, the vagus nerve for the remaining taste buds in the posterior oral cavity that includes the pharynx and epiglottis.

When the impulses reach the ganglion associated with their nerve, they project to the solitary tract, which ends in the nucleus of the solitary tract in the medulla oblongata. The solitary tract and nucleus are structures in the brainstem that carry and receive visceral information from the cranial nerves. The pathway for the second-order taste relay neurons projects to the pontine taste areas, which in turn project to the thalamus, lateral hypothalamic area, and amygdala. From the thalamus, the pathway continues to the lowermost part of the postcentral gyrus and limen insulae of the insula.

The somatosensory cortex is responsible for the conscious perception of taste. The hypothalamus, amygdala, and insula are responsible for the so-called 'affective' component of taste, which in turn is responsible for the behavioral response (e.g., aversion, gastric secretion, feeding behavior).

The Taste Map and Taste Stimuli

Through the process of mastication, humans mechanically separate food molecules that dissociate in the presence of saliva and digestive enzymes. These separated molecules are detected by chemoreceptors within the mouth. Chemoreceptors are specialized cell groups responsible for acquiring information about the chemical environment and subsequently conveying the information to neurons. Specifically, taste receptors respond to the dissolved molecules of the masticated food. Groups of receptor cells are formed and surrounded by support cells and basal cells.

Individual taste buds form within the tough, waterproof epithelium of the gustatory region. This region is capable of perceiving taste through use of a group of receptor, support, and basal cells. The microvilli on the apical membranes of the receptor cells project into the gustatory space to detect incoming food sources. The interaction of molecules with these membranes generates distinct tastes. Each receptor cell is formed to be more sensitive to a certain stimulus or tastant over another. Taste buds typically form in specific factions, allotting certain parts of the tongue to be slightly more sensitive to certain tastes or flavors.

Popular belief is that the human papillae are more sensitive to one taste quality than another such that the tongue can be divided into different receptor areas by taste sensitivities. For example, the tip of the tongue best detects sweet substances, the sides of the tongue demonstrate the most sensitivity for salty and sour tastes, and the back of the tongue is most sensitive at detecting bitter taste. The soft palate is sensitive to sour and bitter tastes. Contrary to popular belief, the current scientific view suggests that papillae possess multiple sensitivity to compounds representative of the four primary taste qualities. As such, all taste qualities are found on all regions of the tongue, as long as taste receptor cells are stimulated.

Even though each type of receptor cell is activated differently, the general pathway is comparable. First, the receptor cell is stimulated by the tastant, typically an ion, a sugar, an alkaloid, or an amino acid associated with a particular taste. A conformational change occurs within a taste receptor protein that results in depolarizing the receptor cell. Depolarization leads to release of neurotransmitter at the chemical synapse connecting the taste receptor cell with the next cells in the pathway to the brain. Information sent from the receptor cells in taste buds is transmitted to taste nerves by neurotransmitters. A number of probable neurotransmitters in taste buds have been proposed including serotonin, enkephalin, adenosine triphosphate (ATP), aspartate, and glutamate. Among these, glutamate is the prominent excitatory neurotransmitter involved in this taste signaling. These neurotransmitters bind to postsynaptic receptors, resulting in the quick opening of ligand-gated ion channels. Neurotransmitters can be short term or long term such that some neurotransmitters stay in the synaptic cleft and produce a neural signal for an extended

period of time, while other specified neurotransmitters involved in taste are only short term in nature.

Since foods have different physicochemical properties, the electric potential of the nerve (nerve excitation) and the membrane potential of the taste cell depend on the type of food consumed. In regard to salty perception, the taste cell only needs to detect simple ions. Salt, composed of sodium and chloride, readily dissociates in water yielding sodium cations. One way the taste cell detects the salt is through a particular type of sodium ion channel that spans the apical membrane of the salty receptor cells. Ion channels are proteins that form a channel through a membrane, allowing specific inorganic compounds to diffuse. The sodium ion channel that responds to NaCl is known as the amiloride-sensitive channel. The amiloride-sensitive channels are different from voltage-gated sodium ion in that they are constitutively open. As Na⁺ ions come across the amiloride-sensitive channel, the receptor cell is depolarized. The influx of Na⁺ ions creates a change or gradient in cellular ion concentrations, which in turn generates the action potential needed to enable the associated neuron to fire.

Sour tastants are prevalent in sour stimuli. Hydrogen ion channels have the capacity to detect H₃O⁺ ions that have dissociated from an acid. The ions enter the taste cells through a proton channel or act by blocking an apical potassium channel. Hydrogen ion flow can induce substantial transmembrane currents through amiloride-sensitive sodium channels. Hydrogen ions also inhibit the potassium channel that normally functions to hyperpolarize the cell. The combination of these mechanisms incurs changes in membrane polarization in sensory neurons that produce the sensation of sour taste.

Utilizing cell-based assay, genetics, and bioinformatics, discoveries of the sweet taste receptors have been made, namely T1R2 and T1R3 members of G-protein linked receptors. GPCRs are integral membrane proteins that span certain areas of the apical membranes of taste receptors. Together, T1R2 and T1R3 form the G-coupled receptor. Via activation of these G-protein-coupled receptors, sweet compounds have been shown to lead to the intracellular synthesis of cyclic adenosine monophosphate (cAMP). cAMP is an intracellular messenger and leads through several steps to the closing of potassium (K⁺) channels on the basolateral membrane of the receptor, ultimately depolarizing the receptor through the small resting influx of Na⁺. Once the receptor cell is depolarized, ion-gated channels open eliciting repetitive action potentials.

In contrast to a sweet taste, which evolved to detect a limited subset of nutrients, a bitter taste has the onerous task of preventing the ingestion of numerous structurally distinct toxic compounds. Despite the vastness of this repertoire, these compounds all evoke such a similar sensation that humans simply know them as 'bitter.' Approximately 30 different GPCR bitter taste receptors have been identified, accounting for the large variety of molecules that are associated with bitter taste.

At the molecular level, umami taste detection is mediated by GPCR receptors sensitive to glutamate and perhaps other amino acids.

Importantly, human perception of taste is significantly influenced by other sensory inputs such as olfactory and visual, as well as experiences such as satiety and hunger. Indeed, much of what we perceive as flavor is actually olfactory.

Lifespan Development of Taste (In Utero to Elderly)

Perceiving taste first occurs in the womb and continues throughout the entire lifespan. Taste sensitivity and food preferences change across the lifespan.

Before Birth

At the 7–8 weeks' gestation, taste buds start emerging, and by the 14th week the taste sensation is formed. By 13–15 weeks a fetus' taste buds already look like a mature adult's and are already communicating with their invading nerves. As early as the 6th month of gestation, observations have confirmed that the fetus will engage in behavioral responses to the presence of taste compounds. Specifically, the fetus will increase its swallowing in response to sweet tastes while also decreasing its swallowing in response to bitter and sour tastes. In addition, the fetus will display sensitivities to different chemicals in the amniotic fluid. As gestation progresses, the fetus will develop a similar number and distribution of papillae as those found in children and adolescents. Similar to prenatal smell, a fetus's taste experience in the womb may bias food preferences.

Newborn and Infant

Taste sensations become heightened in newborns as they are able to perceive the basic tastes of sweet, sour, salty, bitter, and umami compounds. Infants are capable of expressing positive and aversive facial responses to tastes. Although newborns can discern different tastes, it is clear that they prefer sweet tastes. For example, newborns and infants show a positive preference for sweet tastes such that a combination of sugar with a pacifier has a calming effect on newborns. In contrast, newborns and infants may demonstrate a negative reaction to sour tastes, usually signaled with a frown on the newborn's face. Newborns can even tell the difference between different types of sugar and concentrations of the same type of sugar. Newborns seem to prefer sucrose (table sugar) over fructose (found in fruit). Reactions to salty food are more variable with responses ranging from positive to negative, but with the majority of newborns reacting in a neutral manner. Taste abilities continue to evolve during early childhood such that after 4–6 months of age, infants start developing a taste for salty food. Several lines of research indicate that the delay in development of salt sensitivity is associated with the development of the kidney.

Children and Adolescents

Around the age of 2, response to salty food will again change. In addition, children's taste preferences and perception of bitterness also will evolve over time. While it is clear that children like the basic taste of sweet and salt, all other food preferences are due to acquired tastes. Results from a recent study of 8900 school-aged children in Denmark revealed that girls are generally better at recognizing tastes as compared to boys, including all concentrations of both sweet and sour tastes. Furthermore, boys have a sweeter tooth than girls and tend to like the more extreme flavors. Finally, findings indicated that the ability to recognize tastes increases gradually with age, with the greatest

shift occurring at 13–14 years of age when children become markedly more sensitive to sour tastes. In another study that involved youth, young male subjects between the ages of 8 and 10 were compared to adult males, with findings revealing that adolescents had a higher anterior papillae density than the adults, making them more sensitive to sucrose or sweet flavors.

Marketing and expectation also play a primary role in taste preference for children and adolescents. In a study conducted by Stanford University, two identical meals, one in a plain wrapper and one in a package from a popular fast food chain were offered to a group of children. Even young children associated a better taste experience with the name-brand selection.

Adults

Although there are approximately 10 000 taste buds in an adult's mouth, the number of these taste buds will decrease beginning between the ages of 40 and 50 in women and 50 and 60 in men. In addition, each remaining taste bud atrophies with age. However, the decline in taste sensitivity with aging is worsened by smoking, chewing tobacco, and poor oral care.

Advancing Age

An estimated one-third of all older adults report dissatisfaction with their sense of taste. This loss of taste sensitivity is common in the elderly and often results from normal aging in which the number of taste buds gradually decreases with age because the receptor cells are replaced less often. Additional causes beyond normal aging include (1) adverse side effects from medications, (2) surgical interventions, (3) certain disease states (especially Alzheimer disease), and (4) environmental exposure.

As the loss of taste progresses, sometimes from the loss of saliva due to aging, there may be concomitant reductions in the pleasure and comfort from food. This loss of pleasure and enjoyment of food is an important risk factor for decreased adherence to specific dietary regimens as well as nutritional and immune deficiencies such as malnutrition and weight loss. There are some gender differences as men tend to lose taste earlier than women.

Taste Disorders

Taste disorders fall under three broad descriptors: *hypogeusia* is a diminished sense of taste, *ageusia* is the complete loss of taste, and *dysgeusia* is an alteration or distortion in the perception of taste. Ageusia is relatively rare; more commonly, individuals will complain of diminished ability to perceive or distinguish taste quality, which can occur as a general loss across all taste qualities or reduced perception of specific taste qualities such as salty, sweet, or bitter. Total loss of isolated taste modalities (such as an inability to perceive sweet) also is rare but has been described in the literature. Many patients who complain of dysgeusia will report that food is perceived as sour, bitter, or metallic. *Phantogeusia* ('taste phantoms'), often a bitter or metallic taste when no gustatory stimulus is present, has been reported in certain disorders (e.g., schizophrenia) or as a seizure aura in epilepsy. Complaints of taste loss or reduction in taste quality should be thoroughly assessed, as individuals will

often report a taste disorder when the primary dysfunction is olfactory, as smell is contributory to flavor. Although gustatory dysfunction or loss does not typically result in serious disability, it can have adverse consequences if one is unable to detect tainted or spoiled food. Specifically, gustatory dysfunction can signify a number of systemic or neurological disorders, which increases the clinical significance and underscores the need for psychophysical taste and smell testing. For example, loss of taste can be psychologically distressing and lead to anorexia or depression. Nutritional deficits or excesses are notable sequelae of taste disorders and can put a patient at risk for additional health problems, such as hypertension, heart disease, or diabetes resulting from modifications to diet (e.g., increased sugar or salt intake to compensate for decreased taste perception).

Taste disorders are generally the result of certain medical conditions, pharmacologic or surgical interventions, environmental exposure to toxic chemicals, head injury, or advanced age. Poor oral hygiene is a common cause of taste reduction and *cacogeusia* (a foul or unpleasant taste). Brushing the tongue is associated with *hypogeusia*. Dentures or other palatal prostheses can result in a deficit in sour or bitter perception, although, in at least 10% of cases, this deficit is caused by an allergic reaction to the prosthetic material. Smoking, particularly pipe smoking, can impair taste perception. Upper respiratory infections also affect both taste and smell, thereby decreasing taste appreciation. Influenza-like infections or viral hepatitis can cause taste disorders. Dryness of the mouth from inadequate saliva can result in *hypogeusia* or *ageusia*, as occurs in Sjögren syndrome. Deficiencies in certain nutrients such as zinc, B12, niacin, or copper can result in changes in taste. Finally, endocrine disorders such as Cushing's syndrome, hypogonadism, diabetes mellitus, pseudohypoparathyroidism, and adrenal cortical insufficiency can result in aberrant taste function.

Burning mouth syndrome (BMS) is characterized as a taste disorder. BMS (also known as *glossodynia* or *glossalgia*) is characterized by persistent, severe intraoral pain generally described as a burning or scalding sensation, usually occurring on the tongue. BMS is accompanied by complaints of *dysgeusia* and dry mouth. The etiology of BMS is not well understood, but some evidence indicates that it can be idiopathic or secondary to another pathological condition such as mucosal disease, hormonal disturbances, nutritional deficiencies, medication side effects, or psychosocial stressors. In addition, the epidemiology and pathophysiology are not well defined, suggesting that more research is needed to clarify these issues.

There are a number of neurological syndromes and diseases in which taste disorders manifest as part of the clinical presentation. Central nervous system disorders such as Alzheimer's disease, Bell's palsy, Parkinson's disease, multiple sclerosis, and epilepsy can produce deficits or dysfunction of taste. Familial dysautonomia has a reduced number of circumvallate and fungiform papillae, leading to deficits in sweet and salty perception. Taste disorders also have been described as a prominent early feature in Creutzfeldt-Jakob disease and speculated to occur in early rabies infection.

Another cause of taste disorders are various surgical and treatment procedures. Taste loss resulting from otologic surgery is rare, but occurs most often following middle ear surgery due to manipulation and stretch, dryness, or injury of the

chorda tympani, which carries gustatory fibers and parasympathetic fibers for the salivary glands. Damage to these fibers can result in taste distortion, reduction, or loss. These taste changes are often unnoticed by patients and are temporary; however, those individuals whose chorda tympani have been severed during surgery have the worst prognosis for recovery and may experience a permanent sensory loss. Very rarely, transitory taste problems are reported following tonsillectomy. Cancer and its associated treatments are common causes of taste disorders. For example, oropharyngeal tumors can invade the chorda tympani or lingual nerves and the resectioning of oral or cervical structures can result in damage to taste fibers. In terms of cancer treatment, chemotherapy and radiation treatment to the oral cavity and neck can cause damage of the salivary glands and taste buds. Salivary gland necrosis and mouth dryness can persist after radiotherapy, while taste bud regeneration typically resumes.

A prevalent cause of taste disorders is drug-induced taste alterations, and up to 33% of older adults will experience taste distortion or deficit as a result of medications. Popular pharmacological culprits include antihistamines, antibiotics, antineoplastics, anticholesteremics, antidepressants, antipsychotics, bronchodilators, diuretics, and anticonvulsant medications. Taste dysfunction can be induced by a single medication or by drug interactions between two or more medications. Typical medication-induced taste complaints include 'metallic taste,' *hypogeusia*, and *dysgeusia*.

Lesions occurring along the central taste pathway, including select areas of the brainstem, thalamus, cranial nerves, or cerebral cortex can result in gustatory dysfunction. Lesions or traumatic injury to cranial nerves VII, IX, or X also can result in taste loss. Taste disorders caused by brainstem lesions generally occur as a result of ischemia or hemorrhage, or a demyelinating process at the level of the solitary tract or pons. Thalamic or corona radiata infarcts can result in *dysgeusia*. Contributors to cortical taste disorders include neoplasm, epilepsy, or cerebrovascular disease. Head trauma can also result in posttraumatic taste dysfunction, although gustatory dysfunction in isolation is relatively rare (<1% of cases) without a concomitant loss of olfaction. Damage to the tongue can occur from self-inflicted bites, facial fractures, or foreign-body-induced lacerations following a trauma, although gustatory dysfunction is typically transitory. Cranial nerve injury can occur from head trauma in which there are temporal bone or skull base fractures, leading to deficits in taste.

Glossary

Afferent fiber Neural fiber that carries information from the receptors to the brain.

Cutaneous Of or relating to the skin.

Glabrous skin Hairless skin; for instance, on the palmar surface of the hand.

Mechanoreceptor A neuron that is activated by mechanical deformation of the skin.

Primary somatosensory cortex Located just posterior to the central sulcus, the primary somatosensory

cortex comprises four areas, each containing a full body map.

Receptive field A patch of skin which, when stimulated, results in the activation of a receptor or neuron.

Secondary somatosensory cortex Located in the parietal operculum, the secondary somatosensory cortex contains neurons with large receptive fields and complex response properties.

Somatotopic organization Adjacent neurons in the brain have adjacent receptive fields on the body.

We are capable of using our hands to produce remarkably fine and precise movements, such as those involved in writing with a pen or playing a musical instrument. Our ability to interact seemingly effortlessly with objects is mediated not only by a sophisticated motor system – comprising both muscles and brain structures specialized for controlling these muscles – but also by a complex sensory system, which informs us of the consequences of our actions. The sense of touch forms a critical component of this sensory system, playing a key part in mediating our ability to explore and dexterously manipulate tools and act upon our environment. Indeed, for individuals with impaired touch, the activities of daily living are slow, clumsy, and require great concentration. The sense of touch also plays a powerful role in social communication, as evidenced by the fact, for example, that deprivation of parental touch in infants severely impedes emotional development.

Sensors in the Skin

Deformations of the skin or changes in skin temperature activate receptors in the skin, and different types of receptors are sensitive to different types of skin stimulation. In glabrous skin (for instance, on the fingertips or on the palm), four types of receptors signal mechanical deformations of the skin: Merkel cells, Ruffini organs, Meissner corpuscles, and Pacinian corpuscles (Figure 1). An individual Merkel cell is activated when light pressure is applied to a small patch of skin (the diameter of the receptive field of a typical Merkel cell is about 5 mm) and will not respond when other parts of the hand are touched. These receptors play a key role, for example, in signaling how much force is applied on a grasped object. Without these receptors, we would either routinely drop objects or crush them. Ruffini organs have large receptive fields, are sensitive to skin stretch, and, in the glabrous skin, are concentrated around the nail. In hairy skin, these receptors may convey information about movement of the joints. Like Merkel cells, Meissner corpuscles have small receptive fields. However, Meissner corpuscles do not respond to steady pressure applied to the skin but to changes in pressure or to movement across

the skin. These receptors are thought to play a critical role in signaling a slip between the skin and an object, which in turn signals to our muscles to increase our grip. Pacinian corpuscles have very large receptive fields and are exquisitely sensitive to small vibrations applied to the skin, the types of vibrations we experience when a breeze is blowing across our skin or when we scan our hand across a finely textured surface. In hairy skin (of the arms and legs, for example), other types of receptors are closely bound with each hair and are activated when the hair is deflected (Figure 2). In addition, two populations of receptors in the skin respond to changes in skin temperature – one responds to cooling of the skin (aptly named cool fibers) and the other responds to warming of the skin (warm fibers). If the skin is cooled or warmed a lot, to the point where it may become damaged, other populations of receptors become activated. The activation of these receptors (nociceptors) is associated with sensations of pain. Other nociceptors become activated when the skin is deformed violently (and in a potentially damaging way), such as when one stubs one's toe. In this article, we focus on the so-called discriminative touch – our ability to perceive shape, texture, vibration, and motion – which is mediated primarily by Merkel, Meissner, and Pacinian receptors.

Signals from the receptors are carried to the spinal cord, and ultimately to the brain, by afferent fibers. Receptors send signals to neurons in the spinal cord when action is required at a short latency. Indeed, sending signals up to the brain and back down to the muscles takes time, and, under certain circumstances, too much time, for example, when we touch a burning object or when a tool is slipping from our grip. Neurons in the spinal cord directly activate muscles that trigger a withdrawal reflex or an increase in grip force. Ultimately, however, signals from the receptors, carried by afferent fibers, are conveyed to the brain.

The afferent fibers that carry information from Merkel, Ruffini, Meissner, and Pacinian receptors have relatively large diameters (on the order of 10 μm) and thus conduct signals very fast (up to 70 m s^{-1}). The afferent fibers that carry signals from Merkel cells are called slowly adapting type 1 (SA1) fibers because, when steady pressure is applied to their receptive field, they produce a response that fades (adapts) slowly.

Figure 1 Cross section of the glabrous skin illustrating its innervation and principal structures.

Figure 2 Cross section of hairy skin illustrating its innervations and principal structures.

Similarly, afferents that carry signals from Ruffini organs are called slowly adapting type 2 (SA2) fibers. In contrast, rapidly adapting (RA) fibers, which innervate Meissner corpuscles, produce a response only at the onset and offset of the pressure stimulus (and are thus said to adapt rapidly). Signals from Pacinian corpuscles are carried by PC fibers, which also exhibit RA properties.

Touch in the Brain

Signals from Merkel, Ruffini, Meissner, and Pacinian corpuscles – carried by SA1, SA2, RA, and PC fibers, respectively – ascend the spinal cord and terminate in neurons in the dorsal column nuclei, located in the brainstem. Neurons in the dorsal column nuclei in turn send signals to neurons in

Figure 3 The human brain. Regions involved in somatosensory processing are highlighted, as are various landmarks. SI, primary somatosensory cortex; SII, secondary somatosensory cortex; PI, posterior insula; AI, primary auditory cortex; MOC, medial occipital cortex; MST, medial superior temporal; LOC, lateral occipital complex. Left panel: view of the brain from the left side; right panel: coronal slice of a cortical hemisphere, taken approximately at the location of the black arrows. The red dashed line denotes where the somatosensory cross section in **Figure 4** was taken from.

the ventral posterolateral nucleus of the thalamus, which then send projections to the primary somatosensory cortex. Tactile signals in the brainstem and in the thalamus essentially mirror those from afferent fibers, that is, there is very little transformation of the sensory information until it arrives at the primary somatosensory cortex. The primary somatosensory cortex is located just posterior (toward the back of the head) of the central sulcus, which separates the frontal and parietal lobes (see **Figure 3**).

The primary somatosensory cortex consists of three areas, demarcated according to the organization of the neurons they contain (cytoarchitecture) and the response properties of these neurons (**Figure 4**). According to the nomenclature established by the German neurologist Korbinian Brodmann, the primary somatosensory cortex comprises areas 3, 1, and 2, and area 3 can be further subdivided into two areas: area 3a, which contains neurons that respond primarily to joint movements, and area 3b, which contains neurons that respond primarily to stimulation of the skin. Like their counterparts in area 3b, neurons in area 1 also respond almost exclusively to skin stimulation, whereas neurons in area 2 respond to both stimulation of the skin and movement of the joints. Importantly, each area of the somatosensory cortex contains a full representation of the body, that is, the receptive fields of neurons in each area of the primary somatosensory cortex tile the entire body. Furthermore, the three areas of the somatosensory cortex are organized somatotopically, which means that adjacent neurons tend to have adjacent receptive fields on the body. The somatotopic organization of the somatosensory cortex is illustrated in the famous cortical homunculus (**Figure 5**), which shows the location of the receptive fields on the body surface of neurons as a function of their location on the cortical surface. As can be seen from the cortical homunculus, different amounts of brain volume are dedicated to different parts of

Figure 4 Primary somatosensory cortex (areas 3, 1, and 2) and adjacent cortical areas.

the body. For instance, the hand and lip representations span a wide swath of cortex, whereas the back and leg representation are relatively diminutive (**Figure 5**). The amount of cortex dedicated to a body region is related to how important the sensory information from that body region is. For instance, we use our hands to manipulate objects and to explore our environment. Sensory feedback from our hands is thus critical and this region is thus overrepresented in the brain (a phenomenon called 'cortical magnification'). Similarly, as we use our lips to speak, to eat, and to kiss, tactile sensations from these are also important. In contrast, we do not require fine sensory feedback from our back or from our forearm, as reflected in the smaller cortical volume dedicated to these regions.

The somatosensory cortex is organized hierarchically such that the first stage of processing of cutaneous information is area 3b, the second is area 1, and the third is area 2. This hierarchical structure is reflected in the fact that neurons in area 3b have small receptive fields (with diameters less than about 1 cm), whereas the receptive fields of neurons in areas

Figure 5 Cortical homunculus. This coronal view of the brain shows a cross section of the somatosensory cortex, along with the location of the associated neuronal receptive fields.

1 and 2 can span multiple digits. Also, neurons in the primary somatosensory cortex tend to be selective for certain aspects of the stimulus but not others. For instance, some neurons respond when a bar at a specific orientation is indented into the skin. Those neurons respond less or not at all when something other than a bar is indented into the skin or when the bar is not at their preferred orientation. The degree to which neurons selectively respond to specific stimulus features increases as one ascends the perceptual pathway from area 3b, through area 1, to area 2. Thus, neurons in area 3b will respond at least somewhat to just about any stimulus applied to their receptive field on the skin, whereas neurons in area 2 might respond only when a bar at a specific orientation is pressed into the skin. This hierarchical organization is characteristic of all sensory systems.

The next stage in the processing hierarchy is the secondary somatosensory cortex, located in the parietal operculum (Figure 3). Neurons in this brain area have very large receptive fields, sometimes covering the entire body, and more complex response properties than their counterparts in the primary somatosensory cortex.

Brain activity during tactile manipulation is not restricted to regions traditionally considered to be somatosensory, however. In the visual processing region of the brain, two distinct areas receive tactile input. The first is an area that has been implicated in the processing of visual motion (the medial superior temporal area). This area is activated not only when motion is presented visually but also when mechanical vibrations are applied to the skin of the hands or feet. When this region is temporarily inactivated, smooth hand movements are not possible, suggesting that this brain area may integrate tactile and visual information necessary for tasks such as tracking and grasping objects, playing video games, and writing.

The second visual area that is activated during tactile manipulation (the lateral occipital complex) seems to be involved in processing the geometrical shape of objects, whether these are explored visually or tactually. That is, similar activity

is observed whether the object is seen or felt and seems to be sensitive to the shape of the object. One possibility is that the activity observed in this area during tactile manipulation is due to mental imagery. In other words, when we manipulate an unseen object, we may form a mental image of the object. The alternative interpretation is that this area is involved in the processing of shape, regardless of modality. Ultimately, we can identify an object both visually and by exploring it tactually, and perhaps the lateral occipital complex is a brain area where visual and tactile information about objects converge.

In addition to cross talk between vision and touch, there is an intimate relationship between touch and audition. Indeed, certain brain areas that typically process auditory stimuli are activated when vibrations are delivered to the skin of the hand, specifically the belt areas of the auditory cortex, buried in the superior temporal sulcus (Figure 3). As will be discussed later, skin vibrations may play an important role in the perception of texture, and, while we rely more heavily on touch to acquire information about texture, acoustic signals produced when we rub our skin across a surface also convey a lot of information about its texture.

Tactile Acuity

As mentioned earlier, cutaneous information from certain body regions plays a greater role in our interactions with the environment than that from other regions. This disparity in the importance of sensory feedback across the body surface is reflected in the deformity of the so-called homunculus, which shows that the cortical volume dedicated to some areas (hands, lips) is much greater than that dedicated to others (back, legs). This increase in cortical volume is also associated with a greater spatial acuity in those magnified regions relative to the mini-fied regions.

In vision, spatial acuity is typically measured using a Snellen chart (eye chart). The patient's or subject's task is to read successive lines of increasingly small letters until he or she can no longer make out the letters. In effect, this tests the ability of the subject to discern small spatial details, those that distinguish one letter from another. Typically, visual acuity is constrained by the ability of the lens and cornea to focus light on the back of the eye (or the retina), and the purpose of the Snellen chart is to determine whether a given patient requires a correction on the optics of the eye.

While object (and thus spatial) perception is the principal purview of the visual system, we can also distinguish spatial form tactually. In fact, we can even distinguish embossed letters of the alphabet through tactile exploration. The ability of the somatosensory system to convey spatial information is best illustrated in the ability, after extensive training, to read Braille characters – letters optimized for touch rather than vision – rapidly and effortlessly. However, to measure tactile acuity, an eye chart, such as that used in vision, cannot be used because most people have little to no experience in identifying letters through touch. As mentioned earlier, subjects can be taught to discern letters by exploring them tactually, and their performance increases as the letters get bigger (such as is observed in vision), but letter identification is impractical as a test of tactile acuity because of the extensive training it requires.

For a long time, the standard test of tactile acuity was the two-point threshold. The task consists of indenting two fine probes on a subject's skin, using an instrument akin to a compass, and having the subject judge whether the two points are perceptually distinguishable. In other words, do they feel like a single poke or two spatially distinct pokes? If the two points are very close together, they feel like a single point; if they are far away, they feel like two distinct points. The two-point threshold is the shortest distance between the two indentations at which they feel distinct. The problem with the two-point threshold is that there is perceptual continuum between the two points feeling completely distinct and the two pokes perceptually merging into a single one. Because of the subjective nature of the judgments involved in the two-point threshold, it has been replaced with a more objective test of acuity, the grating orientation discrimination task. In this task, a grating is pressed in the skin of the finger at one of two orientations (perpendicular to one another) and the subject's task is to judge the orientation of the grating (Figure 6). When the grooves of the grating are wide enough, the task is trivial. As they get narrower, the task becomes more difficult because the ridges and grooves become increasingly indistinct. The grating orientation threshold is the narrowest groove width at which subjects can still distinguish the orientation of the grating.

Tactile spatial acuity has been shown to vary widely across the body surface, being most sensitive on the fingertips and lips, and least sensitive on the back. Two-point thresholds are around 1 mm on the fingertips and lips, and 4 cm or more on the calf, thigh, back, shoulder, and upper arm. Spatial acuity decreases rapidly even as one progresses from the fingertips (1 mm), to the palm (12 mm), and the forearm (35 mm). Such a progressive decrease in spatial acuity is also observed in

Figure 6 Johnson-Van Boven-Phillips domes. These gratings are used to measure tactile acuity. They vary in the width of their ridges and grooves. The subject's task is to determine the orientation of the groove. As the grooves get smaller, the task becomes increasingly difficult.

vision, if one measures acuity in different parts of the visual field. Indeed, peripheral vision is far less acute than vision at the center of our visual field. In both vision and touch, the acuity is ultimately limited by the density at which receptors innervate the sensory sheet (the retina or the skin). Indeed, at the fingertips, Merkel receptors, which mediate fine spatial form, are spaced on average 1 mm apart, so that the spatial resolution of the hand is approximately 1 mm. In the palm, Merkel receptors are about ten times sparser, which leads to a 10-fold decrement in acuity. Note that the increased density of receptors in the fingertips and lips would not lead to an increase in acuity if it were not accompanied by the increased cortical volume dedicated to those body regions. Indeed, many cortical neurons are required to interpret the signals from the large number of receptors innervating the skin of the fingertips and the lips.

Form Perception

When we reach into our pockets for loose change, we can distinguish it from other items such as keys, a cell phone, etc. This ability is mediated by information about object shape conveyed by cutaneous mechanoreceptors in the skin and their associated afferents. The afferents that primarily mediate this ability are SA1 afferents as these are highly sensitive to the spatial configuration of the stimulus and densely innervate the skin. At the fingertips, RA afferents innervate the skin even more densely than do their SA1 counterparts (the spacing between adjacent receptive fields is about 0.7 mm), but signals from multiple Meissner corpuscles converge onto individual RA afferent fibers, which serves to blur the spatial image these afferents convey. Information about the shape of an object is thus primarily represented in the spatial profile of the activity of SA1 afferents. The spatial profile of the activity of populations of SA1 fibers matches the spatial profile of the stimulus. In other words, if a grating is pressed into the skin, the spatial profile of SA1 afferent activity will consist of alternating bands of active and inactive fibers, reflecting the alternations of ridges and grooves of the grating. More complex spatial stimuli (such as keys) will evoke more complex spatial patterns of activation in SA1 afferent populations. Our ability to distinguish the shape of an object is mediated by the spatial patterning in SA1 afferent activity. Populations of neurons in the primary somatosensory cortex then interpret these spatially patterned signals emanating from these afferents (transmitted via the dorsal column nuclei and the thalamus) to infer the shape of the object that produced them.

In the primary visual cortex (the visual equivalent of the primary somatosensory cortex), the visual scene is first parsed as a set of oriented contours. In other words, neurons in the primary visual cortex are feature detectors that respond if a bar at a specific orientation is present in their receptive field. Similarly, a large proportion of neurons in the primary somatosensory cortex respond if a bar at a specific orientation is indented into their receptive fields but not otherwise. Our ability to perceive the orientation of objects grasped in our hand is mediated by this population of neurons. The tactile perception of orientation is important in tool use because it is critical to monitor the orientation of the tool relative to our hand.

When we write with a pen, for example, we do not have to visually monitor the orientation of the pen in our hand because signals from our skin provide constant feedback about its orientation.

In the visual system, information about objects, represented initially as sets of oriented contours, is elaborated into more complex representations. Some neurons higher up in the visual processing hierarchy, for example, respond to simple geometrical shapes that comprise multiple contours at different orientations. Some of these neurons respond to curved contours, whose orientation changes more or less gradually. Similarly, neurons higher up in the somatosensory processing hierarchy (in area 2 and in the secondary somatosensory cortex) also selectively respond to curved contours, with each neuron preferring a specific curvature and orientation. For instance, some neurons might respond when a U-shaped curvature is pressed against their receptive field, whereas other neurons may prefer a V-shape, oriented leftward ($<$). In both systems, then, neurons become increasingly complex feature detectors, responding to increasingly complex combinations of object features. Ultimately, visual and tactile representations of objects may converge onto a single area, possibly in the lateral occipital complex (see section 'Touch in the Brain'), which would serve to bind object representations emanating from the two senses.

Texture Perception

Texture refers to the perception of surface material and microgeometry. Though textural information can be obtained both visually and auditorily, touch yields much finer and more complex textural information than do the other sensory modalities. When we run our fingers across a surface, we may perceive the surface as being rough, like sandpaper, or smooth, like glass; the surface may also vary along other sensory continua, such as hardness (e.g., stone) versus softness (e.g., moist sponge), and stickiness (e.g., tape) versus slipperiness (e.g., wet soap). Also, whether a texture is thermally isolating (e.g., leather) or thermally conductive (like metal) contributes to the textural percept. Texture is represented at the somatosensory periphery in the spatiotemporal pattern of activity in populations of afferents innervating the skin. Different aspects of texture are encoded by different populations of afferents.

The tactile exploration of a surface has been shown to yield a multidimensional textural percept that includes sensations of roughness/smoothness, hardness/softness, stickiness/slipperiness, and warmth/coolness. The overall textural percept of a surface is strongly determined by three of these texture properties, namely roughness, hardness, and stickiness. Of all textural continua, the study of roughness has been the most extensive, whereas much is unknown about how information about hardness and stickiness is processed by the nervous system.

The subjective sense of roughness seems to vary along a single dimension and has been shown to vary predictably with surface properties. In psychophysical studies, the perceived roughness of sandpapers increases with particle size, the roughness of gratings increases with spatial period, and that of embossed dots increases monotonically with interdot spacings up to about 2–3 mm, then decreases with further increases. For gratings, however, the spatial period does not seem to be

the relevant stimulus property since changing the width of their grooves and changing the width of their ridges have opposite effects on perceived roughness. The main determinant of perceived roughness seems, at a first approximation, to be the extent to which the skin is deformed when in contact with the surface. However, surface roughness varies over a wide range, and many discriminable surfaces essentially do not deform the skin at all when we press our finger against them. To distinguish the microgeometry of these surfaces, we scan them with our fingers. In the absence of such movement, they feel almost completely smooth. Note that, for coarser surfaces, such as embossed dots or gratings, movement between skin and surface is not necessary to discern their surface properties. The basis for this dichotomy is that roughness perception relies on two distinct neural mechanisms.

For coarse textures, the perceived roughness is determined by the spatial pattern of activation in SA1 afferent fibers. Specifically, neurons in the primary somatosensory cortex compute the degree to which the activation of SA1 afferents varies across the skin. For a completely smooth surface, all SA1 afferents will be activated approximately equally, so there is no variation in the activity of these neurons. The roughness of a grating, embossed dot pattern, or coarse sandpaper can be predicted from the degree to which the activation produced in SA1 afferents varies across the sensory sheet.

For fine textures, movement between the skin and the surface is necessary to acquire a percept of roughness. Indeed, when we run our fingers across a finely textured surface, small vibrations are produced in the skin. These vibrations activate PC fibers, which, as mentioned earlier, are highly sensitive to skin vibrations. As surfaces get coarser, the strength of these vibrations increases and the strength of the response of PC fibers increases. The perceived roughness of fine textures, then, is determined by the degree to which the texture-elicited vibrations excite PC afferents. This Pacinian-mediated mechanism operates over a range of surface microgeometries. If the surface texture is coarse enough, the SA1-mediated mechanism dominates.

Information about roughness is encoded in the primary somatosensory cortex as evidenced by the fact that the responses of neurons in this brain area are sensitive to changes in surface properties that determine perceived roughness, namely, the spatial period of embossed dot patterns and the groove width of tactile gratings. Lesions in the primary somatosensory cortex, particularly in areas 3b and 1, lead to severe impairments in roughness discrimination. The second somatosensory cortex has also been implicated in the processing of surface roughness as it contains neurons that are sensitive to the relevant surface properties, and lesions in the secondary somatosensory cortex also cause impairments in roughness discrimination. Finally, the posterior insula and the medial occipital cortex are selectively activated when human subjects perform a roughness discrimination task, indicating that they too are involved in the cortical processing of roughness information.

Hardness/softness is the subjective continuum associated with the compliance of an object. Hardness ratings have been shown to be inversely proportional to softness ratings; these ratings are, in turn, related to surface compliance. Softness perception has been shown to rely primarily on cutaneous

cues: as an object is pressed against the hand, it conforms to the contour of the hand in proportion to the contact force. The compliance (and the softness) of the object may be signaled by the growth of the area over which the skin contacts the object as the contact force increases, as well as the increase in the force exerted by the object on the skin across the contact area. Softness perception likely relies on signals from SA1 fibers: First, PC fibers are too sparse and their receptive fields too large to play a significant role in softness perception. Second, the response of RA fibers to a surface indented into the skin is not modulated by the compliance of the surface whereas the response of SA1 fibers is. One possibility is that the average pressure exerted across the contact area is predictive of compliance and that this quantity is signaled by populations of SA1 afferents.

Stickiness/slipperiness is the sensory continuum associated with the friction between skin and surface. Indeed, magnitude estimates of stickiness have been shown to closely match the measured kinetic friction between skin and surface, that is, the ratio between the force exerted normal to the surface and that exerted parallel to the plane of the surface. Furthermore, when judging stickiness, subjects do not substantially vary the normal forces they apply on the surface, but the applied tangential forces tend to vary across surfaces, suggesting that tangential forces are critical in the perception of stickiness. The neural mechanisms that mediate stickiness perception are yet to be conclusively identified but SA2 fibers are likely to be involved, given their sensitivity to skin stretch.

Motion Perception

When an object brushes against our skin, we acquire information about its direction and speed of motion. Information about tactile motion is important in at least two respects. First, a hallmark of tactile exploration is that it involves movement between skin and object. A blind or blindfolded individual asked to recognize an object by touch will scan the object with both hands. Without this exploratory strategy, we would only gather information about part of the object, the part that contacts our fingers at any given time. Instead, we integrate information about the object over time as we explore it with our hands. Information about the motion of the skin relative to the object is necessary to reconstruct the relative positions of successively touched object features. Second, detecting when an object begins to slip from our grasp triggers adjustments in grip force, critical in object manipulation.

Motion between skin and object consistently evokes activity in RA and PC fibers. These two populations of afferent fibers, particularly the former, play an important role in slip (and thus motion) detection. While activation of these afferent populations often triggers a motion percept, our ability to perceive the direction in which an object moves is mediated primarily by SA1 afferents. Motion can be inferred from the spatiotemporal sequence in which these afferents are activated. A moving object will successively contact adjacent patches of skin, and thus successively activate small populations of SA1 fibers with adjacent receptive fields. Furthermore, many SA1 afferents respond anisotropically to skin movement, that is, they respond

Figure 7 Responses of a neuron in area 1 to bars scanned across the finger in different directions. This neuron responds most strongly when a neuron is scanned up and to the right across the (right) index finger. As the direction of motion diverges from this preferred direction, the neuron's response decreases. This neuron was recorded from a Rhesus macaque, but the same principle is thought to apply to human somatosensory cortex.

more strongly when the skin is pushed in one direction than when it is pushed in another, thereby conveying information about the direction in which the object is moving across the skin. Thus, while motion detection is mediated by RA and PC afferents, information about motion direction is conveyed by SA1 afferents.

In the primary somatosensory cortex, many neurons respond selectively to stimuli moving in a particular direction (see Figure 7). These neurons thus convey information, not about the properties of the object that is contacting the skin, but rather about the motion of this object across the skin. Analogous neurons, selective for the direction of visual motion, are found in the primary visual cortex and in the middle temporal area, a visual area dedicated for motion processing.

The Role of Touch in Object Manipulation and Tool Use

Cutaneous cues play a critical role in the dexterous manipulation of objects. First, signals from mechanoreceptive afferent fibers innervating the glabrous skin of the hand convey information about the location of contact between the skin and the object and about the forces that are exerted on the skin when the object is grasped statically. As discussed earlier, mechanoreceptive afferents also signal when our grip on an object is slipping. Without these fibers, then, we would routinely

crush or drop grasped objects. Second, cutaneous afferents convey information about object properties that are useful for manipulation. For instance, information about the orientation of a writing utensil in the hand plays an important role in our ability to maintain the proper grasp on the utensil while writing. Information about the slipperiness of a surface helps to determine how much force will be needed to grasp it. Third, cutaneous signals play an important role in guiding the dexterous manipulation of objects in that they signal contact events. For instance, establishment of contact with an object signals the end of the reach phase and the beginning of the grasp phase. Although this information is sometimes (though not always) available visually, visual signals are slower, less reliable, and require greater concentration to guide movements.

Pleasant Touch

The importance of touch in emotional development was illustrated in a well-known series of experiments conducted by Harry Harlow, in which he showed that surrogate mothers made out of terrycloth (and thus tactually more similar to real mothers) were more attractive to infant monkeys than surrogates made from wire. The tactile experience provided by the two surrogates was the determinant of the infants' choice. The infants with the terrycloth surrogates developed relatively normally, while those with the wire surrogates did not. This controversial series of studies was interpreted as providing support for a critical role of contact comfort in development.

The importance of touch in social and emotional communication is illustrated in the ubiquity of tactile contact in interpersonal relationships, ranging from handshakes to kissing. Much less is known about the neural mechanisms of pleasant touch than about other aspects of tactile processing. However, some evidence suggests that activation of a subpopulation of receptors in the hairy skin (C-tactile receptors) may elicit pleasant sensations. Furthermore, pleasant touch is known to cause activity in an area of the brain (the left anterior insular cortex),

that receives information from C-tactile receptors and processes positive emotional feelings.

Glossary

Garden-path sentence A sentence that ends with an interpretation that differs from the interpretation that the reader or the listener initially expected.

Incremental processing The integration of incoming words into a linguistic structure immediately at the moment at which they are encountered.

Locality A theory of sentence processing in which integrating words that are far apart creates a higher processing cost than integrating words that are close together.

Prosody The acoustic–phonetic properties of speech that are independent of the sounds of the actual words being produced. This can include pitch, loudness, tempo, rhythm, and pausing.

Reanalysis The process of reanalyzing a sentence's meaning and structure when the reader or the listener's initial interpretation turns out to be incorrect.

Sentence processing The cognitive process of understanding the structure and meaning of a sentence.

Surprisal A theory of sentence processing that predicts a higher processing cost when the predictability of a word or a syntactic structure is low.

Syntactic processing (or parsing) The process of analyzing the relationship between words and phrases in a sentence to recover a sentence's syntactic structure.

Syntax A level of linguistic structure that specifies how words are combined with other words or phrases to create a well-formed sentence.

We produce or encounter a tremendous number of sentences throughout our life. The productive nature of human language means that an infinite number of sentences are possible, yet we have little difficulty understanding these sentences, even when they are completely novel. We understand what a speaker or a writer intends to convey quickly and reliably even though everyday language is riddled with ambiguity and has the potential for confusion. Even though this process may seem effortless, a wide array of psychological processes are deployed to make sentence processing possible. In this article, we discuss how people comprehend sentences, what kinds of processes are involved, what kinds of information sources are used, and what factors lead to processing difficulty.

Sentence Structure

Sentences consist of a sequence of words. Native speakers of a language share intuitions about how words should be ordered to construct a well-formed sentence. Consider (1).

- (1) a. The boy saw the girl.
b. The girl saw the boy.
c. *The boy the girl saw.

The basic or canonical word order in English is subject (S), followed by a verb (V), followed by the direct object (O). Although there are many variations of this basic word order that might include things like indirect objects, prepositional phrases, adjectives, and many other grammatical categories, SVO is the basic word order in English. English speakers agree that (1a) and (1b) are grammatical, and (1c) is ungrammatical (as indicated by an asterisk). The linear order of words in English is important not just because it determines the grammaticality of a sentence but also because it contributes to the meaning of a sentence. Sentences (1a) and (1b) consist

of the same words and both sentences are grammatical. However, these sentences convey different meanings about who did what to whom because their words are arranged in different orders. In (1a), the boy is doing the seeing, while in (1b), it is the girl who is doing the seeing.

Sentences are also not just a sequence of linearly ordered words. The elements in a sentence are hierarchically organized: Words are organized into larger units such as phrases and clauses, which serve as subunits of a sentence. A phrase structure tree in [Figure 1](#) illustrates the structure of sentence (1a) graphically.

The node 'S' at the top of the tree diagram stands for 'sentence.' The nodes at the bottom indicate the parts of speech of the words (Det: determiner, N: noun, V: verb). The other nodes represent phrasal categories, subunits that are smaller than a sentence but larger than words (NP: noun phrase, VP: verb phrase).

This linear and hierarchical relationship between words in a sentence is called a language's syntactic structure. Sentence comprehension requires a process called syntactic parsing or processing, a process by which readers or listeners recover the grammatical structure of the sentence with the goal of recovering the sentence's meaning. Syntactic parsing involves identifying the linguistic categories of each word and recognizing how these words and phrases are linearly and hierarchically organized relative to one another. For example, in (1a), our knowledge of syntax allows us to identify 'the' as a determiner and 'boy' as a noun and to build a NP by combining them. The syntactic parser also identifies 'saw' as a verb and combines it with the following NP 'the girl' to form a VP.

Psychologists and linguists are generally interested in understanding the cognitive mechanisms that underlie syntactic parsing. One way to study parsing has been to investigate how the parsing system handles syntactic ambiguity, that is, instances in which the parser must decide among more than

Figure 1 Tree diagram for the sentence 'The boy saw the girl.'

one potential syntactic structure for a given sentence. The types of decisions made by the parser under these circumstances can reveal how the mechanisms of sentence processing operate more generally.

Structural Ambiguity

Language is riddled with ambiguity, that is, instances in which there is more than one interpretation of a sentence, phrase, or word. A type of ambiguity that is of particular interest to psycholinguists who study sentence processing is syntactic, or structural, ambiguity. In this type of ambiguity, there is more than one potential syntactic structure for a given string of words. Consider (2).

- (2) The boy saw the girl with the binoculars.

Sentence (2) can be interpreted in more than one way. One possible interpretation is that the boy used binoculars to see the girl. The other possible interpretation is that the boy saw the girl who was holding binoculars. The ambiguity arises because more than one syntactic structure can be associated with this sentence, which is illustrated in [Figure 2](#).

The structures illustrated in [Figure 2\(a\)](#) and [2\(b\)](#) differ in how the prepositional phrase 'with the binoculars' is structured with other words and phrases in the sentence. In [Figure 2\(a\)](#), the prepositional phrase directly attaches to the VP node, which leads to a reading in which the prepositional phrase is interpreted as an instrument of the action denoted by the verb (i.e., The boy used binoculars to see the girl). In contrast, in [Figure 2\(b\)](#), the prepositional phrase is structured as part of the NP, which leads to an interpretation in which the prepositional phrase modifies the preceding noun 'girl' (i.e., The boy saw the girl who was holding binoculars).

Ambiguous sentences can be either globally or temporarily ambiguous depending on whether the ambiguity is resolved later in the sentence or not. Sentences like (2), which contain an ambiguity that is never resolved, are called globally ambiguous. In contrast, sentences like (3) are temporarily ambiguous. In these sentences, an ambiguity arises during the processing of the sentence, but later information eventually rules out one of the interpretations.

- (3) The boy saw the brothers of the girl who was holding the binoculars.

The modifying clause (i.e., the relative clause) 'who was holding the binoculars' is ambiguous because it can potentially modify either of the preceding nouns. This ambiguity arises when the onset of the relative clause is encountered (at 'who'), but it is resolved upon encountering the auxiliary verb 'was.' This is because 'was' is singular and must agree with a singular noun. Because 'girl' is singular and 'brothers' is not, the relative clause must be associated with 'girl.' Another example of a temporarily ambiguous sentence is shown in (4a).

- (4) a. The horse raced past the barn fell.
 b. The horse raced past the barn.
 c. The horse that was raced past the barn fell.

In sentence (4a), the tense of the verb 'raced' is ambiguous. It is either a past tense verb as in (4b) or a past participle as in (4c). How this ambiguity is resolved has consequences for which grammatical interpretation is chosen. If the verb has a past tense, then it must be the main verb of the sentence. If it is a past participle, it is a verb of a relative clause that modifies the subject of the sentence. The ambiguity arises because in English, the full relative clause 'that was raced past the barn' in (4c) can be reduced to 'raced past the barn' by deleting the relative pronoun and the following auxiliary verb (i.e., 'that was') as in (4a). When this verb is encountered, the processor immediately determines whether it is a past tense verb or a past participle without waiting until all the words in the sentence become available. Individuals tend to preferentially interpret the verb as a past tense verb, processing 'the horse raced past the barn' as a main clause. When the verb 'fell' is encountered at the end of the sentence, however, the reader either judges the sentence to be ungrammatical because there is an extra verb or the reader reanalyzes the sentence after realizing that 'raced' cannot be a main verb. Studies that have measured the amount of time taken to read each word in a sentence observe a noticeable slowdown at the point of 'fell' in (4a). The slowdown is taken to be an indicator of the difficulty that the processing system undergoes in recovering from incorrectly analyzing 'raced' as a main verb when it turns out to be a past participle. The main verb 'fell' would be read more quickly if it was preceded by a full relative clause in which a temporary ambiguity does not arise as in (4c). Sentences that end with an interpretation that differs from the interpretation that the reader initially expected are called garden-path sentences. The garden-path effect comes about when the processor encounters a temporarily ambiguous sentence that is eventually disambiguated toward a less preferred interpretation (such as the reduced relative clause interpretation in (4a)).

Incremental Processing

What does the garden-path effect discussed earlier reveal about the human sentence processor? It suggests that sentence comprehension is highly incremental. The human processor does not wait until the entire sentence becomes available to start building syntactic structure. As sentences are heard or read, the processor incorporates each incoming word into the syntactic structure being currently constructed. Expectations about what is coming next are continuously updated as is the syntactic representation.

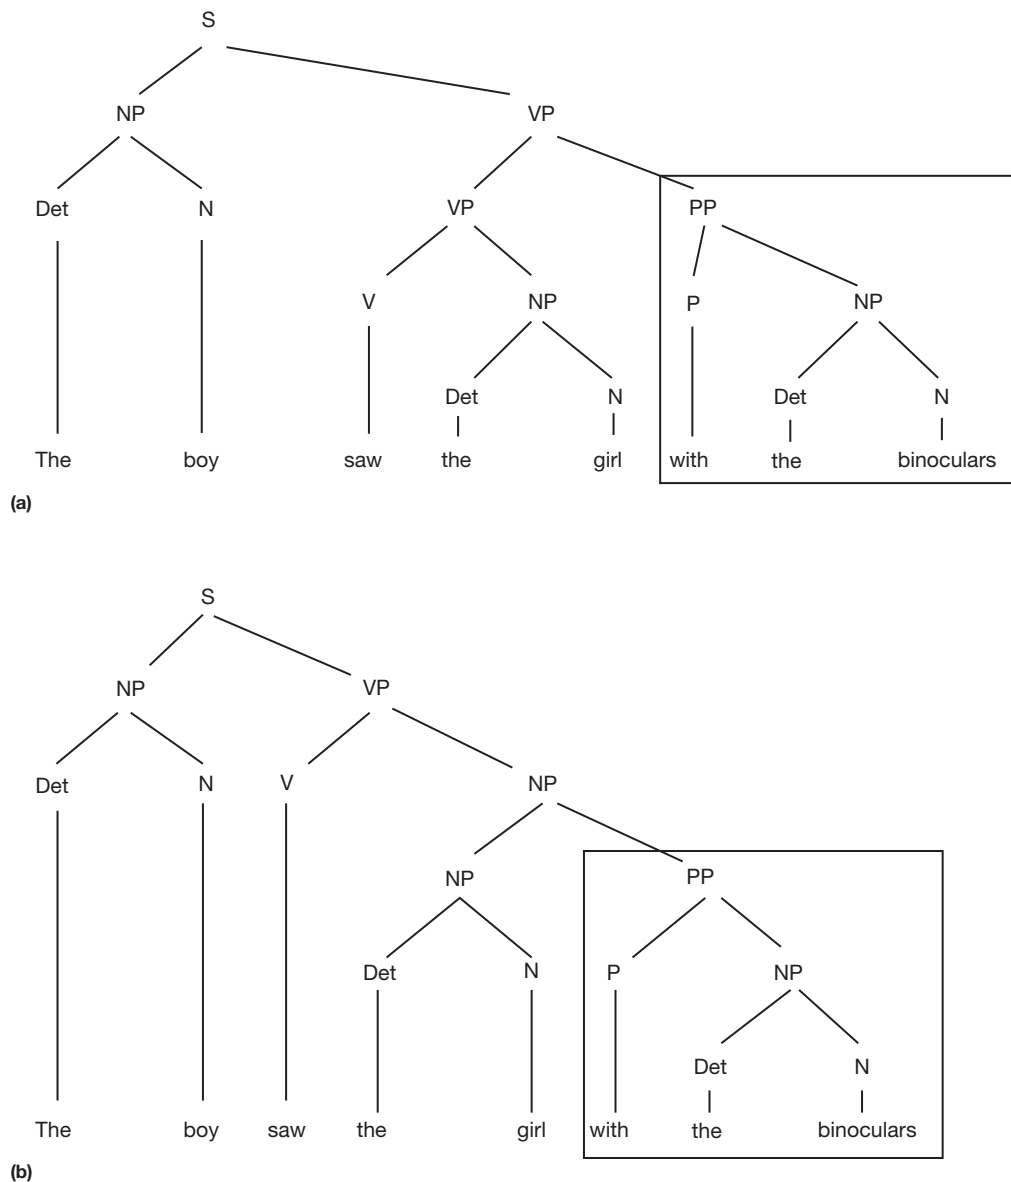

Figure 2 Tree diagrams for (a) an interpretation in which the boy used binoculars to see the girl and (b) an interpretation in which the boy saw the girl who was holding binoculars.

In an unambiguous sentence like (1a), there is only one way to integrate each incoming word into the syntactic representation. However, in globally or temporarily ambiguous sentences like (2) and (4a), it is not always clear how to incorporate new words into the structure being built. For example, the processor is required to determine whether to attach the prepositional phrase to the NP or to the VP in (2), or whether to identify the verb 'raced' as a main verb or as part of a reduced relative clause in (4a).

One solution would be to wait until the end of the sentence to compute a syntactic structure. If we postpone determining which interpretation to take until the end of the sentence, a penalty need not be paid for guessing incorrectly. However, this strategy would require holding all the words in the sentence in memory until the end of the sentence, increasing the burden on memory systems. An incremental

parser reduces memory load but at the expense of potentially being garden-pathed.

How does the processor determine which structure to commit to when there is ambiguity? Comprehension of sentences is not just based on syntactic knowledge. The human sentence processor relies on various sources of information to recover the message intended by the speaker or the writer. First, sentence comprehension requires access to semantic information that encodes how meaning is mapped onto syntactic structure. Second, written or spoken communication is typically composed of a set of connected sentences in a conversation or discourse, and thus, the processor also uses context to make parsing decisions. The sentence processor also uses frequency information, which can include the probability of a given structure or a word, to make syntactic decisions. Prosodic information, which includes the rhythm,

tune, and grouping of words in an utterance, also contributes to the meaning of a sentence.

There is a general agreement among researchers that humans use multiple information sources to determine linguistic structure when they comprehend a sentence. However, there is controversy surrounding when each of these information sources is used: whether all relevant information sources are used at one time or whether syntactic information takes precedence over other information sources. In the next two sections, we outline two major models of sentence processing that provide differing views regarding this question.

Models of Sentence Processing

Garden-Path Model

The garden-path model assumes that only syntactic information is used to construct an initial interpretation. Other non-syntactic knowledge sources such as semantics, discourse contexts, and frequency are used only if a problem occurs at the initial syntactic stage. If the initial analysis is deemed to be implausible or ungrammatical, a structural reanalysis occurs.

The garden-path account posits that two universal syntactic principles guide initial parsing by directing the processor toward a syntactic analysis that creates the simplest possible structure. One of those principles is minimal attachment. Under minimal attachment, the processing system prefers a structure that contains as few nodes as possible in

incorporating a new item into the existing structure. This is motivated by a desire by the processing system to reduce memory load. Consider Figure 3 to see how the minimal attachment principle accounts for a preference for the main clause analysis in sentence (4a).

As illustrated in Figure 3, the main clause analysis (Figure 3(a)) is simpler than the relative clause analysis (Figure 3(b)) in integrating the verb into the existing structure. While the main verb analysis requires no intervening node between the VP node and the S node, the reduced relative clause analysis requires postulating two additional nodes, NP and S. This leads the processor to initially adopt the structurally simpler main clause analysis over the reduced relative clause analysis.

Another strategy proposed under the garden-path model is *late closure*. The late closure principle refers to a general preference for listeners to attach new inputs to the phrase that is currently being constructed over other potential locations. Consider the following example:

- (5) The boy saw the brother of the girl who was holding the binoculars.

Sentence (5) is ambiguous because the relative clause 'who was holding the binoculars' can attach to more than one NP. It can attach either to the NP 'the brother of the girl' as in Figure 4(a) or to the NP 'the girl' as in Figure 4(b). According to minimal attachment, these two structures are equally preferred because the relative clause directly attaches to the NP in both cases, and there are no differences between

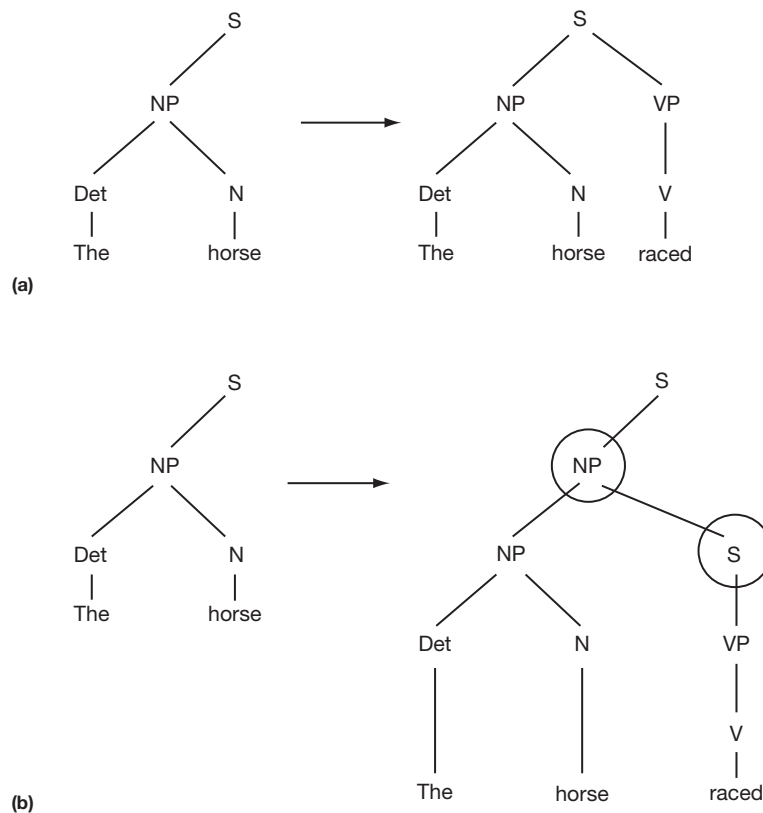

Figure 3 Tree diagrams for (a) an analysis in which 'raced' is a main verb and (b) an analysis in which 'raced' is part of a reduced relative clause.

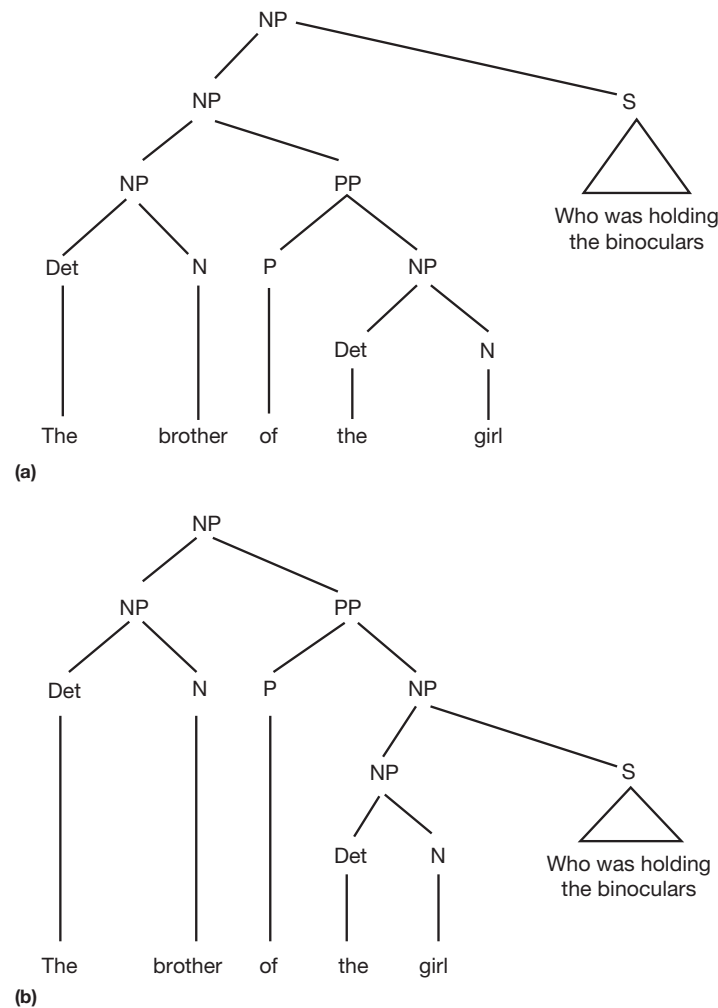

Figure 4 Tree diagrams for (a) an interpretation in which the relative clause is associated with the phrase 'the brother of the girl' and (b) an interpretation in which the relative clause is associated with the phrase 'the girl.'

the structures in terms of the number of nodes. Thus, attachment falls under the late closure principle and there is a preference to attach the relative clause to the NP 'the girl' because it is the most recently constructed phrase.

Under the garden-path model, when minimal attachment or late closure yields a sentence that is ungrammatical or semantically anomalous, the parser must go back and reevaluate the structure it has chosen. This process is called reanalysis. While in sentence (5), there is no conflict between the initially committed analysis and the interpretation forced by the auxiliary verb 'was' in the relative clause, in sentence (4a), the initially preferred main clause analysis is not consistent with a correct analysis of the sentence. During the process of reanalysis, other sources of information like semantics, plausibility, frequency, context, and prosody can influence the corrected interpretation.

Constraint-Based Models

The other dominant class of sentence processing models is constraint-based models. According to these theories, multiple

sources of information guide initial processing in parallel. Nonsyntactic information sources such as semantics, referential context, frequency, and prosody are used with syntactic information to resolve ambiguity in the very earliest stages of parsing. Unlike the garden-path model, which assumes a serial processing mechanism by which only a single analysis is activated at a time, the constraint-based account assumes that processing occurs in parallel with all possible syntactic analyses activated simultaneously.

In constraint-based models, all possible syntactic analyses are ranked in terms of activation level. Initial processing is guided by the syntactic analysis that is most highly activated by virtue of receiving the greatest support from relevant sources of information. The relative ranking of possible syntactic analyses is continuously reordered depending on the most current information. Processing difficulty arises when more than one syntactic analysis is activated to a similar degree, resulting in competition, or when the most activated analysis is not the analysis that must eventually be chosen.

In the following sections, we discuss how various nonsyntactic sources of information influence initial parsing decisions.

Animacy

Lexical semantics concerns how words in a sentence are related to an event denoted by the verb. These relationships can affect sentence processing decisions. For example, animate nouns, like animals or people, are more likely to serve as the 'doers' of the action denoted by the verb. These nouns are called agents. Inanimate nouns are more likely to be the 'undergoers' of the action denoted by the verb. These are called patients. Consider (6).

- (6) a. The researcher examined...
b. The data examined...

Like the verb 'raced' in (4a), 'examined' can be a past tense verb or a past participle. The verb serves as a main verb if it continues with a patient (e.g., *the question*), that is, the entity that is being examined by the researcher or the data. If the sentence continues with a 'by-phrase' that includes an agent (e.g., *by the lawyer*), that is, the entity that examines the researcher or the data, the verb is a past participle that is part of a reduced relative clause (e.g., *The data that was examined by the lawyer was important*).

According to the garden-path model, the main verb analysis is preferred in both (6a) and (6b) because of minimal attachment's requirement that the parser choose the simplest structure. Even though 'data' is unlikely to examine something, the parser under the garden-path theory is blind to animacy information until ungrammaticality is detected later downstream in the sentence.

Empirical studies have shown that the animacy of the main subject NP can influence processing. When reduced relative clause sentences are followed by a disambiguating by-phrase like 'by the lawyer', readers experience less difficulty in processing this phrase in (6b) than in (6a), suggesting that initial processing is guided by subject NP animacy information. An animate subject is more likely to be initially recognized as the agent of the main verb, while an inanimate noun is more likely to be identified as the patient of the verb, that is, the thing to be examined. Thus, when the sentence is disambiguated toward a reduced relative clause analysis, the processor encounters greater difficulty at the disambiguating by-phrase when the subject noun is animate than when it is inanimate.

Plausibility

Plausibility information that reflects real-world knowledge may also guide initial parsing decisions. Consider (7).

- (7) a. The doctor examined...
b. The patient examined...

In (7a) and (7b), both 'doctor' and 'patient' are animate nouns, but they differ in the plausibility of their being the agent of the verb 'examined'. For the verb 'examined', the 'doctor' is more plausible as an agent, that is, the person examining someone, while the 'patient' is more plausible as the person who plays a patient role, that is, the person being examined. Studies have shown that readers use plausibility information in sentence processing and preferentially interpret the verb as a past tense verb in (7a) and as a past participle in (7b).

Lexical frequency

Example sentences (6) and (7) show that animacy and plausibility information associated with the NP is rapidly used by the

processor to resolve ambiguity. Another factor that influences ambiguity resolution is the frequency with which a verb co-occurs with different types of syntactic constituents. Information about how often verbs are used in particular sentence structures may influence initial parsing decisions. Consider the following examples:

- (8) a. The journalist confirmed the rumor...
b. The journalist believed the rumor...

The sentences in (8) are temporarily ambiguous because the NP 'the rumor' can be the direct object of the verb (e.g., *The journalist confirmed the rumor about his death*) or the subject of an embedded clause (also called a sentential complement) as in (9).

- (9) a. The journalist confirmed the rumor was true.
b. The journalist believed the rumor was true.

The frequency with which a verb has occurred with a direct object or a sentential complement in the language can lead the processor to develop expectations about what will follow the verb. The verb 'confirm' occurs more often with a direct object, while the verb 'believe' is more likely to occur with an embedded complement clause. Thus, the processing system is more likely to assume that the NP following the verb is a direct object in (8a) and a subject of the complement clause in (8b). Experimental studies have shown that readers tend to spend more time reading at the disambiguating auxiliary verb 'was' in (9a) than in (9b), suggesting that the frequency bias of the verb leads readers toward the direct object interpretation in (8a).

Referential context

The interpretation of an ambiguous sentence may also be influenced by the context in which it occurs. Suppose that the sentence 'The boy saw the girl with the binoculars' that we discussed earlier could be preceded by two different context sentences as shown subsequently.

- (10) a. There was a boy and a girl in the park. The boy saw the girl with the binoculars.
b. There was a boy and two girls in the park. The boy saw the girl with the binoculars.

The sentence 'The boy saw the girl with the binoculars' is ambiguous because the prepositional phrase can be a modifier of the preceding noun or an instrument of the verb. According to Minimal Attachment, the instrument interpretation is preferred over the modifier interpretation. However, the modifier interpretation is often necessary to point out which referent (i.e., the entity being referred to) is being mentioned when more than one potential referent of the noun has been established in the discourse. In (10a), the discourse establishes only one girl. In (10b), two girls have been mentioned. While in (10a), it is obvious which girl the boy was looking at (as there is only one), in (10b), the reader expects the writer to indicate which one.

Studies have found that in sentences like (10b), a reader is more likely to interpret the prepositional phrase as a modifier. The prepositional phrase indicates which girl is being referred to so that the reader knows that it is the girl who was holding binoculars and not, for example, the girl who was holding a telescope.

These effects have also been found in visually presented referential contexts and this information seems to be used very rapidly. Researchers have used the visual world eye-tracking paradigm to examine how referential contexts influence the online processing of ambiguous sentences. In this paradigm, listeners hear auditory instructions that include ambiguous sentences like (11). Researchers monitor the listener's eye movements to real objects in a visual display using an eye-monitoring system. Listener's fixations provide researchers with hints about how the listener is interpreting the sentence as they hear it.

(11) Put the apple on the towel in the box.

Sentence (11) is temporarily ambiguous because the prepositional phrase 'on the towel' can be interpreted either as a goal of the event denoted by the verb 'put' (i.e., where the apple is to be put) or as a modifier of the preceding noun. It is only clear that the prepositional phrase 'on the towel' has to be a modifier once the second prepositional phrase 'in the box' is encountered. Because the verb 'put' requires a patient and a goal, listeners tend to initially interpret 'on the towel' as a goal, increasing fixations to the incorrect location in the referential context, that is, an empty towel. When the display contains two apples (e.g., one apple on a towel and the other apple on a napkin) and thus, requires a modifier for listeners to know which apple is being referred to, listeners are more likely to interpret 'on the towel' as a modifier, reducing fixations to the incorrect goal. This early effect of the referential context on ambiguity resolution suggests that the referential context is rapidly integrated with unfolding linguistic information, guiding initial processing.

Prosody

Prosody refers to a variety of phenomena that encode the acoustic-phonetic properties of spoken sentences. It includes pitch, loudness, tempo, rhythm, and pausing. In spoken communication, these factors can affect how a sentence is interpreted. One aspect of prosody that has been observed to influence initial syntactic processing is pausing. These rhythmic pauses are called 'prosodic boundaries.' Prosodic boundaries roughly correspond to a comma in written sentences. When there is a prosodic boundary, the word preceding it tends to be lengthened and followed by a pause (though not always). Prosodic boundaries also tend to co-occur with either a drop or rise in pitch.

Prosodic boundaries can guide the analysis of ambiguous sentences like (12) by signaling the location of major syntactic boundaries.

- (12) a. The journalist confirmed // the rumor was true.
b. The journalist confirmed the rumor was true.

As discussed earlier, a direct object-bias verb 'confirm' tends to lead the processor to be garden-pathed at the disambiguating verb 'was.' When there is a prosodic boundary (which is marked by the double slash marks) after the verb as in (12), listeners are less likely to be misled toward a direct object interpretation because the boundary signals that there is a clause boundary.

Researchers have also demonstrated that prosodic boundaries may guide initial processing using paradigms like the

cross-modal naming paradigm. In this task, listeners hear sentence fragments like 'The journalist confirmed the rumor' and are visually presented with a disambiguating word like 'was' that continues the sentence. The time taken to name the visual probe is used as an index of how the listener initially thought the sentence fragment would continue. In (12), naming times are shorter when there is a prosodic boundary after the verb than when there is not. Many studies have found that prosodic boundaries are used in the earliest stages of parsing.

Garden-Path versus Constraint-Based Model

Under both the garden-path and constraint-based models, nonsyntactic sources of information influence syntactic processing. However, these theories differ with respect to when these sources of information are thought to come into play. Experimental evidence from the psycholinguistic literature has shown very early effects of these nonsyntactic sources of information during syntactic processing, suggesting that the processing system is interactive. Proponents of the garden-path model, however, interpret these early effects as reflecting the process of reanalysis, arguing that they do not necessarily rule out the garden-path model. For the garden-path model to account for these data, reanalysis must occur very rapidly, and thus the outstanding differences between the garden-path and constraint-based models are now fairly minimal. Thus, consistent with both models, we can conclude that a wide array of information sources are used very rapidly to determine the most likely structure of a sentence.

Incomplete Processing

The processing system constructs syntactic and semantic representations to reach the meaning of the sentence intended by the speaker or the writer. Both the garden-path and constraint-based models predict that the processing system eventually reaches a single correct interpretation even if reanalysis or re-ranking is necessary. However, some recent evidence suggests that the processing system sometimes constructs an incomplete representation of a sentence's meaning by failing to eliminate initial misinterpretations from memory. This phenomenon is claimed to be an example of good-enough processing, the idea being that the processing system computes a representation that is good enough. Consider (13).

- (13) While the mother washed the baby cried.

When sentence (13) is presented without a comma after the verb 'washed,' readers are frequently garden-pathed toward an interpretation in which the mother washed the baby. Once the verb 'cried' is encountered, it becomes clear that the mother washed herself and that 'the baby' is the subject of the upcoming clause, not the direct object of the verb 'washed.' While the processing system eventually comes to the correct reading, it sometimes fails to completely rule out the incorrect interpretation. As a consequence of good-enough processing, the incorrect interpretation 'the mother washed the baby' remains activated in memory, possibly affecting the representation of the sentence's meaning.

Sentence Complexity

In temporarily or globally ambiguous sentences, processing difficulty arises when the processor is led to recover from an initial incorrect analysis. However, even unambiguous sentences can lead to processing difficulty. Consider (14).

- (14) a. The lady who helped the florist took care of the child.
b. The lady who the florist helped took care of the child.

In (14a) and (14b), the relative pronoun 'who' refers to the same entity as the 'lady.' We call relative clauses like the one in (14a) subject-extracted relative clauses because 'who' is a pronoun that refers to the subject of the relative clause (i.e., 'who helped the florist'). We call relative clauses like the one in (14b) object-extracted relative clauses because 'who' refers to the object of the relative clause (i.e., 'who the florist helped'). To process the relative pronoun 'who,' the pronoun must be linked with the empty subject or empty object position in the relative clause. In English, object-extracted relative clauses have been found to be more difficult to process than subject-relative clauses.

Why are object relative clauses more difficult than subject relative clauses? One theory is that the distance between two related words affects processing difficulty, an idea that has been formalized in the dependency locality theory (DLT). Central to the DLT is the notion of integration cost. These costs reflect the amount of memory resources that are required to integrate incoming elements into the existing structure. Integration costs increase as the number of intervening new referents increases between two elements in a dependency relationship. For example, while in (14a), the subject position in the relative clause (i.e., where the subject is typically located) is locally integrated with the relative pronoun 'who' with no intervening new referents, in (14b), integration between the typical object position in the relative clause (i.e., after the verb) and the relative pronoun 'who' occurs over two new discourse referents, 'florist' and 'helped'. According to the DLT, object-relative clauses are more difficult because they involve more long-distance integrations than subject-relative clauses.

The DLT also accounts for parsing decisions in ambiguous sentences. Under this theory, listeners prefer to choose syntactic structures with the shortest dependencies between words. Consider (15).

- (15) The lady said that the florist helped the child yesterday.

In (15), the adverb 'yesterday' can be associated either with the verb 'said' in the main clause, resulting in an interpretation in which the lady spoke yesterday, or with the verb 'helped' in the subordinate clause, resulting in an interpretation in which the florist helped the child yesterday. English speakers prefer attaching 'yesterday' to 'helped' rather than 'said.' This parsing preference is consistent with the prediction of the DLT. Attaching 'yesterday' to the main verb 'said' is less preferred because it is farther away, requiring a longer integration distance.

While the DLT attributes sentence complexity to integration costs and memory, other theories attribute sentence complexity to predictability, and these are called surprisal theories. Surprisal is estimated from the negative log probability of a word or a syntactic structure in a sentence where the

probability is estimated by various information sources such as syntax and semantics. The lower the predictability of a word or structure given its semantic and syntactic context, the more difficult it will be to process. According to surprisal, (14b) is more difficult than (14a) because object-extracted relative clauses are less common and thus less probable than subject-extracted relative clauses.

Under surprisal, the processing system incrementally updates its expectations about upcoming words as each new word is encountered. Consider (16).

- (16) a. The lady who helped the florist took care of the child.
b. The lady who helped the florist in the park took care of the child.
c. The lady who helped the florist in the park yesterday took care of the child.

In (16b) and (16c), a reader encounters additional information (i.e., 'in the park' in (16b) and 'in the park yesterday' in (16c)) before he or she reaches the main verb 'took', compared to (16a). Surprisal predicts that as listeners encounter words in the relative clause, their expectation of encountering the main verb should increase. The longer the relative clause is, the higher is the probability of the main verb when the main verb is finally encountered. Thus, in (16c), expectation for the main verb at the end of the relative clause is higher than in (16a) and (16b) because expectations for the main verb are higher after a long relative clause. Consequently, processing the main verb in (16c) should be easier.

Thus, surprisal and the DLT make differing predictions for sentences like (16). The evidence is somewhat mixed. Some studies have found that long-distance dependencies, which require the integration of the elements that are structurally distant, are hard to process, which is consistent with DLT. Other studies, however, have found that for certain structures, longer distances facilitate processing, which is consistent with surprisal.

It is not clear how integration costs and surprisal should be theoretically integrated to explain these data. More experimental research is required to understand the conditions under which these two sources of processing difficulty play a role.

Summary

Sentence processing is highly incremental. The processing system incorporates each incoming input immediately into the syntactic structure being currently constructed. As the sentence is heard or read, the processing system integrates various sources of linguistic and nonlinguistic sources of information, including syntactic and semantic knowledge, lexical frequency, referential context, and prosody, to choose an appropriate analysis. In addition, factors like ambiguity, long-distance relationships, and predictability play a role in how a sentence is processed and understood.

Glossary

Anxiety A state of apprehension, uncertainty or fear resulting from the anticipation of a real or imagined event or situation, often impairing physical and psychological functioning. Anxiety is characterized by cognitive, somatic, emotional, and behavioral components.

Anxiety disorder A dysfunctional behavior pattern that interferes with adjustment and is marked by distressing, persistent anxiety or maladaptive behaviors intended to reduce anxiety.

Cognitive-behavioral therapy A treatment approach that focuses on monitoring and altering cognitive activity and exposing the individual to the feared situations to affect desired behavior change.

Externalizing behavior problems Behavior patterns directed outwardly toward the social environment,

characterized by undercontrolled responding. Examples include aggression, disruption, defiance, and impulsivity.

Fear A feeling of agitation or dread caused by the presence or imminence of real or imagined danger.

Internalizing behavior problems Behaviors that are directed inwardly toward the self, as seen in an overcontrolled pattern of responding. Examples include social withdrawal, depression, and anxiety.

Multimethod multiinformant assessment An assessment strategy that uses diagnostic information gathered by varied procedures, such as interviews, questionnaires, and observations, from multiple sources of information, including the child, caregivers, teachers, peers, and other important figures.

Introduction

Johnny, a 9-year-old boy described by his mother as her 'shadow,' follows close behind her wherever they go. He reports getting very scared when even thinking about being apart from her and does whatever he can to try to be near her. Getting Johnny to go to school each day is a challenging endeavor, one usually accompanied by pleas to stay home, complaints of stomachaches, as well as temper tantrums that often follow an extended period away from school. He has missed over half of the school days in the last month because of these behavior outbursts, causing his parents to consider home schooling because of Johnny's absenteeism. When Johnny does attend school and is apart from his mother, he sends her multiple text messages to seek assurance that she is all right. His parents were reluctant to buy him a cell phone, but it seemed to be the only thing that could ameliorate his anxiety, even though it was supposed to be used only in emergencies. Johnny has a number of close friends, but playdates always seem to occur at his house. He needs his mother to lie next to him in bed until he falls asleep, and he will often wake up in the middle of the night and crawl into his parents' bed – an occurrence that has been increasing in its regularity and disrupts his parents' sleep.

What is the nature of Johnny's behavior? Is this typical for his age or does it exceed what would be considered appropriate at his developmental level? If the latter, is it a problem that warrants some form of intervention or is creating accommodations in an attempt to conform to the anxiety (e.g., use of cell phones, sleeping in parents' bedroom) a useful approach? These are important questions, ones that many parents frequently ask themselves. This article presents a summary of the clinical picture of this type of child behavior – a pattern

that is referred to as 'separation anxiety' – describing assessment modalities and effective treatment strategies supported by research to address this common yet distressing and interfering behavior in children and adolescents.

Clinical Description

Separation anxiety disorder (SAD) officially became a diagnostic category in 1980 in the third edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM). SAD is defined as developmentally inappropriate and excessive anxiety about separation from the home or from significant attachment figures (e.g., parents, primary caregiver). To receive a diagnosis of SAD, youth must demonstrate three or more of the following eight symptoms: (1) recurrent and excessive distress upon separation, or anticipation of separation, from home or major attachment figures; (2) persistent and excessive worry about losing, or about possible harm coming to, major attachment figures; (3) persistent and excessive worry that some event – such as getting lost or being kidnapped – will lead to being separated from a major attachment figure; (4) persistent reluctance or refusal to go to school or other places due to a fear of separation; (5) persistent and excessive fearfulness or reluctance to be alone, or without major attachment figures at home or in other settings; (6) persistent reluctance or refusal to go to sleep without a major attachment figure present, or to sleep away from home; (7) recurrent nightmares about being separated from major attachment figures; and (8) repeated complaints of physical symptoms (e.g., headaches, nausea) when separation from major attachment figures occurs or is anticipated.

For a diagnosis, the symptoms must cause clinically significant distress or impairment in domains of life that are relevant

to youth, such as disturbance of family functioning at home, academic performance at school, or social relationships with peers. Additionally, a diagnosis of SAD is not warranted if the behaviors occur exclusively as part of another disorder (e.g., pervasive developmental disorder). Finally, symptoms must persist for at least four consecutive weeks and emerge prior to the age of 18 (with a specification of 'Early Onset' if they begin before the age of 6). SAD is typically conceptualized as a problem in youth most commonly occurring in early to middle childhood (e.g., 6–12 years old) and less frequently into adolescence (e.g., age 13 and older); it is the only anxiety disorder within the DSM to be located within the section that describes disorders that are usually first diagnosed in infancy, childhood, or adolescence. The presence of SAD during youth may be associated with increased risk for future mental health issues, particularly phobias, panic, and depression. Adults with SAD may seem excessively attached to their spouses or children, and experience distress when needing to be apart from them; they may also find it difficult to effectively cope with major life transitions (e.g., moving, or the commencement of children's schooling).

Separation anxiety has been hypothesized as stemming from a number of possible causes including poorly developed attachment with caregiver (e.g., insecure attachment style), early separation trauma (e.g., death of a parent), and parental reinforcement (e.g., parents reward attachment rather than autonomy). Epidemiological research indicates that SAD is slightly more common in females than males, though boys tend to outnumber girls in clinical samples, a trend that has been explained by gender norms and treatment seeking patterns. That is, because the display of separation anxiety is less readily culturally accepted as typical for males, its emergence in boys may be interpreted by adults as more of a cause for concern and warranting intervention, resulting in their being brought to clinics for intervention more often than girls. Overall, prevalence estimates suggest that SAD is quite common among children and adolescents, affecting approximately 3–4% of youth.

Clinically distressing separation anxiety must be distinguished from fears and anxiety that are typical in youth and are considered part of a normal developmental pathway. During the months spanning late infancy and early toddlerhood, nearly all children exhibit distress when confronted with actual or anticipated separation from their primary caregiver for any amount of time. At this age, anxiety over separation is normal. As they get older (e.g., ages 4–6), some degree of anxiety is common for children facing their first experience with prolonged separation, such as for daycare or preschool. Indeed, research has found that separation-based concerns persist through middle childhood (e.g., ages 7–12). Interviews with nonreferred elementary school children have revealed that being kidnapped, harm befalling self or a significant other, and being apart from one's parents constitute some of the most frequently reported fears and scary dreams during this stage of youth. However, for many children, concerns are not clinically significant. In general, fears of separation decrease with age from a developmentally normal peak during the preschool years and subside by the time a child reaches his or her teens. Thus, to distinguish between typical and abnormal separation anxiety, one must examine the nature of symptom expression, its severity, duration, and amount of interference.

Features to consider are whether the anxiety is disproportionate to the situation, whether it leads to associated avoidance, and whether it is maladaptive given the child's developmental level.

Assessment

The determination of whether a child is suffering from SAD may not be a straightforward endeavor. For example, there is considerable overlap in symptom presentation among the various anxiety disorders outlined in the DSM, and SAD often occurs with noteworthy rates of comorbidity. To accurately distinguish among disorders and obtain the most comprehensive diagnostic picture, a multimethod approach of gathering information from multiple informants across multiple settings is recommended.

Clinical interviews are one of the most valuable tools for learning about the issues for which a family presents to treatment. Several semistructured interviews are available for assessment of youth, such as the Diagnostic Interview Schedule for Children (DISC), the Schedule for Affective Disorders and Schizophrenia in School-Aged Children (K-SADS), and the Diagnostic Interview for Children and Adolescents (DICA). Another semistructured interview has been constructed specifically to assess anxiety in youth: the Anxiety Disorders Interview Schedule for Children (ADIS C/P). The ADIS C/P allows the clinician to differentiate SAD from other anxiety disorders, as well as from other potential comorbid mood and externalizing disorders. With distinct formats for parents and for children, youth and their caregivers can be interviewed separately to provide multiple perspectives on the problem. Information from both reporters is merged with the interviewer's impressions to produce an overall evaluation of the magnitude of impairment caused by the reported symptoms. The ADIS C/P has good reliability between interviewers as well as over time and is also able to capture beneficial changes produced by intervention.

Questionnaires can also be a useful tool for measuring anxiety, allowing respondents to endorse symptoms of anxiety quickly and discretely with less concern for another individual's immediate judgment. Questionnaires are valuable for gathering information from significant figures in the child's life (e.g., teachers) who can provide critical input but are less realistically able to visit a therapist's office. A drawback to questionnaires is that they are insufficient, by themselves, to yield a clinical diagnosis, though the extensive samples on which measures are normed provides a backdrop against which to determine whether a child is experiencing developmentally typical or problematic levels of anxiety. Questionnaires commonly used include the Revised Children's Manifest Anxiety Scale (RCMAS), the State-Trait Anxiety Inventory for Children (STAI-C), the Screen for Anxiety and Related Emotional Disorders (SCARED), and the Multidimensional Anxiety Scale for Children (MASC). Questionnaires are also particularly useful for providing cross-situational perspectives of the child's mood and behavior.

Behavioral observations of the child are immensely valuable for the clinician to consider when forming an impression of the presenting issue. The interview itself provides an opportunity for informal observation of the child's behavior.

When assessing for SAD, the separate interview format of the ADIS C/P provides the unique opportunity to take note of how the youth behaves when faced with separating from his or her primary caregiver – the very process about which information is being gathered. It should be noted, however, that an absence of distress upon this separation does not immediately rule out the possibility of SAD, as the interviewer's efforts to make the child feel comfortable (e.g., by explaining what is involved in the interview process) may help to alleviate anxiety. On the other hand, observing the youth becoming distressed, crying, and/or clinging to a parent at the moment of parting is a noteworthy behavioral indicator that separation anxiety may be a problem. Although less common, formal behavioral observation can be conducted in naturalistic settings, such as the home or school, where separation difficulties are likely to occur.

Overall, there are a number of avenues to assessment that can be taken in order to determine whether a child's presentation is consistent with SAD. Though interviews are reliable for reaching a diagnosis, other assessment modalities are worthwhile as well. Questionnaires can be a brief and less threatening way to collect data from multiple informants, and behavioral observation offers a first-hand look at how youth react to and cope – or fail to cope – with impending separation. An informed diagnosis incorporates information from as many assessment options as possible. However, arriving at an accurate diagnosis for a given child's presentation may remain a challenge. The following section considers some of the finer distinctions between SAD and another disorder which can sometimes share similar concerns and thus present a particular challenge to accurate case conceptualization.

Differential Diagnosis

A distinct challenge that arises in the assessment of SAD is the difficulty in differentiating it from other mental health disorders that may exhibit separation concerns as an associated feature. This is a particularly difficult task for SAD, which, by virtue of its designation as predominantly a disorder of early youth, already requires that special attention be paid to the appropriateness of the behavior in terms of developmental norms. Thus, it can indeed be difficult to distinguish separation anxiety as a disorder from that which is quite typical of normal development and that which occurs only as a symptom in the context of another disorder.

One disorder that raises special questions in terms of its distinctness from SAD is generalized anxiety disorder (GAD), a disorder characterized by excessive worry about a number of events or activities that is difficult to control. Although some individuals with GAD share very little resemblance to those with SAD, a common occurrence is to encounter children and younger adolescents whose focus of anxiety is centered on their own well-being and that of their parents or other family members. Thus clinicians must pay particular attention to differentiating the focus of the fear as specific to separation concerns or in a wider context involving health and safety. The DSM suggests that GAD and SAD are distinguished by the former's not being restricted to worry about being away from home or relatives while this is the predominant focus of the latter. However, in practical terms, this distinction is often less clear.

Given that two of the main diagnostic criteria for SAD include persistent and excessive concern about (1) harm befalling major attachment figures and (2) being parted from loved ones, it is easy to see how the dividing lines between fear of separation (as in SAD) and worry about health and safety (as in GAD) can become blurred. The diagnostic picture can become even more complicated when parents are described as security figures for their children. In such cases, children are often reported to be unable to engage in various activities if not accompanied by parents, but perfectly able to do so if a parent is present. Moreover, both SAD and GAD are associated with the experience of somatic distress (e.g., stomachaches, nausea, sleep disturbance) when confronted with the situational trigger for anxiety. Thus, the overlapping nature of these common youth anxieties poses a considerable challenge to professionals seeking to accurately understand and categorize a child's presenting problem.

How, then, can one correctly differentiate these two disorders? The key is to pay special attention to particular features of the symptom presentation such as the specific feared outcome and the point at which anxiety surfaces. For example, in the case of a child with SAD, a worry about being kidnapped is focused primarily on the subsequent separation from the primary caregiver that it would cause. Though the notion of being abducted is naturally and normally distressing, it is primarily a concern about being away from loved ones that causes the upset in SAD. By contrast, a youth struggling with GAD who worries about safety will be concerned, not as much about being apart from attachment figures, but rather more so about the danger and possible harm that could result from being kidnapped. Further, with regard to timing, the child with SAD typically feels at ease when in the presence of major attachment figures and is more likely to become distressed only when separation is occurring or expected. This is distinguished from the child with GAD who may be perpetually worried about threats to personal health and safety, even while in the presence of parents or significant others. Thus the focus and timing of anxiety can assist professionals in differentiating SAD from GAD. Of course, it should also be noted that considerable research has shown that children and adolescents commonly present with comorbid anxiety disorders in addition to a principal anxiety disorder. This tendency for comorbidity of SAD with additional psychological disorders, particularly other anxiety disorders, points to the importance of multimethod and multiinformant assessment to develop a comprehensive diagnostic profile for the child presenting with separation concerns. This task, though difficult, is crucial for proper case conceptualization and treatment planning.

Separation Anxiety and School Refusal

Separation anxiety co-occurs at high rates with school refusal, a behavior characterized by child-motivated refusal to attend school and/or difficulties with being able to successfully remain in the classroom for the duration of the school day. Indeed, estimates have suggested that up to a third of youth who refuse school meet criteria for a diagnosis of SAD; further, between one-third and one-half of youth with SAD demonstrate what has been referred to as 'school phobia,' a marked

and intense fear of school that leads to avoidance behavior. Although the long-term consequences of comorbid SAD and school refusal are not yet fully understood, preliminary investigations suggest that these problems lead to higher rates of psychiatric consultation later in life.

An important consideration in determining the presence of SAD when presented with school refusal behavior is that school refusal is a heterogeneous pattern of behavior which encompasses externalizing disorders as well as internalizing disorders. Thus, effectively distinguishing school refusal caused by underlying separation anxiety from that which stems from the pursuit of reinforcement obtained by staying at home (or from noncompliance and/or social nonconformity) is important. This may include, but is not limited to, receiving extra attention from a parent, being able to watch television or play video games, or spending time with peers who may also be refusing school.

This differentiation is accomplished through a process known as 'functional analysis.' Functional analysis determines the purpose of a behavior by investigating what is being achieved by avoiding the school environment. By examining the antecedent causes of the school refusal behavior, its subsequent consequences, and maintaining factors, a clinician can determine the underlying motivation for the behavior. For instance, if the functional analysis reveals that the antecedent to school refusal is threatened parental separation when told to leave for school, the consequence of tantrums is staying home with the parent, and the maintaining factor is negative reinforcement of avoidant behavior, then it is reasonable to conclude that the motivation for school refusal behavior is related to separation anxiety.

Treatment

Cognitive-behavioral therapy (CBT) has been widely recognized as the psychosocial treatment of choice for SAD. A number of clinical trials have demonstrated the efficacy of CBT, and according to accepted criteria, it has been recognized as a well-established, evidence-based treatment for anxiety disorders in youth. The development of the essential components of CBT has been equally influenced by both behavioral and cognitive theories. These approaches emphasize the importance of exposure experiences and change in children's cognitive processes with the intention of enhancing more adaptive coping mechanisms. Additionally, integrative models have incorporated pathways in which early family environment and biological vulnerabilities contribute to childhood anxiety. These models have contributed to the creation of a multifaceted CBT approach that has received empirical support (e.g., the *Coping Cat* program). The following section describes the principal components of CBT treatment for SAD, which consists of: (1) assessment, (2) psychoeducation, (3) coping skills, (4) exposures, and (5) relapse prevention.

Assessment is an essential component of therapy because it provides an idiographic diagnostic picture from which treatment can begin and serves as a means to monitor change over time. Multimethod approaches to assessment throughout therapy aid in the prioritization of the child's problems and are useful in setting goals. Furthermore, evaluating the child's

reactions to, and impairment level in, situations involving separation provides valuable data to guide the treatment process.

The *psychoeducation* component of CBT is an opportunity for the therapist to provide information to the child and parent about the biological, behavioral, and psychological underpinnings of anxiety. The therapist discusses ways in which excess levels of anxiety are learned and maintained and explains the rationale for various treatment techniques. The goal is to foster the understanding that anxiety is an adaptive emotion and that treatment goals are geared toward the reduction and management of anxiety rather than its complete elimination. Specifically, children learn how to uncover the triggers of their separation anxiety and to describe how SAD affects them physically, cognitively, and behaviorally, providing the structure for anxiety management skills.

The *coping skills* component is where the child begins to learn and gather specific tools to manage his or her separation anxiety. There are three crucial techniques that CBT therapists emphasize. *Somatic management techniques* help the child hone in on the skill of relaxation through practice. Procedures most frequently used are diaphragmatic breathing and progressive muscle relaxation, which involves systematically relaxing major muscle groups through the use of tension-release procedures. Children are often provided a personalized relaxation recording that helps them to review and practice these techniques as homework assignments. In addition, these recordings can be used during situations that provoke heightened states of anxiety, such as bedtime, that can be part of a routine to help temper the arousal system. *Cognitive restructuring* is a technique that involves identifying maladaptive thoughts and beliefs and challenging these thoughts with coping-focused thinking and action plans based in reality. Clinicians typically involve parents by teaching them to coach their children in questioning the evidence for their thoughts in order to arrive at other coping solutions. Lastly, *problem solving* is a collaborative step-by-step process that allows the child to create and focus on nonavoidant solutions to a problematic situation. Anxious children frequently utilize avoidant problem-solving strategies that lower anxiety by simply escaping the situation. Though effective in the immediate short term, such strategies only serve to maintain and increase anxiety in the future. Alternatively, the clinician encourages the child to generate a variety of solutions without prejudging the efficacy of these solutions, in order to select, implement, and verify the effectiveness of the chosen result.

A key ingredient in CBT treatment of anxiety-based disorders is *exposure*. Through a collaboratively established hierarchy of anxiety-eliciting events, objects, and situations, the child suffering from separation anxiety is systematically and gradually exposed to his or her fears about being apart from home or attachment figures. Through imaginal, simulated, and *in vivo* methods, the child is given the opportunity to experience the increase and decrease of his or her anxiety in a controlled environment. Additionally, the child experiences the feared situation in a new light, aiding him or her to feel mastery over the ability to manage the anxiety. These exposure tasks provide an avenue for the child to successfully generalize the skill to other anxiety-provoking situations outside of therapy. To increase and encourage brave behavior (e.g., nonavoidant

strategies), clinicians utilize contingency management procedures (e.g., rewards). Such reward systems promote engagement in treatment and behavior change, with the ultimate goal to have the child engage in self-reinforcement that encourages the continuation of brave behavior.

Finally, the *relapse prevention* component in CBT programs is geared toward the consolidation of skills and promoting the generalization and maintenance of treatment gains over time. Skills are practiced across multiple settings and events to practice brave behavior in a variety of contexts.

Manual-based CBT interventions for anxiety disorders in youth have received considerable empirical support. In recent years, several randomized control trials have been conducted with children experiencing a range of anxiety disorders, including SAD, GAD, and social phobia (SoP). In 1994, Kendall conducted the first controlled trial to evaluate a manualized CBT intervention called the *Coping Cat Program*. This study assigned 47 children, aged 8–13 years old, with an anxiety disorder – 38% of whom had a diagnosis of SAD – to a CBT intervention consisting of sixteen 60 min sessions or to a waiting-list control condition. Pre- to posttreatment results revealed a significant change in anxiety for the treatment group, whereas the control group remained relatively unchanged. The majority of the treated children (64%) no longer met diagnostic criteria for an anxiety disorder at posttreatment, indicating clinically significant treatment effects. In a follow-up study of these treated children, results indicated that treatment gains were maintained approximately 2–5 years after treatment.

A second randomized control trial evaluated a CBT intervention for 94 children between the ages of 9 and 13 (23% with a SAD diagnosis) assigned to a treatment or wait-list control condition. Results revealed that 50% of the treated children were free of their primary diagnosis at posttreatment, with significant reductions in anxiety levels for those who continued to report anxiety symptoms. At 1-year follow up, these gains were maintained, and children continued to show improvements. In one of the longest follow-up studies conducted, at an average of 7.4 years later, not only did children continue to maintain treatment gains but also treatment responders reported significantly less substance use and other related problems compared to those with a less successful response. These findings support the long-term utility of CBT in treating anxious children and adolescents, including those with SAD.

Further outcome studies have demonstrated evidence for the efficacy of using CBT in a group treatment format (GCBT) for SAD. Controlled trials demonstrate that GCBT is equally as effective in treating anxiety disorders as child-focused individualized CBT. For instance, a randomized clinical trial evaluated the outcome of 37 anxious children (ages 8–14) assigned to CBT, GCBT, and wait-list control. Results revealed that a majority of children who received 18 weeks of CBT or GCBT did not meet criteria for their anxiety disorder (73% and 50%, respectively) compared to the control condition (8%). In addition, the study concluded that CBT interventions delivered individually or in a group format were similarly effective in treating SAD and other anxiety disorders.

In recent years there has been an emphasis on the parent–child relationship in understanding the maintenance of child anxiety, and studies have examined the role of parent

involvement in treatment. Randomized controlled trials have revealed that family CBT (FCBT) compared to a wait-list control group is efficacious, while each of the two versions of CBT (child-focused CBT and FCBT) were comparably effective. In 2008, another randomized clinical trial assigned 161 anxious children (29% with SAD) of ages 7–14 years to 16 weeks of CBT, FCBT, or a family-based education, support, and attention therapy (FESA) that served as a comparative alternative treatment to CBT. Results revealed that both child and FCBT interventions were superior to FESA in reducing anxiety symptoms and the presence of an anxiety disorder, concluding that the two versions of CBT were comparable.

Recent evidence suggests that medication can also be an effective and well-tolerated treatment for SAD. Double-blind control trials have found the use of selective serotonin reuptake inhibitors (SSRIs) to be efficacious in treating SAD, GAD, and SoP. The promising effects of SSRIs and CBT interventions sparked further examination of the relative efficacy of CBT, medication, and their combination to identify the best ways for treating anxiety disorders in children and adolescents. In the CAMS multicenter controlled trial, 488 children (ages 7–17), diagnosed with SAD, SoP, and GAD, were assigned to four conditions of short-term (12-weeks) treatment: CBT, sertraline (SSRI), their combination (CBT + sertraline), and a placebo drug. These results indicated that the three active treatments – CBT, sertraline, and their combination – compared to placebo were effective treatments for children with SAD, SoP, and GAD. The combination treatment of CBT and sertraline (81%) was superior to CBT alone (60%) and sertraline alone (55%) in terms of the percentage of youth rated as ‘much improved’ or ‘very much improved’ by the end of the study. Additionally, results revealed that CBT alone and sertraline alone were equally good treatments for child anxiety.

Building on the success of programs appropriate for multiple types of anxiety disorders, recent efforts have also sought to evaluate the efficacy of interventions specifically tailored for the treatment of SAD. Santucci and colleagues developed an approach to delivering components of CBT through an intensive 1-week summer camp-like program. In a progressive fashion, children and parents moved from receiving joint psychoeducation and spending most of the first day together, to parting immediately upon arrival for separate child and parent groups by the fourth day. Participants also engaged in creative and developmentally appropriate play activities (e.g., artistic crafts, field trips) akin to what might be experienced at a summer camp. The program culminated with a sleepover on the final night and an award ceremony the following morning. Initial pilot testing of this approach yielded promising results, as participants exhibited reductions in separation anxiety at posttreatment and further decreases in anxiety at 2-month follow-up. This program is currently in its next phase of evaluation.

Some recent efforts have sought to determine whether other existing models of treatment can be applied to the treatment of SAD. In one example, Pincus and colleagues applied Parent–Child Interaction Therapy (PCIT), an empirically supported intervention originally designed for reducing disruptive behaviors in youth, with SAD children. As an approach developed to alter the dynamic of maladaptive interactions between youth and their parents, the PCIT model thus lends itself well to SAD treatment. More appropriate child behavior could be

fostered through parental reinforcement of bravery and coping in the face of separation while decreased attention is paid to clingy or even oppositional behavior that can sometimes be exhibited. After observing some shortcomings of conventional PCIT applied to SAD, Pincus developed an adaptation of this approach. A formal evaluation is ongoing, with preliminary results suggesting favorable outcomes.

As described earlier, most of the research on the treatment of SAD has been obtained from evaluations of CBT interventions that have been established as efficacious in the treatment of several childhood anxiety disorders; however, several modifications to these manual-based treatments are recommended to adapt them to treat children with SAD. Specifically, the treatment of SAD typically involves a multimodal approach that, within a CBT framework, includes school consultation and intervention, additional family components to treatment, and depending on the severity of the child's symptoms, pharmacotherapy.

Family-based treatments are relevant for treating SAD due to the uniquely close child–parent relationship and the frequent account of separation anxiety symptoms in the parent. For instance, parents of anxious children may inadvertently engage in anxiety-enhancing behavior by modeling fear or avoidance and not promoting autonomy. Thus, a parent training component in CBT interventions geared specifically toward working on effective parenting strategies that encourage brave behavior and extinguish excessive anxiety in their child may further enhance treatment outcome. Time may be spent preparing parents for their child's exposures and emphasizing that an essential component of treatment is allowing the child to independently experience and learn to cope with anxious feelings. A preliminary, multiple-baseline study examined the efficacy of an integrated cognitive-behavioral parent training protocol specifically for parents of children with SAD. Six children, aged 7–10, and their parents received 10 weeks of CBT, with the first two sessions devoted solely to parent education and training. Results revealed that treatment led to positive parental outcomes (e.g., enhanced self-efficacy) that were also associated with positive treatment outcomes for their anxious children. Moreover, five of the six child participants did not meet the criteria for SAD at posttreatment, further supporting the efficacy of family-based CBT for child anxiety.

Due to the high comorbidity rate between SAD and school refusal, consultation with school staff may be essential to CBT interventions. Children with SAD are likely to have school situations as part of their exposure component of treatment; consultation can therefore involve working with school personnel toward gradually reentering the child in the classroom. Guiding teachers and school nurses on how to contribute effectively to treatment goals can aid in limiting the child's visits to the school nurse or calls home to check on parent safety. Consistency on how to manage the child's anxious behavior both at home and in school is optimal for a positive treatment outcome.

The essential components of CBT are tailored to the individualized needs of the child. Clinicians should approach treatment from a developmental perspective and take into consideration the child's environmental and family needs. Despite the solid evidence supporting CBT as an efficacious treatment and the benefits of SSRIs for treating anxiety

disorders in children and adolescents, including SAD, it is suggested that future research continue to examine unique treatment aspects for this particular type of anxiety disorder. Additionally, ongoing investigations are focusing on the dissemination of these treatments to nonclinical settings, such as schools, primary care settings, and community centers as well as identifying at-risk youth for prevention interventions.

Conclusions

SAD is one of the most prevalent disorders in preadolescent youth. It is characterized by developmentally inappropriate anxiety and fear of separation from home or significant attachment figures, followed by avoidant behavior, such as refusal to attend school or to sleep alone. Such pathology causes significant impairment in functioning, including peer relationships, academic performance, and relationships within the family. If left untreated, SAD has the potential to have long-term negative effects on social and emotional development.

Due to its common co-occurrence with other related disorders, utilizing a multimethod and multiinformant approach to assessment is most effective in achieving a comprehensive diagnostic picture. Multiple pathways accounting for the etiology and maintenance of SAD has fueled the creation of multifaceted approaches to treatment. There is solid empirical evidence supporting the efficacy of CBT, and the benefit of SSRIs, for the treatment of child and adolescent anxiety disorders, including SAD. Preliminary and ongoing investigations focused on treatment tailored specifically to SAD have thus far yielded very promising results. Overall, assessment and treatment of this disorder should be conceptualized and examined from a developmental perspective. As we continue to further understand the etiological mechanisms of SAD, the investigation and implementation of integrated approaches to treatment will be important.

Glossary

Cultural success The achievement of status and the control of resources that are important in a given society or cultural niche.

Operational sex ratio The ratio of sexually receptive males to sexually receptive females in a local area and at a given point in time.

Relational aggression Use of gossip, lies, and rumors to derogate sexual competitors and disrupt their romantic and social relationships.

Sexual selection Competition among member of the same sex (intrasexual competition) for access to mates or control of the resources mates need to reproduce, and discriminative choice of mating partners (intersexual choice).

Darwin's theory of sexual selection and the component processes of intrasexual competition (e.g., male–male competition) and intersexual choice (e.g., female choice of mates) have guided the scientific study of sex differences in hundreds of nonhuman species. These same processes have occurred during human evolution and provide a means to organize our understanding of the many sex differences in our species. The usefulness of this theory for approaching the study human sex differences is illustrated with a discussion of sex differences in mate preferences and in intrasexual competition. Cultural influences on these behaviors demonstrate that the social context and evolutionary history interact in the expression of evolved biases.

Introduction

Over the past 100 years, social and biological scientists have identified many human sex differences, ranging from risk of cardiovascular disease to brain organization to competence in reading and writing. Most of these differences are found across cultures and historical periods, although their magnitude and how they are expressed can vary across these social contexts. Despite wide agreement about the existence of sex differences, their origins remain a matter of debate. The search for these origins has included studies of hormonal, social, and evolutionary processes, and often results in an unproductive focus on either social and environmental explanations or biological ones. Many, if not most, of the human sex differences that have been identified result from multiple social and biological influences that can be traced in varying degrees to our evolutionary history. An evolutionary perspective is not an alternative to social influences, but rather a different level of analysis. The former provides a broad theoretical framework that places human sex differences in the context of sex differences found in other species, and social influences along with hormones help to explain how these differences are expressed in one context or another.

Sexual Selection

Darwin is of course well known for his masterwork, *On the origin of species*, and the codiscovery (with Wallace) of the principles of natural selection. Darwin also discovered another

group of processes that operate within species and are the principle sources driving the evolution of sex differences. These processes are called *sexual selection*, and involve competition with members of the same sex over mates (*intrasexual competition*) and discriminative choice of mating partners (*intersexual choice*). Although both intrasexual competition and intersexual choice can be found for both sexes, as is the case with humans, the most common pattern involves male–male competition over access to mates and female choice of mating partners. The reason this pattern is so common can be found in underlying sex differences in the rate of reproduction and in investment in parenting.

Parenting and Rate of Reproduction

More than 100 years after Darwin introduced the concept of sexual selection, Williams and Trivers proposed that the tendency to compete or choose is tightly linked to parenting. In brief, any sex difference in the tendency to compete or choose largely, but not exclusively, turns on the degree to which females and males invest in parenting. The sex that provides more than his or her share of parental investment becomes an important reproductive resource for members of the opposite sex. The result is competition among members of the lower investing sex (typically males) over the parental investment of members of the higher investing sex (typically females). Members of the higher investing sex are in demand, and thus can be choosy when it comes to mates.

The bias to invest in parenting or not is influenced by the potential rate of reproduction. The sex with the higher potential rate tends to invest more in competing for mates than in parenting, and the sex with the lower rate tends to invest more in parenting. The pattern emerges because members of the sex with the higher potential rate of reproduction can rejoin the mating pool more quickly than can members of the opposite sex and it is often in their reproductive best interest to do so. Individuals of the lower investing sex typically have more offspring if they compete for mates than if they parent, whereas members of the higher investing sex show the opposite pattern, and benefit more from being choosy than do members of the lower investing sex.

For mammals, internal gestation and obligatory postpartum suckling create a very large sex difference in the potential

rate of reproduction, and thereby creates the potential for large female–male differences in the mix of parenting and competing; this difference is found in 95–97% of mammalian species. Basically, female care of offspring frees males to compete for mates, and successful males have many offspring each breeding season and most other males never reproduce.

Intersexual Choice

Female choice is more common than male choice, because females' investment in parenting makes them a valuable resource for males and allows them to choose among many prospective mates. One evolutionary result is an exaggeration of the male traits on which females base their mate choices. In many species, traits such as those shown in Figure 1 are an indicator of the physical or genetic health of the male, or serve as an indicator of his ability (e.g., vigor in searching for food) to provide parental investment. Male birds with an elaborate and colorful plumage or more complex songs are chosen as mating partners more often than their duller peers, because these traits provide females with information on males' immune system and physical health; the former has a heritable component and thus offspring sired by healthy males have lower mortality. Males who are sick or cannot tolerate high levels of

testosterone – which can suppress the immune system – cannot develop these traits and thus are not chosen as mates.

In short, male ornaments, such as the long tail features of the male shown in Figure 1, are barometers that are strongly affected by the condition of the male, and female mate choice reflects the evolution of the female's ability to read these barometers. Females have evolved to be sensitive to these barometers and males to develop them if they can, because they advertise the reproductive benefits the female will accrue if she mates with the male. For species in which males' parent and species in which there are differences in females' ability to successfully rear offspring, male choice is also found and females evolve traits that males use in their choices.

Intrasexual Competition

One of the more common expressions of male intrasexual competition is physical threats and fights over access to receptive females or for control of the territory or resources that females need to raise offsprings (e.g., nesting spots). The typical result is that physically larger, healthier, and aggressive males monopolize access to sexually receptive females. The accompanying individual differences in reproductive success – some males have many offspring, others few or none – result in the selection for and evolution of sex differences in physical size, armament, and weaponry, as well as aggressiveness, as illustrated in Figure 2.

The traits that facilitate intrasexual competition are not always physical. Sexual selection will operate on brain and cognitive traits in the same manner as physical ones, if the associated abilities and behavioral biases provide reproductive

Figure 1 Male *Paradisea Papuana*. From Darwin C (1882) *The Descent of Man, and Selection in Relation to Sex*, 2nd edn., vol. II, p. 386. London: John Murray. In the public domain.

Figure 2 Sexually selected characteristics used in physical male–male competition. To the left is the male kudu (*Strepsiceros kudu*). benefits. Competition can also involve a strong social component, when males form coalitions to facilitate their ability to compete for access to females or resources needed to attract females. Female–female competition occurs when males provide some investment in offspring. Whether it occurs among males or females, evolution will favor the exaggeration of whatever traits are needed to successfully compete. Sex differences emerge when the intensity or nature of intrasexual competition differs for males and females.

Operational Sex Ratio and Sex Hormones

Social and ecological conditions as well as sex hormones can also influence how evolved sex differences are expressed. The operational sex ratio (OSR) is one of the more important of the social influences. The OSR is the ratio of sexually active males to sexually active females in a given breeding population at a given point in time, and is related to the rate of reproduction. An actual sex ratio of 1:1 represents a population in which there are as many sexually *mature* females as males, but any sex difference in the rate of reproduction will skew the OSR. Because mammalian males have a faster potential rate of reproduction than females, there are typically many more sexually *receptive* males than sexually *receptive* females in most populations. The resulting bias in the OSR creates the conditions that lead to intense male–male competition over access to a limited number of sexually receptive females. Male–male competition, in turn, creates the conditions in which female choosiness can evolve.

In some situations, the sex with the higher potential rate of reproduction is better off by investing in parenting than in competing for mates. For instance, social monogamy and high levels of male parenting are common in *canids* (e.g., coyotes, *Canis latrans*), where females tend to have large litters. Large litter sizes, prolonged offspring dependency, and the ability of the male to provide food during this dependency result in *canid* males being able to sire more offspring with a monogamous, high-parenting reproductive strategy than with a polygynous high-competition strategy. The result is a more balanced OSR. Generally, it appears that paternal investment occurs in species in which males are reproductively more successful when they parent than when they compete, although a mix of competing and parenting is evident in some species, including humans.

The proximate expression of the above described sex differences and many others are also influenced by prenatal and postnatal exposure to sex hormones. The influences of sex hormones on physical development and on the brain, cognition, and behavior are complex and sometimes very subtle, often interacting reciprocally with genetic sex, physical health, as well as social and ecological contexts.

Sexual Selection and Human Sex Differences

The same processes of intrasexual competition and intersexual choice and the social factors (e.g., OSR) and sex hormones that influence the expression of the associated traits can be used to understand many human sex differences. Among the evidence supporting this conclusion are the same patterns of human sex

differences in physical size, musculature, rate and pattern of physical development, and hormonal and other physiological responses to stressors and competition as that found in other primates with intense physical male–male competition. Unlike most other primate and mammalian species, human reproductive dynamics are complicated by men's investment in their children. This investment results in female–female competition over investing men and male choice of long-term mates, in addition to the more common male–male competition and female choice. A full discussion of the associated sex differences in physical and social development and in brain and cognition is beyond the scope of this article, but the utility of sexual selection for understanding human sex differences is provided by a contrast of women's and men's mate choices and how they compete for mates. The contrast also illustrates how the expression of these social dynamics is influenced by social and cultural contexts.

Mate Choices

In all species, female choice is influenced by the reproductive benefits they will receive from males. These benefits may be genetic, assistance with provisioning for the offspring, social support, direct parenting, or some combinations. Women are no different. They prefer long-term to short-term mates and long-term mates who are in good physical health, who control culturally important resources, have social influence, and are willing to invest these in the woman and her children. Men also have preferences and these are similar to many ways to those of women, which follows from men's investment in parenting. There are nonetheless several areas of difference that can be understood within an evolutionary context. These include enthusiasm for casual sex, the importance of cultural success, the preferred behavioral traits of long-term partners, and the age and beauty of these partners. Before we move to these, note that due to competition over mates, there is often a gap between actual and preferred choices. This is because not everyone can marry the most attractive or successful member of the opposite sex, even if this is their preference, and the corresponding sorting of mates reduces the magnitude of many sex differences in the traits of actual mates.

Casual sex

A sex difference in *preference* for casual sex follows from the sex difference in the costs and benefits of reproduction. As with all mammals, the biology of reproduction results in higher costs and a slower potential reproductive rate for women than for men. In addition to a 9-month pregnancy, women in traditional cultures will typically breast feed for 2–3 years. These costs are predicted to result in an evolved bias for women to be selective and cautious in the choice of mating partners, and a parallel prediction that men who do not bear the same costs and have the potential to benefit reproductively will show an evolved bias to be less discriminating and more enthusiastic about casual, short-term mating relationships.

Many lines of evidence support these predictions. Men fantasize about casual sexual partners and more of them more frequently than do women. Prostitution is by definition a short-term sexual relationship and the demand is almost entirely driven by men. Women are more likely to feel disgust

and regret following a short-term sexual encounter than are men, and women are more likely to become emotionally attached to casual sexual partners than do men.

There are cultural influences as well. Over the past 50 years, mores against sex outside of marriage have changed in Western culture and the number of women (and men) engaged in such relationships has increased. This is not however the same as casual sex, as most women who have sex before marriage do so in the context of what they believe will be a long-term relationship. Socially, the OSR greatly influences how well men are able to put their preferences into practice. When there are more women than men, men are more successful in achieving their preference for casual relationships, but when there are more men than women, women are better able to enforce their preference for long-term committed relationships and men's investment in children.

Cultural success

The costs associated with pregnancy and breast feeding also have the benefit of making women more biologically valuable than men; breast feeding is now optional in modern societies but is not in traditional ones, nor during our evolutionary history. In other words, women have more to offer, reproductively, than do men. Men's contribution comes in part from the genes passed to their children, but most of their investment comes from the resources they can provide to their wife and children during their children's development. In traditional cultures and modern ones, women of course contribute resources (e.g., through gathering) to their children's development, but are also better able than men to use their reproductive potential to demand more postnatal investment from their partner. Stated differently, women's heavier biological investment in parenting should not only make them choosier when it comes to mates but also allow them to demand more cultural resources from a prospective marriage partner.

It follows that the social status of men is an important consideration in women's choices of and preferences for marriage partners, because these men have the resources that women can use for their own benefit and to successfully raise their children. Although indicators of social status can vary across cultures, the basic relation is the same – culturally successful men are preferred as mating and marriage partners. The reason is clear: in all cultures in which it has been studied, the children of culturally successful men have lower mortality rates than the children of other men, due, at least in part, to the social and material resources these men invest in their children. Even in cultures in which mortality rates are low, children of culturally successful men benefit in terms of psychological and physical health and in terms of longevity in adulthood. These are exactly the conditions that would result in the evolution of women's preference for socially dominant and culturally successful marriage partners.

Confirmation is found in social-psychological studies about women's actual marriage and divorce patterns and their preferences. In many cultures, choice of marriage partners is technically made by the young woman's kin, but in most cases the parents' decision is influenced by their daughters' preferences. In such cultures, these joint decisions are strongly influenced by the quantity and quality of the resources (e.g., land, cattle) the man and his kin will provide to her and her

future children. In modern societies, men who are culturally successful – indexed by educational level, occupation, and income – are chosen as marriage partners more often than their less successful peers. And, across societies a woman's decision to stay married or not is influenced by the quantity and quality of resources provided by her husband; women married to men who are more successful than they are (e.g., higher educational levels) report higher levels of marital satisfaction, have lower divorce rates, and have more children than women married to men who are less successful than themselves.

Social-psychological studies of women's and men's preferences for marriage partners are an important adjunct to research on actual choices. These preferences more clearly capture the social and psychological processes that influence reproductive behavior because unlike actual choices they are not constrained by the competing interests of others. Studies of peoples' preferences for a prospective marriage partner reveal that women throughout the world rate a partner's social status, cultural success, or attributes that are likely to lead to success (e.g., ambition) as more important than do men. It is not that men do not rate these traits important, it is that they are not weighted as heavily by men as other traits or as heavily as women.

There is also cultural variation in how strongly women weight these traits. In contexts where women do not have political power, access to education, or independent incomes, they rate a man's cultural success or indicators of the likelihood of his achieving success more highly than do women living in societies in which they have independent social and economic resources. In societies with social 'safety nets' (e.g., subsidized income for housing or child care) women tend to rate these traits less highly than do women in societies without these nets. Men's relative focus on women's cultural success or the resources she can bring to a marriage also varies across cultures. Polygyny is found to varying degrees in about six of seven traditional societies, that is, successful men are able to marry more than one wife if they have social influence and material resources to do so. In these societies, men must provide the resources (e.g., access to land, cattle) that women will need to start a family. In societies in which monogamy is legally imposed (i.e., it is against the law to marry more than one person at a time), which includes all Western societies, men value women's income or other resources (e.g., dowry) that they can bring to the marriage, but less highly than do women in these same societies. The increase in men's choosiness in societies with socially imposed monogamy follows from their heavier investment in a single marriage partner (at a time) and a single family, as contrasted with multiple partner's and families for successful men in other societies.

Preferred behavioral traits of a long-term partner

A preference for a culturally successful marriage partner is not enough to be a successful reproductive strategy for women. These successful men are often arrogant, self-serving, and are better able to pursue their preference for multiple mates than other men. As a result, the personal and behavioral characteristics of men provide women with information on his ability and willingness to make a long-term investment in the woman and her children. In addition to ambition and cultural success,

women tend to rate the emotional stability, kindness, and the family orientation of prospective marriage partners more highly than do men, although the sex differences are not as large as those found for cultural success or physical attractiveness (below). These patterns indicate that women prefer husbands who have resources, and have the personal and social attributes that suggest they will invest these resources in a family. Women also seem to prefer men with whom they feel physically safe, and who are physically capable of protecting them from other men, should the need arise.

Many women prefer men with whom they can develop an intimate and emotionally satisfying relationship, but there are cultural differences in the importance of this relationship. In the educated, professional classes of modern societies, families are more isolated from their extended families and thus the spousal relationship becomes a more central source of social and emotional support than is typically the case in traditional societies. Women in these contexts rate this relationship as more central to their marriage choices than do men or women in other societies. It is not that women in these other societies do not want such relationships, but rather these are more of a luxury than a necessity. This is because day-to-day living is more difficult and there are real risks of serious illness or death of their children; as many of 50% of children die before adulthood in many of these societies. In this circumstance, women's focus is on the traits of men that will reduce these risks and help them keep their children alive and healthy.

The behavioral attribute that men rate more highly than women is sexual fidelity. Men's concern over sexual fidelity makes evolutionary sense, because of men's investment of time and resources in their children. The implicit concern is that they will be cuckolded, that is, they will be deceived by their partner into raising the child of another man. The definitive study of human nonpaternity rates has not been done, but it appears that 3–10% of children are raised by cuckolded men; as found in other species, the risk of cuckoldry is higher for lower status than for higher status males. This implicit fear underlies men's sexual jealousy and often contributes to men's violence toward their partners; male-on-female aggression is often about controlling the sexual behavior of their partners and through this, reducing the risk or often times the imagined risk of infidelity. It is not that women are unconcerned about sexual fidelity and do not become jealous at the prospect of a partners' infidelity, it is that it is a deeper concern for men, on an average.

Age and beauty of a mating partner

Throughout the world, the age and facial and body attractiveness of a prospective partner is more important for men's mate choices than for women's. These sex differences make reproductive and therefore evolutionary sense. Age is more important in men's choices than in women's, because women's fertility peaks in their mid-20s and then steadily declines to very low levels over the next 15–20 years; men's fertility also declines with age but much more slowly. Men with a preference for younger wives will necessarily have more children than men with a preference for older wives. When they can, men throughout the world put this preference into practice. In their 20s, men tend to marry women who are 2–3 years younger than themselves, whereas successful men in their 50s

tend to marry women 15–20 years younger than themselves (e.g., following a divorce).

Women's physical traits that men find especially attractive include a waist-to-hip ratio of about 0.7 (i.e., an 'hour glass figure'), facial features that signal a combination of sexual maturity but relative youth, symmetric body and facial features, proportionally longer legs, larger than average breast size and symmetry, and a small abdomen and waist. The key facial features are large eyes, prominent cheek bones, and a large smile area. Body mass index (BMI) – a measure of leanness to obesity independent of height – is also associated with rated attractiveness. Women with these features are more likely to become pregnant, carry the pregnancy to term, and have healthy children than are other women, although the strength of these relations is smaller in societies with modern health care than in other societies. A preference for relatively slender (i.e., a BMI in the average range) women is not universal, however: across 62 cultures, one study found that relatively slender women were preferred in 12 (19%) cultures, moderately fat women in 23 (37%) cultures, and 'plump' women in 27 (44%). The latter are preferred and considered beautiful in cultures in which the food supply is unreliable. Average weight to somewhat slender women are preferred in some societies in which food is readily available and where lower status women are heavier, on an average, than higher status ones.

Again, it is not that age and physical attractiveness are not important to women. Rather, these traits are necessities for men and luxuries for women. When it comes to making decisions about a marriage partner, men will trade a prospective partners' cultural success for her youth and beauty, whereas women will trade a partners' attractiveness for his cultural success. If there were not real life trade-offs when making these choices, women and men would of course want both success and beauty in a partner. Women's preference of partners that have it all is found in classical literature and in romance novels, where the male protagonist is almost always socially dominant, wealthy, *and* handsome.

As with men, a preference for an attractive mate makes biological sense for women. Not only are handsome husbands more likely to sire children who are attractive and thereby sought out as mating and marriage partners in adulthood, these men and their children may be physically healthier than other men. Handsome husbands are somewhat taller than average, and have an athletic (but not too muscular) and symmetric body shape, including a 0.9 WHR, and shoulders that are wider than their hips. The facial features that women rate as attractive include somewhat larger than average eyes, a large smile area, and prominent cheek bones and chin. These facial features and the V shape may be good indicators of genetic variability, which is important for disease resistance, and suggest a healthy developmental period. However, the relation between men's physical attractiveness and their health is lower in modern societies than in traditional ones, due to modern medical care. In societies without this care and high risk of infectious disease, physical attractiveness seems to be a better indicator of health for both sexes and both men and women rate it as more important (men still rate attractiveness more highly than women) than do men and women in societies with lower health risks.

Competition for Mates

As with other species in which females provide more parental care than males, intrasexual competition is more intense among men than among women, especially in traditional societies where successful men can marry polygynously. In addition to the physical sex differences mentioned earlier (e.g., men's larger size), genetic studies of human populations are consistent with an evolutionary history of more intense male–male than female–female competition. Of particular importance is variability of mutations in mitochondrial DNA (mtDNA) genes and genes on the Y chromosome. Children inherit mtDNA genes only from their mother, and boys inherit the Y chromosome from their father. The variability of mtDNA and Y-chromosome genes and their geographic distribution can be used to make inferences about the reproductive dynamics of our maternal and paternal ancestors, respectively. If there has been an evolutionary history of intense male–male competition and polygyny – resulting in some males having several wives and many children and many men dying childless – we should have fewer male than female ancestors. This is the case, throughout the world. In fact, Y-chromosome genes indicate a repeating pattern of one population of men replacing another in Africa, Europe, and Asia.

Competition in traditional societies

One-on-one and coalitional male-on-male aggression is a common feature of hunter–gatherer, horticultural, pastoral, and agricultural societies. Ambushes, raids, and occasional larger-scale battles between male kin groups from neighboring villages or bands are common features of social life in about 70% of hunter–gatherer societies and is even more common in other traditional societies; many of the remaining societies are relatively isolated or politically subjugated to larger groups. In more than half of these societies, intergroup conflict occurs more or less continuously, that is, at least once a year, and ultimately results in the death of about 30% of the group's young men, on an average. Across societies, motives for these conflicts include 'blood revenge' (i.e., retaliation for the killing of a member of the kin group), economic gain (e.g., control of land, cattle), the capture of women, and personal prestige. The latter typically involves the accumulation of culturally important trophies (e.g., the heads of competitors) that influence the man's reputation and social status within the community, which in turn influences his desirability as a marriage partner. One-on-one physical male–male competition (e.g., club fights) are also common within communities but typically occurs to establish social dominance or to resolve conflicts (often involving sexual jealousy) that are not resolvable in other ways.

Whatever form it takes, the reproductive benefits for successful men can be considerable. Dominant men usually have several wives and many children, other men marry monogamously, and still others never reproduce. Almost all women, in contrast, marry and have children. The variability in the number of children sired by men as compared to the variability in the number of children born to women is often 3:1; that is, the reproductive differences among men are three times larger than the differences among women. These are the patterns that would result in the Y-chromosome and mtDNA

gene differences mentioned above, and that explain the sex differences in physical size, strength, development, and behavioral aggression; specifically, traits that facilitate these forms of male–male competition.

It is not that women do not compete or that this competition does not escalate to physical violence, sometimes it does. Typically though the competition is more subtle and often among the co-wives of polygynously married men. The level of competition is likely to vary with whether or not a co-wife is a sister and the extent to which co-wives must cooperate to produce food. Whatever the specifics, polygynously married women typically have children who are not as healthy and who have lower survival prospects than the children of monogamously married women. The reasons for this are not fully understood, but cannot be completely attributed to the level of investment the father makes in each individual child. The covert and sometimes overt maltreatment of children by co-wives is also a contributing factor; sometimes women will poison the children of co-wives to increase the resources available to their children.

Competition in modern societies

Warfare of course occurs among modern societies and is typically over control of culturally critical resources, and is largely a male activity. One-on-one physical aggression sometimes escalates to homicide in these societies, with the precipitating events often centered on sexual jealousy or male status competition, as in traditional ones. Nonetheless, in modern societies with socially imposed monogamy, male–male competition is most generally focused on the acquisition of social and material indicators of success. Successful men in these societies have a college education and a high paying job, which on the surface is very different than establishing dominance through club fights or the murder of rivals from neighboring villages, but the underlying motivation is the same: men throughout the world are motivated to achieve social status vis-à-vis that of other men and control of socially important resources. They want to achieve cultural success.

Prior to wide-scale industrialization and modern health care, the relation between cultural success and reproductive success was the same in modern nations as is currently found in traditional societies. As a result of socially imposed monogamy, birth control, and the sharp decline in infant mortality over the past 200 years, the relation between cultural success and reproductive success is no longer as strong as it once was, but it still matters. Men with higher incomes report more sexual activity than men with lower incomes and women at any income level, in keeping with the importance of a man's cultural success in women's choice of mating partners. Large-scale studies in the United States and other nations indicate that men in the top 25% of income have, on an average, 2.5 children as compared to an average of 1.4 children for men in the bottom 25% of income. The pattern largely emerges because the risk of remaining childless is higher for lower status men; about one out of three men in the bottom income category are childless by age of 50, as compared to one in nine in the top income category.

The achievement of cultural success is important for women too, as it determines the quantity and quality of the social and material resources they can provide to their children.

To a much greater extent than men, however, women can achieve status and access to resources through marriage. In fact, the relation between years of education and thus earning potential and number of children is the opposite of that found in men. Over the past 100 years in the United States, women with a high school diploma had, on average, 2.8 children, whereas women with a graduate degree had 1.8 children. Compared to high school graduates, three times as many women with postgraduate degrees were childless (9% vs. 27%). These education and income differences are largely due to the delay in childbirth commonly associated with obtaining a higher education in modern societies.

Even if women do not compete as intensely for cultural success as men, they do compete with one another. In modern societies, men and women put considerable effort into enhancing the traits that members of the opposite sex find attractive, which includes men's focus on cultural success. Among women this competition involves enhancing or bringing attention to physical traits that influences men's mate choices, as well as the derogation of these traits in potential competitors; men do this as well, but it is not as central to male-male competition as it is to female-female competition. Women, for instance, are more distressed than men after viewing an attractive face or body of a same-sex competitor, whereas men are more distressed by the cultural success of a competitor. The same tactics used by single women to attract mates are often used to keep them. Women married to culturally successful men (e.g., ambitious men with relatively high incomes) use more mate retention tactics, including enhancing their appearance and monitoring his activities, than do women married to less successful men.

Women and girls may not injure and kill one another as frequently as men and boys do, but they manipulate relationships and spread malicious gossip at least as frequently if not slightly more so. These social tactics are called relational aggression, which includes use of gossip, rumors, and lies to sully the reputation, manipulate the friendships, and socially ostracize potential competitors. This form of aggression emerges during the preschool years and becomes especially prominent for girls during early and mid-adolescence and becomes increasingly focused on competition with other girls over romantic relationships. Although both sexes engage in and are the targets of relational aggression, it affects girls and women more than boys and men. This is because girls and women are more socially attuned to the subtleties of these behaviors and because they reveal more personal and potentially more embarrassing information to their best friends than do men and boys. If the relationship with their best friend dissolves, as it often does, girls and women often use this information to embarrass or disrupt the relationships of the former friend.

Sex differences in the form of intrasexual competition should result in sex differences in the supporting cognitive and brain systems. There are in fact many sex differences in the areas that are likely to be related to intrasexual competition; and others that are related to intersexual choice. The point is illustrated by relational aggression. If relational aggression has been a more important feature of female-female competition than male-male competition during human evolution, then the supporting traits should be more elaborated in women than men for the same reason men are physically larger than women; it facilitates

success at intrasexual competition. These traits include language fluency, sensitivity to social information, such as the facial expressions of members of the same sex, biases in social comparisons such that women focus on physical attractiveness and men on physical size and strength, among others. The empirical research is consistent with these predictions: Girls and women have advantages in most areas of language production and comprehension; in sensitivity to and memory for faces and facial expressions, especially those of other girls and women; and, self compare on traits men use in their mate choices. There is also evidence that areas of brain that support aspects of language processing are larger in women than in men, after controlling for the sex difference (favoring men) in overall brain size.

Summary

Darwin's sexual selection is a firmly established and well-supported area of study within evolutionary biology. The corresponding processes of intrasexual competition and intersexual choice and the hormonal and social (e.g., OSR) influences on how these behaviors are expressed have been studied in hundreds of nonhuman species. Sexual selection thus provides a solid foundation for the theoretical and empirical study of human sex differences.

The dynamics of intrasexual competition for status and control of reproductive resources helps to explain why men are physically larger, stronger, and more physically aggressive than women, and why boys develop more slowly (associated with achieving larger size, among other things) than girls – male-male competition during human evolution, in traditional societies and today is often physical and lethal. In traditional societies, groups of related men cooperate in order to compete with other men for control of resource-rich ecologies and control of other important resources. Within these groups, men compete for dominance and political influence, and dominant men have more wives and children than do other men. Laws, cultural mores, and other factors can influence the details of how this competition is expressed – for instance by suppressing polygynous marriage and lethal male-male competition – but the underlying motives and behavioral biases remain the same. Men compete intensely for the achievement of status vis-à-vis that of other men and for control of culturally important resources.

On the basis of men's investment of resources in children, competition among women for marriage to the most successful men is predicted and found. Women do not typically use physical aggression to compete, but they do enhance the appearance of the physical traits men use in their mate choices, and they try to manipulate the social relationships and reputations of their competitors and in some cultures maltreat their competitors' children; the latter are future competitors of the aggressors' children. There is no real mystery to these findings, as they all follow logically from cost and benefits of intrasexual competition in the social context in which men and women are embedded, as in many other species.

Intrasexual competition and intersexual choice are often opposite sides of the same coin. Men compete for cultural success and control of culturally important resources

(e.g., money, cattle) and women choose mates based on this success. The bottom line is that women choose mates based on the social, material, and in some societies interpersonal resources the man has to offer her and her future children. In traditional and developing societies, access to these resources influences how many of her children will survive to adulthood. The man's physical traits are important as well, but if forced to choose one or the other, most women choose success over looks. Men are different. They focus more on the age and physical appearance of a prospective mate than on her cultural success. Again, this bias makes reproductive and therefore evolutionary sense. The physical traits that men find most attractive are indicators of the woman's fertility.

Of course, humans form more complex societies than other species, have language, social customs, and sophisticated cognitive competencies that can result in more nuanced social and developmental influences on the expression of sex differences than found in other species. The point here is not that these other influences are unimportant, but that the evolutionary footprint of sexual selection remains with us today, despite these other influences.

Sex Roles

J D Sinnott and J S Rabin, Towson University, Towson, MD, USA

© 2012 Elsevier Inc. All rights reserved.

Glossary

Femininity Socially constructed behavioral and personality expectations based on being perceived as female.

Gender role stereotypes Rigid ideas about appropriate role behaviors.

Gender roles Organized patterns of interpersonal behaviors defined by a culture as appropriate for one's biological sex.

Masculinity Socially constructed behavioral and personality expectations based on being perceived as male.

Opposite sex Popular societal approach to gender, defining behaviors and emotions of women and men as polar opposites.

Sex roles or gender roles can be defined as role-related behavior ascribed by society to women because they are women and to men because they are men. The designation of an individual as a woman or a man may be done by the individual, by the society, or by both. Factors used as designation criteria are not consistent. The field of sex roles is one in which definitions have had more than usual importance. The questions in this field are emotionally loaded ones, which are tied to social expectations, history, taboos, and strong biological urges. Definitions determine what is studied, and what is seen as unchangeable or 'given' by nature over the life span. Sex roles, roles once seen as simple and unchanging, are now seen by psychologists as more complex, more context-determined, and more malleable, especially considering issues relating to an individual's identity as heterosexual, lesbian, gay male, bisexual, or transgender.

Further Definitions and Models

Several definitions and further distinctions need to be made to avoid confusion. The first distinction can be made between *sex* and *gender*. In 1979, Unger attempted to clarify the distinction between sex and gender for the discipline of psychology. She argued in the *Encyclopedia of Human Behavior, Volume 4* that sex should be limited to the biological bases of producing the two primary genders: the presence of XX or XY chromosomes, hormonal output from the gonads, internal and external reproductive anatomy, and secondary sex characteristics. Gender on the other hand is what culture does with the evidence of biological sex. Ultimately the culture creates expected behavior patterns or styles which are deemed gender-specific. A second distinction can be made between *sex roles* and *sex role stereotypes*. The former include the actual behaviors of males and females, which have considerable variability. The latter are oversimplified, socially-shared perceptions of idealized 'male' or 'female' actions, perceptions which usually allow little variability. Third, *sexuality* differs from *sex roles*. The roles are overt behaviors of many kinds, including sexuality, linked to 'maleness' and 'femaleness.' Sexuality is the behavior directly associated with having sex or being sexually involved. Fourth, *gender identity*, one's sense of oneself as essentially 'male' or 'female,' may or may not be reflected in one's *roles* or one's

sexuality. Fifth, *gender schemes* are the cognitive constructs used to conceptualize 'male' or 'female' roles or identity, and, although held very deeply by the person, may not be congruent with his or her behavior.

Gender differences, defined as distinctions that can be made between maleness and femaleness or between males and females themselves, are a problematic category. Psychologists often find it difficult to decide *how much* difference is a true difference. We often confuse differences in perceptions or constructs of sex roles with differences in the actual behavior of males and females. Yet, decisions about 'differences' often lead to broad public policy decisions.

Defining and measuring sex roles in polarized terms (i.e., 'male' vs. 'female') may be erroneous. *The idea that there are only two biological sexes needs reexamination.* Rabin emphasizes numerous examples from biology that indicate more possibilities than just two complementary sexes. We find hermaphroditic species which contain both reproductive capacities within one body, and even *all-female species of whiptail lizards and Hawaiian geckos* which reproduce parthenogenetically. There are large numbers of coral reef fishes and tropical sand fishes which change sex.

The popular polarization of the enormous range of human variability into two boxes at opposing ends of the human spectrum may be the consequence of normative thinking in the social sciences, added to our penchant for creating dualities by ignoring the overlapping frequency distribution curves for male and female performance. Even when a statistically significant sex difference in performance in math skills or verbal skills can be demonstrated, this larger overlap between distributions means that the individuals whose performance falls within the overlap area cannot be distinguished on the basis of gender. Many females excel in math. Many males do poorly in math but excel in verbal skills. Differences that emerge are far more likely to be individual differences than actual gender differences separating all women from all men. So the most useful approach may be to think of and to measure maleness and femaleness on a continuum.

Confusion among these terms and models leads to negative results for science and for individuals. Conceptualizations of sex roles have been a function of philosophy, history, economics, and politics. Awareness that sex roles exist, and are influential, and that this occurs at all times in life, has also been a

function of those four forces. These influences quietly shape the choice of problems to investigate and research projects to pursue. Most scientists in a given field accept some view of the world that dominates their field and choose problems accordingly. Driven by a need for cognitive consistency, individuals adopt the new view as 'natural.' In a world at war, for example, the role of a man is seen as that of a warrior, 'naturally,' and the role of a woman 'naturally' becomes that of a worker/mother; after a return to peace, the woman may be 'naturally' redefined as mother (only) while the now suddenly 'non-war-like' male is redefined as worker. Theories of adjustment, development, and mental health are quick to conform to the demands of the belief system and historical situation. For example, the integration of women in the military is taxing cognitive consistency needs in a novel way. As women are seen in warrior modes at a time when most men are not in the military, a fascinating cognitive challenge is emerging for society and for researchers. Social psychology has made it clear that even radical shifts in ideas and behavior are accepted to maintain thinking consistency, provided motivation is high enough. Researchers in human development are not immune to these general laws. We study what seems important at the time.

Gender Role Development Across the Life Span

Childhood Developmental Theories

Early views of sex role development considered masculine and feminine roles as biologically based and, once established in childhood, consistent throughout the life span. The testing movement provided the impetus to quantify and validate such views. Masculinity and femininity were conceptualized as marking the two extreme endpoints of a continuum. Individuals were assumed to be optimally adjusted if their biological sex and their sex role identity were the same. An individual who deviated from a prescribed sex role was seen as one whose psychosexual development was inadequate, rather than as possibly a person who was flexible in meeting changing environmental demands. This view reflected the Freudian approach which depicted sex role identification in terms of resolution of the Oedipal conflict. Such a resolution involved the identification of a boy with his father and the girl, in a somewhat more circuitous way, with her mother. The possible learned nature of sex roles came to the forefront with the advent of social learning theory, cognitive developmental theory, biologically oriented inquiries, anthropological investigation, and the life span approach. We are currently examining the potential validity of biological factors in gender-differentiated (on the average) behavior; for example, fetal testosterone predicts gender-differentiated behavior to some extent in both girls and boys.

Social Learning Theory

Whereas Freud and other functionalists implied that sex roles merely unfold out of an innate potential, the social learning theorists such as Bandura posited that such roles were learned via imitation and observation of parents and other adult models. Reinforcement then led to the establishment of behavioral patterns. Although changes in reinforcement contingencies allowed the possibility for sex role change, it was assumed

that the sex-typed roles did not change significantly during one's life span. Modeling the behaviors of the same sex was thought to begin at a very early age and to be reinforced into adulthood. However, research that has focused on modeling of adult behavior or global personality traits shared by parent and child has *not* found that children closely follow the behavior or personality of the same-sex adult.

Cognitive Developmental Theory

A cognitive developmental approach such as Kohlberg's held that the child's perception of sex role identification precedes sex appropriate behavior. The child discovered that two sexes existed, thought about himself or herself as being a boy or a girl, considered differences between the sexes, and came to some fairly stable notions as to what 'boy/man' versus 'girl/woman' connoted. Some of the same behavioral factors that the social learning theorists proposed were also expected, except that cognitive identification with a same-sex parent *preceded* the modeling of behaviors in terms of observation and imitation. Cognitive developmental psychologists also assumed that both children and adults maintained a relatively consistent concept of themselves as male or female, and that the search for congruence between beliefs and behavior led to the maintenance of appropriate roles. This view may be contrasted with the social learning view in which reward is the key to the persistence of sex-appropriate behavior. Both theoretical viewpoints, however, emphasize the establishment of such an identity early in life with consistency in adulthood.

The learning perspective on sex roles has also received a valuable contribution from the biological perspective of Money and Ehrhardt. These researchers have studied children who genetically, and on the basis of prenatal hormones, would have been expected to develop the gender identity of one sex but because of mishap (e.g., structural damage or deformity of the genitals) were assigned to the other sex. Interview data collected from the families of such children indicated that seeming acceptance of the assigned sex and gender role identity development proceeded commensurate with the child's acceptance of assigned gender identity. While these studies are by no means conclusive, they do point out the overwhelming impact of socialization.

Anthropological Investigations

Anthropological study has supported the learned nature of sex roles and has led to questioning the notion of consistent, appropriate behaviors for each gender. The large impact of culture on any given society's notion of what is appropriate male and female behavior dates back to Mead's (1936) comparison of three primitive societies. Both the men and women of the Arapesh tribe were described as being passive, nurturant, cooperative, and sensitive, traits perceived as feminine in American culture. The Mundugamore men and women were characterized as aggressive, suspicious, and uncaring, traits perceived as masculine in American culture. The Tchambuli men behaved in ways our society typically defines as feminine while the women exhibited what we might define as stereotypically masculine traits. The importance of culture-specific specialization has been expounded in numerous articles and

books with respect to more modern societies as well, for example, Wood and Eagly. Division of labor between the sexes is universal in traditional societies, partly because whatever women do has to be compatible with infant and child care, and partly because division of labor is an efficient survival mechanism. Sex roles show a high degree of variation across cultures, even to the point of the sex role reversal of the Tchambuli.

The issue is not the existence of sex roles so much as the unequal valuation of women's and men's roles common in so many cultures, including that of North America. Even in Tchambuli society whatever men do is valued more than what women do. The roots of gender inequality were first studied by Sanday and continue to be examined by anthropologists. Sanday's premise was that gender inequality (not valuing women's roles and men's roles equally) comes about largely as a consequence of the physical environment in which a group is trying to survive. Harsh environments are associated with patriarchal societies high on aggression including both war and rape. Gentle environments are associated with equalitarian societies which are typically peaceful and where rape is rare or unknown altogether. The most extreme environments (the polar regions and the Kalahari desert) produce gender equality because everyone must contribute fully just to survive (Tanner) and there is no time or energy for war.

The anthropological perspective has been used by researchers such as Gutmann to explore the function of sex roles in terms of survival of the species. Cultural universals are presumed to reflect basic human propensities; their consistency is assumed to be of some importance in terms of survival. Proponents of the learning approach, which emphasizes socialization, view exceptions to cultural universals as evidence for the greater impact of environment on heredity. Opponents point out that a few exceptions do not make a case against biological mechanisms but rather show evolutionary change within some special environmental conditions. These arguments are completely superseded by the new science of epigenetics in which the old nature-nurture dichotomy is made irrelevant. Epigenetics reveals complex ways in which gene expression is turned on and off by environmental influences. The mechanisms enabling the environment to modify genetic readout are RNA interference which can silence the DNA, histone modification, and DNA methylation, both of which can alter gene function. Rabin has long maintained that dualistic thinking needs to be replaced by developmental-interactionist paradigms, which the emergence of epigenetics now makes imperative.

Adult Developmental Theories

The life span approach to sex role development has been a relatively recent phenomenon. In early work, Neugarten, Gutmann, and Block explored changes in male and female role expectations during adulthood that were based upon social expectation and major developmental tasks. Block and Riegel viewed the manifestation of cultural sex roles as a function not only of biological demands and past learning experiences, but also of the nature of economic systems, the historical moment, and the philosophical system within which they are defined. Thus, sex roles in this perspective imply dynamic change based upon the individual change and the social and cultural climate.

Loevinger's milestones of ego development and their extrapolations to sex role development form the basis of Block's approach. In the earliest period, the main development concerns of the child are genderless, and identity constitutes a mere naming of gender: 'I am a boy/girl.' Later, conformity to learned patterns becomes the main task; this is reflected in the development of sex role stereotypes and sex role bifurcation. This conformist stage is followed by one of self-criticism based on comparison with an abstract ideal, thereby moderating the stereotypical role. With the advent of autonomy, individualization results as conflicts, aroused during the conformity and conscientious stages, are resolved. At this point, differentiation of sex role is said to occur. The highest, most integrated level of functioning finds the individual evolving a complex identity which combines aspiration, experience, and previously polarized traits. In sex role terms, this period is one of androgyny.

Hefner, Rebecca, and Oleshansky have proposed a life span approach to the development of sex role identity. Their hierarchical stages include: (1) global, undifferentiated sex roles, (2) polarized or traditional masculine/feminine roles, and (3) transcendent roles which combine both masculinity and femininity. While the young child most likely has not defined a sex role and the adolescent most likely has overdefined it, the adult synthesizes roles into more complex wholes. For individuals who have 'transcended' masculinity and femininity, psychological adjustment is no longer tied to these dichotomous sets of traits, or even the blend of androgyny. Unfortunately, the measurement of 'sex role transcendence' as distinct from androgyny has not yet been fully operationalized.

A problem with sex roles is that they are most often unequal in power. The social dominance theory of gender (Pratto and Walker) indicates that males promote hierarchy-enhancing values based on male power and status whereas women use hierarchy-attenuating strategies that favor equality.

Garnets and Pleck have presented a concept called sex role strain analysis. Their viewpoint combines social learning and life span development. They feel that the ultimate harm of traditional sex roles is the devaluation an individual may experience if he or she does not conform to traditional standards set by sex role norms. Thus, strain results from discrepancy between the individual's self-perception and his or her perceptions of social expectations. Pleck delineates the damage that the male sex role does to both the individual and society. As long as the core of masculinity is perceived as power and dominance there can be no equality between the sexes. Femininity defined as niceness and nurturance is counterproductive to success and achievement in North American culture. As women increase their access to power, they are accused of being unfeminine and threatened with being labeled lesbian. Gender role nonconformity in males is dealt with far more harshly as being labeled a gay male typically results in violent consequences.

Sinnott described a postformal theory of adult sex role development. A number of investigators have recently addressed the topic of 'postformal' operations, that is, those structures of thought which are a stage more complex in organization than Piaget's formal operations. More work on postformal, mature adult thought is being done, possibly since the idea of cognitive development beyond adolescence is an appealing one. The question of interest here is: How might

formal and postformal operations be related to a life span model of sex role development? To address this question, it is necessary to examine some aspects of postformal operations and the argument itself more closely. The argument is a post-modern one.

What kind of case is being made for a relation between cognitive development, especially formal and postformal operations, and sex roles? To oversimplify, it is the same type of case that Kohlberg makes about cognitive development and early sex role development and about cognitive and moral development. Social relations, of which sex roles and moral development are examples, may be seen as based upon cognitive skills. As cognitive skills develop, social relations can be understood and can also become more complex. At those times, when the world can be known in a manner more complex than an abstract, formal one, roles also might be known in a way that is more complex. Having thought of the role in a complex way, one could then live it in a complex way.

How would roles be known in postformal terms? To answer this question, one must look at theories of postformal operations. According to Kramer, authors of these theories all state that postformal thought is: (1) a distinct stage, (2) which subsumes formal operations, and (3) which incorporates a relativistic view of truth. Generally, then, a postformal cognitive stage could underlie a view of sex roles in which roles are not absolute but are created relative to the actor. Some given formal structure of roles would be consciously chosen, based on some belief system that is a subjective view of 'truth' from among a number of formal role structures. Further, what constitutes a given role would be known to be somewhat arbitrary and based partly on the perceiver's own experiences and resultant ideas of the role. The postformal concept of sex roles, then, includes a necessary subjectivity. It operates by laws such as those of the new physics as described by Sinnott.

The role taken, or the role which one perceives that another takes, becomes what is agreed on by the persons in the interaction. The reality of the role is therefore determined by a system of beliefs held by the persons in the interaction. The individual is not in a roleless, undefined state, nor in possession of an absolute unchanging role, which is a permanent descriptor of one's identity. Rather he or she is constantly, perhaps even consciously, creating a flexible role definition in relation to individuals and circumstances in context. In the framework of Kelly's theory of personality, persons are always constructing a new social meaning for the self in the context of evolving social structures within a given society's institutions.

Role behaviors also may be seen as attempts to solve everyday life problems. Individuals learn to act in a way which helps them meet their goals. In the context of problem-solving, which is a cognitive function, postformal thought-based roles might permit greater creativity in using strategies to solve problems where the problem goal is unclear. Most everyday problems fall into this category.

Systems Theory and Adult Sex Roles

Systems theory is a theory of interacting processes and the way they influence each other over time to permit the continuity of some larger whole. Systems act so as to continue. Systems

change because their own balances are not optimal or because they are influenced by other systems. Some authors who provide excellent descriptions of these general ideas are van Bertalanffy and Miller. Miller's discussion of *living* systems is especially useful to consider for a discussion of sex roles. Individuals, societies, and cells all appear to use similar processes to create boundaries, to take in stimulation, to process information, to act, and to change. For example, for cells, information may be chemical and may be filtered by cell walls; for persons, information may be conceptual and may be filtered by perceptions; for societies, information may be news and may be filtered by censors. Cells, persons, and societies all exist in relation to each other, which further complicates matters. Within systems theory, roles are structures of the social system which are equivalent to organs in the physical/person system; they are organized ways of ensuring that some vital function is performed.

As living systems – be they cell, person, or society – develop and age, they appear to proceed through a regular set of stages. They begin in disorder, that is, with a few parts concrete and defined. They become more orderly, defined, and bounded over time. They become rigid before they disintegrate and die as systems. System changes may be further described in chaos theory and complexity theory.

How does this relate to sex role development over the life span? Consider the person and society as living systems, each seeking continuity and meeting survival needs. These needs include control of information and energy flow. Sex roles are ways in which persons and social systems can regulate the flow of information and energy (effort) while taking care of survival needs. The early stages of these systems are disordered with regard to roles, that is, no roles are apparent. For example, the newborn is sex roleless, and a group of strangers are roleless as a group. Later stages are associated with more concretized roles; in the person and in the group, masculinity and femininity may emerge. Final stages find the roles rigid and inflexible, so they would fail to respond to the pull of new needs. This failure of response leads to disorder and a search for new, more complex order. Systems theory suggests that this may be the kind of transition we are seeing in societies now, and in the individual after the reproductive period and parental imperative (Gutmann). The person having rigid roles (sex roles or other roles), faced with new demands, might adapt with new complex integrations of role-related behaviors, or might keep a *dysfunctional* system. Chaos theory and theories of self-constructing systems may also prove to be important sources of hypotheses.

Major Conflicts in the Field of Sex Role Research

Six major conflicts have emerged in the field. Future research is likely to focus on these, as well as moving along to others. First, to what extent are roles fixed or flexible? Early theorists saw roles as biological and fixed, at an early age, for life. More recent theorists see roles established, then evolving, based on age, societal demands, etc. Second, how central are roles to personality? In more traditional societies in need of population growth, sex roles seem to be a core organizing principle of

personal functioning; in less traditional cultures, they seem to be adopted and cast off with less impact on the person's sense of self. Would the population or environmental concerns influence behaviors today? Third, how closely do roles relate to identity? This is a subdivision of the second question. Fourth, should roles be measured taking into account context and self-perception versus actual behavior? If roles need not be fixed, *context* might be extremely important to self-description since success as a parent (for example) often requires different traits from success as an employee. In another example, the single female parent may best use a combined role the earlier theorists labeled 'masculine' as well as 'feminine.' Also, one's consistent self-concept, as perceived by the self, may be very different from what witnesses see the person actually doing, since the person may be verbally expressing what he or she has been told *should* be said. Fifth, are stereotypes, sexism, and power politics inherent in sex roles? Some theorists maintain that since roles have always been connected to power, domination, discrimination, and stereotypes, this is a part of their dynamics. Other theorists maintain that roles could be conceived of (and studied) as value free and power neutral. Sixth, should we study *change* over time in roles? Developmental studies have demonstrated that changes seem to occur, based on age and history. How important are they for day-to-day applications of sex role knowledge?

Consideration of these conflicts, and the issues on which theorists agree, leads to several recommendations for future research and theory. Several conclusions can be drawn from early and recent literature on life span sex role development.

1. We must not jump to conclusions that responses on a scale will be predictive of behavior. Individuals may say that they are 'masculine' by their scale responses, but may mean they are masculine with regard to stereotyping concepts. They may perceive themselves differently in different situations, may act other than their self-ratings, and their behavior may vary from situation to situation. They may do what is most rewarding and that may happen to be masculine. They may score themselves masculine due to the development of an identity labeled masculine. They may do so since masculine behavior is socially desirable. They may change in self-definition due to life stage demands, or when their own concept of masculinity is no longer like their behavior, even if to everyone else they are still 'masculine,' by some other definition. And they may label themselves or act as they perceive society expects them to do. Since all these factors may underlie their responses to the scale, it is difficult to predict behavior based on scale responses.
2. Responses to sex role instruments do mean something. What is meant may be tempered by each person's perception of unspoken situational constraints and other factors mentioned above. If individuals respond appropriately, they are matching themselves to global standards designed to reflect the clearest opposition between gender-assigned roles.
3. Masculinity, femininity, and androgyny have been shown to be adaptive. Depending upon the situational demands, subject to the constraints above, any of the roles might be adaptive. The real question is, what is the most useful role in a certain setting: masculine, feminine, both, or neither? Useful may mean 'liable to be rewarded' or 'consistent,' or 'workable by some external criterion.' Androgyny may be the most adaptive response in terms of the last criterion; masculinity may be the most adaptive in terms of the first.
4. Sex roles are meaningful in terms of social expectations. The concept of global, oppositional, gender-linked roles is present for all members of society, and society imposes these role expectations on individuals so long as the real characteristics of those individuals are not known. So whatever complex designation of role and behavior one adopts, the general 'other' is still seen as conforming to the global stereotypes. Individuals also perceive role expectations projected by others, and, to the degree they are conformists, attempt to conform to them.
5. Sex roles are meaningful ways to order one's sense of self as socially efficacious, to create a sense of personal conformity, and to order self-concept. The creation of the self-concept is partially accomplished by acting and noticing that the self is the center of effective actions. Roles permit structured action likely to work in a society. They are also labels that live on beyond the individual and can be generalized to many situations. Knowing a sex role without knowing the meaning of that role to the person is to take only half a step toward knowledge.
6. We must distinguish between gender roles and gender identity. An individual can engage in gender role nonconformity and still be completely self-identified as the gender congruent with their biological sex. Lesbians and gay men are often perceived as gender-role nonconformists and punished by society for upsetting the social order. The societal assumption that lesbians identify with masculinity and gay men with femininity entirely misses the female gender identity of lesbians and the male gender identity of gay men. Further, the large number of lesbians and gay men who are gender-role conformists are often viewed as less problematic in terms of sexual orientation diversity than are gender nonconformists.
7. The meaning of sex roles depends on age and developmental stage. Meanings are related to modes of cognition and social demands at each period. They are also related to the previous history and experience of the person and the historical period in which the society finds itself. Infants can know roles in direct physical forms, but cannot know them in the abstract. The concrete operational person can know roles in the abstract, and the formal operational person can build logical systems of roles. The postformal person can see roles relativistically as cocreated by persons in them.
8. Models of sex role changes over time can be of many types. Change can be more complex than increase or decrease in global qualities. Change might occur on one dimension but not on another, or in global role traits but not in behavior, or vice versa. Change might be triggered by specific events or might represent an accretion over time. It may be reversible. Change might result from diffusion of a self-concept until its meaning is so muddy that it can

become something new. Change might depend on past rates of change. It is useful for investigators to be clear about their underlying model of change as they discuss sex role development.

9. Sex role complexity and adult sex role development may be linked to cognitive abilities like postformal thought or problem-solving skills. Roles have been linked to cognitive processes such as concept formation. As cognitive operations become more complex, their associated roles might be seen as multifaceted rather than one-dimensional.
 10. Sex role development-related questions (e.g., 'Am I being feminine?' 'What is the masculine thing to do at any age?') may be conceptualized in decision theory or problem-solving theory as ill-structured problems. This means among other things that they have an unclear goal. Decisions must be made about the nature of the goal as a part of solving the problem. Problem-solving literature can be a guide to dimensions we need to test to understand the process of solving sex role behavior/self-concept problems. This application of cognitive theory has not yet been attempted.
 11. Sex role developmental theories suggest new physics concepts and might make use of them. A multivariate approach needs to be taken in sex role studies, in that adjacent centers of causality – other persons, the social order – cause changes in an individual's sex roles. The person, in turn, causes changes in the social order by his or her perception of roles and by action on that perception. It is clear that one's vantage point in measuring sex roles is very important in drawing conclusions about the results. These models have companion models in the physical sciences that could be used in studies of change, both change in a person and change among systems.
 12. Sex role development theory can make use of ideas in systems theory. Personal and social systems are connected by many roles, among them sex roles. Theories of living systems give us an outline of the processes within and between those two systems. The flow of information can be studied within and between systems, and roles are part of that information flow. A study of system boundaries can be conceptualized as a study of rigid or flexible roles and the capability of the society or person to perceive or enact them. Future studies can take this model of living systems into account. Models of complexity and chaos may also be useful.
 13. Emerging ideas suggest that in the future, roles will be orchestrated consciously by the person, rather than being imposed consciously or unconsciously by society, or being left to the mercy of unexamined forces. Each child may grow up aware that she or he has a wide spectrum of role possibilities that can be acted out in spite of any biological predisposition.
 14. Sex- or gender-related behavior may have some biological underpinnings. To what degree might they be influenced by other factors over the course of the life span or be in circular causal relationship with other factors?
1. Role stereotypes (positive and negative), role-related behavior, and gender-linked expectations must all be considered as potentially different phenomena in sex role research. The nature of test questions themselves is important. The scope, nature, variability, and contextual factors in each must be explored.
 2. Roles must not be assumed to be linked to actual behavior or to be predictive of behavior, without evidence.
 3. Role strength must be considered; one can be considered masculine, feminine, or androgynous only relative to some standard.
 4. Perceptions, intentions, belief systems, and meanings are important neglected variables in sex role research.
 5. Sex role life span research should be integrated with Piagetian approaches, cognitive work in general, and problem-solving research.
 6. Sex role development research should use models of change over time from new physics, chaos theory, complexity theory, and systems theory to broaden the repertoire of multivariate approaches at its disposal and better reflect the reality of these complex multisystem changes.
 7. The impact of roles on society and the species and the utility of roles for society and species need to be considered.
 8. Learning and developmental effects need to be considered jointly in future research.
 9. The degree of intersection of biological and other factors in sex/gender roles and behavior cannot be assumed but must be tested.
 10. What is adaptive depends on situation, developmental stage, reward and punishment contingencies, past history, and the energy-available state of the person-system at that time. The factor of fear of change or deviance is important.
 11. People have different styles of achieving the same goal or enacting the same intention, or reporting the same attitude.
 12. Self-concept personal continuity, and personal effectiveness are seldom examined but enter into the picture of sex role development.
 13. Methodological issues need to be clarified, especially including longitudinal research on factor changes. But current approaches still give useful information with careful interpretation.
 14. Evolutionary psychology strives to reduce sex differences to genetic differences derived from human evolutionary history, and gender roles are explained as deriving from genetic advantage. Yet, same-sex attractions abound in nature. We need to clarify the effects of the degree of equality between the sexes in each society, which appears to have a stronger impact on the selection of a human mate than does evolutionary history.

Future work should address the following questions and issues:

Glossary

Atypical sexual behavior Sexual activities that many people consider outside the norm, often motivated by sexual fetishes.

Female orgasmic problems Difficulty in becoming sexually aroused, staying excited, and reaching orgasm.

Fetish A body part, material, or object that arouses sexual desire and may become necessary for sexual functioning.

Premature ejaculation Ejaculation before a man wishes, also called early or rapid ejaculation.

Typical sexual behavior Sexual activities that fall within typical developmental patterns.

In an article of this length, human sexuality is best approached from a developmental perspective, starting with infancy and tracing behavioral changes into adulthood. This is arguably the most interesting and theoretically valuable approach for understanding human sexuality. Some form of sexual behavior has been observed in utero, before birth; and babies engage in a variety of sexual activities in the first few years of life. It is most informative to study how more complex sexual behavior develops from the earliest manifestations. Understanding the biosocial processes behind sexual development is intellectually fascinating and of great practical value for people who want to improve their own sexual lives – even if they do not draw upon this knowledge until some later phase in life.

Before Puberty

Infants are born with sexual reflexes, and newborns can have vaginal lubrication and penile erections from the earliest days of life. In fact, ultrasound imaging of pregnant women reveals that male fetuses sometimes have erections before birth. It is more difficult to study the sexual responses of female fetuses, but there is evidence that some of them have vaginal lubrication and genital swelling in utero.

After birth, many infants and children have sexual experiences, such as spontaneous erections and vaginal lubrication in the first months of life. Many infants discover masturbation by their second year. Most people cannot recall these events later in life, as the early years of life are often poorly remembered, if recalled at all. The earliest sexual activities are not consciously planned or intentional in nature: they are based on inborn reflexes that are mediated by the lower parts of the spinal chord.

Infants are born with numerous other reflexes, using their fingers, arms, and other body parts in exploratory movements, gazing at various stimuli in their visual field, and startling with sudden sounds. Beginning in the first week of life, they are exploring the world of novel stimuli they have been born into – using various sense modalities. As they develop better hand-eye coordination and improved motor control, they gradually gain improved skills at exploration and eventually their hands make contact with their genitals, along with many other parts of their bodies.

As touch to the genitals is capable of eliciting the sex reflexes and activating the pleasure centers in the brain, babies

experience pleasurable feelings when their exploratory fingers stimulate their genitals. Because of these reinforcement processes, many infants learn to repeat such genital touching with increasing frequency over time. Infants do not innately know that they should or should not touch their genitals during early exploration, but such touching is very common.

Infants may also experience sexual responses when bed sheets or clothing rub against their genitals. In some cultures, adults touch babies' genitals to sooth and calm them with pleasurable sensations, although that could be called 'child sexual abuse' in many developed nations.

Some parents accept their infants' masturbatory behavior as natural and allow their children to learn additional masturbatory skills. When children are not punished for genital self-stimulation, the natural reinforcers associated with touch to the genitals can lead children to learn increasingly effective habits of self-touching. A small percent of children learn how to stimulate themselves to orgasm in the first couple of years of life.

In homes where parents punish their children for genital touching, the punishment may suppress genital exploration and leave the children with inhibitions about doing sexual activities – if the punishment is frequent and strong enough. As these children grow up, they may never remember why they feel inhibited about genital self-stimulation – or sex in general.

The degree of inhibition that children feel about masturbation lies on a continuum from low to high. Repeated experiences with the pleasures of self-stimulation along with low levels of punishment produce few inhibitions, and uninhibited children may even masturbate in public places, such as grocery stores, parks, preschools, and so forth. Usually, there comes a time when someone – a family member or preschool teacher – senses that the child is engaging in too much public masturbation. At this time, some socializing agent may try to teach the child a basic discrimination: "It is all right to touch your genitals in the privacy of your own bedroom, but not in public." Sooner or later, most children learn to abstain from public masturbation, but many children also learn that genital self-stimulation can be done in privacy – without negative consequences – when done discreetly.

Children from homes where genital touching has been strongly inhibited may not masturbate for years, if ever. Many factors influence the time at which a young person may overcome earlier inhibitions and begin to masturbate. If a young person hears peers talking about masturbation or sees peers

doing it – or sees the activity portrayed in a movie – even well-established inhibitions may eventually be countered by observational learning or sex-positive information, after which the pleasures of genital self-stimulation may boost the frequency of masturbation and either partly or completely diminish the earlier inhibitions.

Young children often have questions about their bodies, other people's bodies, where babies come from, and more. These childhood questions are often simple, as children's understanding of life is still quite rudimentary. If parents answer these youthful questions simply and honestly, children can begin to learn explicit verbal knowledge about sexuality – along with the fact that their parents are happy to help them understand sexuality. As they continue to learn, children tend to ask increasingly complex questions, and parents can answer with increasingly detailed answers – or say that they need to check a book or website before they can answer. Parents should not feel bad if they cannot answer all of a child's questions about sex, especially if their willingness to locate the information shows their openness to the child's questions and an appreciation of the child's curiosity.

Unfortunately, many parents do not respond to their child's questions with relaxed and useful answers. If they show nervousness, discomfort, or other negative emotions in their voice or demeanor, they may signal the child that there is something bad or inappropriate about the topic. After several such experiences, many children stop asking sex questions, which is unfortunate, as parents can be very effective at giving sexual information to their children. Many families claim that parents should be the primary source of sex education, yet the majority of parents continue to cause their children to feel inhibited about asking questions and talking freely about the topic.

Parents may fear that their children might become overly interested in sex if they answer their children's questions, but that is usually not a warranted fear. Most children are curious about so many facets of their lives that sex usually does not occupy a large portion of their total range of concerns. Most children ask about a few dimensions of sexuality, and then move on to explore other interests.

Some children engage in sex play with other age mates and learn about sexual things on their own. The number of possible scenarios and learning experiences is enormous, as the dynamics of sex play can vary so much from child to child. Children may play 'doctor,' 'show,' 'house,' or kindred games with other children. A child 'doctor' may listen to another child's complaints about a sore throat, and then decide to examine the other child's genitals. Childhood sex play is usually quite innocent and may go no further than viewing the genitals of a playmate.

A few children learn about taking off their clothes and rubbing their bodies together, and a smaller number discover sexual intercourse. Even though people often think that incest taboos would prevent brothers and sisters (or other relatives) from exploring coitus, most children have never heard about incest taboos – or do not know what those words mean. Even though there exist some evidence for the presence of inborn psychological mechanisms that diminish children's interest in exploring sex with relatives, such mechanisms do not completely prevent incest. Once these children discover that their incestuous sex play is socially unacceptable, they may feel

guilty and be mortified that they have done such things; but it is understandable that unguided sex play can lead closely related, similar aged individuals to discover intercourse. Several empirical studies show that even explicit childhood sex play does not produce long-term adverse effects in most cases – although abusive relations involving adults can.

Parents and teachers should know the normative data about sexual learning. By the ages of 2–5 years, children commonly masturbate, reach toward or touch female breasts and try to observe others when they are undressed or disrobing. Psychologists do not consider these activities to be unusual or problematic. By ages 10–12, these types of public sexual activities tend to decrease in frequency, although many children at this age begin to show an increased interest in the other sex – or the same sex if homosexual.

There are a few warning signs that suggest a young child might be too interested in sex. The very mildest sign is that the child shows a preoccupation with sexually explicit conversations or frequent masturbation. The next more serious signs include a child's repeatedly touching the genitals of others or having sexually explicit conversations with people who are of quite different ages. The most serious signs of possible problems involve a child's having oral, vaginal, or anal penetration with dolls, animals, or other children: this most serious level might warrant professional counseling.

Theoretical Interlude

This article began by stating that a developmental perspective on sex is theoretically valuable, and we can now explain why. Tracing the emergence of sexual behavior from infancy onward helps us understand how nature and nurture interact. Both biological and learning processes are involved in the gradual emergence of sexual behavior, and developmental studies reveal how nature and nurture interact and entwine with each other.

In the past, many people tended to fall into the trap of wanting to explain sexual activities – and many other types of behavior – as 'completely due to biology' or 'completely due to learning.' This is still seen when people begin arguing for *either* 'nature' or 'nurture' in the frequently held discussions about nature *versus* nurture. Modern science avoids this 'either/or' logic by focusing instead on ways in which biological, learning, and social inputs interact to shape our thoughts and behavior – which in turn are mediated by multiple neural systems that operate at both the conscious and unconscious levels.

Studies on sexual behavior allow us to intertwine data and theories that incorporate biology, psychology, and sociology. Men and women are biologically different in many ways and some of these differences influence their thoughts, emotions, and behavior significantly. People's location in society also affects their thoughts, emotions, and behaviors. The simplest way to integrate all the elements that shape sexual behavior is to follow a developmental time line that starts with birth and traces the following decades of maturation, learning, and socialization.

We have already given descriptive information about several features of prepubertal sexual development. It is time to detail the key elements of the nature–nurture interactions, beginning where this article started.

Reflexes

Both vaginal lubrication and penile erection are based on sexual reflexes, which are biologically built into the body's neural and cardiovascular systems. From infancy, stimulation of the genitals activates these reflexes – causing the sexual organs to swell – and elicits pleasurable feelings in the reinforcement centers of the brain. These positive emotions are the primary reinforcers which lead to various types of learning.

Operant Learning

The pleasurable feelings associated with sex serve as reinforcers that can strengthen behavior, through a process called operant learning. Reinforcers explain why an infant's early random touching of the genitals can become more frequent and eventually a habit. In common parlance, this type of learning is often referred to as 'trial-and-error' learning, although the word 'trial' is a bit misleading. When infants are first touching their genitals, they are not 'trying' to get sexually excited or reach orgasm. They are merely exploring with their hands and they accidentally discover the pleasures associated with sexual stimulation. Infants have no intentions of discovering sexual pleasure, but when early random explorations lead to pleasing feelings, positive reinforcement increases the chances that, on later occasions, exploring infants will repeat those types of self-stimulation that were pleasurable in the past.

As infants touch themselves in different ways, the more rewarding forms of self-stimulation become 'habits' and the less rewarding ones gradually become less frequent. The result is that infants become increasingly skillful at self-stimulation, and adults begin to call the behavior masturbation. Of course, babies do not have a word for masturbation; hence, they cannot verbalize or subjectively understand the words adults use to describe the activity.

Operant learning derives its name from the fact that some behaviors (such as touching) operate on the world in ways that may produce consequences. There are two kinds of consequences that affect operant learning: reinforcement and punishment. The pleasure that a child experiences when touching the genitals provides positive reinforcement for repeating the activity. To reinforce means to 'strengthen,' and reinforcers strengthen behavior (much as steel rods can be used to strengthen concrete, to produce reinforced concrete). The pleasures of genital stimulation are called 'primary reinforcers' to indicate that they are biologically 'wired in' as part of the sexual reflexes. This shows how biology and learning interact, helping to avoid an 'either/or' approach to the nature-nurture debate that emphasizes the importance of one element and devalues the other.

There are 'primary punishers,' too; and they are also biologically 'wired in.' Hitting the testicles or ovaries is painful for biological reasons: it endangers these important reproductive organs, and we have evolved to find such experiences aversive. The primary punishers of pain help us learn to avoid hurting our ovaries and testicles when possible.

Not all reinforcers and punishers are 'primary,' meaning biological, in origin. Social reinforcement for exploring sex with others can occur when a child's peer group rewards taking a dare about some sexual activity. As we have already seen,

social punishment can occur when caregivers punish a child for masturbation; the stronger the punishment, the more the inhibitions it produces.

Rule-Guided Learning

Young infants can learn how to masturbate, even though they cannot put words on the behavior or think about it in symbolic terms. Once children begin to use language, they can take verbal information and use it as 'rules' to hasten operant learning. If a teen frequently hears about the importance of using condoms to reduce the risks of becoming pregnant or contracting sexually transmitted diseases (STDs), the words can serve as rules that help the teen avoid the errors that too many young people still experience through 'trial-and-error' learning. Rules can be helpful in guiding people to learn more effective bedroom techniques, relationship skills, and much more. Having positive consequences strengthens the habits of continued rule use.

Observational Learning

Even when no words are spoken, people can learn operant activities by watching others, through a process known as observational learning. For example, sex therapists encourage people to observe how their partner masturbates to see what they can learn from these observations. It can help both observers increase the range of techniques they can use together. When a girl sees her best girlfriend getting pregnant, this observation can be a big wake-up call about the need for using contraception. Movies, DVDs, books, and the Internet make it easy to learn about sex, although not all the information is accurate. Much of our behavior is learned by observing others, and sex is no exception.

Pavlovian Conditioning

While operant learning affects the frequency of behaviors that operate on people and things, Pavlovian conditioning alters the reflexes – which evolved to respond to a narrow range of stimuli. Pavlovian conditioning allows inborn reflexes to be linked with *new* stimuli in ways that we did not evolve to experience. Because salivation helps start the digestion of food, dogs (and many other species) have evolved to salivate when they smell food. By ringing a bell before presenting food, Ivan Pavlov conditioned dogs to salivate to the sound of a bell, thereby expanding the range of stimuli that elicit salivation.

The pleasurable feelings of the sexual reflexes can be associated with all sorts of stimuli via Pavlovian conditioning. We are biologically prepared such that touch to the genitals triggers the sex reflex, but many other stimuli can become associated with sex via Pavlovian conditioning. A young woman who pays attention to her boyfriend's hairy chest while having sex may come to find hairy chests to be a sexual 'turn-on' or 'erotic stimulus.' Later she may notice that she becomes sexually aroused when she sees other men who expose hairy chests.

Whatever people are thinking about when genital touch elicits the sex reflexes can become a sexual turn-on. A young man who masturbates while watching pornography is pairing new stimuli with the sex reflex, and he may end up feeling

sexually excited by seeing or thinking about such activities in the future. Even if he does not masturbate while viewing porn, he may think about the pornographic images when he masturbates at a later time, thereby sexualizing those stimuli. If he asks his girlfriend to do some of the things shown by the porn videos, his girlfriend may be happy to oblige; but some girlfriends are surprised that their boyfriends would even think about enacting porn scenes, and this can create problems for the couple.

Masculinization of the Brain

During a critical period of fetal development, boys' testicles produce a burst of prenatal testosterone, which alters their brains in ways most females do not experience. As a result, boys and men tend to prefer somewhat higher levels of rough-and-tumble play, rowdy activities, and vigorous physical movements, compared with girls and women. There is a great deal of variation in optimal activity levels in both males and females, but males tend to prefer higher activity levels than females do. These differences often persist well into adulthood. This does not mean that boys cannot learn to control themselves and play gently with others, but many males continue to prefer higher levels of activity and sensory stimulation than do females well into adulthood. This contributes to a commonly observed gender difference in the activities that males and females gravitate toward. For example, it is easier for males than females to learn to love football, soccer, and dirt biking.

There are genes that lead some males not to secrete enough testosterone to fully masculinize the brain, and this may predispose these males to become homosexual. The biologically heritable component of male homosexuality is about 50%. Lesbians appear to have about a 25% heritable component to their sexual orientation. Personal learning, culture, and many other variables complement the heritable influences in the development of homosexuality.

In summary, both biology and learning are important in the development of sexual behavior and both are intertwined starting from infancy. The following sections show how nature and nurture continue to interact after the onset of puberty.

Puberty and Afterward

During puberty, males begin to produce higher levels of testosterone than in childhood, and females begin to produce more estrogen and progesterone. As a result, the genitals become larger and hair develops in various parts of the body. Girls develop breasts, and boys who exercise vigorously see their muscles grow larger. Testosterone allows males to develop considerably more muscle mass in the upper body than can females who do the same amount of exercise.

The sex hormones also make the sexual reflexes more sensitive and responsive than in childhood. Sexual stimulation feels more exciting and rewarding; sexual responses are more noticeable. Therefore, masturbation feels better after the onset of puberty than before. No wonder the frequency of masturbation tends to increase after the sexual hormones rise to the adult levels.

As adolescents experience these bodily changes, they may feel proud or embarrassed, depending on the family and

society in which they live. Families and cultures that acknowledge the beauty of the natural processes of puberty and sexuality are likely to have children who feel good about the changes in their bodies and sexual feelings. On the other hand, sex-phobic homes and communities create conditions where children may feel unhappy or guilty about the changes of puberty and try not to think about them.

Girls who are not told in advance what might happen with their first menstruation can be terrified when they have their first period, thinking that their bleeding stems from a disease. As sex education has become better incorporated in elementary education curricula, fewer girls are traumatized by their first menstrual period than in the past. Boys who are not told in advance that they may begin to have nocturnal emissions (or 'wet dreams') can likewise be frightened when these natural processes begin. Some think that they may have a cancer or some other serious disease. If they have already learned to masturbate, they may fear that the nocturnal emissions are symptoms of a malady caused by their self-stimulation.

Obviously, good sex education can help young people avoid the anxieties and fears that many adolescents had in the past. Young people who learn accurate sex information early in life are most likely to make the transitions of puberty with the least anxiety and trauma. Many studies have shown that young people who receive comprehensive sex education do not become more sexually active or promiscuous than peers who are deprived of such knowledge. Additionally, well-educated young people are more likely to use contraception and take precautions about STDs, which reduces their risks of having problems, compared with peers without accurate sex education.

The increased interest in sex that many young people experience during puberty may lead to more questions and a hunger for knowledge. If young people can talk with their parents and/or teachers, they can learn valuable information from them; but many young people turn to their peers – where they may obtain various mixes of accurate and inaccurate information. The mass media and Internet also contain a complex assortment of valuable and misleading information, and it can be difficult to distinguish between the two types of inputs.

One important point in life for most young people is the time at which they lose their virginity. There are various definitions for the milestones that mark the loss of virginity, and these vary from culture to culture. The traditional definition for heterosexuals is the first experience of penile–vaginal intercourse, but teens may not know if the first experience with oral or anal sex marks the loss of virginity.

In cultures where young people think that engaging in oral or anal sex does not involve a loss of virginity, some may explore these activities in hopes of remaining 'technical virgins.' Unfortunately, oral and anal sexual activities can transfer STDs, some of which have serious repercussions. Gays and lesbians typically define the loss of their virginity without reference to penile–vaginal intercourse, which can include their first passionate kissing, naked body rubbing, oral sex, or anal sex.

Modern industrialized societies tend not to place as much emphasis on the importance of virginity and having an intact hymen nearly as much as in the past. However, there are still many cultures that focus on the intact hymen as the proof of

virginity, thinking that a torn or broken hymen is proof that a female is no longer a virgin. This is unfortunate because a female who has never had penile–vaginal intercourse may tear her hymen by other means, and this event can have serious repercussions for females in cultures that value the intact hymen as proof of virginity.

The age of losing virginity varies from society to society, and even within subcultures in any given society. In the United States, typical ages of virginity loss are the mid-teens and the next 2 years. It is best to think of there being a bell-shaped curve of ages with these ages being in the middle, with fewer and fewer individuals starting sex as the bell curves spread out before and after these ages.

After the sexual revolution, starting in the late 1960s in modern industrialized societies, there was an increase in the frequency of sexual activities – as people began to use more effective forms of birth control. Sexual exploration continued to rise until around 1990 in many industrialized nations, after which it began to decline. Many people became more sexually cautious after 1990 when the mass media made it increasingly clear that a new disease – HIV/AIDS – was becoming epidemic and that it could be fatal. After 1990, people have gradually shifted to having fewer partners than before.

Fetishes and Atypical Sexual Behavior

As males tend to masturbate more than females and think about sexual stimuli while masturbating, males are likely to learn more sexual turn-ons and fetishes. Many males and a number of females eroticize such things as short shorts, bikinis, high heels, biceps, hairy chests, leather clothing, heavy metal chains, certain hair colors, and far more.

The strength of sexual turn-ons can vary from mild to strong. Mild fetishes are very common, and most people have heard others say that they get turned on by breasts, butts, or legs. Stronger fetishes can lead people to obsess about the object of their sexual desire, and sometimes engage in atypical sexual behavior. A man with a fetish for female underwear may love to masturbate with women's panties, and he may try to steal such clothing from laundromats or stores, because of the sexual excitement this brings. A man who masturbates while wearing women's clothing may develop a clothing fetish and become sexually aroused by merely thinking about wearing women's clothing. Men who enjoy cross-dressing are referred to as transvestites, and the behavior is called transvestic fetishism.

People who link sex with the giving and/or receiving of pain may develop sadomasochistic fetishes. Urophilia is the fetishistic attraction to urine. People with klismaphilia derive sexual pleasure from receiving enemas. Those who sexualize feces develop coprophilia.

In some circumstances, people with atypical sexual behavior can cause problems for themselves or others. Some men like dressing in diapers while masturbating, thereby turning diapers into a fetish object. All may be fine until they want to use diapers when having sex with a partner and discover that it is difficult to find a partner who wants to participate in these sexualized fantasies, which can cause the diaper fetishist much frustration.

Some atypical sexual behaviors can cause a person to be arrested. Exhibitionists, voyeurs, and frotteurs may be arrested for violating the privacy of others. People who derive sexual pleasure from exhibiting their bodies to other people are called exhibitionists and they often masturbate before exposing themselves, or afterward as they mentally recall the events. Voyeurs love to spy on others who are undressing or nude, especially if they masturbate during or after the event. Frotteurs get sexually excited by rubbing sexually against others – usually in public places. People who engage in atypical sexual behavior are mostly male, and the data presented on Pavlovian conditioning helps explain why.

Many people have mild fetishes that are not problematic for individuals who have them or their partners. 'It's just fun.' Even more extreme atypical sexual behaviors may not be problematic for people who can find willing partners who want to share in the activities. In recent years, the Internet has allowed many people to locate others who would be interested in participating in atypical sexual activities.

Not only can Pavlovian conditioning create sexual turn-ons, but it can also create 'turn-offs,' which are negative emotions that can inhibit or suppress the sex reflexes. If parents punish a child who is masturbating, the negative emotions evoked by the punishment become associated with sex. This can make a child feel guilty, shameful, anxious, depressed, or fearful about sexual thoughts and actions. People with such fears are called erotophobes, having phobias about sex, which can make them fearful of sex education and many sexual behaviors. It can also inhibit their ability to have and enjoy sexual activities. Fortunately, such negative conditioning can be reversed by discontinuing the aversive conditioning and switching to more positive sexual interactions. This may happen when a sexually anxious person finds a loving partner who shows how positive and caring sex can be.

Sexual Problems

Many young people think that sex is 'natural,' hence good sex should be easy and ecstatic. There are countless joys during the first years of sexual interaction, but many young adults are surprised by the difficulties they experience in their early sexual explorations. That is because many of the sexual techniques that make sex most gratifying are not innate: they have to be developed through operant learning, which often involves trial-and-error processes, and the errors can be painful or embarrassing. A few of the solutions that people need to minimize errors are somewhat obvious, but many are not.

The most common sexual problems that do not disappear quickly are premature ejaculation (for males) and difficulty in reaching orgasm (for females). The causes of the problems are easy to understand with the information we have presented in this article, again revealing the interplay of nature and nurture.

Male Concerns

Premature ejaculation – also called early or rapid ejaculation – is the most common sexual problem for males. When males are in a sexual situation, many become very excited and move vigorously, reaching the point of orgasm and ejaculation quite

quickly. It is not uncommon for early ejaculators to reach an orgasm in 1 or 2 min, and some take less time than that. Anthropologists who have studied simple tribal societies around the world note that such timings are typical in many societies. Biologists observe that being fast might have an evolutionary value.

After the 'sexual revolution' in Western societies (starting in the late 1960s), many women have encouraged men to learn how to last for longer time periods so that both partners can enjoy prolonged sexual pleasures, and this increases the chances that women can reach orgasm during intercourse. Many men have learned how to last 10 min or longer before ejaculating, and it seems to make many people's sex lives happier when men can master this type of ejaculatory control.

Why do many men tend to come quickly? Teenage males begin having experience with spontaneous sexual arousal and nocturnal emissions about 2 years earlier than females do – and they experience these sexual feelings more strongly – which helps males learn to like masturbatory sex early in adolescence. During masturbation, many males discover that strong forms of stimulation get them excited quickly, so they receive immediate reinforcement for rapid masturbation.

In addition, there are sociological reasons why many males learn to masturbate quickly: boys are less likely to be caught by their parents or roommates if they masturbate quickly rather than taking a leisurely approach. When they begin having sex with a partner, they are less likely to be walked-in-on by parents or roommates if they have quick sex. After a couple of years of learning the habits of seeking strong and fast stimulation, it can be difficult to change those patterns.

If the cause of premature ejaculation is getting too much stimulation too fast, one obvious solution is for males to slow down and enjoy sexual stimulation at more leisurely rates. One of the most popular therapies for premature ejaculation is called the 'stop-start' method, in which a man learns to alternate between enjoying the sexual stimulation that activates the sex reflexes and then stopping movement long enough to slow the reflexes and prolong the rise toward orgasm. In a variation on this theme, a man can learn to do sex in 'slow motion,' which allows him to appreciate the sexual sensations over a prolonged period, without becoming overly stimulated in 1 or 2 min. Men who master these techniques begin to have voluntary control over their sexual response and can adjust the timing of their orgasm to suit the needs of each sexual situation.

Female Concerns

The most common sexual problems that women report involve difficulty in becoming sexually aroused, staying sexually excited, and reaching orgasm. All three of these problems are closely related and occur when women do not receive enough sexual stimulation to fully elicit the sexual reflex.

In essence, the most common female problems are the opposite of the male problem of premature ejaculation – which arises when men receive too much stimulation too fast. Females often do not receive enough appropriate stimulation to reach orgasm in 5–30 min of sexual interaction. In addition, many women do not like to continue having sex for 40 min or longer, as their natural vaginal lubrication tends to dry up after those longer periods of time, making coitus uncomfortable.

Women's orgasmic problems can be traced to their (1) receiving too little pleasurable stimulation to fully elicit the sex reflex and (2) having too many inhibitions about sex. Both of these involve nature and nurture – biological and social factors.

First, many couples lack the knowledge and/or skill to bring enough effective stimulation to the female to activate her sexual reflex enough to reach orgasm. On the biological side of the nature and nurture interaction, genital size is important. The area of greatest erotic sensitivity on the female body is the glans and shaft of the clitoris, and these organs are considerably smaller than the glans and shaft of the male penis. The small size of the clitoral structures can make it difficult for girls and women to find these erotic zones and discover the pleasures they afford.

Society plays an important role, too. Throughout history most societies have not focused much attention on female sexual pleasure, and few have amassed or passed on enough information for girls and women to learn about their genitals and the types of stimulation they need to reach orgasm. In the past several decades many significant steps have been taken to improve the science of female sexuality, but many females still do not have access to the information, because of limited amounts of sex education about and distorted media coverage of these topics. Even today many people think that the vagina is the woman's most erogenous zone, even though the vagina and the G-spot (on its front wall) do not activate the sex reflex as effectively as does clitoral stimulation. Few people learn that cunnilingus (oral stimulation of the female genitals) is the most effective way for women to reach orgasm, especially when the tongue explores above, below, and on the clitoris. Fortunately, there are increasing numbers of books and websites that make this information available.

The second main cause of female orgasmic problems involves sexual inhibitions. Negative social experiences related to sex can produce guilt, shame, and other painful emotions that can (a) cause a woman to limit her range of sexual experimentation, hence decrease the chances of her receiving the most effective stimulation; and/or (b) inhibit the sexual reflex, even if she does obtain good stimulation.

Many societies raise their girls to feel uncomfortable if not guilty about their sexuality, causing females to have various sexual inhibitions about exploring their sexuality, touching their genitals, masturbating, and asking their partner to provide better stimulation. The negative emotions learned during childhood and adult socialization help explain why many girls and women do not discover how to reach orgasm. These inhibitions are also sexual 'turn-offs' which can suppress the sex reflex even when a woman does experience effective sexual stimulation.

Most forms of female sexual therapy focus on exercises that encourage a woman – and her partner, if she has one – to touch the erotic zones of her body in sensitive and caring manners. Special attention is focused on the entire clitoral area, the minor lips, the vagina, the G-spot, the mons pubis (above the pubic bone), and the breasts. Different women like various combinations of stimulation of these areas, so each woman needs to explore what works best for her. As a woman and her partner discover her areas of greatest sensitivity, they can play with various means of stimulating those areas, using different

levels of pressure, patterns of movement, and so forth. Many couples need to take the time for prolonged trial-and-error learning as they experiment to discover what feels best.

Sex therapists encourage women to start by masturbating in private, then showing their partner the types of stimulation that work best. Some women benefit from using a vibrator as a sex toy for exploring the kinds of stimulation that are most effective in reaching orgasm. Women may also need to increase their general bodily muscle tone to facilitate orgasm, perhaps tensing the pelvic floor and leg muscles. Also helpful is focusing on positive thoughts about sex (rather than worrying about getting excited or reaching orgasm); therefore it is important for the woman's partner to tell her all sorts of positive things about her body (how good it feels, looks, and smells) so she will be free of negative thoughts during sexual activities. Sexual fantasies provide another useful tool for boosting the positive sexual thoughts that excite a woman's mind.

Many of the sexual problems that both males and females experience could be averted if children were raised with better knowledge and fewer inhibitions about sexuality. If they are also raised to respect all individuals and their personal boundaries, this sexual knowledge will not lead to abusive or coercive actions.

The science of sexuality is still only a few decades old, so we can expect that future generations will know more than we do. There is still much work that needs to be done to reduce the frequency of unintended pregnancies, STDs (including HIV/AIDS), rape, sexual assault, domestic violence, and

discrimination against sexual minorities. The more people advocate for advances in the science of sexuality, the faster we may progress in reducing the dark side of sex and helping people experience the pleasures of intimacy and sexuality.

Glossary

Iconic When the form of a sign resembles the concept or object that it denotes.

Modality Language modality refers to the medium by which a language is perceived and produced. Sign languages are perceived and produced in the visual-manual modality, while spoken languages are perceived and produced in the aural-oral modality.

Morphology The structure of words and the rules governing the structure of words.

Nonmanual grammatical markers Elements of a sign language that are not produced by the manual articulators (hands). Nonmanual elements are produced by movements in the torso and head, and by changes in facial configuration.

Phonology The system of nonmeaningful elements and rules for their combination to form words or signs.

Syntax The system of rules for building grammatical sentences out of words or signs.

Sign languages are visual-spatial languages primarily used by deaf people. In contrast to spoken languages, which are produced using the vocal tract and perceived by the auditory system, sign languages are produced in the manual modality, with the hands, upper body, and face, and are perceived by the visual system.

This article debunks common myths about sign languages, and then lays out their linguistic properties, acquisition, and neurological underpinnings. The ways in which sign languages are similar to and different from spoken languages are considered throughout the article.

A Note on Modality Differences

The modality of sign languages is visual-spatial, whereas the modality of spoken languages is aural-oral. This article considers whether differences in modality lead to differences in the structure, the acquisition, and the neural organization of a sign language.

Much of the research on sign languages has focused on American Sign Language (ASL). The following review reflects that bias; but, when possible, examples from other sign languages are included. Although the review focuses on ASL, the principles outlined are believed to apply to all sign languages.

Myths About Sign Languages

Myth 1: Sign Languages Are Universal

No single sign language is used by all deaf people around the world. Sign languages emerge naturally among communities of deaf people. Sometimes divisions among sign languages parallel those among spoken languages. For example, in Spain, Catalan Sign Language is used in Catalan-speaking areas, while Spanish Sign Language is used in Spanish-speaking areas. Conversely, some areas that share the same spoken language do not share the same sign language. ASL and British Sign Language are mutually unintelligible even though English is the dominant spoken language in both countries. Sign languages are generally named after the country or region in

which they are used (e.g., French Sign Language, Quebec Sign Language, Israeli Sign Language). In a few cases, different countries share the same sign language, for example, ASL is also used in the English-speaking parts of Canada.

Myth 2: Sign Languages Are Mimetic Gestures

One of the hallmarks of a language system is that its words have an arbitrary relationship to their referents – the form of the word does not resemble the referent. The word ‘cat’ does not represent any feature of the animal. Sign languages, because they are visual languages, more readily lend themselves to iconicity. In other words, many signs look like their referents. But not all sign languages iconically depict a referent in the same way. Whereas the sign CAT (signs are glossed in all capital letters; [Figure 1](#)) in ASL appears to trace a cat’s whiskers, the same sign in Australian Sign Language depicts petting a cat. Both signs are iconic, but each represents a different characteristic of the referent; thus both languages conventionalize the sign differently.

Although some signs are iconic, most have an arbitrary relationship to their referent. For example, the ASL sign APPLE ([Figure 2](#)) is made by a hooked index finger twisting at the side of the cheek, and thus bears no resemblance to an apple. Other signs may have iconic origins that have become less transparent over time. The ASL sign GIRL ([Figure 3](#)) traces the string of a bonnet, but in today’s bonnet-less society, that iconic relationship is virtually invisible.

Some signs look like pantomimed actions. But sign languages differ from pantomime in several distinct ways. First, they constrain the articulation of a sign to a limited space in front of the signer’s body extending from the hips to just above the head, whereas pantomime can be articulated anywhere on or around the body. Second, sign languages are communicated with movements by only the arms, torso, and head, but in pantomime the entire body can be engaged (e.g., running in place to represent running). Finally, pantomime lacks the requisite hierarchical structure that characterizes language. Both spoken and signed languages are built up from the smallest units (phonemes), which combine to create words, which then combine

Figure 1 ASL sign CAT.

Figure 2 ASL sign APPLE.

Figure 3 ASL sign GIRL.

to create sentences. The brains of fluent signers are sensitive to this structural difference between sign languages and pantomime: different areas of the brain are activated when perceiving signs than when perceiving pantomime.

Myth 3: Sign Languages Are Just Spoken Languages on the Hand, and Have No Formal Grammar of Their Own

Sign languages are not signed versions of the local spoken language. For example, the word order in a sign language often differs from the word order of the spoken language. The word order in German Sign Language is subject–object–verb, whereas the word order in spoken German is subject–verb–object. In English, verbs carry information about when an event happened; the ending ‘-ed’ tells us that the event happened in the past. ASL, on the other hand, conveys tense information by adding a separate sign like YESTERDAY or BEFORE to the sentence. This tense system is similar to that observed in Mandarin.

Sign languages have developed their own grammar distinct from spoken languages and are not derived from the local spoken languages. Although we cannot trace the origins of all sign languages, recently emerging sign languages such as Nicaraguan Sign Language and Al-Sayyid Bedouin Sign Language reveal that sign languages emerge across multiple generations when there is a critical mass of deaf people. Other sign languages emerge through contact with another sign language. For instance, ASL traces part of its origins to an earlier form of French Sign Language (LSF). A deaf French teacher, Laurent Clerc, helped establish the first deaf school in the United States where he and other teachers from France used LSF. LSF mixed with the sign languages and the gestural systems used by children entering the school, and became the foundation for what is now ASL. Although ASL has its origins in LSF, its current form is distinct from LSF, and both languages are mutually unintelligible.

Myth 4: Sign Languages Cannot Convey the Same Meaning as Spoken Languages

Sign languages share the same level of complexity and productivity as spoken languages. Consequently, they can capture the same array of meanings with equal eloquence, and can convey complex concepts in all fields of study from neuroscience to philosophy. For words that may not have a sign equivalent, fingerspelling offers an alternative way to manually express the word (see section ‘Fingerspelling’).

Some reports indicate that the vocabulary size of sign languages is generally smaller than that of spoken languages. But languages such as English or Spanish have been used in such comparisons, and these spoken languages have amassed very large vocabularies as they emerged as the dominant languages used in academic and technical arenas. When comparing sign languages to most spoken languages around the world, we see comparable vocabulary sizes. As sign languages gain more use in academic and technical fields, new signs are generated to meet the needs of specific fields of study.

Linguistic Structure of Sign Languages

Phonology

In spoken languages, phonology includes the system of sounds that combine to create words, and the rules that constrain how sounds are combined. A phoneme is the smallest sound unit that, when changed, can create an

entirely new word with a different meaning. For example, the English words *cat* and *bat* differ in a single phoneme /k/ and /b/; a change in the initial phoneme changes the meaning. The word *phonology* contains the Greek root *phono* (sound). Accordingly, it would seem that phonological systems only appear in sound-based languages. Yet research spanning the last 50 years has established that sign languages have a sublexical structure that can be characterized as phonology.

A salient way to see the phonological structure of any language is to find minimal pairs, words that differ in only one phoneme, for example, *cat* and *bat*. Close examination of minimal pairs in sign languages has uncovered four phonological parameters that define a sign: handshape, location, movement, and orientation (Figure 4). Signs can differ in handshape, in where they are located on the signer's body, or in how the movement of the sign is articulated. Movement in a sign can travel along a path (e.g., straight, arc) from one location to another, and can include a sign's internal movement (e.g., wiggle, change in handshape). Finally, several signs differ in the way the hand is oriented in space: the signs *SOCK* and *STAR* are articulated with the same handshape, location, and movement, but with a different palm orientation. Psycholinguistic studies have demonstrated that the movement and location of a sign are the strongest part of the representation of the word and consequently are more resistant to errors, while handshape is the most error prone. The phonological structure of all sign languages seems to include the same four phonological parameters, although each language may constrain the variability within each parameter differently.

Recently, a fifth phonological parameter has been considered: the incorporation of facial expressions, called nonmanuals (see section 'Nonmanual Markers'). Some signs are produced alongside facial expressions, and without them, the signs are incorrect. For example, the sign *TRY-OUT* in the Sign Language of the Netherlands is articulated with a puffing of one cheek; without the puffed cheek, the same manual sign takes on a different meaning, *DAYS*.

In spoken languages, phonemes are sequentially strung together to form a word. The first phoneme of the English word *cat* is /k/, followed by /æ/ then /t/. Such sequentiality suits spoken languages because rapid changes in sound are deftly produced by the vocal system and perceived by the auditory system. But manual articulators are larger and move slowly, and therefore sequential information cannot be produced as rapidly. Consequently, sequentiality is observed in sign languages to a lesser extent. The need to transmit and perceive linguistic information efficiently likely shaped the evolution of sign languages to convey many of the componential elements of language simultaneously. Thus, a single sign is made up of a set of simultaneously articulated phonological units.

Sign languages have also developed phonological rules that guide sign formation. For example, such rules can govern when a movement of a sign can be deleted or a handshape can be assimilated during a signed sequence. The existence of a set of phonological parameters and rules in soundless languages establishes the universality of sublexical structure in human languages, spoken and signed.

Figure 4 Minimal pairs in ASL.

Morphology

In the hierarchical structure of language, the next level up from a phoneme is a morpheme, the smallest meaningful unit of a word or sign. As with spoken languages, sign languages have free morphemes, which can occur on their own, like the sign *CAT*. They also have bound morphemes that attach to a stem (i.e., a sign). In spoken languages, bound morphemes sequentially attach to a word as an affix (e.g., prefix or a suffix). For example, the suffix '-s' conveys plurality. In sign languages,

most bound morphemes are simultaneously, not sequentially, presented. Remarkably, sign languages allow for the modification of all possible parameters of a sign (movement, handshape, location, or orientation) to convey additional meaning.

Sign languages exhibit both derivational and inflectional morphology. The process of derivational morphology creates new words from existing words. In English, the suffix '-er' can change a verb to a noun (e.g., *teach*, *teacher*). In sign languages, nouns are derived from verbs by reduplicating and reducing the size of the sign's movement. The ASL sign CHAIR and SIT share the same handshape, location, and orientation (Figure 5), but the movement is reduplicated (i.e., repeated) for the noun. New compounds can be formed from two independent signs. In English, compounds such as 'wallpaper' have a different stress pattern than that of the independently articulated words 'wall' and 'paper.' ASL constrains what elements of two signs are preserved in a compound. In the compound GOOD-NIGHT, the end point of the sign GOOD is eliminated. In addition, the handshape of some signs can be replaced by numeral handshapes to specify the exact amount represented. For example, the sign WEEK (Figure 6) is made with an

extended index finger handshape. To specify two weeks, the index finger handshape is replaced with the handshape for TWO, but the movement, location, and orientation of WEEK remain the same (Figure 6). Enumerable signs can specify up to nine units; for amounts greater than nine, the specific number sign is produced before the sign (e.g., TWELVE WEEK).

Finally, to talk about spatial relations in English, speakers use prepositions such as *in*, *on*, and *under*. Sign languages rarely use such prepositions and instead describe objects in relation to each other with a system of classifiers that refer to different object classes (e.g., vehicles, animals, cylindrical objects, flat surfaces, etc.). To describe a cup on a table, a signer would place the hand articulating the classifier for a cylindrical object on the hand denoting a flat surface (Figure 7). For the cup under the table, the signer would move the cylindrical object under the flat surface (Figure 7). In essence, the signer diagrams the spatial relation. Although the utterance appears almost gestural, it is subject to a set of rules dictating the form of the morphemes.

Under the process of inflectional morphology, grammatical information is added to existing words (e.g., the English

Figure 7 Example of a spatial classifier describing (a) a cup on a table and (b) a cup under a table.

plural marker ‘-s’). Inflectional morphology in ASL can convey verb aspect and agreement. Modifying the movement of a verb expresses temporal information, such as whether the action was habitual, continuous, or iterative (i.e., repeated). The movement in the verb *STUDY* can be changed to communicate whether someone is studying regularly, occasionally, or continuously. Information about who is doing what to whom (who is the subject, and who is the object) is also conveyed by differences in the start and endpoints of a sign’s movement. Signers associate referents with locations in the signing space, and then use those locations as the verb’s arguments. In the sentence, ‘the father watches the boy’ the signer can indicate which part of the signing space will stand for the father (e.g., to the right) then locate the boy somewhere else (e.g., to the left). The sign *WATCH* begins at the location of the father and moves toward the location of the boy to convey that the father watches the boy. The location where the verb begins agrees with the location associated with the referent of the subject, and the endpoint agrees with the location associated with the referent of the object. As such, changing the start point of *WATCH* in the above example, to the location of the boy and directing the sign toward the location of the father, puts the boy in the role of the subject, the one doing the watching. Only a subset of ASL verbs falls in this class of agreeing verbs.

Syntax

For plain verbs, like *LOVE*, which cannot be spatially modulated to express agreement, word order can provide information about who is doing what to whom. The canonical word order in ASL is subject–verb–object. Thus the sentence *CAT LOVE DOG* means the cat loves the dog, and switching the order changes the meaning of the sentence. Other sign languages, such as German Sign Language and Brazilian Sign Language, have auxiliary signs that can be spatially modulated to indicate person agreement. Under such a system, *CAT* and *DOG* are first associated with different spatial loci, *LOVE* is expressed, then a separate sign marking person agreement is articulated by moving from the location associated with the referent of the subject to the location associated with the referent of the object.

Although ASL has a basic word order, its word order is more flexible than English word order. Through topicalization, the signer can move the object to the beginning of the sentence, for

example, *DOG, CAT LOVE*, meaning, ‘as for the dog, the cat loved it.’ The fronting of the topic is also marked by the signer raising her eyebrows (see section ‘Nonmanual Markers’). In addition, ASL, like many other spoken languages including Japanese and Italian, allows speakers to drop the pronoun when context supplies sufficient referential information. In the sentence, *MY WIFE SICK. NEED GO-TO DOCTOR*, the pronoun in the second sentence can be inferred from the previous sentence mentioning the wife.

Overtly articulated nominative pronouns (e.g., I, you, he, she) in ASL are articulated with an extended finger that resembles the pointing gesture. Given the surface similarity, there is debate over whether the pronominal system is gestural or grammatical. From the perspective that takes the pronominal system to be grammatical, changes in fingertip orientation mark changes in person. The direction of the point indicates whether it is a first-person (toward the signer’s chest), second-person (away from the signer), or third-person pronoun (toward the space to the right or left of the signer). Although most methods of ASL instruction focus on a three-person pronominal system, most linguists agree that the ASL pronominal system is best characterized as a first/non-first person system. Changing the handshape from an extended pointed finger to a flat open hand creates a possessive pronoun, and adding a sweeping movement (moving from left to right) to either the nominative or possessive pronoun indicates plurality.

Pronouns can refer both to immediately present and non-present entities. As with agreeing verbs, signers assign arbitrary locations in the signing space to referents; any pronominal point to an assigned location refers to that referent. The assigned locations remain constant across the discourse until they are reassigned to new referents. This spatial system can be used for pronominal reference, verb agreement, reported speech, and reported action. In reported speech and reported action, a signer shifts his body toward an established locus to adopt the perspective of the associated referent; any utterance or action following the shift is attributed to the referent, not the signer, just as in the English example of direct speech, “The teacher said, ‘you better do your homework!’”

Both the system of inflectional morphology and the pronominal system illustrate how sign languages convey all of the syntactic complexity of a spoken language through both sequential and simultaneous presentation of grammatical elements.

Nonmanual Markers

Signers produce facial expressions to convey both affective and grammatical information. The grammatical facial expressions are called nonmanual markers. Changes in eyebrow, mouth, head position, and body position can systematically affect the meaning of a signed sequence. For example, if a signer raises his eyebrows while signing YOU GO STORE, it becomes the question, 'Are you going to the store?' Adding a headshake changes the meaning to, 'You aren't going to the store?' Without the raised eyebrows, the same sequence of words is an imperative, 'You are going to the store.' Nonmanual markers produced on the mouth provide adverbial information. In Sign Language of the Netherlands, a pursing of the lips accompanying a verb carries the meaning, 'in a relaxed manner,' while puffing the cheeks and squinting the eyes conveys, 'with difficulty.'

Nonmanual markers are produced alongside the signed sentence and mark sentence types such as topicalizations, conditionals, yes/no questions, wh-questions, and negation. Their production is usually timed with the onset and offset of the signed clause. Nonmanual markers can be distinguished from affective facial expressions by their precise timing, constrained linguistic function, and specific form.

Across different sign languages, there is some similarity in the form and function of nonmanuals, yet there are some reported cross-linguistic differences. Nonmanual markers are argued to have their origin in the affective facial gestures produced by the hearing community. For example, in ASL and some other sign languages, wh-questions are marked by the signer furrowing his brows. The furrowed brow is a facial gesture often used to express puzzlement and a request for more information. Users of spoken language produce the furrowed brow sporadically, but signers produce it consistently, indicating that it has become a grammatical marker. Where we observe cross-linguistic similarities in affective facial expressions we may also observe similarities in nonmanuals across different sign languages. Conversely, any cross-linguistic differences in nonmanuals may be related to cross-cultural differences in the use of affective facial expressions.

Fingerspelling

Many signing communities use a manual alphabet – a system of individual hand configurations that matches the local orthographic system. By all accounts, the manual alphabet is an artificial system invented by hearing adults. Some countries use a one-handed alphabet, while others use a two-handed alphabet. Items that are fingerspelled but not lexicalized (see below) are not subject to the grammatical rules of the sign language.

Few deaf people use fingerspelling as their sole means of communication because it is labor intensive. A signer fingerspelling all of the time is equivalent to a speaker spelling out every word. Signers anecdotally report that the use of fingerspelling varies across different sign languages and socioeconomic status. In general, signers use fingerspelling when there is no sign equivalent, but they may also fingerspell words with sign equivalents for discourse purposes, such as to add emphasis.

Frequently fingerspelled items can undergo a gradual process of lexicalization where they become new signs incorporated into the sign lexicon. A set of phonological rules governs this process. Typically one or more letters are deleted or assimilated so that not all of the individual letters can be identified. For example, the sign #BACK (the # denotes a lexicalized fingerspelling) is articulated without the 'C.' Lexicalized fingerspellings often exhibit reduplication: the sign #DO is a reduplicated movement from the letters 'D' to 'O.' Once lexicalized, they are subject to grammatical rules and, for example, can become agreeing verbs (see section 'Morphology'). The process of lexicalization of fingerspelling looks very similar to the phonological process that shapes the way words are borrowed from foreign spoken languages.

Dialect Differences and Register Use

Speakers of the same language who are from different regions or socioeconomic classes often speak slightly different variations of the same language. Regional and ethnic differences have been documented in the dialectical variation observed in ASL, and they are argued to stem from the decentralization of deaf education. Many schools for the deaf are regulated by state governments, and as such, policies about language use in the classroom varied state by state. Until recently, most schools did not use ASL, and if they did, there was often no formal instruction in ASL. With little standardization of ASL in the educational system, the communities in each school developed and passed down region-specific signs. Deaf adults report that they can identify where someone went to school from their signing. Countries with even less centralization of deaf schools report greater dialectical variation in the local sign language. The history of segregated schooling of African-American deaf children in the United States has also contributed to dialect differences. However, with school integration, these ethnic differences seem to be fading. In addition to regional and ethnic differences, some researchers have observed generational differences in sign vocabulary.

Although most of the discussion of dialect differences centers on vocabulary, some regional phonological variation in ASL has been observed. Signers in the southern regions of the United States tend to use more two-handed signs, whereas signers in the northern regions use primarily one-handed signs. In some regions, signers produce signs with a thumb extension, and in other regions, they tuck in the thumb (e.g., BUTTER, FUNNY).

Social situation can also affect the form of signing. In formal situations, signers sign slowly, use a larger signing space, and accentuate the pauses between signs. In less formal settings, the pace speeds up, the signing space is reduced, moving closer to the center of the body, and sequences of signs blend together such that you can see elements of the next sign appearing before the previous sign has been fully articulated (i.e., coarticulation). These situational modifications in signing style parallel the speech modifications made by speakers in different settings. In formal settings, speakers also speak slowly, include more pauses, and choose different words than they would in less formal situations.

Fluent signers acquiring a second sign language seem to exhibit something like a foreign accent. The most consistent finding is that accent appears in hand formations and is most pronounced with handshapes that are not among the handshapes allowed in the signer's first sign language.

Poetry in Sign Languages

Deaf communities have had a long tradition of storytelling, but the artistic use of sign languages has emerged only recently with the broad acceptance of sign languages as natural languages and with the founding of organizations such as the National Theater of the Deaf in the United States. The art of poetry is one of the fastest growing areas of artistic expression in sign languages.

Spoken language poets play with the sounds and rhythms of language and often use metaphor to create a poem. Sign language poets also play with the phonological structure and rhythm of a sign language, and take advantage of the visual-spatial modality to create metaphors. Rhyme in sign languages, like spoken languages, is based on the phonological parameters that create a sign. For example, a poet may select one handshape to appear periodically in a poem. Rhythm and meter are created by manipulating the flow of movement and the pauses of signs – both may be longer or shorter than would be observed in normal discourse. Sign language poets often go beyond modifying existing signs and create novel signs as a part of their artistic expression. Because of the great potential for iconicity in sign languages, poets will manipulate or even generate novel iconic signs to create a more metaphorical mapping between the sign and the target. Poetry in sign language has become such a wide-reaching art form that schools for the deaf are incorporating poetry lessons into their curriculum as early as kindergarten.

The Acquisition of Sign Languages

The modality differences between signed and spoken languages could lead to differences in the pattern of language acquisition, yet research over the past 30 years has uncovered striking similarities. Children learning a signed language hit the same developmental milestones at the same time as children learning a spoken language. They also make similar errors along the way, indicating that the mechanisms underlying the language acquisition process are common to both spoken and sign languages. This article considers first the native acquisition of a signed language by children born to deaf parents, then the late acquisition of sign languages by deaf children born to hearing parents.

Infant-Directed Signing

Infants' first exposure to language is from caregivers who subtly modify their language production to sustain their infants' attention. Infant-directed speech is characterized by an elevated pitch, expanded pitch range, and frequent repetition relative to normal speech. Similarly, infant-directed signing has large slow movements with frequent repetition. And surprisingly both deaf and hearing infants, regardless of whether

they have had previous exposure to a sign language, find infant-directed signing attractive.

In the first year of life, hearing infants engage in 'joint attention,' following their parents' pointing and eye gaze while listening to their parents' speech. Joint attention is a multimodal activity that requires the infant to incorporate both visual and auditory information. Deaf infants, however, must attend to both the object of their caregivers' attention and the linguistic information being signed in a single modality. Skilled caregivers help infants learn how to balance their visual attention by moving signs into the infant's field of vision or by displacing signs normally articulated on their own bodies onto the infant's body. Sign displacement happens when the infant is not looking at the caregiver or when the child is sitting in the parent's lap and cannot see the caregiver.

Caregivers also negotiate the dual functions of the face – affective and grammatical – when signing with their infants. Some research has demonstrated that deaf mothers primarily use affective facial expressions with infants, and rarely use grammatical facial expressions, especially those that could be mistaken for negative facial expressions. In this way, caregivers continue to make their language attractive to their infants.

Babbling

Infants exposed to a spoken language begin babbling – producing vocalizations with no meaning or reference – between seven and ten months of age. Deaf children exhibit early vocal babbling, but such babbling declines just at the age when hearing infants' babbling increases. Thus, babbling may begin as a function of motor development but is only maintained when reinforced by auditory feedback.

Studies of infants exposed early to sign language have documented a manual equivalent of babbling that shares many of the same characteristics of vocal babbling. Babbling includes a reduced set of phonological parameters that reflect the syllabic organization of the language. Several handshapes appear frequently in manual babbling, and are often produced in a variety of locations, most typically in neutral space, on the head or on the face, and within a more constrained space relative to the arm movements produced by nonsigning infants. In addition, the manual babbles of infants exposed to a sign language are typically repetitive, multicyclical movements articulated at a slower velocity. Manual babbling has been documented in different sign languages, providing cross-linguistic support that babbling cannot merely stem from the maturation of the vocal system. Rather babbling, vocal and manual, serves a linguistic purpose for infants – to help them figure out the phonological properties of their language.

First Words

Although some researchers have reported first sign production as early as 6 months of age, the average is around 10 months. The observed early production of signs may be related to earlier development of the gross motor skills necessary to produce a sign relative to the fine motor control required by the oral articulators. This observation is the foundation of the movement to teach hearing infants signs to allow them to communicate at an earlier age. However, when more stringent criteria

of symbol use are applied – where the sign produced is not imitative or context dependent – the sign advantage disappears. Consequently, the sign advantage may actually be a gestural advantage. Both signing and speaking children produce their first true symbols at about 12 months, indicating that the cognitive prerequisites for symbol use are common to signed and spoken language. Indeed, signing children reach all of the same word learning milestones as children learning a spoken language, for example, producing their first 10 signs at 12 months and first 50 signs at 24 months.

Signing children also make errors similar to those made by nonsigning children. Their first words are bare, uninflected signs, often with phonological errors. The handshape parameter seems to be the most error prone. Children replace more complex handshapes with the easier ones that appeared most frequently in their babbles. Movement and location seem to be more resistant to errors, likely a consequence of the earlier developing gross motor skills. Infants tend to correctly produce the phonological elements that are easiest to articulate, easiest to perceive, and are the most frequent in the sign language. The differential development of the motor skills required to produce a sign versus a word leads to a unique set of movement errors in sign development. Some signs that are made with distal joints (e.g., wrist, elbow) are first produced by children using more proximal joints (e.g., shoulder). For example, adults produce the sign YES with a movement at the wrist, but infants often produce the sign with a movement at the elbow or even the shoulder.

Crucially, the first words an infant acquires are not necessarily iconic. Less than one-third of a child's earliest vocabulary consists of signs with iconic properties. Instead the earliest words focus on the people (e.g., DADDY), things (e.g., COOKIE), and events (e.g., BYE-BYE) of their daily routine. The development of semantic relations in spoken and sign languages appears to follow the same trajectory, with children first talking about the existence or nonexistence of objects, followed by action and state relations, then locative relations. In both types of languages, the later-developing semantic expressions are datives, instruments, causatives, and manners of action.

As their vocabulary grows, children start combining signs. The first stages of this transition can be seen just after their first birthday when they point to an object and then sign the name of the object. At about 16 months, infants point to an object and produce a separate sign, for example, pointing at a cookie and signing EAT. Once children acquire a vocabulary size of approximately 115 words, they reliably start producing two-sign combinations, for example, MORE COOKIE.

Morphology/Syntax

When speech-exposed children begin stringing words together, they reveal their understanding of the grammatical rules of their language through the errors they make. For example, they often overgeneralize the past tense marker '-ed' to irregular verbs such as 'go' even though they have never heard the form 'goed' in their input. Their overregularization errors reveal an internal system of rules for which they have yet to learn the exceptions. Sign-exposed children make similar errors as they acquire a sign language.

An obvious question is whether early gesture experience facilitates the acquisition of a sign language. For example, as speech-exposed children acquire the pronoun system they make pronoun reversal errors, using 'you' as a first-person pronoun, and 'I' as a second-person pronoun. The nominative pronoun in ASL is expressed with a handshape that resembles a pointing gesture (see section 'Syntax'). Like other children, sign-exposed children use the gestural point, but this experience does not support an error-free entry into the pronominal system. Sign-exposed children also make pronoun reversal errors because they treat the second-person pronoun, 'you,' as an alternative name for themselves. Thus signing children interpret the pronominal point as a lexical item, not as a pointing gesture. At 24 months, sign-exposed children start to use pronouns with some errors, producing them correctly only with immediately present referents. After 27 months of age, they use the pronouns with absent referents.

The use of affective facial expressions also does not facilitate the acquisition of nonmanual markers (see section 'Nonmanual Markers'). For example, negation in ASL can be expressed with a headshake that extends over the element being negated. All children readily know how to shake their heads, but the negation in ASL requires coordination of the headshake with the signed sentence. Although the negative headshake emerges as early as 12 months, sign-exposed children prefer to use manual signs for negation instead of the headshake. The manual signs are acquired around 18 months, but there is a 1–8-month delay before children produce them with a negative headshake. In essence, sign-exposed children acquire the freestanding lexical item, before acquiring the 'bound' facial expression. The correct production of the nonmanual marker for negation is not acquired until 24–28 months. But for many other nonmanuals, the timing and scope of their production is not mastered until the age of 8. The sum of the evidence on the development of nonmanual markers shows that experience with affective facial expressions does little to speed up the acquisition of grammatical facial expressions.

Finally, iconicity does not seem to support children's acquisition of verb morphology. Recall that there is a class of verbs that is spatially modified to indicate the arguments of the verb; the form of these verbs relates to the spatial location of the referents associated with the verb (see section 'Morphology'). There is an iconic relationship between the movement of the verb and the movement of the action represented. Yet children take years to master this verb agreement system and other aspects of spatial syntax. Initially, children produce bare verbs without any spatial inflection. Three-year-olds begin modifying these verbs spatially, but only with present referents. Four-year-olds start to associate locations in space with absent referents, but do so inconsistently. Only once children are 5 years of age do they consistently use loci for absent referents and maintain those loci across an extended discourse for verb agreement. Between 7 and 8 years of age, children have mastered most of the elements of spatial syntax, including classifier constructions and referential shift. The pattern of acquisition documented for the verb agreement system in sign languages reveals that sign-exposed children acquire the morphology of the language in a componential way, mastering one element at a time before they are able to consistently and flexibly articulate the agreement system.

Late Acquisition

Studies of second-language learning have demonstrated that language is best acquired during infancy and early childhood. This sensitive period of language acquisition is argued to be related to maturational changes in the brain. But what are the consequences of never fully acquiring a first language within the sensitive period? Most of our understanding of late-language acquisition comes from studies of second-language acquisition. With the exception of a few case studies of so-called 'wild children,' little is known about the effects of the late acquisition of a first language. However, the case of deaf children acquiring a sign language late in life gives us greater insight into what aspects of language can and cannot be acquired after the sensitive period.

First-language acquisition in childhood is the norm for typically hearing children but not for deaf children. Ninety percent of deaf children are born to hearing parents who do not know a sign language. Consequently, some deaf children do not learn a sign language until they enter a school that uses one. Others learn a sign language only in adulthood because some schools withhold sign language exposure, believing that it hinders the acquisition of spoken language. No empirical research supports the belief that sign language use interferes with learning a spoken language. In fact, research shows that most deaf children who are not exposed to a sign language early in life rarely acquire full competence in a spoken language. Thus, when congenitally deaf people learn a sign language later in life, it is often their first experience with a fully accessible first language. These circumstances mean that many deaf signers are late learners of a first language.

Research on deaf late learners of a sign language shows that late language acquisition leads to imperfect acquisition. Late learners are less fluent and have poorer comprehension and retention of signed narratives. They make many phonological errors and use words in incorrect semantic and syntactic frames. Their morphology is significantly affected; they tend to produce fewer grammatical inflections than early learners. Importantly, these delays are not related to the number of years of signing experience. When number of years of signing experience is equated, those who acquired the language earlier still show greater proficiency. Age of first-language exposure also affects the ability to acquire a second language. The earlier you learn your first language, the better you are at acquiring a second language at any age. Deaf adults who learned a sign language early in life are more proficient in the spoken language than those who learned a sign language later in life.

Brain Organization

Identifying the neural underpinnings of sign languages helps us understand the role that different areas of the brain play in producing and comprehending all languages, signed and spoken. The study of patients with brain damage and of unimpaired adults using neuroimaging technology, for example, event-related potentials (ERPs), functional magnetic resonance imaging (fMRI), and positron emission tomography (PET), have convincingly demonstrated that spoken language processing primarily takes place in the left hemisphere. Two left

hemisphere regions, Broca's area and Wernicke's area, are involved in speech production and in speech comprehension, respectively. Some researchers have proposed that Wernicke's area plays a role in language comprehension because of its proximity to the primary auditory cortex, and that the left hemisphere's specialization for language evolved because of its sensitivity to rapidly changing temporal patterns found in speech. Such proposals would predict that sign languages are not necessarily processed in the left hemisphere (perhaps relying more on spatial processing in the right hemisphere), and therefore may not recruit Wernicke's area for comprehension.

Most studies, however, have uncovered striking similarities in the neural organization of spoken and sign languages. Sign aphasia is observed only in patients with left, not right, hemisphere damage. In addition, neuroimaging studies have documented left-hemisphere activation in sign language processing. Broca's area (left inferior frontal gyrus) is activated during sign language production, even though signs are articulated manually instead of orally. And Wernicke's area (left posterior superior temporal gyrus) is activated during sign language comprehension, even though signs are perceived visually. Importantly, the iconicity of a sign (e.g., the sign for HAMMER looks like the action of hammering) does not affect its neural processing; the same neural systems are activated for both iconic and noniconic signs. In sum, spoken and sign languages engage similar areas of the brain, indicating that these areas are central to language and that the left hemisphere serves all language processes, regardless of modality.

Although signs, gestures, and pantomimes are articulated in the manual modality, the sum of the research shows that sign languages are processed differently than gestures and pantomimes. Sign aphasics can produce and understand pantomime, but not signs, even signs that appear gestural, like 'BRUSH TEETH'; they can pantomime the act of brushing their teeth but not produce the sign. This dissociation between pantomime and sign in aphasic patients indicates that their sign impairment is not a motor impairment but rather a language impairment. Furthermore, the strong left-hemisphere activation observed for signs and words is not observed for nonsymbolic gesture and pantomime; pantomime activates areas in both hemispheres. However, experience with a sign language does lead to different patterns of activation when observing pantomime; pantomime elicits less activation in the parietal regions of signers' brains versus nonsigners. Further, gesture and sign are not completely independent; similar areas of the brain are also activated when processing signs and gestures. Ongoing research is working to uncover the properties of gesture and sign that lead to a subset of shared neural systems.

Although there is strong left hemisphere involvement in the production and processing of sign languages, some features of sign languages may recruit the right hemisphere. For example, because the facial grammar of sign languages (see section 'Nonmanual Markers') shares some characteristics with affective facial expressions, the facial grammar may be processed in the right hemisphere where affective information is processed. The evidence, however, does not support this claim. Some patients with left-hemisphere damage omit nonmanual grammatical markers but produce affective facial expressions. Conversely, some right-hemisphere damaged patients produce nonmanual markers but omit affective facial expressions.

Neuroimaging studies have also confirmed more left hemisphere involvement for perceiving linguistic facial expressions compared to affective facial expressions. However, the right hemisphere shows some activation during the processing of facial grammar. Whereas nonsigners process all facial information predominantly in the right hemisphere, signers show bilateral activation during the processing of both linguistic and affective facial expressions. Thus, the signing brain may reorganize the neural systems used for affective facial expressions to process the facial grammar of a sign language.

The right hemisphere is also specialized for processing spatial information; most patients with right hemisphere damage have problems perceiving spatial orientation and spatial perspective. Thus, some of the spatial grammar of sign languages may recruit areas in the right, not left, hemisphere. Recall that sign languages talk about spatial relations by mapping these relations in signing space through the use of 'classifier constructions' (see section 'Morphology'). Strikingly, this very aspect of sign languages is impaired in signers with either left or right hemisphere damage. In addition, imaging studies show activation not in Broca's area but in the inferior parietal cortex in both hemispheres for processing spatial classifiers. Studies with nonsigners have demonstrated that as spatial descriptions increase in complexity (e.g., number of objects), more of the right hemisphere is recruited. It has been proposed that the mapping of a real-world spatial relation onto an internal representation of the signing space recruits the areas of the right hemisphere that are crucial for processing how objects are located with respect to other objects in the environment. Even nonsigners show right parietal activation when describing spatial arrays of novel shapes. Thus, the unique characteristic of sign languages that allows for the analogical representation of spatial relations recruits more right hemisphere regions than is observed in spoken languages, where such an analogical representation of space is absent.

As the technology develops, we will learn more about the neural systems supporting the processing of both spoken and sign languages. The inclusion of sign languages in the study of the neurological basis of language has yielded strong evidence that the left hemisphere is specialized for language regardless of modality. However, the mystery of why the left hemisphere is so good at language remains unresolved. In recent years, the neurological study of sign languages has uncovered some of the ways in which sign language and spoken language processing differ. Identifying the similarities and differences between signed and spoken languages tells us which aspects of language processing are universal to all languages, and which aspects are shaped by language modality.

Glossary

Chronotype Morning and evening chronotypes describe the tendency to feel most alert and function optimally at either morning or evening times of the day.

Circadian rhythm A biological rhythm with a period of about 24 h, for example, the sleep–wake cycle.

Electroencephalogram (EEG) EEG is the tracing of brain wave activity typically recorded with electrodes placed on the scalp. The waveforms which vary in frequency and amplitude arise from the postsynaptic potentials of mainly pyramidal-type neurons in the higher cortical layers of the brain.

Lapses Slow or missed behavioral responses during periods of sleepiness which represent deficits in attention processes.

Masking Confounding variables or factors that, if not controlled through careful research design, may remove all measurable effects of sleep deprivation.

Non-REM sleep Includes Stages 1–4 sleep which are increasingly deep stages of sleep.

REM sleep Rapid-eye movement sleep constitutes about 20–25% of the night in adults. It is characterized by saccadic eye movements, low muscle tone, and active EEG.

Sleep architecture The pattern of change in sleep stages as they vary across the night, typically seen as a progression from wakefulness to increasingly deeper stages of non-REM sleep (Stages 1–4), followed by an REM period. The non-REM–REM cycle repeats every 90 min throughout the night in healthy adults.

Sleep debt Describes the cumulative increase in sleepiness and deficits in neurocognitive performance that build up over successive days of sleep loss.

Sleep hygiene Behaviors that promote and are conducive to healthy, efficient sleep. Some examples include a regular sleep/wake schedule, avoiding stimulants, and having a good sleep environment (dark, quiet).

Sleep inertia Refers to the feeling of grogginess one experiences upon awakening. After a full night of sleep, the sleep inertia period lasts from 10 min to an hour or more depending on the nature of the performance test.

Sleep and wakefulness are controlled by two interacting processes: sleep homeostasis reflects the drive or propensity to sleep that builds up while awake, and circadian rhythms are our endogenous biological clocks that govern the timing of when we are sleepy and alert. There is a bidirectional relationship between sleep and waking function. The quantity, quality, and timing of sleep impact waking cognition, emotion, and performance. Waking behaviors also impact sleep. For instance, napping, medications, and common substances like caffeine may affect the ability to sleep at night, and newly learned information and skills are rehearsed and consolidated during sleep. The following article will review the current understanding of the role of sleep and circadian rhythms in waking alertness and performance.

Sleep Characteristics and Function

Sleep is ubiquitous behavior, occurring in all mammals and birds, characterized by observations of reduced movement, a stereotypic posture within species, diminished responsiveness to stimuli, and the ability to awaken (which differentiates it from states like coma or brain death). Since the application of the electroencephalogram (EEG) to the study of sleep in the 1930s, sleep has more often been described by electrophysiological variations in brain waves, eye movement, and muscle activity to determine the stage or depth of sleep. The measurement of sleep is referred to as polysomnography (PSG). Respiration and limb movements are also often recorded in the Sleep Disorders Clinic to assess common sleep disorders. Normal

sleep is characterized by five distinct stages which are called rapid eye-movement (REM) sleep and Stages 1–4 (collectively termed non-REM sleep). Refer to [Table 1](#) for a description of physiological features of each sleep stage relative to the waking state. Healthy young adults will typically fall asleep within 10–20 min, first entering Stage 1 which is a brief transition state to deeper sleep. During this transition, there is awareness of the outside world but dream-like reverie at the same time. The sleeper then descends into Stage 2 sleep, a light stage of sleep that will be the predominate stage of the night. Next, the sleeper moves into deeper sleep, Stages 3 and 4, which is characterized by slow brain waves and is therefore also termed slow-wave sleep (SWS). It is more difficult to awaken the sleeper from this deep sleep, and when roused the person is often confused and reports only vague mental activity. Often after a brief return to lighter sleep or an arousal, the sleeper then enters the first REM period. REM sleep was not identified until the 1950s when Eugene Aserinsky and Nathaniel Kleitman observed periodic eye movements under the lids of sleeping infants. REM is a paradoxical state of sleep where the brain waves are similar to the waking state, yet it is difficult to awaken the sleeper. A defining characteristic of REM is widespread muscle atonia where most of the body's muscles are paralyzed. REM sleep is an active brain state, where the most vivid and bizarre dream reports occur; however, dreaming or mentation is present in all stages of sleep. Identification of the REM sleep state led to a paradigmatic shift in the field of sleep research; sleep was no longer seen as a unitary state. There were two distinct states within sleep, REM and non-REM, which were as different from one another as sleep was from the

Table 1 Physiological features of sleep stages

Wake – alert, eyes open	EEG is low voltage, mixed frequency (e.g., 0.5–70 Hz) and desynchronized. Eyes show scanning of the environment, and muscle activity is high often depicting gross body movement
Wake – relaxed, eyes closed	Alpha EEG waves (8–12 Hz) are predominant
Stage 1	EEG is low voltage, mixed frequency. Alpha waves (8–12 Hz) begin to disappear, theta waves appear (4–7 Hz), and slow rolling eye movements are observed
Stage 2	EEG is relatively higher voltage and slower frequency compared to the waking state. Two periodic EEG events are apparent: (1) sleep spindles (12–16 Hz sinusoidal waves lasting 1–2 sec) and, (2) K-complexes (the largest human brain wave, observable as a biphasic negative wave followed by a positive wave)
Stage 3	EEG is highly synchronized, consisting of large delta brain waves (0.5–4 Hz) for 20–50% of a 30-s time window
Stage 4	The large delta waves appear for more than 50% of the 30-s time window
REM	EEG is low voltage, mixed frequency, and desynchronized. Muscle activity is low, and rapid eye movements appear in bursts

waking state. This distinction led to a greater understanding of brain mechanisms controlling sleep, more focused research methods for dream researchers, and improvements in diagnosis and treatment of a number of sleep disorders (including sleep apnea, narcolepsy, and REM-sleep behavior disorder).

A complete non-REM–REM cycle as described above takes the adult sleeper about 90 min, and then the cycle repeats four to five times throughout the night. REM periods get progressively longer as the night continues. REM thus dominates the later half of the night, while SWS dominates the earlier half of the night. The functions of sleep are still debated among scientists. In general, SWS is thought to play a restorative role for both the brain and the body. There is a great deal of evidence that newly learned information (e.g., language) is consolidated in REM sleep and procedural learning (e.g., learning to play piano) is rehearsed in Stage 2 sleep. The sleep spindle, the 12–16 Hz periodic waveform generated in non-REM sleep, is a marker of this sleep-dependent learning process. Experiments show that spindles increase during the sleep period following procedural learning compared to a control group; they are also correlated with measures of learning potential (i.e., IQ). Sleep also plays a role in maintenance of physiological systems, such as the endocrine and immune systems. It is likely that there are multiple functions for this complex state which takes up approximately one-third of our 24-h day. Some functions of sleep may be primary (i.e., sleep developed to serve that specific purpose), while others may be secondary (i.e., sleep provides an optimal time for certain variables to act or be maintained). Some researchers look to the phylogeny of sleep for clues about its function. By determining the presence or absence of sleep (or REM sleep) in different species through evolution, researchers may be able to

hypothesize when and why sleep emerged as a behavior. The presence of REM in both mammals and birds would be best explained by its emergence in their common ancestor, the reptile. However, there is currently no evidence for REM sleep in modern-day reptiles, and thus researchers surmise that REM must have developed independently in mammals and birds. Despite the lack of understanding about the function(s) of sleep, it is clear that lack of sleep leads to impaired mood and alertness, and deficits in attention and performance.

Sleep and wakefulness are regulated by both homeostatic and circadian processes. Sleep homeostasis refers to the drive for sleep that builds up while awake. SWS is a marker of this homeostasis in sleep; the longer one remains awake, the more intense the SWS during the next sleep episode (i.e., its onset is abbreviated, duration longer, and magnitude of the slow-waves greater). Over the course of the sleep period, the amount of slow-wave activity falls off exponentially as sleep pressure dissipates. In the waking state, theta brain wave activity (i.e., 4–7 Hz waveforms in the EEG) is thought to reflect this homeostatic process because its presence increases in parallel with the level of sleepiness.

Widespread brain regions and mechanisms are implicated in the control of sleep and wakefulness. In order to determine what areas of the brain play a role in wakefulness, non-REM and REM states respectively, researchers use techniques such as transection (cutting the brain tissue systematically at different areas to determine if the behavior remains intact), lesions (destroying brain tissue in isolated areas), or chemical or electrical stimulation. Using these methods, researchers have determined that wakefulness is controlled by neurons located in the ascending reticular activating system (ARAS) of the brainstem. Neurons in this area project to the thalamus, hypothalamus, and basal forebrain, and from there project to the cortex which results in the EEG activation observed in wakefulness. Sleep onset involves active inhibition of neurons in ARAS, which in turn leads to the generation of sleep spindles from the reticular nucleus of the thalamus, effectively blocking transfer of information to the cortex. The spindles and delta waves recorded on the scalp during non-REM sleep arise from hyperpolarization of thalamocortical systems. Lesions to areas in the brainstem and forebrain will lead to loss of SWS, while stimulation will lead to EEG synchrony. Transection studies reveal that the pons and medulla brain areas are needed for the generation of REM sleep. In sum, there is not one single localized area in the brain that controls sleep; rather, sleep is a behavior that involves widespread regions and connections throughout the brain.

Circadian Rhythms

A biological rhythm is an event or function that repeats over time with a predictable period. Circadian (meaning ‘about a day’) rhythms are those with a period of about 24 h. These daily biological rhythms are controlled by our endogenous clock, the suprachiasmatic nucleus (SCN), located at the base of the hypothalamus in the brain. Peripheral oscillators have also been identified in cells and organs throughout the body which may play a role in regulation of various physiological systems and health; however, the SCN is regarded as the master clock controlling the timing of sleep and wakefulness.

These rhythms are linked to and reset by the natural light–dark cycle in our environment. They control fluctuations in physiological variables, arousal, mood, and performance. Ultradian rhythms are those that have a period of less than 24 h. Examples of ultradian rhythms are the non-REM–REM cycle that repeats throughout the night, and a basic rest and activity cycle (BRAC) that describes peaks and troughs in our alertness level throughout the day. Both have a periodicity of about 90 min.

Homeostatic and circadian processes interact to determine our level of alertness and the timing of sleep onset and awakening. Circadian rhythms determine the timing of sleep and wakefulness, but they do not explain the function(s) of sleep. Circadian rhythms can be measured in individuals using core body temperature or melatonin concentrations in urine. An early afternoon period of reduced alertness and performance commonly referred to as the postlunch dip is in fact determined by a nadir in circadian rhythms and not actual food intake. A time of peak alertness occurs in the early evening and has been called the forbidden zone because it is a time when it is most unlikely to fall asleep in a nap. A number of neuroendocrine factors are under circadian control. For example, cortisol and prolactin rise and fall within the 24-h period regardless of whether sleep takes place. Other factors such as growth hormone and thyroid-stimulating hormone are sleep-dependent; they are secreted during sleep and will not be released when deprived of sleep. Sleep disruption will alter the natural secretion profile of these endocrine factors which is thought to contribute to the negative health consequences of chronic sleep loss.

Circadian rhythms can be altered by natural light in the environment and other zeitgebers. Zeitgebers are external cues that synchronize circadian rhythms with the environment. In addition to the light–dark cycle, other nonphotic zeitgebers controlling our circadian rhythms include food and a variety of social interactions and habits. Our biological rhythms are entrained or reset by these zeitgebers each day. If we are removed from the influence of these external time cues (e.g., living for an extended period in a bunker or cave with no natural light or other time cues), we begin to free-run, that is, the usual 24-h period of the circadian rhythm changes, resulting in the timing of sleep/wake episodes shifting systematically around the clock. In summary, circadian rhythms are physiological phenomena which allow organisms to interact with their environment in an optimal or efficient manner.

Circadian rhythms can be disrupted by conditions such as shift work, jetlag, and daylight savings time. Research has shown that the disruption to sleep and circadian rhythms following daylight savings time in the Spring leads to increased automobile accidents on next morning. It is more difficult to adapt to the clock change in Spring when the clock is moved forward compared to the Fall when it is moved back; this is because it is more difficult to phase-advance our rhythms (i.e., going to bed earlier vs. staying up late). Humans can adapt to changes in timing and schedules more easily by shifting sleep episodes gradually and seeking or avoiding daylight exposure appropriately. There are individual differences in the ability to adapt, particularly with shift work and especially if the shifts changes are rapid (e.g., after limited time off), extreme (e.g., days to midnights vs. days to evenings), or

require phase-advancing. Shift work becomes more difficult to adapt to for older adults and has been associated with higher cancer rates in women. A maladaptation syndrome has been described which outlines factors associated with the likelihood of failure to adapt to shift work. These factors include fixed ones, such as age and individual differences in tolerance or adaptability to changes in circadian rhythms, and adjustable factors, such as work and social schedules. Taken together, these factors aim to predict individuals who will fail to adapt immediately and over months to years of shift work. One particular individual difference variable that may affect the ability to tolerate shift work or disruptions to sleep schedules is one's chronotype. Morning or evening types that feel they function optimally during morning or evening hours respectively have long been referred to as larks and owls. Recent research has identified genetic markers underlying these chronotypes that may account for their differences in tolerance to sleep deprivation.

There are disorders of circadian rhythms that disrupt the timing of sleep and wakefulness. If sleep cannot occur at the appropriate time, sleep architecture and quality of sleep are affected. In turn, waking arousal, mood, and performance are impacted. Some disorders of circadian rhythms include: delayed phase syndrome, advanced phase syndrome, jet lag, irregular sleep/wake pattern, and non-24-h sleep/wake syndrome. In advanced or delayed sleep phase syndrome, the total sleep time is the same as a normal bout of sleep, but the timing is different (e.g., an advanced sleep phase may occur 9 p.m.–5 a.m. and a delayed sleep phase may occur 2–10 a.m.). Older adults are normally somewhat phase-advanced and adolescents are normally phase-delayed, but delayed or advanced phase syndromes can occur at any age. Jetlag occurs when there is a misalignment between one's endogenous circadian rhythms and the zeitgebers of the destination several time zones away. Although one may experience fatigue associated with a long-distance travel, jetlag is specifically the result of travel east or west across three or more time zones. Traveling east is more difficult because it requires the biological clock to phase-advance as opposed to delay. Irregular Sleep/Wake Pattern refers to a disorganized pattern of sleep and wakefulness due to a loss of circadian rhythms, where the total amount of sleep may be normal but it is fragmented. It is often seen in Alzheimer's patients or other neurological conditions where there is damage or reduced function of the SCN. Non-24 h sleep/wake syndrome refers to a sleep cycle that has a periodicity of more than 24 h. For these individuals, the sleep period is continually phase-delayed around the clock, leading to difficulties in falling asleep at the desired time and daytime sleepiness. All of these disruptions to circadian rhythms make sleep less optimal and less efficient thereby affecting waking arousal and performance.

Sleep Need

Each person has an individual sleep need (e.g., a person with a 9-h daily sleep requirement cannot function well on less sleep). While adults sleep 7.5–8 h on average, people vary in their sleep need with most adults reporting a habitual sleep time between 6 and 9 h. Women report a greater sleep need

than men. A small number of people are thought to be true short sleepers, that is, they sleep efficiently for a short time (e.g., <5 h), but experience no ill effects in their waking function. Research has shown that both short and long sleepers have a shorter lifespan. While this striking finding has been replicated many times in various cultures, it is not known to what extent sleep length is causally related to mortality. Other factors such as health and genetics that are related to sleep likely play a role. There is no evidence that we can change our innate daily sleep need. The strong homeostatic drive for sleep generally ensures that we typically meet our personal biological sleep need. However, sleep and medical disorders, normal aging, and intentionally reducing sleep due to work or social demands can impact the ability to get the sleep one needs.

Sleep Across the Lifespan

Sleep duration and characteristics, as well as circadian control of sleep, vary considerably across the lifespan. In utero, sleep/wake patterns are irregular and poorly organized, and are in part dependent on the mother's sleep/wake cycle, hormones, and substance intake. By about 12 weeks of development, a state similar to non-REM sleep is apparent; REM is evident by 36 weeks. The newborn baby shows a phase-delay each night around the clock, such that sleep occurs later and later each night, and then begins to entrain to external cues around 16 weeks. The newborn sleeps 16–18 h per day, and spends about 50% of that time in REM sleep. Their non-REM–REM cycles are shorter than adults, with a periodicity of about 50–60 min. Researchers have argued that this large proportion of REM sleep in newborns is evidence in support of a role for REM sleep in learning and memory because newborns have a tremendous amount of novel information to process. Adult-like sleep stages are apparent by 6 months of age. The toddler has well-organized and entrained circadian rhythms, and by age 2 he or she typically takes only one nap per day. They sleep 11–12 h of the day, and REM sleep is already reduced to about 25% of the sleep period. In children aged 6–12, sleep is extremely well organized and entrained. Sleep efficiency, that is, percentage of time in bed spent asleep relative to time awake, is 95–97%, the best it will be over the entire lifespan. Daytime naps are no longer needed, but children may continue to nap. Children require 9–11 h of sleep, but many do not achieve this optimal amount of sleep due to early school start times, poor sleep habits, or lack of parental guidance on healthy sleep behavior. At this time, REM sleep has already reduced to about 20% and will remain at that level for the remainder of life; SWS has peaked and already begun to diminish. In adolescents, circadian organization is reduced and there is a tendency for phase delay, that is, going to bed later and sleeping longer. Although adolescents now have adult-like 90-min non-REM–REM cycles, they still require 9 h sleep on average. The amount of SWS has diminished considerably, by 30–40% relative to childhood, and sleep is more fragmented. The tendency for a phase delayed rhythm, combined with the 9-h sleep need and earlier school start times in many high schools, leads to significant problems with daytime sleepiness and poor academic performance in adolescents as a group.

Sleep in adults can be quite organized and efficient; however, lifestyle factors, behaviors, and poor sleep hygiene can grossly disrupt sleep. For example, shift work, high social or work demands, alcohol and drug use, and prescription medications will affect the sleep–wake patterns in otherwise healthy young adults. Adults sleep, on average, 7.5–8 h, although, as mentioned previously, there are considerable individual differences in sleep need. While total sleep time and sleep architecture are generally similar for men and women, premenstrual symptoms, pregnancy, and menopause can have profound effects on sleep due to both hormonal changes and associated physical symptoms. Women report a greater incidence of insomnia, whereas men are diagnosed more often with sleep-related breathing disorders. Older adults as a group sleep on average about 6 h, but often spend more time in bed which leads to greater sleep fragmentation and reduced sleep efficiency. They tend to be phase-advanced, going to bed earlier and waking up earlier. Most of the common sleep disorders increase in prevalence with age (e.g., insomnia, sleep apnea, periodic limb movement). Importantly, the age-related change to sleep duration is not thought to reflect a change in sleep need but rather a change in the ability to sleep. The brain's ability to regulate sleep and the function of the SCN are thought to be compromised as we age. There are a number of changes to sleep architecture with aging, including less SWS, fewer spindles, and smaller amplitude K-complexes. One interesting gender difference in sleep is apparent in older adults; the age-related decline in SWS begins much sooner for men than women.

Despite the fact that we outgrow our biological need for daytime naps in childhood, many adults continue to nap throughout the lifespan. Indeed, for some cultures, daily napping is the norm. For healthy adults, napping leads to improvements in alertness and well-being without disrupting the ability to sleep at night. For poor sleepers, who have difficulty falling asleep and staying asleep, naps are not recommended because they may reduce the efficiency of sleep at night. People nap for a variety of reasons. Naps may be taken to recover from sleep loss, as a prophylactic measure to minimize sleepiness and performance impairment for an upcoming period of extended wakefulness, or for appetitive reasons. Older adults nap more frequently, possibly due to increased time for napping in retirement or to compensate for age-related changes to sleep quality and increased daytime sleepiness. Naps of 10–20 min have been shown to have benefits for alertness and performance with minimal sleep inertia (i.e., the grogginess experienced upon awakening). Longer naps allow time to enter SWS and REM which will result in greater sleep inertia. Naps longer than 20 min are therefore not recommended, particularly in the workplace where it is necessary to awaken and return immediately to work duties.

Sleep Deprivation and Performance

The first research study on the effects of sleep loss on human performance was published by Patrick and Gilbert in 1896. Despite not having the use of technology that exists today to measure brain activity, a number of observations were made about human behavior that remarkably still hold true today.

These early researchers noted uncontrollable micro-sleeps or naps, dream reports during these brief periods, mental lapses during performance, diurnal variation in performance, and recovery sleep that was characterized by deeper sleep. Although few studies were conducted in the first half of the twentieth century, some contributions of this early work included identifying task characteristics that were sensitive to sleep loss (e.g., long tasks, requiring more extensive processing and sustained attention), revealing factors that masked deficits in performance (e.g., learning, effort, motivation), and observations of variability in the data (both individual differences and diurnal fluctuations). This early work on sleep deprivation was driven by an interest in elucidating the functions of sleep; removal of a behavior would reveal its function. However, sleep deprivation was not found to be an ideal way to determine its function since researchers cannot entirely eliminate sleep (e.g., micro-sleeps and brain slowing occur despite efforts to remain awake), and when we deprive individuals of sleep, we are replacing it with extended wakefulness (to which there may be physiological consequences apart from the lack of sleep).

The use of EEG to study sleep, first applied in the 1930s, drastically changed the number of studies performed in this area and the knowledge gained on the effects of sleep loss. The 1950s through the 1970s was a period of intense study into the effects of sleep deprivation, largely driven by a military interest in optimal human performance and sustained operations. This work further refined our understanding of the types of performance tasks that were impaired during sleep loss. Researchers described and characterized changes in EEG associated with the frequent pauses in reaction time; they referred to these momentary changes in responsiveness as lapses. These lapses were observed to accompany EEG changes similar to those seen at sleep onset. Quantitative analysis of the EEG spectra has shown that alpha (8–12 Hz) and theta (4–7 Hz) are sensitive markers of physiological sleepiness. Similar to EEG changes seen at sleep onset, a sleepy individual with eyes closed will show lower alpha and higher theta EEG. When recorded with eyes opened or during task performance, alpha, theta, and high-frequency EEG bands (e.g., beta, 16–30 Hz) are higher in sleep-deprived compared to well-rested individuals. During task performance, greater alpha reflects inattention and greater beta may be associated with effort (i.e., the sleepy participant exerting more effort to perform on the task). A few studies have shown that these EEG changes are strongest at frontal sites. Over several days of continuous sleep restriction, the frontal brain regions show reduced arousal immediately, while posterior regions are preserved until the restriction is more severe. This corresponds with findings that performance tasks involving frontal brain regions (e.g., involving organization, planning) are compromised during sleep loss. Studies examining the brain's processing of stimuli using event-related potential (ERP) techniques show that sleep deprivation impairs attentional mechanisms involved in early encoding as well as more complex cognitive processing such as target discrimination and novelty processing.

Brain imaging techniques can provide insight into understanding behavior during sleep loss by identifying brain areas associated with the performance deficits. The earliest studies used PET imaging techniques and showed that certain brain areas were deactivated during sleep loss (notably the thalamus

and cortical regions), and that the extent of deactivation increased with the length of time awake. Later, using fMRI imaging techniques, a series of studies showed patterns of either brain activation or deactivation that seemed to depend on the specific task that was performed during the brain scan. Drummond put forth the compensatory recruitment hypothesis to explain the phenomena that additional brain regions (e.g., parietal regions) could be activated in order to compensate for reduced function in other brain regions (e.g., frontal). Thus, the brain appears to be adaptable during the challenge of sleep deprivation which may explain performance instability and variability during sleep loss. It is not currently known what limits or constraints influence such brain adaptation during sleep loss.

Together, a substantial body of research on sleep loss, conducted for more than a century, converges to show that performance and well-being are profoundly and systematically affected by sleep loss. Sleep loss impairs alertness and mood, memory and attention, visual and motor acuity, and response time. Meta-analyses show that mood is one of the most robust effects and that reaction time is impacted more than accuracy. Despite the fact that mood changes were described in the earliest studies on sleep deprivation, and that alteration to mood is one of the most reliable findings in this large body of research, researchers have just recently begun to explore the impact of sleep loss on emotion regulation and reactivity. Many neuropsychological tests are not ideally suited to assess cognitive deficits related to sleepiness because they were designed to assay more severe and stable impairment. One of the hallmark features of performance during sleep loss is increased variability in performance. Indeed, brain function and performance do not simply decrease linearly as the extent of sleep loss worsens. Human performance varies because of homeostatic and circadian influences, other factors at play such as effort, motivation, the environment (see section 'Factors Affecting the Impact of Sleepiness on Performance'), and rapid fluctuations in arousal and attention. Despite being awake for more than 24 h, a medical resident may be able to perform a particular task with 100% accuracy at one moment; however, the sleepy brain will lapse more often and for longer periods of time. This lapsing in attention is beyond one's control and leads to performance variability and failure (including catastrophic accidents in the case of the transportation workers and power station operators).

Studies of total sleep deprivation (i.e., greater than 24 h awake) have helped to reveal the nature of impairment during extreme levels of sleep loss. More recently, researchers have focused on levels of sleep loss more commonly experienced in modern society and have approached this research with an interest in understanding the impact of sleepiness on health and safety. Sleep fragmentation studies have been carried out in healthy, good sleepers to model the type of frequent disruption to sleep that occurs in disorders like apnea and periodic limb movement. These studies show that when sleep is fragmented, without reducing total sleep time, deficits in performance and information processing are apparent. Thus, sleeping for a consolidated, uninterrupted period of time is important for optimal waking function. Studies of continuous sleep restriction (e.g., reducing an 8-h sleeper down to a daily sleep time of about 5 h for a week or two) have shown that deficits in performance and physiological arousal and attention accumulate

over the period of sleep restriction. Moreover, there is a dose-response effect, such that the deficits in neurobehavioral performance and EEG arousal change systematically with the degree of sleep restriction. Most remarkable is that the performance deficits observed even after a night or two of sleep restriction are similar in nature and extent to those reported following total sleep deprivation. Researchers are now interested in the impact of a long-term sleep debt from chronic sleep restriction on performance and health, as well as understanding factors related to individual differences in vulnerability (or resiliency) to sleep loss.

Research has also been carried out to investigate performance during the recovery period following either total sleep deprivation or cumulative sleep restriction. Recovery sleep will not be equal in duration to the exact amount of sleep lost. Instead, sleep will be somewhat longer than usual in duration, but it mainly changes in character. A sleep-deprived individual will typically fall asleep immediately, descend into SWS more rapidly, and spend more time in both SWS and REM. The lighter Stage 2 is minimized in order to get more SWS and REM. Performance and well-being may not improve after a single night of recovery. More research is needed to characterize the time course of recovery for various types of performance tasks, the physiological aspects of sleep associated with recovery, and individual differences in the extent of recovery. People should take caution in assuming they can make up for lost sleep at some later time. One reason for this is that the effects of sleep loss, even a few hours on a single night, have consequences for performance and safety on the following day. In other words, one cannot wait for the weekend to catch up on sleep lost during the week. Secondly, chronic sleep restriction has been shown to have long-term consequences for health, including increased risk of weight gain, diabetes, heart disease, and depression.

Factors Affecting the Impact of Sleepiness on Performance

There are a number of factors that will affect the degree of sleepiness and performance deficit that is experienced during sleep loss. Researchers need to be aware of these influences when studying the impact of sleep loss on performance. A failure to control or account for these factors may lead to erroneous conclusions about the effects of sleep loss. Factors that affect homeostatic and circadian processes, individual differences in participants, variation in arousal, and testing conditions may all play a role. The following variables may mask or cover up the true effects of sleep loss on human performance in an experimental setting. These factors could also influence the level of subjective alertness and perception of impairment in individuals who are not getting sufficient sleep.

Time of Day

Due to both circadian influences and the number of hours since awakening, the time of day can affect the sensitivity of measures in revealing deficits due to sleepiness. For people with regular sleep schedules, peaks in alertness and performance typically occur in the morning (9 a.m.) and evening (6 p.m.);

troughs occur following lunch (1 p.m.) and mid-afternoon (4 p.m.). A person who has stayed up all night will experience a period of relative well-being early in the morning despite having been awake; this is due to the underlying circadian rhythms.

Sleep History

The amount and quality of prior sleep and the duration of time since awakening could affect performance assessment due to variation in homeostatic sleep pressure. Moreover, cumulative sleep debt will influence the extent of sleepiness and performance deficit that is experienced in an acute sleep loss scenario.

Individual Differences

The same amount of sleep deprivation may affect people in different ways, some showing greater vulnerability while others apparent resiliency. Factors contributing to these individual differences may include sleep history and habits, genetics, gender, intelligence, experience with sleep loss, etc. General health and fitness, as well as personality, mood, or psychiatric disorders may also play a role.

Gender

Much of the earlier work on sleep deprivation was done primarily on male subjects, and more recent work lacks the sample size to properly investigate the influence of gender. Studies are needed which systemically investigate the effects of sleep deprivation in male and female participants matched for age and education, as well as investigation of phases of menstrual cycle.

Genetics

Circadian rhythms are under genetic control and the genetic basis of chronotypes has been described. While one's circadian profile might influence the impact of sleep disruption, the genetic basis of sleep homeostasis (i.e., differences in sleep pressure) has not been determined.

Age

Sleep deprivation is generally not as well tolerated in older adults. However, in some cases, older individuals may perform better than younger adults during sleep loss due to other factors that vary by age such as motivation or conscientiousness. Alternatively, a task involving fine motor movements practiced in video games may be better performed by the younger group simply due to experience with similar technology.

Health

General health may affect mood, arousal, and tolerance to sleep deprivation.

Exercise

Exercise will influence heart rate, body temperature, and ultimately arousal level. If aerobic activity is not controlled in a sleep deprivation study, participants could use exercise to temporarily improve arousal for periods of time.

Substance Intake

Food, beverages, over-the-counter vitamins and herbal remedies, and pharmaceutical drugs all could increase arousal and mask the effects of sleep loss. The influence of food and drugs on the central nervous system must be understood and controlled, for example, caffeine and nicotine use is typically eliminated in experimental investigations of sleep deprivation.

Effort/Motivation

Both effort and motivation may influence the level of performance during sleep loss. For this reason, short tasks are generally avoided since it is possible to maintain effort and motivation for short periods of time.

Workload/Fatigue

Tasks or performance batteries that are too long or demanding on participants may lead control participants to show performance deficits due to workload or fatigue. Thus, ample breaks are needed when monitoring human performance over an extended period.

Environment

Light, temperature, and noise all could influence the effects of sleep deprivation by impacting arousal level. Typically, the light and temperature are kept constant during a sleep deprivation protocol.

Practice Effects

If a participant continues to perform better on a task over time due to practice, learning, or insight into the task, the effects of sleep loss could be diminished. It is thus important to choose tasks that do not have a substantial learning curve (e.g., simple reaction time) or make sure that participants have ample practice before the experimental manipulation of sleep (e.g., achieve a high score or asymptote level of performance).

Test Characteristics

A variety of test characteristics can influence the extent to which individuals will show deficits during sleep loss. For example, deficits are more likely to be captured in tasks that are of longer duration, more difficult, and cognitively complex. Further, tasks involving multitasking, no feedback on performance, and a fast, automated rate of presentation will optimize the likelihood of measuring deficits due to sleepiness.

Conclusion

Daytime sleepiness is a pervasive phenomenon in contemporary society. People experience sleep loss because of lifestyle choices, shift work, normal aging, and sleep and medical disorders. Sleep loss leads to impairments in broad aspects of waking function, including mood, arousal, attention, memory, and visual-motor function. The risk of performance failure and accidents increases as the length of sleep loss continues. Sleep restriction that is chronic over days to weeks has an impact on waking performance similar to that seen following total sleep deprivation. It is important for people to know their individual sleep need and to make an effort to get this amount of sleep each night. Insufficient sleep has profound consequences for alertness and performance as well as health, safety, and productivity. Future directions of research in this area aim to elucidate the neural mechanisms controlling performance deficits, and the nature of individual differences in vulnerability to sleep loss.

Glossary

Apnea Abrupt cessation of respiration.

Cataplexy Abrupt paralysis of muscle tone.

Chronotherapy Treatment of sleep–wake schedule misalignments by resetting the biologic clock.

Circadian rhythm Near 24 h rhythm.

CPAP Device used for noninvasive ventilation.

Hypopnea Shallow respiration.

Neurosomnology Body of neurological sleep disorders.

Parasomnia Undesirable motor or sensory events during sleep.

Polysomnogram Recording of sleep parameters.

Polysomnography Registration of nocturnal sleep physiologic parameters.

Introduction

Sleep is a universal function of all vertebrates and some invertebrates. Sleep develops, matures, and declines in consonance with other functions of the brain. Despite extensive research, the ultimate physiological function of sleep remains unknown. It is known, however, that sleep intervenes in functions of growth, regeneration, and memory.

Such is the importance of sleep that its severe and prolonged deprivation may lead to death in lower mammals. Severely sleep-deprived humans have an uncontrollable tendency to fall asleep and appear slow when performing mental or motor tasks. Profound sleep deprivation has been equated to the effects of alcohol intoxication. Most individuals require between 6 and 8 h of sleep at night. In Mediterranean countries, the daytime siesta allows subtraction of an equivalent amount of time from nocturnal sleep.

Sleep is a preconceived function of the brain modulated by the circadian rhythm. Nocturnal sleep progresses in stages and cycles. In the first half of the night, non-REM sleep (N1 – light sleep, N2 – intermediate sleep, and N3 – deep sleep) predominates, whereas in the second half, rapid eye movement (REM) sleep or dream sleep is increasingly prevalent. The fetus spends much of its time in REM sleep and the infant shows great abundance of REM sleep. Sleep exhibits consolidation to the nocturnal period by the age of 2 years, with ~25% of the total time asleep in REM sleep. In old age, deep stages of non-REM sleep decline while REM sleep remains at 20–25% of total sleep time, despite modestly reduced requirements of total sleep every 24 h.

Polysomnography is the name of the clinical method used to record nocturnal sleep and to register clinical phenomena associated with it. The technique is generally performed in the sleep laboratory and combines recording of brain waves, eye movements, electrocardiography, electromyography, respiratory excursions, and saturation of oxygen. Video-taping of the sleeping individual serves to record motor behaviors when present and constitutes an integral part of polysomnography.

Landmarks in sleep research have included the discovery of various forms of brain waves during sleep that determine the different stages of sleep, as well as the discovery of REM sleep and its association with dreaming. The identification of the brainstem and the diencephalon (thalamus and hypothalamus) as centers of localization of sleep generation, and the

discovery of hypocretin (also called orexin), a neurotransmitter produced by the hypothalamus that is necessary to maintain alertness, have given anatomical and physiological structure to the clinical science of sleep.

More than 80 clinical sleep disorders are codified in the 2005 International Classification of Sleep Disorders and the list keeps growing. Sleep disorders may provoke family pathology, disturb work routines, alter social activities, increase the risk of serious accidents, and affect the health of the affected person. Sleep disorders are common and pervasive, modifying the quality of life of the individual. Excessive daytime somnolence may lead to motor vehicle accidents, poor academic performance, reduced work productivity and social decline. On the other hand, sleeplessness causes fatigue, daytime misery and reduced efficiency. Although sleep is a function of the brain and the brain is central to most sleep alterations, a variety of clinical specialists other than neurologists, psychiatrists, and psychologists are interested in sleep and its disorders. This diversity illustrates the ubiquity and far reach of sleep alterations. Sleep disorders may not only cause abnormal nocturnal behaviors but may also modify respirations, heart function, endocrine secretions, blood composition, and cause many other significant changes. Medicine for sleep disorders uses diagnostic tools centered in the sleep laboratory, and sleep specialists have been trained to procure comprehensive management of most sleep afflictions.

Neurosomnology is an active subspecialty of neurology and of sleep medicine that will acquire increasing notoriety among neuroscientists and clinical neurologists as basic and clinical research continue to unravel the neurological intricacies of sleep and its disorders. The growth of sleep medicine will follow the expansion of neurosomnology. As a function localized in the brain, sleep is channeled in the dynamics of growth, maturation, and decline that modulate other complex functions also localized in the brain such as cognition and language. Sleep lodges in a multiplicity of structures tightly linked in a network of nuclei and tracts served by neurotransmitters that respond to the mandates of the circadian rhythm. The demands to comprehend and manage sleep dysfunctions is driven by sleep disorders as a medical discipline, in which ailments such as narcolepsy, sleep apnea, restless legs syndrome (RLS), and others are studied. Evolving fronts are also emerging in the academic camp where alertness is needed to enhance learning

efficiency, as well as in government sectors to reduce fatigue while improving safety on the road; in labor, where guidance is required to best align shift-work programs; and in aerospace science, where jet-lag creates safety hazards.

Restorative sleep, like a healthy diet and regular exercise, has become one of the pillars of today's health program. And yet, violations continue to occur despite the fact that sleep is the only free voluptuousness given to humans by nature. Better education and more widespread access to sleep clinics will undoubtedly increase public respect for the importance of sleep and enhance prevention of sleep disorders, while improving their management by certified sleep specialists in accredited sleep centers.

History of Sleep Medicine

The intuition that altered sleep was a manifestation of poor health and vice versa was tersely expressed by Hippocrates (~460–370 BC) in his aphorism 'Somnus, vigilia, utraque modum excedentia, malum' (sleep and wakefulness, when excessive, anticipate a bad prognosis). In the middle ages, the Persian Avicenna (980–1037) identified in his Canon, three factors conceding good quality to sleep: continuity, depth, and duration. Furthermore, Avicenna stated that sleeping supine weakened the body, a phenomenon that is well established today in patients with sleep apnea.

In Vienna, Sigmund Freud (1856–1939) and his disciples popularized the analysis of dreams as a portal to subconscious brain content. Hans Berger's (1873–1941) demonstration in Germany of changes in the electroencephalogram during sleep provided the first confirmation that the dormant brain is functionally active. In the early twentieth century, the classic neuropathological studies of encephalitis lethargica by Constantin von Economo (1876–1931) in Vienna localized sleep functions to the hypothalamus. Later in the century, experiments of thalamic stimulation and the discovery of the reticular activating system of the brain provided major advances in the understanding of the neuroanatomical substrate of sleep and wakefulness. In the 1950s, the identification of paradoxical sleep or REM sleep in the cat by Michel Jouvet (1925) in France, the association of dreaming with REM sleep reported by Eugene Aserinsky (1921–1998) and Nathaniel Kleitman (1895–1999) in the United States, and the detection by William C. Dement (1928) and Eugene Aserinsky in the United States of periodic cycles of REM and non-REM sleep throughout the night led to a new view of sleep as an active process with distinctive neurophysiologic substrates underlying two major states, non-REM and REM sleep.

The recognition of specific sleep disorders started in the latter part of the nineteenth century. The neuropsychiatrist Jean-Baptiste-Édouard Gélinau (1859–1928) practicing in Paris described several patients with irresistible sleep and brief episodes of muscle collapse. He termed the condition narcolepsy and called the collapses cataplexy. The breathing disorder of sleep, popularly known as sleep apnea, was first described by various European investigators in 1965. Today we know that sleep apnea affects up to 4% of the general population and is a risk factor for aggravation of several vascular diseases such as hypertension, myocardial disease, and stroke, and for ailments

such as diabetes. The first sleep clinics devoted specifically to diagnose and treat sleep disorders appeared in the 1970s. In the United States, the Association of Sleep Disorders Centers was organized in 1975 and provided a strong platform for the development of sleep disorders medicine. Specialized journals appeared soon after and the first classification of sleep disorders was published in 1979. The International Classification of Sleep Disorders was updated in 2005 by the American Academy of Sleep Medicine. By the end of 2005, 3249 professionals in the United States were diplomates of the American Board of Sleep Medicine. The first board exam on sleep medicine sponsored by the American Board of Medical Specialties took place in November 2007. National and international sleep organizations have proliferated worldwide and the first World Sleep Day was celebrated on March 14, 2008, under the slogan *Sleep well, live fully awake*.

Major Sleep Disorders

Sleep complaints generally fall into the following categories: insomnia, excessive somnolence, snoring and sleep breathing difficulties, sleep-wake cycle disruptions (circadian dysrhythmias), bizarre sleep-related behaviors (parasomnias), and sleep-related movement disorders. Insomnia refers to difficulty falling asleep, staying asleep, awakening too early, and a feeling that sleep has not provided the usual sense of restoration. Conversely, excessive daytime sleepiness is the term for pervasive drowsiness and unwanted sleep episodes during waking hours. Circadian dysrhythmias are disorders of timing of the sleep/wake pattern with the night/day cycle. Parasomnias are defined as undesirable physical phenomena that occur primarily during sleep. A particular sleep disorder may be associated with one or more major categories of symptoms. The chief complaint provides a focus for assessing the disorder of sleep. Information from the bed partner or other observers must often be obtained, as many patients are partially unaware of their sleep manifestations.

The daily schedule, including time of awakening and going to bed; time of naps; time of meals and social activities; and time and use of caffeine, alcohol, tobacco, and prescription and over-the-counter medications may point to particular sleep disorders. Patients with excessive sleepiness may describe drowsiness, increased need for sleep, or irresistible daytime sleep episodes. Mild sleepiness most often occurs after lunch in the afternoon particularly in quiet, boring situations, while severe sleepiness may render the patient asleep when eating, in conversation, or while standing even in the mornings.

Symptoms associated with sleep provide important clues to diagnosis. Loud snoring and witnessed apneas during sleep strongly suggest the presence of obstructive sleep apnea. This condition is highly prevalent in the general population and is one of the most common sources of daytime fatigue, as well as a risk factor for a variety of vascular disorders and motor vehicle accidents.

Generalized muscle abrupt weakness in conjunction with laughter or other emotions is characteristic of cataplexy, which in combination with excessive sleepiness is virtually diagnostic of narcolepsy.

Patients who complain of insomnia may have a psychophysiological disturbance or a psychiatric disorder affecting

sleep. Insomnia and excessive daytime sleepiness may also occur as a result of a circadian rhythm disorder like jet-lag syndrome, shift-work, or more rarely congenital delay of the onset of sleep. Patients with parasomnias complain of a variety of abnormal nocturnal sensations or exhibit bizarre movements, behaviors, or bodily events. Some patients are entirely unaware of the nighttime activity, and a history from the bed partner or other observers is necessary. Some of the more distressing symptoms include nocturnal urinary incontinence (enuresis), shouting or screaming, and violent motor behaviors.

Sleep Apnea

Sleep apnea is a very common disorder and a major sleep-related risk factor for cardio- and cerebrovascular disease. It is also known by the name of sleep-disordered breathing. It becomes the sleep apnea *syndrome* when snoring and sleep-related respiratory lapses are associated with clinically significant symptoms, such as excessive daytime sleepiness and morning headaches. The sleep apnea syndrome affects 2% of women and 4% of men in the general population. It becomes increasingly common as age advances past 45 years and is very prevalent in morbidly obese individuals with a BMI higher than 40 kg m⁻². Snoring when loud, sustained, disruptive, and obnoxious is a marker of clinically significant obstructive sleep apnea and in itself a source of disease. In addition, patients with sleep apnea exhibit lapses in respiration (apneas), shallow respirations (hypopneas) and restless sleep, as reported by bedmates; they also complain of excessive daytime somnolence, morning headaches, physical and mental fatigue, and depression.

The presence and severity of sleep apnea are best diagnosed with attended full polysomnography in the sleep laboratory. Unattended home polysomnography with limited recording channels is acceptable but serves best as a follow-up diagnostic tool. Treatment of sleep apnea with noninvasive positive airway ventilation is generally successful. Compliance with treatment applications has failed in about one fourth of patients, particularly when sleep apnea is of mild severity. For mild forms of sleep apnea the application of mandibular advancement devices, also known as oral appliances, can be beneficial. Surgery removing excessive tissues in the oropharynx may be considered for individuals who cannot tolerate noninvasive equipment or who have severe obstruction to airflow in the oropharynx by redundant tissue growth that includes globular tonsils. Excessive daytime somnolence generally improves with successful treatment of sleep apnea.

Epidemiological studies have shown that the severity of sleep apnea determines the risk of developing vascular complications such as systemic hypertension, stroke, myocardial infarction, and sudden death in sleep. There is proof that successful correction of sleep apnea with noninvasive positive airway pressure ventilation lowers ambulatory mean blood pressure. More recent reports have suggested that clinically significant sleep apnea is also a risk factor for development or aggravation of diabetes.

There is a strong association between sleep apnea and traffic accidents. In patients with an apnea/hypopnea index (AHI) of 10 events or higher, the odds ratio for having a traffic accident is multiplied by a factor of 6. Consumption of alcohol increases the odds even further.

Narcolepsy

Narcolepsy is characterized by severe, unrelenting excessive daytime sleepiness. In the classic form, cataplexy is added, often in association with sleep paralysis and hypnagogic hallucinations. Gélinau coined the term 'narcolepsy' (narcos = somnolence and lepsy = seized) to describe sleep attacks and muscle weakness following intense emotion. In the mid-twentieth century, the classic narcoleptic tetrad of hypnagogic hallucinations, sleep paralysis, excessive sleepiness, and cataplexy was described; in 1960, the occurrence of REM sleep at the onset of sleep in a narcoleptic subject was reported. The observation that narcolepsy was associated with human leukocyte antigens (HLA)-DR2 suggested a biologically based substrate rather than a psychiatric condition. More recently, investigators reported a decrease of the neurotransmitter hypocretin in cerebrospinal fluid of patients with narcolepsy-cataplexy, providing a firm neurobiological explanation and a new test to diagnose the condition. Narcolepsy may occur without cataplexy in milder forms of the disease, or more rarely as the manifestation of a structural disease of the brain, such as tumors or multiple sclerosis.

Onset is typically in the second or third decade of life. Sleep tends to occur in boring or monotonous situations and may be temporarily forestalled by physical activity and mental stimulation. Following brief naps, the patient awakens refreshed. Patients often report episodes of amnesia with 'automatic behavior' during which they may carry out complex nonsensical activities. Accidents due to sleepiness and automatic behavior may occur while driving or operating dangerous equipment. Cataplexy is characterized by sudden loss of muscle tone, usually provoked by strong emotions, particularly laughter. Consciousness is preserved and memory is intact. Hypnagogic hallucinations are vivid dreams that occur at sleep onset, often associated with fear or dread. Sleep paralysis is a transient, generalized inability to move or to speak during the transition between sleep and wakefulness. The experiences are often frightening. Disrupted nocturnal sleep with frequent awakenings is common.

Polysomnography provides objective confirmation of narcolepsy and helps to rule out other disorders that could explain the symptoms. The multiple sleep latency test (MSLT) or daytime nap test provides an objective measure of excessive sleepiness and demonstrates the presence of sleep-onset REM sleep periods which are diagnostic of narcolepsy.

Narcoleptic patients have an increased risk of accidents while operating automobiles and other dangerous equipment. Other psychosocial complications include interpersonal and marital difficulties, loss of employment and academic opportunities, and depression. Personality changes and memory problems are common. Some patients appear to adapt well to narcolepsy; however, for most patients, the disease has a pervasive adverse effect on social and occupational functioning. Many patients report that narcolepsy seriously affects interpersonal, marital, work, academic, and social activities.

Effective treatment of narcolepsy often includes pharmacologic, educational, and lifestyle interventions. The primary treatment for excessive sleepiness consists of brain stimulants. Many patients with narcolepsy take stimulants daily for decades without significant adverse effects. Overuse and abuse of

stimulants are rare in narcoleptics; usage below the amounts prescribed is more common.

Sodium oxybate is approved for treatment of cataplexy. It is also effective for treating excessive daytime sleepiness. Other drugs useful for treatment of cataplexy are imipramine, clomipramine, protriptyline, fluoxetine, and some antidepressant serotonin reuptake inhibitors.

Planned daytime naps may help control sleepiness while reducing the total required daily dose of stimulants. Education of the patient, family, and coworkers plays an important role in adaptation to narcolepsy. Families should understand that narcolepsy is a chronic neurologic disease, and that pathologic sleepiness should not be confused with poor motivation or low intelligence. Patients with narcolepsy should be cautioned about the hazards of driving an automobile or operating dangerous equipment.

Restless Legs Syndrome

RLS is a common, frequently undiagnosed sensorimotor disorder characterized by an urge to move the legs, often accompanied by uncomfortable, unpleasant sensations. RLS impairs sleep and reduces the quality of life. RLS is a dysfunction of the dopamine system. The essential diagnostic criteria are:

- urge to move the legs, usually with uncomfortable leg sensations,
- worsening of symptoms at rest or inactivity,
- worsening of symptoms in the evening and at night,
- relief with movement, walking, or stretching.

Secondary RLS may occur in patients with iron deficiency, renal failure, pregnancy, and advanced peripheral neuropathy. Signs supportive of the diagnosis of RLS are the presence of periodic limb movements (PLMS) in the polysomnogram. These are repetitive movements of the legs, sometimes of the arms, occurring at 5–90 s intervals, often associated with arousals and altering the continuity of sleep. Blood pressure and heart rate rise with PLMS, increasing the risk of hypertension and cardiovascular disease.

Nonpharmacologic therapy of RLS and PLMS rests on abstention from nicotine, caffeine, and alcohol, as well as discontinuation of medications that exacerbate RLS. Iron replacement should be added if appropriate. Pharmacologic drugs of choice are dopamine agonists, followed by gabapentin and low potency opioids. L-DOPA preparations are also effective but may cause augmentation, a peculiar worsening of symptoms caused by pharmacologic intervention. Dopamine agonists are safe but in rare occasions individuals may develop excessive somnolence and compulsive behaviors such as pathologic gambling.

Parasomnias

These are undesirable motor behaviors or abnormal perceptions that occur during non-REM or REM sleep. Patients with parasomnias complain of a variety of nocturnal sensations or exhibit bizarre movements, behaviors, or bodily events. Some patients are entirely unaware of the nighttime activity, and a history from the bed partner or other observer is necessary. Shouting or screaming and violent behavior are highly distressing symptoms and patients are rightly concerned about possible nocturnal accidents or injuries to the bedmate. Some

violent behaviors occur in response to a dream (dream-enacting behaviors) as is commonly observed in REM sleep behavior disorder, a condition that generally appears in older adult males and may signal the future appearance of Parkinson disease or some other neurodegenerative disorder.

Arousal disorders including sleep walking, sleep terrors, and confusional arousals are quite common in childhood and tend to disappear in the early teen-age years. Proper evaluation in an accredited Sleep Center of parasomnias that are frequent, disturbing or distressing is highly recommended. A differential diagnosis with seizure disorders is frequently entertained. Proper treatment is necessary when events occur more than once per week or are considered risky to the patient or the bedmate.

Insomnia

Insomnia is the inability to initiate or maintain sleep. Loss of continuity, lack of depth or insufficient sleep duration contribute to poor quality of nocturnal sleep and lead to complaints of insomnia and fatigue. Insomnia only becomes clinically relevant when the individual reports subsequent daytime sleepiness and fatigue. In addition to a complaint of difficulty initiating and maintaining sleep, or of dissatisfaction with nocturnal sleep, there should be daytime impairment taking one of the following forms: fatigue or malaise; attention, concentration, or memory impairment; social or vocational dysfunction or poor school performance; mood disturbance or irritability; daytime sleepiness; motivation, energy, or initiative reduction; proneness for errors or accidents at work or while driving; headaches, or gastrointestinal symptoms in response to sleep loss; concerns or worries about sleep. The complaints should occur despite adequate opportunities and circumstances for sleep.

When sleep fails, the individual suffers physically, emotionally, and mentally. Sleeplessness and poor restorative sleep are the consequence of a diversity of pathologic mechanisms that interfere with the complex fabric of neural events that lead to restorative sleep and a sense of satisfaction and refreshment every morning when we wake up. Severe sustained lack of sleep over many months can lead to physical disease, whereas partial loss of sleep modifies many brain functions and is very distressing.

Approximately 70 million Americans suffer insomnia that is sufficiently intense or chronic enough to warrant medical consultation. And yet, few physicians outside sleep centers can give patients a proper answer regarding causes, prognosis, and management of an insomnia disorder. Sleep medicine investigates the diversity of factors that predispose, precipitate, and perpetuate insomnia. Events involving the circadian rhythm, the suprachiasmatic nucleus of the hypothalamus (biologic clock), the secretion of melatonin by the pineal gland, and the complex sequence of electrophysiological stages marking sleep, need to be invoked to understand insomnia. Psychophysiological factors and psychiatric disorders generally become imbricated in the mesh of mechanisms leading to chronic insomnia.

Most psychiatric disorders, virtually all psychophysiological conditions and many neurodegenerative disorders such as Parkinson disease and Alzheimer dementia are associated with

complaints of insomnia. Special mention should be made of idiopathic insomnia a condition starting in childhood with familial origins that leads to a life-long litany of complaints and misery related to insomnia. Fatal familial insomnia is a rare neurological disorder that is emblematic of the neuropathology of insomnia and certifies the brain as the source of sleep and its failures. Other conditions associated with insomnia are RLS, the circadian dysrhythmias and even the common sleep apnea disorder.

Psychophysiological insomnia is likely one of the most common forms of insomnia. It develops when the individual focuses attention on the inability to sleep, which is perceived to be the only source of distress, while other emotional or mental concerns are put aside. Contributing factors such as stress, caffeine ingestion, and poor sleep hygiene are modifiable factors and should always be addressed. Not uncommonly there is a precipitating factor such as divorce or the death of a relative, followed by perpetuating factors at the core of which is the negative conditioning to sleep. Predisposing factors such as idiopathic insomnia are not modifiable and when present reduce the efficacy of therapies.

Patients with psychophysiological insomnia respond initially to hypnotic medications but long-term results are more favorable with cognitive behavioral therapy and similar techniques imparted by psychologists. These methods include sleep restriction with sleep consolidation, sleep hygiene education, relaxation therapy, stimulus control therapy and correction of distorted perception of sleep. Sleep laboratory tests are of value when used to exclude underlying contributing physical problems, such as sleep apnea or PLMS affecting sleep.

Testing in the Sleep Center

Polysomnography is the central test performed in the sleep laboratory. It consists of simultaneous recording of brain waves (electroencephalogram, EEG), eye movements (electrooculogram, EOG), heart rate (electrocardiogram, EKG), respiratory effort and airflow, oxygen saturation of oxihemoglobin, and chin muscle tone (electromyogram, EMG) along with videotaping. Polysomnograms (Figure 1) are required to diagnose

Figure 1 Epoch of polysomnogram showing channels for electroencephalography (C3A1, C4A2, 0102), electrooculography (LOCA1 (left ocular), ROCA1 (right ocular)), electromyography (CHIN muscles), electrocardiography (EKG), surface electromyography left leg (LLEG), flow of air nose and mouth (CFLOW), thoracic excursions (THOR), abdominal excursions (ABDM), oxihemoglobin saturation of oxygen (SAO2). Epoch shows REM sleep with intermittent enhancement of muscle tone (CHIN) registering snoring.

Figure 2 Hypnogram (histogram integrating sleep-related parameters) shows positional sleep apnea. During the first half of the night the patient slept supine. The hypnogram shows many arousals (AR – vertical blue lines), obstructive apneas (OA – vertical green lines), hypopneas (HYP – vertical red lines), mixed apneas (MA – vertical brown lines), central apneas (CA – vertical light green lines), desaturation of oxygen (SaO_2), and heart rate instability (heart rate). Supine (SUP). Right side (RS).

sleep apnea (Figure 2), titrate continuous positive airway pressure (CPAP) devices, diagnose narcolepsy, register PLMS, and record motor disorders of sleep, including REM sleep behavior disorder. The MSLT is a nap test performed during daytime hours, starting at 8 a.m. after a nocturnal polysomnogram. Recordings are conducted over 20 min at 2 h intervals. Four or five naps are generally registered. The MSLT is necessary for the diagnosis of narcolepsy without cataplexy (presence of REM sleep in two or more naps). It also serves to quantify excessive daytime sleepiness. Although polysomnography is not required for diagnosis of insomnia, it may be helpful to identify factors that interrupt the continuity of sleep, or to ascertain the occurrence of sleep in some patients with refractory insomnia with sleep state misperception. The maintenance of wakefulness test (MWT) is designed to test the capacity of the individual to remain awake over 40 min of testing time in the sleep laboratory in four consecutive segments. It is helpful to assist in the determination of the ability to drive continuously without falling asleep.

Portable monitoring devices that record esophageal acidity, electrocardiogram, respirations, oxihemoglobin saturation of oxygen, or sleep/wake electroencephalogram may be useful in

selected patients. Although laboratory polysomnography is the diagnostic gold standard, portable monitoring has been developed and is widely used outside the United States as an alternative diagnostic approach for sleep apnea evaluation. A portable monitor records fewer physiologic variables but is typically unattended and can be performed in the home. In 2008, the US Centers for Medicare and Medicaid Services released a statement allowing the use of portable monitoring to diagnose sleep apnea and prescribe continuous positive airway pressure equipment.

Wrist actigraphy, a device that monitors body movements over an interval of hours to weeks, may provide a cost-effective approach to diagnosis in some patients with insomnia or circadian disturbances (cycles of movement and quiescence).

Cerebral function can be studied with neuroimaging techniques in human subjects who are asleep. Human brain activity during sleep alternates within specific areas in relation to the sleep stage and previous waking activity. The work on neuroimaging is providing new data that describe aspects of the mechanism of insomnia, sleep apnea, and RLS. Future studies will offer the opportunity to use neuroimaging in correlation with clinical and electrophysiological evaluations,

as a helpful tool in the diagnosis, classification, treatment, and monitoring of sleep disorders in humans.

The measurement of hypocretin-1 in CSF may be most useful in cases of narcolepsy without cataplexy, in children with excessive somnolence who have not, as yet, developed cataplexy, or when the MSLT is difficult to interpret because of medication effect, and in psychiatric conditions.

Management of Sleep Disorders

Management depends on the particular sleep disorder. Treatment of sleep disorders includes nocturnal application of non-invasive ventilators, oral appliances, pharmacotherapy, surgery, chronotherapy and cognitive behavioral therapies, along with education in proper sleep hygiene.

Continuous positive airway therapy and its variants are the most effective treatment modalities for alleviation and control of clinically significant sleep apnea. Most sleep specialists follow the guidelines posted by The Centers for Medicare and Medicaid Services that recommend the following criteria for prescription of CPAP:

Apnea/hypopnea index > 15 events/hour of sleep, or apnea/hypopnea index > 5 and < 14/hour, with documented symptoms of excessive daytime sleepiness, impaired cognition, mood disorders, or insomnia, or documented hypertension, ischemic heart disease, or history of stroke.

CPAP devices have a fixed pressure titrated in the sleep laboratory. AutoCPAP machines have pressures set between wide parameters and will adapt to the required nocturnal airway pressures from breath to breath. These more expensive devices are useful when defined pressures are unobtainable or when set pressures begin to fail and it is not practical to repeat polysomnography. Bilevel devices deliver a high pressure on inspiration and a lower pressure on expiration. Patients with neuromuscular disorders tend to prefer bilevel machines. Modern noninvasive devices carry a computer chip that records therapeutic compliance over many weeks of treatment.

Oral appliances are useful to decrease the intensity of snoring and alleviate mild to moderate forms of obstructive sleep apnea. The diversity of oral appliances requires that the devices be fitted by dental sleep specialists.

Pharmacologic treatment includes stimulants for hypersomnolence, hypnotics and melatonin agonists for insomnia, dopamine agonists for RLS and PLMS, and sodium oxybate for narcolepsy/cataplexy. A diversity of benzodiazepines and antidepressants are also used in a variety of sleep disorders.

Surgery may be indicated in some forms of obstructive sleep apnea with advanced structural obstruction of the oropharynx by large tonsils or redundant soft tissue. Children and younger adults tolerate better and benefit more than older adults with these forms of oropharyngeal surgery that are generally undertaken by specialized ear, nose, and throat physicians. Maxillofacial surgeons have also devised interventions that reconstruct and augment the oropharyngeal space.

Cognitive behavioral therapy is useful to improve sleep efficiency and continuity in patients with psychophysiological forms of insomnia. This form of therapy is generally delivered

Table 1 Ten commandments of sleep hygiene

-
1. Fix a bedtime and an awakening time
 2. If you are in the habit of taking siestas do not exceed 45 min of daytime sleep
 3. Avoid excessive alcohol ingestion 4 h before bedtime and do not smoke
 4. Avoid caffeine 6 h before bedtime. This includes coffee, tea, and many sodas, as well as chocolate
 5. Avoid heavy, spicy, or sugary foods within 4 h before bedtime. A light snack before bed is acceptable
 6. Exercise regularly, but not right before bed
 7. Use comfortable bedding
 8. Find a comfortable temperature setting for sleeping and keep the room well ventilated
 9. Block out all distracting noise and eliminate as much light as possible
 10. Reserve the bed for sleep and sex. Do not use the bed as an office, workroom, or recreation room
-

in a few sessions by psychologists with special training. Chronotherapies for restoration of conventional sleep–wake schedules are less well defined and variably effective. Chronotherapy is generally aided with the administration of melatonin or a melatonin agonist at bedtime along with the application of light therapy upon arising. Compliance with strict rules of sleep hygiene (Table 1) is necessary for chronotherapy to be effective.

Social Implications

Education pertaining to sleep, sleep hygiene, and awareness of sleep disorders is probably the most important means of prevention. High school and college students learn little about sleep and the effects of sleep deprivation. Findings of the National Sleep Foundation Sleep in America poll from 2007 revealed that tiredness is an epidemic in adolescents. Twenty-eight percent of high school students admit to falling asleep at least once a week while in school, and 10% of high school seniors admit to have nodded off while driving over a 1-year period. Although physicians are well positioned to educate patients about sleep and sleep disturbance, they also receive little education on this topic. It has been suggested that hypnotic medications are being used excessively. In the United States, sleeping pills worth \$2.5 billion are sold each year.

Sleep deprivation is common in modern society and perhaps constitutes one of the most pervasive of sleep alterations. It may be the result of behavioral traits or of work demands. In 2008, the CDC examined data from over 400 000 subjects throughout the United States and found that 11.1% reported insufficient rest or sleep every day during the preceding 30 days. The consequences of sleep deprivation are as devastating as those associated with primary sleep disorders. Fortunately, sleep deprivation is a modifiable condition if properly identified by the health provider and duly acknowledged by the patient.

Individuals suffering excessive daytime sleepiness and fatigue are less productive at work and in the academic setting. Furthermore, they are at higher risk of motor vehicle accidents and complain of a decreased quality of life. Not uncommonly,

family relationships are strained. Control and alleviation of sleep disorders improve quality of life and well-being, while reducing the risk of accidents. Although the ultimate goal of a cure may not be achievable for many sleep disorders, an accurate diagnosis and proper management to control and alleviate the alteration are always desirable.

Glossary

Acceptance and commitment therapy (ACT) A form of psychotherapy that is based on radical behaviorism combined with techniques that are consistent with Eastern philosophies.

Cognitive-behavioral therapy (CBT) A form of psychotherapy targeting maladaptive thoughts and avoidance behaviors.

D-cycloserine (DCS) A partial agonist of the NMDA receptor that facilitates fear extinction in animals and exposure therapy in humans.

Generalized subtype Diagnostic specifier to identify individuals with SAD who fear most or all social situations.

Interpersonal therapy (IPT) A form of psychotherapy focusing on bereavement and interpersonal relationships.

Mindfulness A process that leads to a mental state characterized by nonjudgmental awareness of the present

moment to encourage openness, curiosity, and acceptance of emotional states.

Monoamine oxidase inhibitors (MAOIs) A class of drugs for treating symptoms of anxiety disorders by inhibiting the breakdown of the neurotransmitter monoamine.

Selective serotonin reuptake inhibitors (SSRIs) A class of drugs for treating symptoms of anxiety disorders by inhibiting the reuptake of the neurotransmitter serotonin.

Social anxiety disorder (SAD) The clinical expression of extreme fear of negative evaluation by other people.

Taijin kyofusho (TKS) A unique expression of social anxiety prevalent in Asian countries, such as Japan and Korea, in which the concern is doing something or appearing in a way that offends or embarrasses another individual.

Introduction

Approximately 50 000 years ago, probably somewhere in Africa, the modern human was born. Compared to its ancestors, this new species had a much greater brain, walked upright, and used hands to make sophisticated tool. Members of this species developed ways to communicate with one another and created a complex social system that gave them an enormous advantage over potential predators.

Social contact and affiliation are fundamental needs of essentially all species. Humans in particular have evolved such that they possess high-level motivational incentives to compete for the approval and support of others. Evolutionary psychology assumes that humans need to be liked, valued, and approved of in order to elicit parental investment, develop supportive peer relationships, attract desirable mates, and engage successfully in many types of social relationships. Our species is highly dependent on the social support of others. Ostracism from the social group impacts negatively on a variety of health-related variables, including one's self-esteem and sense of belonging. Humans are, therefore, constantly engaged in a competitive bid for social resources, and failure in this regard is costly. Because time and energy are precious commodities, humans choose to invest their resources in people who are likely to be useful to them and help them achieve their own self-interests in order to defend and maintain, or increase their social standing (e.g., attractiveness and reputation) in the eyes of others.

Social standing is maintained partly through displays of submissiveness that are directed toward higher-ranked individuals, and by displays of dominance or hostility that are directed toward other, lower-ranked members of the social group. Social contact is perceived as rewarding, and the lack thereof as punishing. If an individual of a social group violates

social norms by showing deviant behaviors, this individual is often punished by being isolated or expelled from the group. In serious offenses, such as criminal behaviors, the person is sent to prison, which reduces social contact with the rest of the community. Furthermore, if the individual violates social norms in prison, this individual is sent to solitary confinement. Thus, social contact is an essential human need, and withholding social support creates a great degree of psychological, and also physical, pain and suffering.

This basic need for social support and the associated fear of negative evaluation by others is at the heart of social anxiety disorder (SAD). Because of its evolutionary significance, the possibility of losing social support as a result of negative evaluation by other humans causes a great degree of suffering in the affected person.

Description

People who suffer from this disabling condition fear and avoid a wide range of situations that involve social performance and social interactions. Examples of such situations include eating or writing in public, initiating or maintaining conversations, going to parties, dating, meeting strangers, or interacting with authority figures. Among those, public speaking is the most commonly feared situation. When the person fears most or all social situations, the individual may receive the generalized subtype specifier of SAD and may also meet the additional criteria for avoidant personality disorder.

The average female to male gender ratio in community studies of SAD prevalence ranges between 1:1 and 3:2. The problem often begins in the mid-teens, but can also occur in early childhood. During childhood, SAD is commonly associated with

anxiety-related disorders, including overanxious disorder, mutism, school refusal, separation anxiety, behavioral inhibition, and shyness.

Epidemiological data show that the lifetime prevalence rate of SAD among US adults is 13.3%. Very similar rates are observed in Latin countries, such as Chile (10.2%) and Brazil (11.8%), and slightly lower rates in European countries (7%). Considerably lower rates were reported in Middle-Eastern countries, such as Iran (0.8%), and Asian countries (0.6%). Although epidemiological rates of SAD are lower in Asian countries than non-Asian countries, studies have found that social anxiety symptoms are endorsed more frequently on self-report scales by East Asian samples than in the United States and Europe. It is possible that countries such as Japan or Korea with stronger collectivist orientations may consider social anxiety symptoms to be more acceptable. This could lead to higher endorsement on self-report scales and a lower likelihood of meeting the excessiveness and impairment criteria of SAD. In addition, there is evidence to suggest that social anxiety is expressed differently among Asian people than among non-Asian people. Studies from Japan and Korea suggest that there is a subgroup of patients, who do not avoid social situations because of fears of being observed, but whose concern is doing something, or presenting an appearance, that will offend or embarrass the other person. This type of presentation is locally labeled as the offensive subtype of Taijin kyofusho (TKS) or 'fear of interpersonal relations' in Japanese. The offensive subtype is characterized by two features considered atypical of SAD, namely the belief that one displays certain physical defects and/or socially inappropriate behaviors that are rarely reported in western SAD samples, such as an unpleasant body odor or staring at others' body parts in public, and the fear of offending others as a result of these presentations.

SAD often co-occurs with other psychiatric disorders, such as other anxiety, mood, and substance use disorders. Because SAD typically precedes onset of other disorders, SAD may be a risk factor for other psychopathologies at a later point in life. A longitudinal study of adolescents with SAD found their risk for later onset of major depression to be increased by 3.5 times. Furthermore, comorbid depression occurs in about one-third of individuals with SAD.

When left untreated, the course of SAD is generally chronic. The disorder is associated with significant impairment in work and social functioning and reduced quality of life. In clinical samples, patients with SAD describe difficulty keeping a job, attending school, or getting married. SAD causes considerable economic cost to society, primarily in the form of academic and employment difficulties.

Etiology

It is often assumed that unpleasant or traumatic events might 'cause' an anxiety problem in the future. However, there is little evidence to suggest that traumatic experiences play a dominant role in the onset of social fears. In fact, traumatic external events, as well as vicarious and informational learning, are notably uncommon among individuals with SAD. Other theories assume that social fears are largely biologically determined and that people with SAD are overly sensitive to

threatening social cues, such as disapproving human facial expressions. Consistent with this notion are studies that have shown that angry faces and happy faces elicit different patterns of electromyographic activity in people, and fear conditioning to angry faces shows much more resistance to extinction than do responses to happy or neutral expressions. Interestingly, this conditioning effect is only obtained when the stimulus person directs his or her anger towards the subject; angry faces looking away are as ineffective as happy faces in conditioning paradigms. This suggests that direct eye contact is crucial. In primates, direct eye contact is interpreted as frightening. Moreover, various species display eye-like spots to frighten potential predators. Although the response to eye contact is greatly altered by contextual and learning factors among humans, it is also a hard-wired evolutionary response that is common to all mammals. Therefore, it has been suggested that for individuals with SAD, the fear of being watched is an exaggeration of the normal human sensitivity to eyes. Memory experiments further suggest that individuals with SAD recognize more critical than accepting faces, whereas people without SAD recognize more of the accepting than critical faces. Interestingly, this effect has not been found in studies using words as stimulus material.

Evidence for a genetic contribution to social anxiety comes from family studies and twin studies. Family studies suggest that the risk for developing SAD is ~ 3 times higher for relatives of individuals with SAD than for control relatives who have never been mentally ill. Similarly, twin studies report substantial concordance rates for SAD in identical (24%) and fraternal (15%) twin pairs.

Although the genetic disposition to develop SAD may be nonspecific, it seems to be closely connected to certain temperament variables. In particular, shyness, one of the most heritable temperament factors, seems to be closely related to SAD. Another likely precursor of SAD is behavioral inhibition, which refers to a child's fearfulness, timidity, and weariness when encountering novel people, objects, or events. Numerous studies have found that behavioral inhibition in childhood is closely associated with social anxiety and SAD during adolescence. For example, there is evidence to suggest that behaviorally inhibited children are more likely to have parents with SAD than noninhibited children. However, it has yet to be examined whether parents with SAD are also more likely to have behaviorally inhibited children, and whether behavioral inhibition in childhood leads to SAD in adulthood. If this relationship between behavioral inhibition and SAD holds true, future studies will need to identify the factors that protect behaviorally inhibited children from developing SAD in adulthood. Examples of such protective factors could include family factors and strong peer relationships.

Prevention

SAD typically starts at an early age, with the highest standardized incidence rates per person-year between 10 and 19 years of age. Familial factors and peer relationships can have a profound influence on the onset and course of the disorder. For example, studies suggest that parents who reinforce avoidance behaviors in anxious children tend to reinforce avoidance

behaviors in the future. Furthermore, school-based prevention programs can target highly anxious and shy children by providing coping skills and building peer relations. Finally, children of parents who have SAD may benefit if their parents undergo therapy for SAD.

Pharmacological Treatments

Biological Models

Since SAD was officially recognized as a diagnostic category in 1980, a number of pharmacological agents have been examined. Similar to other anxiety disorders, pharmacological treatments are based on the assumption that medications, which regulate neurotransmitters in the brain, should alleviate symptoms of social anxiety.

The most common drug treatments for SAD include monoamine oxidase inhibitors (MAOIs; i.e., phenelzine), selective serotonin reuptake inhibitors (SSRIs), benzodiazepines, antidepressants, and β -blockers. Thus far, paroxetine (an SSRI) is still the only Federal Drug Administration (FDA) approved drug for SAD.

Monoamine Oxidase Inhibitors

The results of various double-blind placebo-controlled trials show evidence for the efficacy of phenelzine in SAD. One of these studies showed that 64% of patients receiving phenelzine, 30% of patients receiving atenolol, and 23% of those receiving placebo were classified as responders. Similar results were reported in a study that compared the efficacy of phenelzine, the reversible MAOI, moclobemide, and placebo for treating SAD. Overall, these findings demonstrate the short-term efficacy of MAOIs for the treatment of SAD. However, the use of irreversible MAOIs is limited by the risk of hypertensive crisis if dietary restrictions are not followed, as well as its adverse effects profile.

Selective Serotonin Reuptake Inhibitors

The FDA approved paroxetine HCl (Paxil) for the treatment of SAD, making it the first (and only) medication approved for this disorder in the United States. The study that eventually led to FDA approval of paroxetine was a 12-week, placebo-controlled, double-blind, and flexible dose design that included 187 patients. The results showed that 55% of patients receiving paroxetine and 23.9% of those receiving placebo were classified as responders. On average, the reduction in social anxiety from baseline was more than twice as large in the paroxetine group (39.1%) as in the placebo group (17.4%). In addition, various smaller studies have tested the efficacy of other SSRIs, including fluvoxamine and fluoxetine, with promising results.

β -Blockers

β -blockers (such as propranolol or atenolol) have been widely used for treating performance anxiety since the 1970s. However, despite the enthusiasm for this drug to treat social anxiety, its efficacy has not been supported by double-blind studies. For example, when comparing the effects of phenelzine, atenolol,

and placebo for treating SAD, there is no documented advantage of atenolol over placebo. Only 30% responded to atenolol as compared to 64% of patients receiving phenelzine and 23% of patients taking a pill placebo. These and other studies provide little empirical support for atenolol as a treatment of SAD when used on a standing dose. However, β -blockers might be clinically useful for treating individuals with a nongeneralized subtype of SAD when administered on an as-needed basis.

In sum, there is considerable evidence to suggest that gains from medications are not well sustained once these medications are discontinued. For example, recent data from placebo-controlled discontinuation trials with paroxetine indicate that about 40–60% of patients relapse when they are switched from paroxetine to placebo. Furthermore, the relapse rate is high with rates at 6-month follow-up ranging from one-third to about two-thirds of respondents. A further limitation of medication is that many patients with SAD may not be appropriate for medication treatment because of medical problems or pregnancy. In addition, a significant percentage of SAD patients seeking treatment are unwilling to take medication and express a preference for psychotherapy. Therefore, investigators have examined psychological treatments as alternative intervention strategies.

Psychological Treatments

Cognitive-Behavioral Therapy

Cognitive-behavioral therapy (CBT) is the most studied and validated form of psychotherapy for SAD. It is most accurately described as a family of interventions that are derived from the behavioral and cognitive traditions. Early formulations of CBT emphasized psychoeducation, in-session and in vivo exposure to feared situations, techniques intended to modify maladaptive or irrational thinking patterns common among persons who have SAD, relaxation techniques, and social skills training.

The initial formulation of the CBT model posited that individuals with SAD believe that they are in danger of behaving in an inept and unacceptable fashion, and that such behavior will have disastrous consequences in terms of loss of status, loss of worth, and rejection. More specifically, it is assumed that effective psychotherapy provides patients with a range of learning experiences that modify the patient's anxio-genic beliefs and expectations, or deactivates them while making other interpretations and beliefs available. More recent formulations of the CBT model assume that individuals with SAD are apprehensive in social situations in part because they perceive the social standard (e.g., expectations and social goals) as being high. They desire to make a particular impression on others but doubt that they will be able to do so, partly because they are unable to define goals and select specific achievable behavioral strategies to reach these goals. This leads to a further increase in social apprehension and increased self-focused attention, which triggers a number of additional cognitive processes.

CBT models predict that, once a situation is perceived as holding the potential for social evaluation, individuals with SAD become preoccupied with negative thoughts about themselves and the way other people perceive them. The negative impression is assumed to occur in the form of an image from

an 'observer' perspective in which people with SAD can see themselves as if from another person's vantage point. Therefore, it can be assumed that the treatment is most effective if it targets the dysfunctional cognitions directly and systematically via cognitive therapy.

Consistent with this notion are results from studies showing that socially anxious individuals believe that negative social events are more likely to occur than positive social events. Additionally, they assume that most people are inherently critical of others and are likely to evaluate them negatively. The belief system of individuals with SAD appears to magnify the competitive aspects of interpersonal relationships but minimizes the cooperative, supportive aspects.

The efficacy of earlier formulations of CBT for SAD has been demonstrated in a number of well-designed studies. Treatment drop-outs are generally low and not systematically associated with any patient variables. Traditional group CBT is administered by two therapists in 12 weekly 2.5-h sessions to groups consisting of four to six participants each. A comparison between fluoxetine (a popular SSRI), CBT, placebo, CBT combined with fluoxetine, or CBT combined with placebo showed that that all active treatments were superior to placebo. Interestingly, the combined treatment was not superior to the other treatments. The response rates in the intention-to-treat sample were 50.9% (fluoxetine), 51.7% (CBT), 54.2% (CBT plus fluoxetine), 50.8% (traditional CBT plus placebo), and 31.7% (placebo only). Although these results emphasize the efficacy of CBT, either alone or in combination with pharmacotherapy, the data also show that many participants remain symptomatic.

More recent formulations of CBT for SAD specifically target some of the core maintenance factors, safety behaviors, self-focused attention, and perceived social cost. The efficacy of these targeted CBT protocols has considerably improved over earlier, more traditional CBT protocols. The treatment efforts of targeted CBT are directed toward the systematic teaching of an alternative cognitive framework for understanding social situations, social performance, and social risk. Interventions are richly cognitive in nature, as they ask patients to examine their expectations about social situations and the social costs of imperfect social performances. Patients then specifically examine the veracity of these expectations as evaluated by logical evaluation, and particularly by specific 'behavioral experiments' that are designed to test anxiogenic expectations. An effect size analysis of such a targeted CBT approach showed that the uncontrolled effect size of the severity rating based on the clinical interview was 1.41 (pretest to posttest) and 1.43 (pretest to 12-month follow-up) in the targeted CBT group. The composite score was associated with an uncontrolled pre-post effect size of 2.14. These are exceptionally strong effects, suggesting that CBT for SAD can be significantly improved by targeting the specific maintenance factors.

Mindfulness-Based Treatments

Mindfulness refers to a process that leads to a mental state characterized by nonjudgmental awareness of the present moment experience, including one's sensations, thoughts, bodily states, consciousness, and the environment, while encouraging openness, curiosity, and acceptance. The techniques are based

on ancient Eastern philosophies, most notably Buddhism and Zen. In recent years, these treatments have been combined with traditional CBT to reduce stress and anxiety (e.g., mindfulness-based cognitive therapy and mindfulness-based stress reduction). Although these treatments are very popular, relatively little data exist to support their efficacy.

A related treatment to mindfulness-based cognitive therapy on the level of therapeutic techniques is acceptance and commitment therapy (ACT). ACT recently has been applied to the treatment of SAD. In the first stage, patients came to understand the failure of their past efforts to control anxiety. The next phase encouraged patients to accept their unwanted or distressing thoughts while being exposed to difficult social situations. Mindfulness techniques were presented in the third stage to help teach nonjudgmental experience and appraisal of anxious thoughts and to move toward cognitive defusion, which is the exercise of distancing the self from internal experiences. The final stage facilitated participation in experiences that reflect the participant's valued choices. The treatment incorporated traditional behavior therapy techniques such as in-session role-plays, in vivo exposure, and social skills training. Patients displayed significant decreases in social anxiety, fear of negative evaluation, experiential avoidance, and a significant increase in quality of life at posttreatment and 3-month follow-up. The size of the treatment effects was similar to more recent formulations of CBT.

Interpersonal Therapy

Interpersonal therapy (IPT) is a new form of treatment that is based on the assumptions that psychiatric disorders occur and are maintained within an interpersonal context. Similar to CBT, IPT is a time-limited 12- to 16-week therapy. The treatment has been primarily used in the past for depression and eating disorders. More recently, IPT has also been adopted for the treatment of SAD.

IPT focuses on core interpersonal problem areas rather than social interaction and performance situations through various techniques that primarily focus on the patient's affective response to interpersonal issues and unresolved conflicts. This is done with role playing of target situations but without a focus on exposure. Nevertheless, there are striking similarities to CBT on the level of the therapeutic techniques.

The empirical support of this relatively new treatment is fairly sparse. In an uncontrolled study of IPT for SAD, seven of nine individuals (78%) were classified as responders, but a randomized trial that compared IPT to a supportive therapy control group failed to replicate these initial findings. Both groups demonstrated improvement in social anxiety, but they did not differ on the majority of measures or in the proportion of responders. Another recent study, however, did provide some support for the efficacy of IPT for social anxiety. Conducted in an inpatient setting, this study compared 10 weeks of IPT and CBT. Patients in each condition received four group sessions and one individual session per week. Treatments were modified to include individual and group components to better fit an inpatient setting. Both groups demonstrated improvements on measures of social anxiety, and these gains were maintained at 1-year follow-up. Definitive conclusions about the efficacy of IPT for social phobia cannot be made, however,

because there were few differences between inpatient IPT and CBT (CBT was superior on a single secondary measure), and no control condition was included.

Psychodynamic Therapy

Little empirical evidence exists to support the use of psychodynamic therapy for SAD. In fact, not a single randomized controlled trial exists of this widely practiced intervention. The psychodynamic treatment model for SAD assumes that people with SAD experience shame because of an unconscious need to be the center of attention, guilt related to an unconscious need to eradicate social competition, doubt concerning the ability to eradicate social competition, separation anxiety because of an unconscious need for autonomy, and loss of love from a caregiver because of autonomy. Representations of others, such as caregivers or parents, are assumed to be internalized as critical, shaming, or abandoning. These internalized representations are then projected onto others, which bring about a need to avoid social situations. The treatment typically focuses on the conflicting relationships, goal setting, enhancing insight, and understanding the role of shame and unrealistic demands. Patients are often encouraged to confront feared social situations as part of the treatment.

Combined Pharmacotherapy and CBT

Traditional Combination Treatments

Combining pharmacotherapy and CBT is a popular strategy for treating anxiety disorders in general. Between 55% and 95% of patients are estimated to receive such combination treatment. A recent meta-analysis showed that combined therapy was only effective for patients in the short term. These effects disappeared at follow-up. Moreover, the combined therapy was not equally effective for all anxiety disorders. Large average effects were found for panic disorder and medium to large effects were found for generalized anxiety disorder, but only small and nonsignificant effect sizes were found for obsessive-compulsive disorder and SAD. For example, one recent study that investigated the efficacy of the combination of fluoxetine with traditional CBT relative to either treatment alone or pill placebo showed that combination treatment was associated with less than a 3% increase in response rates for the addition of fluoxetine to CBT. For this reason, authors have cautioned against the routine use of combination therapy over provision of CBT alone when available.

Novel Combination Treatments

CBT is an exposure-based treatment. Its efficacy can be enhanced by targeting specific cognitive maintenance factors. For example, recent animal (preclinical) and human studies have shown that the efficacy of CBT can be improved by enhancing extinction learning, which is an important mechanism through which CBT leads to fear reduction, with a pharmacological agent. This process is more likely to be enhanced if the pharmacological agent (1) produces few side effects and has little affect modulating effects to minimize state-dependent learning; (2) allows full activation of the fear structure and

emotional processing of feared stimuli during the exposures; and (3) can be delivered in isolated dosing to allow patients to attribute a significant degree of the therapeutic effects to the successful exposures. Finally, and perhaps most importantly, the pharmacological agent should support aspects of the therapeutic mechanism of exposure-based therapy. These recommendations seem to be overly ambitious and practically unattainable with conventional pharmacotherapy for anxiety disorders. However, basic research in animal extinction learning has recently been translated into clinical applications. This research points to a pharmacological agent that meets all of the above-mentioned recommendations for enhancing exposure-based therapy.

Modern learning theories of extinction assume that conditioning occurs as subjects form representations of the relevant cues (conditioned stimulus, CS; and unconditioned stimulus, US) and situational contexts, and as they acquire information about the association between these cues and the situations. These associations can be either excitatory (i.e., activation of one representation activates another) or inhibitory (i.e., activation of one representation inhibits activation of another). Acquisition of conditioned responses is explained by the formation of an excitatory association between representations of the CS and US. The US representation is activated indirectly through its association with the CS representation, which in turn triggers the conditioned response. Extinction is assumed to proceed through multiple mechanisms that also include new learning that inhibits the excitatory association between CS and US. As part of this new form of learning, the subject changes the CS-US contingency in such a way that the CS no longer signals an aversive event and thereby inhibits the expression of the fear response.

Glutamate is one of the most important excitatory neurotransmitters in the mammalian brain and performs an important role in the brain circuitry underlying fear processing. The *N*-methyl-D-aspartate (NMDA) receptor is an ionotropic receptor for glutamate. In fact, fear and extinction learning are both blocked by antagonists at the NMDA receptor. Activation of NMDA receptors requires binding of both glutamate and the coagonist glycine for the efficient opening of the Ca^{2+} ion channel. Some of the subunits bind the coagonist glycine and other subunits bind the neurotransmitter glutamate. It has been shown that D-serine can coagonize the NMDA receptor with even greater potency than glycine. D-4-amino-3-isoxazolidone (D-cycloserine, DCS) is an analog of D-alanine and a partial agonist at the glycine recognition site of the glutamatergic NMDA receptor that works very similar to D-serine. Studies have shown that DCS facilitates the process of extinction of conditioned fear when administered in individual doses prior to or soon after extinction trials in animals. DCS also happens to be an established antibiotic medication for the chronic treatment of tuberculosis at high doses (500 mg daily) in humans. It should be noted that the antibiotic effects are unrelated with DCS's ability to facilitate extinction learning.

Our research team conducted the second double-blind placebo-controlled study in 2006 in a human sample of anxiety disorder patients. This study randomly assigned 27 patients with a principal DSM-IV diagnosis of SAD to either receive exposure therapy plus DCS (50 mg) or exposure therapy plus pill placebo.

The first treatment session consisted of an introduction of the treatment model and psychoeducation. The following four sessions emphasized stepwise social exposures, with administration of the study pill 1 h before each session. The exposure exercises consisted of giving speeches of increasing difficulty level about topics chosen by the therapists in front of the other group members or confederates and a video camera. At the end of each exposure session, patients were encouraged to continue to apply home-practice strategies (such as giving speeches in front of a mirror). Although the in-session exposure exercises only focused on public speaking, 51.9% of the subjects had a generalized subtype of SAD, and 40.7% had at least one additional DSM-IV Axis I diagnosis. The level of social anxiety was assessed at baseline, posttreatment, and at 1-month follow-up. Participants who received DCS augmentation as compared to placebo augmentation demonstrated significantly greater improvement at posttreatment as assessed by clinician-rated and self-report instruments, with evidence of maintained and extended treatment effects at the follow-up evaluation.

The difference between the DCS and placebo group increased linearly with time, with the greatest effects of DCS being evident at the 1-month follow-up. Similar results were observed for the other measures. The between-group effect sizes at both posttreatment and follow-up indicated a medium to very-large effect size for the advantage of DCS over placebo, with larger effects at follow-up than immediately following treatment. Similarly positive effects of DCS as an augmentation strategy for CBT have been reported for the treatment of other anxiety disorders, including specific phobia, obsessive-compulsive disorder, and panic disorder.

It is possible that we are at the beginning stage of a genuine paradigm shift of treatment research, as basic knowledge from the field of neuroscience is directly translated into novel clinical applications. These new applications are unlike the traditional 'horse race comparisons' of clinical trials that typically lack a sound theoretical rationale for combining pharmacotherapy and psychotherapy. For the first time, a pharmacological agent that does not have any anxiolytic properties was used to enhance some of our most effective psychological treatments for anxiety disorders on the basis of a known mechanism. Future research in this exciting field may not only maximize the efficacy and cost-effectiveness of the treatments, but may also answer some of the remaining important theoretical questions concerning the mechanism of treatment change of exposure-based therapy for anxiety disorders.

Summary

SAD is the clinical expression of social anxiety, an evolutionary adaptive fear of negative evaluation by others. It is one of the most common mental disorders and associated with significant suffering to the affected individual. The disorder begins at

an early age and follows a chronic and remitting course, unless it is effectively treated. The cause for this disorder is still not very well understood, but genetic factors that predispose people to extreme shyness are likely involved. Family factors and other peer relationships are also implicated. Focusing on these factors can offer effective prevention strategies for high-risk individuals. The most popular and best-studied pharmacological treatments include monoamine oxidase inhibitors (i.e., phenelzine), SSRIs (i.e., paroxetine), and β -blockers (i.e., propranolol and atenolol). The empirical data question the efficacy of these interventions as long-term strategies. The most studied psychological treatment for SAD is CBT. The efficacy of CBT is promising, especially for the newer formulations of the treatment protocol and as a long-term intervention strategy. Among the less studied or less empirically validated therapies are IPT, psychodynamic therapy, and mindfulness-based interventions. Combining traditional antianxiety medications and psychotherapy (predominantly CBT) is not more effective than either of the treatments alone. A more promising approach is combining exposure-based treatment with a pharmacological agent that enhances extinction learning.

Glossary

Category accessibility The readiness or ease with which a stored category is activated from memory and used to encode stimulus information.

Cognitive heuristics Mental rules of thumb used for reducing complex judgmental tasks to simpler procedures.

Cognitive process The mental operations that are used to make a judgment or engage in behavior.

Concept activation The process of bringing an element of knowledge from long-term memory into preconscious or conscious awareness.

Dual-process models A class of theoretical models that distinguish between a style of information processing that is

effortful, deliberative, and controlled, and one that is fast, effortless, and automatic.

Implicit processes Affect-laden associations between cognitive elements that can be automatically activated by an internal or external stimulus.

Schemas Abstract knowledge structures containing the attributes of a stimulus, along with the rules specifying the interrelationships among the stimulus attributes.

Social stereotypes Knowledge structures that contain beliefs and expectations about the attributes of people belonging to specific social groups.

Introduction

The manner in which social information is interpreted, encoded, stored, and retrieved from memory is critical to understanding how we perceive and interact with the social world. Social cognition represents the scientific approach within social psychology dedicated to studying these processes. With its emphasis on the cognitive structures and processes underlying social behavior, social cognition also has much in common with cognitive psychology. However, social cognition is not synonymous with either field. Furthermore, it is not associated with any one theory or tied to any specific area of research. Rather, it examines a wide range of questions about how people form impressions and attitudes and make social judgments and decisions. The following sections sketch the framework of social cognition, discuss its relation to traditional social psychology and cognitive psychology, and consider its origins and intellectual history. Finally, by presenting a selective overview of theory and research in several substantive domains, the last section illustrates how social-cognitive approaches have contributed to an understanding of social behavior.

Social Cognition, Traditional Social Psychology, and Cognitive Psychology

Social-psychological theories have long accorded cognitive processes a central role. However, as cognitive processes are not directly observable and cannot be easily measured, social-psychological research has traditionally inferred the existence of cognitive processes based on overt behavioral data. By using outcome data to explore questions of process, social psychologists employed S–R methodologies to test S–O–R (stimulus–organism–response) models of social behavior. What distinguishes social cognition from this more traditional approach in social psychology is the relatively formal way in

which it treats the O's unobservable processes. The major thrust of social cognition research is to provide conceptual models of, and consequently more detailed evidence for, the mediating role of cognitive processes.

To illustrate how social cognition more clearly addresses the 'why' and 'how' behind the relationship between a stimulus and a response, consider research on attitudes and behavior. In one line of research, social psychologists have examined how the amount of experience one has with an attitude object affects the strength of the relationship between attitudes and behavior. This research indicates that attitudes formed on the basis of direct experience more strongly predict behavior than attitudes formed in the absence of such behavioral experience. Typically, researchers only studied the beginning and end of the presumed causal sequence, neglecting questions regarding why experience strengthens the relationship between attitudes and behavior. Subsequent social-cognitive research by Fazio and others has shown that attitudes based on direct behavioral experience are more cognitively accessible – that is, more easily retrievable from memory – than attitudes formed on an indirect basis. Moreover, this research has shown that people who can quickly retrieve their attitudes from memory demonstrate higher attitude-behavior correspondence than those whose attitude retrieval is slower. Therefore, one reason why attitudes based on direct experience better predict behavior is because they are more accessible in memory than attitudes formed via indirect means.

This research illustrates how more direct measurement approaches in social cognition research, compared with traditional social-psychological research, bring the processes that mediate social behavior into clearer focus. By directly incorporating cognitive processes into theoretical models of social behavior, theory and research in social cognition is able to enrich our understanding of the processes that underlie various forms of social behavior.

To be clear, social cognition is not merely the application of cognitive psychology's theories and methods to a social

context. Broadly speaking, cognitive psychology and social cognition use similar methodological tools and share a concern for cognitive representation (structure) and process. Despite these surface similarities, fundamental differences between social and nonsocial cognition do exist. As social psychologists Leonard Martin and Leslie Clark observed, "We do not think about people in the same way that we think about other things." Perhaps most importantly, in social – as opposed to nonsocial – cognition we are simultaneously the perceivers *and* the targets of perception. This fact has important implications for social perception and behavior. For example, research has shown that how we categorize others strongly influences the ways in which we think about them and interpret their behavior. Our impressions of others also directly influence our behavior toward them, which has in turn, been shown to influence their actual behavior. In this way, if I am a female CEO, whether others categorize me as a female CEO, as a woman, or as a CEO likely determines how they perceive and treat me, and consequently, how I come to see myself and behave toward others.

Social cognition also differs from nonsocial cognition in that the former is more highly intertwined with emotion; in the social domain, certainly more so than in object perception, our feelings influence our thoughts and vice versa. For example, research shows that when people feel angry, they are more likely to stereotype others. In a somewhat different vein, research shows that our attributions about the causes of other people's behavior affect the emotions we experience toward them. If we believe that Laszlo failed his chemistry test because he chose to party with his friends rather than study, we may feel anger or disgust toward him. In contrast, if we attribute the failure to illness, we may pity Laszlo.

To better appreciate the work of contemporary social cognition, a brief discussion of its intellectual origins follows.

Historical Background and Intellectual Origins

Social psychologists have always stressed that people are thinking organisms. At the turn of the century, prominent scholars such as James, Cooley, and Mead had already placed a thinking, evaluating self at the center of social-psychological inquiry. Even during the reign of behaviorism, social psychologists continued to accord cognitive constructs a central place in their theorizing. By World War II, an influx of psychological scientists escaping fascism and genocide in Nazi Germany found an intellectual home in American social psychology, with its emphasis on unobservable processes.

Moreover, the war itself dominated the attention of many seminal thinkers in the field. German and American psychologists alike wondered how a nation like Germany could undergo such a massive and rapid 'attitude change' as to blind the German people to the overthrow of humanitarian values and the genocide of millions. Focusing on the powerful Nazi propaganda machine, some social psychologists (e.g., Kurt Lewin) investigated the factors that influence attitude indoctrination and persuasion, while others focused on persuasion as a form of authoritarian compliance. But the Holocaust also brought to the forefront the problems of stereotyping, prejudice, and discrimination that continue to occupy the field today. Thus, the war was instrumental in terms of channeling both cognitively

oriented scientists and phenomena into the newly developing area of social psychology.

Nevertheless, it was not until the early 1970s that social cognition began to emerge as a subfield of social psychology in its own right. As a consequence of the cognitive revolution, researchers studying social perception began to apply experimental psychology's models of human cognition and memory. Developments within social cognition informed and influenced social psychologists' understanding of social behavior – from attribution to stereotyping and from impression formation to persuasion.

Although the subfield of social cognition is relatively young, we can trace its influences to two philosophical orientations: The first, which has been referred to as the *elemental* perspective, focuses on how different pieces of information are combined to form organized cognitive structures. The second, which has been termed the *holistic* perspective, focuses on the subjective nature of perception and on the organizational principles that guide higher-order cognitive and perceptual processing.

Within the elemental school, associative network models early on probably had the greatest influence on social cognition. Developed within cognitive psychology in the 1960s and 1970s, these models address two fundamental questions in cognition. First, how do people cognitively represent and organize (i.e., structure) information from the external world? Second, how do we process information that we have perceived and stored? In answer to the first question, associative network models suggest that cognitive structures arise through the pairing or association of cognitive elements in memory. These pairings and associations are based on similarity, temporal or spatial contiguity, and frequency and recency of association. In a similar fashion, further associations and connections can build to form more complex cognitive structures, a process known as 'bottom-up' processing. Structurally, these models posit that verbal propositions represent concepts or nodes in long-term memory and that links represent the relationships between nodes. Associative network models also make important assumptions about the processes that operate on memory structures, such as the metaphor of concept activation. When a concept is encountered in the environment (e.g., when I see a dog), its corresponding memory node is activated. This activation then emanates outward, spreading along the associative pathways to other concepts linked to the activated concept (e.g., the concept of 'attack' may be brought into conscious awareness or may unconsciously affect behavior). The strength of association between concepts or nodes determines the degree to which a given concept activates other linked concepts.

In contrast to the 'bottom-up' perspective of associative network theories, adherents of holistic or 'top-down' notions of cognition emphasize that all the information represented within a given cognitive structure operates as an indivisible cognitive unit. The cardinal axiom of this school is the original Gestalt idea that the whole is more than the sum of its parts. For example, Sir Frederick Bartlett, who emphasized the constructivist nature of social perception, demonstrated that people perceive and remember stimuli as higher-order units, rather than as collections of independent elements. Bartlett's work also foreshadowed important developments in social cognition by proposing that existing cognitive structures provide

interpretive frameworks from which people process new information in the environment. In fact, a major theme of Bartlett's research was that cultural expectations and previous experience often distort social perception. Indeed, as will become evident below, subsequent research has shown that cognitive structures can have wide-ranging effects on perception; they influence the environmental features to which people attend, the manner in which such information is interpreted and encoded, and which information is most likely to be available for later retrieval. In essence, this approach highlights the inherently subjective nature of perception, thought, and memory.

The Structure and Processing of Social Information

One of Sir Frederick Bartlett's long-lasting contributions has been his coining of the term *schema* to refer to the ideas, or cognitive structures, of narratives. Now employed in most modern research, the definition has expanded to include stimuli of a wide variety of entities, including objects, persons, social categories, events, or situations. More formally, it is defined as the abstract generic knowledge about the attributes of any stimulus and about the interrelationships among the stimulus attributes. A stereotype (or schema) about the social group 'scientists,' for example, may contain descriptive information in the form of beliefs, expectations, and knowledge about scientists (e.g., scientists are 'ingenious,' 'unsociable,' 'eccentric,' and 'no fun at parties'). The schema also provides a framework for understanding how the attribute information relates to each other (e.g., 'scientists are eccentric because they are very intelligent').

In addition to providing cognitive representations of stimuli, schemas also guide the processing of subsequent information and facilitate the construction of social reality. Social situations are often ambiguous or contain limited information, and consequently, are open to many interpretations. When information is limited, schemas allow us to 'go beyond the information given' and to make inferences about a given stimulus. Using solely the information that a person is a scientist, people could conclude that that same person is also 'unsociable' and 'ingenious.' These schemas about the attributes of social groups – social stereotypes – can affect what kinds of behaviors we expect from individual members of those groups, thus potentially biasing the interpretation of ambiguous behavior. Such behavioral expectations are often based on visually prominent characteristics such as gender, race, and age. For example, Sagar and Schofield showed that when a Black and a White child engaged in identical ambiguously aggressive behaviors, people viewed the Black child's behavior as more aggressive and the White child's behavior as more playful.

Expectations about others can also influence our own behavior toward others. Gendered schemas about occupations, for example, can lead to further sex segregation of employment by altering expectations about the appropriateness of the occupation for each sex. Indeed, Rudman and Glick found that people who stereotyped men as more assertive and directive and women as more nurturing were more likely to hire men for a masculine managerial job. Perhaps most important, research on behavioral confirmation suggests that schema activation results in self-fulfilling prophecies. Studies have shown that when our beliefs

and schemas lead us to perceive others in stereotypic terms (e.g., as an African American) rather than as unique individuals, our behavior (e.g., unfriendly) elicits from them confirmatory behavior (e.g., hostility), thus bolstering our preexisting schemas. This dynamic provides an important insight into the reasons why social stereotypes are so difficult to change.

Another function of schemas is that they allow us to simplify and organize information from otherwise unmanageably complex environments. By taking a 'top-down' approach and inferring information based on category membership rather than learning each individual's personal attributes, we expend less effort and conserve cognitive energy. Observing that people often exert minimal cognitive effort and tend to overrely on schemas, Fiske and Taylor coined the term *cognitive miser*. They argued that people habitually tend to take mental shortcuts, even when they are capable of more careful analytic thought. In addition to schemas, people also overrely on heuristics, or general rules of thumb that allow people to make quick and easy inferences. And like schemas, heuristics can lead to systematic errors. Instead of taking the time to learn base-rate information, for example, people use the availability heuristic to quickly infer the frequency or probability of an event occurring based on how easily it comes to mind (cognitive accessibility). Because people tend to overestimate the probability of more salient or familiar events, a person might overestimate the frequency of deaths that result from something dramatic, like a plane crash over the more common but mundane heart disease. By relying on these mental shortcuts rather than engaging in more analytical thought, people sometimes sacrifice accuracy for the sake of efficiency.

As the role of motivational influences on information processing emerged, social cognition researchers in the 1990s began to view people as *motivated tacticians*. According to this perspective, people are not *always* motivated to exert minimal cognitive effort. In addition to efficiency, other motives (e.g., accuracy, ego defensive, consistency) can affect the cognitive strategies people use when processing social information. The *tactician* component implies a more deliberate choice of processing strategy than suggested by more recent research on unconscious motivations. As a result of research on automaticity and control (see below), social psychologists began to develop models that examined when and how people automatically (and sometimes unconsciously) adjust their motivations, emotions, evaluations, and behavior as a function of adapting to different social environments.

Dual-Process Models

We have discussed how people may default to processing information in a low-effort manner, relying on mental shortcuts in everyday contexts. At other times, however, we take a more effortful, data-driven approach to gathering information. To explain when and why people use one approach over the other, a number of dual-process models have appeared in different subdomains of psychology – attitudes and persuasion, person perception, implicit social cognition. All these models distinguish between two different modes of processing: one that is effortful, deliberative, and controlled, and one that is fast, effortless, and automatic. According to Smith and DeCoster, despite differences in domain, level of specificity,

and underlying motivations, all dual-process models tend to possess three major components: (1) they explain when or how people process information in a 'quick and dirty' fashion; (2) they explain how people process information more extensively when motivated and capable; and (3) they outline the conditions that facilitate shifts between the two modes. Capturing many of the similarities in models across domains, Kahneman recently proposed a two-system model with an intuitive system and a reason-based system, with connections to underlying neural subsystems.

Dual-process models were originally developed to account for impression formation processes and have typically focused on the long-lasting effects of stereotypes, a category-based form of processing that tends to occur automatically. The pioneer dual-process models were Brewer's dual-process model of impression formation and Fiske and Neuberg's continuum model. Both of these distinguish between when people will rely on more individuating pieces of information and when they tend to use stereotypes when forming impressions of others. In general, these models propose that people tend to rely more on individuating pieces of information when they observe inconsistency between the stereotype and a target's behavior, but people otherwise predominantly rely on social categories in making social inferences and judgments.

When forming impressions of others, people's motivations can also affect which mode they rely upon. According to Fiske and Neuberg's continuum model, the motivation to belong encourages people to take a more piecemeal (or data-driven) approach in interdependent situations. When people must work with others to succeed, as on a sports team or military squad, they tend to pay more attention to stereotype-inconsistent information. Learning individuating pieces of information, rather than relying on stereotypes, enables people to better predict others' behavior, and as a result to work more effectively together as a cohesive unit. In addition to interdependent situations, when people want to be accurate or they think they may be held accountable to others for the reasoning behind their judgments, they tend to be motivated to process information more carefully and consciously.

Researchers who study attitudes and persuasion are interested in the different processes by which people make attitudinal judgments based on available information. Introduced at approximately the same time, Chaiken's heuristic-systematic model and Petty and Cacioppo's elaboration likelihood model dominate the field of persuasion. The heuristic-systematic model proposed that people can process information in a heuristic or systematic mode, or both. The heuristic mode involves judgments based on rules of thumb or 'heuristics,' which guide processing, often automatically, but in accordance with various principles that account for when one or the other mode of processing is in play. In the more analytic systematic mode, people exert effort to pay attention to message-relevant information. Likewise, the elaboration likelihood model distinguishes between two routes by which a person can process a message: the peripheral (similar to, but not isomorphic with, the heuristic) and the central route (similar to systematic). As with the HSM, which route a person takes depends on his or her ability and motivation to think carefully about the quality of the arguments contained in the message. For example, if you are deciding whether to buy a Honda or a Toyota and

processing information heuristically, you might be particularly persuaded to buy the Toyota because of Cameron Diaz's celebrity endorsement. However, if buying a car is an important decision for you, then you would be more likely to consider such issues as recent recalls, cost, gas mileage, warranty, and environmental impact, more than a celebrity endorsement.

For reasoning about attitudinal judgments, three major motives converge in the attitudes and persuasion literature. These motives correspond to concerns about the self, concerns with rewards/punishments associated with other people, and a desire to form a valid picture of reality. These motives line up nicely with the three included in the heuristic-systematic model (HSM) of persuasion, which affect both the extent and direction of processing: accuracy, defense, and impression motivation. According to the HSM, when driven by accuracy motivation, people should engage in an effortful and unbiased search for judgment-relevant information. The defense motivation, in contrast, can lead people to process information superficially or carefully, depending on which method better serves the self. Striving to defend the self-concept, people may select information that preserves preexisting beliefs about the self. Information that is inconsistent with the self-concept, however, should motivate people to carefully process that information in an effort to discredit it.

Despite the prominence of dual-process models, critics have raised several issues pertaining to the pros and cons of different modes of processing. Most of the criticism has revolved around the theory and research behind Kruglanski's unimodel of persuasion. Kruglanski and colleagues argue that distinctions between the two processing modes are artificial and that both modes operate according to hypothesis-testing and inference. That is, because effortful and automatic processing both rely on 'if-then' syllogistic reasoning, the two 'modes' are qualitatively the same. According to Kruglanski, rules of thumb such as 'if an expert makes this argument, then it must be valid' operate similarly to message-based processing (e.g., if this argument is true, then the proposal must be bad). He further argues that differences in judgments previously observed between the two modes simply correspond to quantitative differences in degrees of processing that have been methodologically confounded in past dual-process research.

However, the main premise of the unimodel – that the two processes are qualitatively the same – does not square with recent neurological findings. In particular, Lieberman's research on X and C systems, identified by functional magnetic resonance imaging (fMRI), indicates that some regions of the brain are associated with effortful processes and others with automatic processes. Further, these neurological differences cannot simply be explained by quantitative differences in the extent of processing, as evidenced by research on people with damage to the hippocampus (an area associated with automatic processing). Smith and DeCoster point out that although people with damage to the hippocampus cannot form new associations with novel stimuli, they nevertheless can apply previously learned knowledge (prior to the damage) to perceive similarities in the stimuli. That is, it seems that they used previously learned heuristics. People without damage to the hippocampus, in contrast, are able to automatically learn new associations from experience, often without conscious awareness.

Implicit and Explicit Processes

Another distinction researchers have made between the two modes involves the emotional component of automatic processing. Gawronski and Bodenhausen made this distinction most clearly in their associative propositional evaluation (APE) model of explicit and implicit attitudes. In typical dual-process fashion, the APE model classifies implicit attitudes as automatic processes and explicit attitudes as more controlled. More specifically, however, Gawronski and Bodenhausen define implicit attitudes or associations as *affect-laden* associations activated automatically by an internal or external stimulus. Importantly, these associations do not depend on whether people believe the association to be valid. A person may have a negative association with people with foreign accents simply because he or she grew up watching a lot of movies with accented villains. This does not necessarily mean that the person believes that people with accents tend to be evil. All that matters for implicit attitudes is that the stimulus automatically activates the affect-laden association. Explicit attitudes or propositions, in contrast, depend on whether a person accepts the belief or evaluation to be true and valid.

Conceptualizing implicit processes at a theoretical level is a relatively easier task than measuring them at an empirical level, given that implicit processes presumably occur automatically and outside of a person's awareness. That said, measures of implicit attitudes and associations have become increasingly popular in the last decade. The most popular of these measures are the implicit association test (IAT) and affective priming tests. The IAT uses a timed computer-categorization task to measure the strength of association between a category (e.g., Black and White people) and an attribute (usually affect-laden like 'good' or 'bad'). For example, a person might first be asked to categorize all Black faces and positive words (e.g., summer, good) with their left forefinger and all White faces and negative words (e.g., bad, vomit) with their right forefinger. Then they would be asked to categorize Black with bad and White with good. Faster responses for the Black-positive/White-negative pairing would indicate a stronger association between Blacks, as compared with Whites, with positive valence. Lending validation to this new tool, a recent meta-analysis revealed that compared to explicit measures (most commonly assessed using self-report), the IAT better predicted socially sensitive criterion variables, such as those related to race or other intergroup relations. For example, a Black-White IAT better predicted nonverbal behaviors such as participants' eye blinking and physical distance between the participant and a Black confederate than the participants' self-report of their feelings toward Blacks.

Based on a similar rationale of associative pairing, Fazio and colleagues developed the affective priming method for measuring implicit attitudes. In this paradigm, a computer quickly flashes a prime (e.g., a man or woman's face) before showing a positive or negative word and then measures the amount of time it takes participants to categorize each word as good or bad. This paradigm is based on the assumption that positive attitudes toward a category like women should increase the speed with which a person categorizes positive words (e.g., summer, smile) as positive. Like the IAT, research on affective priming has found that response latencies after the prime predicted subtle racial behaviors (e.g., eye contact,

blinking, physical closeness). In one study of implicit racial bias, Fazio et al. found that people who categorized negative words more quickly after a Black prime also tended to place more blame on Blacks for the Los Angeles riots that followed the not-guilty verdict for the police accused of beating Rodney King.

Automaticity and Behavior

Automatic processes, such as implicit attitudes, affect many areas of social life. Social cognition researchers have found that subliminal primes can affect behavior and perception by activating mental representations outside of a person's awareness. In one study, Bargh et al. subliminally primed people with either a Black or White face. When the experimenter subsequently told participants that the computer had lost all their data and they would have to repeat the tedious task, participants primed with Blacks exhibited more hostile facial expressions. Automatic processes also occur when someone is consciously exposed to a stimulus, yet unaware that the particular stimulus has any effect on seemingly unrelated behavior or judgments. In another clever study, Bargh et al. had participants unscramble words that primed the category 'elderly.' As a result, participants were aware that they had just seen words such as 'old' and 'forgetful,' but had no idea that these words might affect their behavior in a completely unrelated domain. After the experiment had ostensibly ended, however, they walked more slowly down the hall to the elevator than participants who had unscrambled neutral words.

People also seem to automatically engage in self-protective processes and behaviors when their self-esteem is threatened. Telling people they did poorly on a task (threatening their self-esteem), for instance, tends to increase their negative stereotyping of others. Such research paints a rather bleak picture of the pervasiveness of automatic biases. But, automatic processes do not all have to be negative and, in fact, people can override their negative biases given the motivation and ability to do so. For example, if people are motivated to be egalitarian, then negative stereotyping does not have to occur. If people admit their potential for prejudicial responses and feel guilt over it, they can learn a new association between the problematic category and a warning for careful processing. Over time, and with practice, people can learn to inhibit the negative response and replace it with a more positive one, thus making the positive response the dominant and automatic one.

Social Neuroscience

As mentioned earlier, recent neuroscientific findings have begun to offer convergent evidence of two separate systems in the brain responsible for controlled and automatic processing. The newly developing interdisciplinary field of social neuroscience – still less than two decades old – uses cognitive neuroscience research tools (e.g., fMRI and PET) to examine the neural locations of social information processing. It allows social psychologists to investigate hypotheses – such as whether automatic and controlled processes are qualitatively distinct – using neuroscience methods. Since the beginning of the 1990s, known as the Decade of the Brain, neuroscientific studies have generated a great deal of excitement about a possible window

into the brain. The marriage of these two previously separate fields should not be particularly surprising given that both neuroscience and social psychology are concerned with how the mind works and how affective and cognitive processes connect to action tendencies and actual behavior.

Studies of neurological processes using functional magnetic resonance imaging (fMRI) are increasingly popular, with new data appearing routinely. Part of the appeal of fMRI to social cognition researchers comes from the belief that self-reports and observations of overt behavior provide only a limited picture of the mechanisms underlying complex attitudes and behavior, especially automatic attitudes. Functional magnetic resonance imaging provides images of brain activity by measuring changes in blood flow and oxygen use while people engage in a particular activity (e.g., categorizing faces as male or female, thinking about someone with whom they are passionately in love). These images of brain activity during different tasks provide clues about the possible functions of different regions of the brain, thereby providing another part of the picture of the mechanisms underlying social cognition processes.

Although social neuroscientific findings have contributed to our understanding of social phenomena such as attachment, morality, prejudice, and decision making, we must be mindful that neuroscience is still conceptually and methodologically in a relatively early stage of development. The colorful images depicting brain activity published in magazine articles suggest a deceptively clear and compelling picture of a highly complex and nuanced process. Most research suggests that complex psychological or behavioral constructs do not cleanly map onto a single area of the brain. It is most likely the case that no region of the brain serves one singular function. With these caveats in mind, general themes have emerged in the literature on social-cognitive neuroscience.

Studies have shown, for example, that different areas of the brain are associated with object perception and person perception. The medial prefrontal cortex (mPFC) – located on the outer side of the brain, about one-third of the way back along the midline – seems particularly important for social-cognitive tasks. For example, along with the superior temporal cortex, the intraparietal sulcus, and the fusiform gyrus, the mPFC was implicated in a social judgment task. Compared to object judgment (could the word ‘shabby’ describe a pair of pants?), social judgments (could the word ‘assertive’ describe a person named Mark?) were associated with a unique pattern of brain activity in the medial prefrontal cortex. Interestingly, thinking about one’s own life and experiences also predicts activation in the mPFC.

As described in the dual-process section, recent neuroscientific evidence provides support for the distinction between controlled and automatic processing, as each kind of processing seems to be associated with different regions of the brain. Lieberman’s research indicates that automatic processing is associated with activation in the amygdala, basal ganglia, ventromedial prefrontal cortex, lateral temporal cortex, and dorsal anterior cingulate cortex. To simplify, Lieberman and colleagues refer to the collective of these regions as the X-system. As further evidence of the amygdala’s involvement in automatic processing, other researchers have found that activation of the amygdala correlates with implicit measures of racial attitudes, but not explicit measures. Controlled processing, in contrast, seems to be associated with the lateral prefrontal

cortex, medial prefrontal cortex, lateral parietal cortex, medial parietal cortex, medial temporal lobe, and rostral anterior cingulate cortex. Lieberman and colleagues refer to these regions as the C-System.

Other neuropsychological evidence supports Baumeister and Leary’s contention that the need to belong and connect with others may be a fundamental motive, or at least has a biological association. Simply being excluded from a computerized ball-tossing game has been shown to increase activation of the dorsal anterior cingulate cortex (dACC), the same part of the brain that reacts to physical pain. Activation of the dACC has also been found to be associated with losing important social connections such as caretakers.

All these findings demonstrate that the use of new neuroscientific tools has helped to create an exciting new subfield within social cognition. As our understanding of brain imaging continues to develop, this new research has considerable potential to enrich theory and research in social cognition.

Conclusion

Since our last review more than 15 years ago, the field of social cognition has steadily evolved. Perhaps the two most promising new directions are implicit attitudes and social-cognitive neuroscience. In bypassing an individual’s conscious awareness, these theoretical frameworks have the capacity to deepen our understanding of the intersection between social interaction and the workings of the mind. Over the last two decades, social cognition has also contributed to a scientific database that serves the research interests of more applied social scientists. For example, political psychologists have relied on social-cognitive concepts such as priming and framing to understand the dynamics of public opinion. In laying out a theory of *implicit* racial priming in elections, Mendelberg argues that the rise of egalitarian norms in American society requires that campaigns seeking to mobilize resentful White voters use subtle forms of racial communication. Social-cognitive concepts have also informed our understanding of the nature of candidate evaluation. In particular, by noting that voters often extract the evaluative implications of political information at the moment of exposure and then proceed to forget the nongist descriptive details, political psychologists have forcefully challenged the long-standing assumption that rational choice flows from information holding and ideological awareness. In sum, we expect that conceptual and methodological advances in social cognition will continue to serve as the basis for scientific advancements both within and beyond the field of social psychology.

Glossary

Assimilation Looking for similarities between oneself and the comparison target and feeling close to or like the target.

Contrast Looking for dissimilarities between oneself and a comparison target and feeling distant or unlike the target.

Lateral Same-level comparison.

Prototype An individual's subjective perceptions about the typical member of a certain category.

Self-enhancement The desire to improve one's feelings of self-worth.

Self-evaluation The desire to evaluate one's behaviors or opinions.

Self-improvement The desire to gain new skills to better oneself.

Social comparison Comparing oneself along one or more dimensions with a real or imagined person.

Target The person, real or imagined, with whom one is comparing.

Introduction

Every day, whether we are aware of it or not, we compare ourselves with others. We compare on a variety of dimensions from appearance ('Am I underdressed for this party?') to opinions ('Is my belief valid? What do others think?'), to performance on a task ('What does my exam score mean? Should I be happy or worried?'). Sometimes, the person we are comparing ourselves with may not even be real. For instance, students might compare themselves in terms of level of stress with their perception of the average student at their school. Although no truly 'average' student exists, feeling that one is experiencing more stress than the average student will nonetheless be disheartening. Thus, it is possible that comparing with an imagined other person will have just as profound an impact as comparing with a real person. These comparisons may be deliberate and conscious, but they also can be triggered unconsciously or can happen spontaneously. It's not just that people are being nosy; these comparisons have specific purposes. In fact, these comparisons serve many adaptive functions. The present article lays out a brief history of research on social comparison and highlights the many factors that influence the type, frequency, and effects of social comparisons. Real world applications are described and future directions in social comparison research are also discussed.

objective information is absent will people compare with others to better appraise the situation. Subsequent research has shown that Festinger was actually underestimating social comparison, and that, in fact, people often prefer knowing their relative status, via comparisons with others, as opposed to their absolute standing. The basic principles of the theory, however, have held the test of time and continue to influence research in the field of psychology.

Social Comparison and Self-evaluation

Festinger proposed that the best way for a person to gain insight about his or her performance would be to compare with someone who is perceived to be similar. For instance, an amateur musician might compare his performance with a person who has similar years of experience, rather than comparing with a professional musician (clearly superior) or someone who has never played before (clearly inferior). The greater the similarity of the comparison target (the person to whom one is being compared), the more precise is the evaluation. Festinger believed that only when similar comparison targets are unavailable will people resort to comparisons with others perceived to be dissimilar from the self; in these cases, the comparer will have less confidence about the conclusions he or she can draw from the comparison.

Festinger's Original Social Comparison Theory

The term social comparison was coined in 1954 by Leon Festinger. His article proposing social comparison theory was instrumental in jumpstarting this line of research. According to his theory, there is a universal drive for people to evaluate their abilities and opinions. One way to gain perspective on one's abilities or opinions is to compare with others. If objective information is available that can inform a person regarding his or her performance or opinion, then social comparison should not be necessary. According to Festinger, only when

Social Comparisons and Groups

Festinger was particularly interested in the role that social comparison plays in the behavior of group members. He demonstrated how social comparison could be used to explain various group processes, including group formation, conformity, and competition. If the group is important to a member and the ability or opinion being evaluated is central to the group, then the member should be motivated to regularly compare with other group members. For example, a member of an important committee at work may find it necessary to compare with his coworkers to assess his status in the group

('Am I contributing enough?'), as well as assess his opinions ('Do others agree with my idea for the project?'). If the worker feels that his status is slipping or his opinions are not shared, then he should be motivated to conform with the group – if it is important to him. If the comparison dimension is not much valued or the group is seen as less important by a member, then he or she will not face the same pressure to engage in social comparison. Members who, upon comparison, are deemed too dissimilar from the rest of the group are most likely to be excluded from the group.

Social Comparison and Improvement

In addition to the desire to evaluate oneself, Festinger also recognized that there is a constant desire to improve one's abilities. Thus, people might be motivated to compare with others who have performed slightly better than they have. This would allow the comparer to gain insight as to why his or her performance was inferior and provide motivation to work harder. Festinger noted that this upward drive for abilities may be more pronounced in Western cultures, because traits such as individualism and autonomy are seen as more important in Western cultures, where people will feel the need to stand out from the crowd. These cultural norms provide motivation to compare as a way to improve one's standing. In Eastern cultures, more value is placed on group harmony. These two motives, self-evaluation and self-improvement, are discussed in more detail in the next section.

Directions and Motives

As noted earlier, Festinger originally proposed that people are most likely to engage in social comparison with those who they think are similar to themselves. These same-level comparisons, referred to as lateral comparisons, were believed to result in the most accurate evaluation of a person's own abilities or opinions. Comparing with a person who is highly divergent, either greatly superior or inferior, would provide less precise information to the comparer. Although self-evaluation is still viewed as a primary reason why people engage in social comparison, researchers now recognize two (at least) additional types of motives: self-improvement and self-enhancement. As these terms suggest, people may wish to compare with others in order to learn new skills or become inspired (self-improvement), or to feel better about themselves or their situation (self-enhancement). Self-improvement is often associated with upward comparisons – it should be easier to gain inspiration and learn new skills from a person who is doing better than oneself as opposed to worse. The reasoning behind providing children with role models is the assumption that they will be motivated to be more like the admired individuals. Role models act as upward social comparison targets that children can learn from and aspire to be like, motivating them to work harder to achieve similar goals.

Self-enhancement is also a common motivation behind social comparison. As a general rule, individuals prefer to view themselves in a positive light and are motivated to sustain their positive self-images. Comparing with others who are perceived to be worse off allows individuals the opportunity

to feel better about their own situation. The self-enhancement motive gained popularity in the late 1970s and early 1980s, as will be discussed in the next section.

Whereas the early focus of social comparison research was selection of comparison targets, it has shifted over the last 30 years to an emphasis on the motives behind, and effects of, engaging in social comparison.

Milestones

Broadening the Scope

As noted in the previous section, Festinger proposed that social comparison played a role in people's assessments of their opinions and abilities. Thus, the initial studies investigating the theory focused on these two dimensions. This line of research was soon broadened to include emotions as well. Stanley Schachter's research in the late 1950s on fear and affiliation demonstrated that during times of high anxiety, people showed a preference to be around others who were in a similar high-stress situation. This was the case even when participants knew they would not be allowed to converse with each other. It was proposed that people could gain insight into how nervous they should be (and how they might cope) by comparing with someone facing the same stressor.

An important outgrowth of Schachter's work on emotional comparison was his two-stage theory of emotion developed with Singer. They suggested that when people experience physiological arousal (increased heart rate, rapid breathing), they will attempt to label that arousal as a particular emotion. Schachter and Singer cleverly showed that, when the source of the arousal is unclear, the emotional label given can be influenced by social factors, specifically, others in the situation. Participants were given adrenaline to produce physiological arousal, but only some were told what symptoms they could expect. All of the participants were then paired with a confederate who acted either euphoric or angry. Those who had not expected the injection to cause physiological arousal behaved similarly to the target (becoming either euphoric or angry themselves), suggesting that these participants labeled their mood state on the basis of a comparison with the confederate. Of course, most of the time when people are aroused they do not try to label and they do not socially compare – they do not need to, as the cause and the emotional reaction are clear. Nonetheless, Schachter's research clearly demonstrated the important role that social comparison can play in emotions, as well as other behaviors.

Downward Comparisons

Another milestone in social comparison research came with the publication of Wills' article on downward social comparison theory. According to the theory, people who compare with others who are thought to be faring worse experience an improvement in their mood (in other words, their subjective well-being increases). People who feel threatened should be most likely to engage in downward comparison, especially if there is no direct way to confront the source of the threat. If there is a direct way to deal with the stressor (instrumental coping), then this will be the first option. Downward social comparison is an emotional coping technique that can help

one feel better in the short-term, although it is often not the best long-term strategy for dealing with a threat (see Coping entry). The threat need not be physical – threats to a person's ego will lead to the same motivation to compare with a less fortunate person. Wills proposed that people with low self-esteem should be more likely to engage in downward comparison than those with high self-esteem, as they are more likely to experience low levels of subjective well-being.

Wills maintained that self-enhancement through downward comparisons can be accomplished through either an active or passive process. The latter occurs when people learn about others who are worse off and then use that information as an opportunity to improve how they feel. With more active forms of downward comparison, the comparer can derogate the target or cause them physical harm, both of which will have the result of lowering the status of the target, and making them appear inferior. For instance, Wills suggested hostile forms of humor can be used to derogate a person or group of people. Putting others down, even in jest, serves to boost one's own status – in comparison. Another illustration of self-enhancing comparisons is when a teenage girl who is feeling insecure about her own appearance calls a classmate overweight and unattractive. Wills also noted that people are generally ambivalent about downward comparisons. On the one hand, they don't like to take joy in someone else's misfortune or be seen as gloating (this has been referred to as *schadenfreude*, or 'joy from damage'). On the other hand, they realize it can have emotional benefits. Wills used the self-enhancement motive and the concept of active downward comparisons to explain a broad range of research, from prejudice to physical and verbal aggression.

Related to downward social comparisons is the notion of downward shifts put forth by Gibbons and colleagues. Whereas downward comparisons are usually motivated by a desire to enhance (damaged) self-esteem, downward shifts usually reflect a desire to protect threatened self-esteem. Downward shifts are more common, because true downward comparison with a person who is believed to be worse off may not always be feasible or desirable. This may be the case for the student who received the lowest grade in the class; there simply is not a classmate who is worse off to compare with. Other times, downward comparisons are unwanted because of the discomfort that arises. In these situations, when people are feeling threatened but either cannot or do not want to engage in true downward comparisons, there is a tendency to lower one's preferred target level. For instance, the aforementioned student will not want to compare with the best student in the class, but selects a classmate who is not quite as accomplished (a student who is doing okay rather than excellent). This downward shift has been demonstrated in a variety of situations, including health: people who are attempting to quit smoking and then relapse show decreasing interest in comparison with successful abstainers.

Factors that Influence Comparisons

Similarity

Researchers have long focused on what factors influence who is selected as a comparison target. As Festinger noted in his seminal article, similarity plays an important role, with people

selecting targets that are viewed as similar to themselves. The more similar the comparison target, the easier it is for people to make a comparison and the greater the certainty they have in their conclusions. Similarity may be on the basis of a dimension relevant to the comparison, such as a golfer comparing with someone with the same handicap; however, people may compare with others who are similar on dimensions less central to the comparison. It has been shown that the type of similarity with the target can be important. A person is more likely to identify with a comparison target if the two share a distinctive quality as opposed to a nondistinctive one. If the target shares a birthday or also has a rare hobby, then the comparer is going to be more influenced by him or her. If the target shares a more common quality, such as a popular hobby, then this target is less likely to have an influence on the comparer.

Assimilation Versus Contrast

The more similar the target, the easier it is to identify with him or her; identifying with a comparison target is known as assimilation. The more a person identifies with an upward comparison target, for instance, the greater is the positive impact of the comparison; conversely, the more similar a downward target is perceived to be, the greater is the negative impact. If comparers identify with someone superior, then they should feel hopeful that they too can experience that level of success. If they feel similar to a person who is worse off, then they are likely to worry that they, too, will experience the same fate. There are times when the comparison target may be viewed as different from oneself along dimensions important to the comparison. Rather than identifying with the comparison target, comparers in this case will contrast themselves with the target. Contrasting with an upward target will have a negative impact ('There's no way I can perform that well'), whereas contrasting with a downward target is more likely to have a positive impact ('I am not like him – that will never happen to me').

Originally, researchers believed that downward comparisons were generally self-enhancing and that upward comparisons could be threatening. Since then, it has become apparent that whether a comparison has a positive or negative impact is determined by whether a person identifies or contrasts with the comparison target. To paraphrase Bram Buunk, both upward and downward comparisons have their ups and downs.

So what determines whether people identify or contrast with a comparison target? Mussweiler has proposed that people do a quick holistic assessment as to whether they are similar to or different from the target. This initial determination of similarity, in turn, influences how they go about making the comparison. If they view themselves as similar, then similarities are more likely to come to mind (target-consistent knowledge becomes more accessible). If they view themselves as being different from the target, then dissimilarities are more likely to come to mind (target-inconsistent knowledge becomes more accessible). Similarity testing is more likely to lead to identification with the target, whereas dissimilarity testing is more likely to lead to contrasting with the target. It has been shown that similarity testing, as opposed to dissimilarity testing, seems to be people's initial default tendency.

Perceived Future Similarity

Another factor that has been identified as playing an important role is attainability – that is, whether comparers believe that what the target is experiencing could happen to them. If people feel that they can be like superior others, for instance, then they will be motivated to work harder. If they feel that they cannot be like superior others, then an upward comparison will be potentially threatening. Along those lines, Lockwood and colleagues demonstrated that whether comparison with a ‘superstar’ – in their case, a graduating senior who had succeeded both academically and socially – had a positive or negative impact on undergraduate college students depended on whether participants were freshmen or seniors. Those in their first semesters in college were inspired by superstars who shared their major. Seniors, however, did not have the time left in college to reach the same level of success. Lockwood and colleagues found that the seniors tended to react defensively in an ego-protective manner, apparently to prevent them from feeling worse about their own situation. For instance, seniors were less likely than underclassmen to rate the superstar as being superior and downplayed the importance of the superstar’s accomplishments.

Similarly, if the experiences of a downward comparison target are seen as likely to occur to the self in the future, then it will affect the impact that the comparison will have. Using an example from the health domain, patients with a deteriorating illness will not want to compare themselves to a patient experiencing more severe symptoms (a downward comparison target), as they realize that they will likely be in the same situation in the future. If people have a health condition that is not likely to deteriorate, however, then making a downward comparison should be self-enhancing and should improve one’s mood.

Individual Differences

Although, social comparison is a universal phenomenon, and often done automatically, there are clearly individual differences in the extent to which people compare – some people compare more regularly than others. Gibbons and Buunk created a scale to measure individuals’ tendencies to engage in social comparison. They have found that people who are more self-conscious socially compare more often. People who are aware of themselves when they are around others, and who often reflect on their thoughts and feelings, are more frequent comparers. High comparers also have a greater ability to imagine themselves in others’ shoes, leading them to be more empathetic than those who compare less often. There is also a downside to frequent comparison, however, as those who socially compare more also are more likely to have lower self-esteem, be more depressed, and experience more mood swings compared to those low in social comparison orientation. Finally, women compare more frequently, on average, than men.

Adaptive Benefits

Why is social comparison so common? Researchers have suggested that social comparison has a number of adaptive benefits. As Festinger originally noted, comparisons with others allow individuals to get a better idea of where they stand in

the group. It was likely important for our ancestors that group members avoid potential harmful competition. Comparing one’s abilities with other group members, can allow a member to determine which specialized role should be taken and which abilities he or she should focus on improving. Thus, members are motivated to improve on behaviors they feel that they are specifically qualified to engage in and that bring a unique contribution to the group. For example, a member who, upon comparison, discovers that he is particularly adept at fishing but not at hunting, will be better off focusing on his role as a fisherman as opposed to his role as a hunter. Feeling like an important, contributing group member, in turn, helps to enhance a member’s self-esteem. Social comparison also plays a role in the cohesiveness of the group. By making sure one’s views and goals are in line with those of the group, members prevent themselves from potentially being excluded – which could have dire consequences. Maintaining the cohesion of the group increases its likelihood of prospering.

In addition to evolutionary benefits, social comparisons are adaptive in terms of how humans process information. Social comparison makes processing information more efficient in that it allows a person to limit the range of information that is needed to make an evaluation or judgment. Humans have many demands on their time and attention (and thus have scarce available cognitive resources), so having a way to simplify the processing of information is extremely beneficial.

Social Comparison and Biased Perceptions

As the field of social psychology turned its collective attention to cognition in the late 1980s and early 1990s, researchers began applying this new approach to the study of social comparisons. People are predisposed to hold themselves in high regard and are motivated to maintain these overly positive beliefs of themselves relative to others, and social comparison processes appear to drive these biased perceptions. One illustration of this phenomenon is that people tend to view their ideas and opinions as being correct or appropriate and therefore more prevalent among the public than they actually may be (this is known as the false consensus effect). Believing that the majority of others share their views strengthens people’s confidence in the validity of these beliefs. This increase in confidence, in turn, will influence their future behavior. There are times, however, when individuals prefer to see themselves as standing out from the crowd, in other words more different or special than they actually are (this is termed the false uniqueness effect). This belief in false uniqueness is maintained by underestimating the prevalence of an ability or belief in the general population.

It has been shown that people have a tendency to select comparison targets that are most likely to lead to these biased conclusions. For instance, a person might compare his or her political views with those of his or her close friends and find that they all hold similar beliefs. Of course, an individual’s group of friends is likely not representative of the general public. Individuals tend to be friends with similar people, and so it is likely that they hold similar political beliefs. In this case, the result is that the person overestimates the percentage of people who share his or her political opinions. This belief, in turn, results in increased confidence in his or her

views and strengthens his or her resolve to promote the political party most associated with his or her views.

Applications to Health

Social comparison plays an important role in health behaviors and cognitions. For instance, the decision to seek medical attention is often influenced by social comparison. When deciding whether to go to the doctor or not, a person will compare his or her symptoms to those of others he or she knows ('My friend had similar symptoms and needed antibiotics. I may be at risk and should see a doctor' or 'My friend had similar symptoms, but was fine the next day. It's not worth seeing a doctor'). Thus, people with the same symptoms may make different decisions on the basis of whom they compare themselves with. Additional examples of health-related social comparison research are described below.

Risk Perceptions

Social comparison plays an important role in people's perceptions of risk. How vulnerable people feel to negative outcomes is largely based on their relative judgments. Along these lines, Jemmott and Croyle found that the more prevalent a behavior or event is thought to be (in their case, contracting a fictitious disease), the less severe it is viewed; in other words, there is safety in numbers. If the behavior or event is less common, then people tend to see it as being more severe and are more worried about the possibility of negative consequences. As noted earlier, people tend to overestimate the extent to which others share their opinions and abilities in order to normalize them. Thus, college students who binge drink overestimate the number of their peers who also drink heavily. Because they think that, 'everyone is doing it,' they perceive the behavior as less risky and are less concerned with its potential consequences.

When estimating the likelihood of experiencing different events, people also display an optimistic bias. As Weinstein has shown, people underestimate their likelihood relative to other people of experiencing negative events (such as getting divorced, experiencing a heart attack), but overestimate their likelihood of experiencing positive events (e.g., winning the lottery). One way that people maintain these beliefs is to choose social comparison targets who lead them to these biased or overly optimistic views of themselves. For instance, when estimating his risk of having a heart attack, a man may choose a target that has a poor diet, or smokes, or does not exercise; by choosing a prototypical unhealthy target, he ends up feeling less vulnerable.

Affiliation

As noted earlier, Schachter proposed that people under stress will be motivated to affiliate with people who are in the same situation, as a way to gain insight into how they should react to and cope with a threatening situation. More recent research, however, has shown that people facing major surgeries (and therefore experiencing stress) actually prefer to spend time with people who have already undergone the surgery, rather than someone who is also waiting for the same procedure. The reason,

apparently, is that they can gain useful information from a person who has already experienced the threat. In fact, several studies support the idea that upward targets are more beneficial in these instances. In a novel field experiment, Kulik and colleagues found that patients who, prior to cardiac operations, were randomly assigned a roommate who had already undergone a cardiac operation were less likely to experience anxiety before the operation, more likely to walk in the days following the operation, and more likely to be discharged from the hospital earlier than those who had been assigned a roommate who was also about to have a cardiac operation or who had a noncardiac condition.

Similarly, one reason support groups work well is that members can learn from each other. For example, a member of a weight loss group may learn better coping strategies from those who have been more successful (upward comparison targets) or they may feel less deviant if others report experiencing the same (or worse) struggles and temptations. Members of the group who may be struggling can gain inspiration from those who have had more success ('if she can lose 25 pounds and keep it off for 6 months, then so can I'), as well as learn new ways to deal with their own obstacles (such as tips on eating healthy while on vacation). The benefits for successful members of support groups are less clear, as they are more likely to make lateral or downward comparisons to other group members. Thus, successful members have less of an opportunity to improve by comparing with upward targets, but they can feel better by making downward comparisons.

Coping Techniques

Although, as Wills suggested, many people are reluctant to admit that they engage in downward comparisons as a way to feel better, research with cancer patients has shown that it is a relatively common coping technique. In a series of studies, Shelley Taylor and her colleagues interviewed breast cancer patients and their spouses. During these interviews, it was found that patients would spontaneously make downward comparisons (e.g., a woman who had a lumpectomy would comment how bad it must be for women who have had a mastectomy). Even though others would probably judge their condition as being quite serious, patients coped by believing that it could be even worse. In some cases, patients did not have a specific person in mind, but imagined the downward comparison target. When interviewing the husbands of breast cancer patients, for instance, many of the men mentioned, 'At least I am not like those husbands who leave their spouses.' They viewed this behavior as being relatively common, even though, in fact, only a small minority of husbands actually left their cancer-stricken spouse. For this reason, Taylor called these comparison targets 'mythical men.' By creating a downward comparison target (or image) of someone who was not coping well, these men were able to feel better about the difficulties they were experiencing by consoling themselves with the fact that they had (at least) stuck around.

Prototype Images

Similar to the 'mythical men' that Taylor found, other mental images have been found to influence health-related behaviors and cognitions through a similar social comparison process.

Gibbons, Gerrard, and colleagues have proposed a prototype/willingness model of health behavior that is based on social comparison. They have demonstrated that people often compare themselves to a prototype, that is, their idea or image of what a typical person who engages in a behavior is like. Using smoking as an example, adolescents have a general idea of what the typical smoker their age is like in terms of popularity, intelligence, etc. They realize that if they were to start smoking, their peers would then see them as being like a typical smoker. The more negative their prototype is of the typical smoker, the less willing they are to engage in the risky behavior for fear of being stereotyped. So, if they view the typical smoker as being uncool and unattractive, then they should be less willing to smoke than an adolescent who has a more favorable image of the typical smoker their age. Not only do prototypes influence a person's future behavior, but the reverse has also been demonstrated, with behavior influencing future prototypes. Adolescents who begin smoking have been shown to increase the favorability of their smoker prototype. Thus, they come to see smokers their age as less negative than they had seen them before they started engaging in the behavior ('They're really not that bad'). And that, of course, can lead to more smoking, and can interfere with quitting.

Gibbons and colleagues examined the prototypes of members of smoking cessation groups both before and after they attempted to quit. They found that the more members were able to distance themselves from their prototype of the typical smoker, the more successful they were at quitting smoking. Contrasting themselves with the smoker prototype actually facilitated quitting. However, for those who identified with their smoker prototype or who had family members who smoked, derogating the typical smoker became more difficult, and, in turn, quitting smoking became harder. Finally, research has shown that prototypes are more influential for those who are chronic social comparers. Those who generally avoid making social comparisons have images that may be positive or negative, but they are less likely to be influenced by those images.

Future Directions

The Influence of Culture

As noted briefly earlier, cultural norms can influence the motivations behind comparison with others. In more interdependent cultures (in East Asian countries, for example), people place great significance in maintaining group harmony and so conformity is stressed. Social comparison is integral to assuring that one is fitting in with the group. In Western cultures, social comparison may be used to assess conformity, but it also plays a large role in competitions, as people will often compare when they are trying to get ahead. In addition to the motives driving social comparison, cultural norms also influence whom one selects as the comparison target. Much attention has been placed on how individuals view themselves (in other words, their self-construals) and how these views differ between men and women. Stronger gender differences have been found in Western as opposed to Eastern cultures for personality traits, values, and emotions. These gender differences are surprising given the greater emphasis placed on gender equality in Western cultures. It appears that these cultural differences

may be driven by the fact that individuals in Eastern cultures, comparatively speaking, are more likely to select a same-gender target, whereas those in Western cultures are more likely to select a target of the opposite gender. Whether a same or opposite gender target is selected, in turn, influences the type of knowledge that comes to mind. Researchers in this area have been exploring the roles of cultural norms, especially beliefs in the social hierarchy, and how these normative beliefs influence people's intergroup versus interpersonal comparisons. We expect future research to give more empirical attention to social comparison processes across cultures.

Neurological Mechanisms

With the development of new technology, researchers have begun investigating the neurological mechanisms involved in social comparison. One important and intriguing question is what happens in the brain when one makes an upward or downward comparison? Functional magnetic resonance imaging (fMRI) and event-related potentials (ERP) have been employed to identify specific neural substrates that are activated when a favorable or unfavorable comparison is made. This burgeoning area of research has so far focused on the impact that social comparison has on reward processing in the brain. As much remains unknown about the neural mechanisms underlying social comparisons, we expect this research to become more popular in the future.

Boundary Conditions and Other Influential Factors

Attention is increasingly being drawn to the factors that impact various aspects of the social comparison process. In particular, more consideration is being given to elements such as comparison dimensions: How does the type of dimension on which a person compares influence the impact of upward and downward comparisons? Patients with a health condition, for instance, can compare themselves on a variety of dimensions and can learn about ways to deal with symptoms and side effects (coping techniques), or feelings they may experience (emotions), or they can learn more about what they should expect from future doctor visits (procedural information) by comparing with others. Buunk and colleagues have been exploring the impact of these three various comparison dimensions among samples of cancer patients. They have also examined the role of neuroticism and how this individual difference factor influenced the reaction that patients had to the different types of comparisons. Neuroticism is a personality trait, with those high in neuroticism (neurotics) being more emotionally volatile than those low in neuroticism. Neurotics are often described as being tense, anxious, or moody. Previous research has shown that people high in neuroticism tend to react more negatively to social comparisons than those low in neuroticism. However, Buunk and colleagues found that these negative effects could be buffered among neurotics if they compare with someone who is either coping well or who describes the procedures the patients will undergo. We expect this exploration of additional individual difference factors and comparison dimensions to continue.

Interest in objective factors that affect social comparisons has also increased. In a recent study, Garcia and Tor investigated

how the number of competitors influences people's desire to socially compare and how this relates to their motivation to compete. Although having others present can facilitate people's performance and act as a motivator to perform better, it is not the case that 'more is always better.' In cases where there are an extremely large number of competitors, an individual's motivation to compete actually decreases. They termed this the N-effect and found that it is driven by the fact that as the number of people increases, interest in social comparison diminishes, which, in turn, lowers motivation. Identifying these boundary conditions will continue to be important in social comparison research.

Broadened Applications

Social comparison research has been conducted in a number of areas in addition to health (such as educational and work settings). It is likely that social comparison will continue to be studied in these real world settings. With the immense popularity of social networking sites, such as Facebook, people routinely find themselves in situations that are ripe for social comparison (whether automatic or deliberate); these situations will increasingly warrant further study. The role of social comparison in other social psychological phenomena has also been investigated. For instance, social comparisons have been shown to influence the stereotypes people hold, how attitudes are formed and changed, and how the impressions of other people are established. As social comparison has proven to be a central part of our daily lives, we expect that social comparison processes will continue to be integrated into a number of different areas of human behavioral research.

Summary

Social comparisons are an integral part of human nature and occur on a regular basis in a wide variety of situations. As Festinger theorized, social comparisons can be used to evaluate one's abilities or opinions. They can also be used to self-enhance or self-improve. The impact that a comparison has on the comparer depends on a number of factors, such as personality traits (self-esteem, neuroticism) and perceptions of the target (similarity). These factors will continue to be explored. In addition, more attention is being paid to the neurological mechanisms that are involved when making social comparisons. Because of its ubiquity, social comparison

can be studied in a variety of settings, including, but not limited to, health-related situations. It is expected that these applications of social comparison theory will continue to expand and, in the process, broaden the theory and our understanding of human social behavior.

Glossary

Attachment A close, enduring emotional relationship between two individuals (e.g., infant and parent), characterized by pleasure in interaction, and a desire to maintain proximity, particularly in times of stress.

Ethology A theory concerned with the adaptive or survival value of behavior, its evolutionary history, and similarities between human behavior and the behavior of other species.

Imprinting An innate or instinctive form of species-specific learning, occurring during a restricted (or sensitive) period, in which the young of certain species will follow and become attached to a moving object (typically their mothers).

Internal working model Representations of self, caregiver, and relationships that infants construct based on their interactions with the caregiver, as well as rules guiding the processing of self- and attachment-relevant information.

Secure base Use of a caregiver as a base from which to explore the environment, and to return to for emotional support.

Sensitive period A loosely bounded period of time that is optimal for the development of particular capacities or behaviors, and during which the individual is especially sensitive to environmental influences that affect these developments.

Strange situation A standard procedure used to determine the quality of attachment security based on infant behavior during a series of separations from and reunions with the caregiver.

Synchrony Harmonious interactions between two individuals in which attention and emotion are matched and shared, and each participant adjusts behavior and emotion in response to the partner.

Children develop in a network of relationships, and the most important social connection in an infant's world is the connection to the caregiver. This attachment relationship – a long-lasting, emotional bond between child and parent – should provide the infant with a sense of comfort and security, and function to promote the infant's safety and survival. However, the character and quality of these bonds can differ dramatically, and according to attachment theorists are a source of variability in later socioemotional development. In the first half of this article, we focus on normative early social development, starting with a description of human attachment behaviors, and contrasting this with ethologists' observations of imprinting in other species. We discuss the emergence of social behaviors and attachment across the first year, along with evidence of the importance and universality of the attachment relationship. In the second half of the article, we describe individual differences in attachment, including infant attachment classifications, and predictors and correlates of secure and insecure attachments. Finally, we consider attachment past infancy, focusing on two questions. First, are attachments stable in development past infancy, and second, what changes in attachment systems take place in childhood and adolescence?

Roots of Attachment Theory: Ethology and Imprinting

The theory of human attachment is rooted in ethology. John Bowlby, a British psychologist and psychiatrist, developed attachment theory, drawing on observations of the developing connection between infants and parents that are common to humans and animals. Particularly influential was ethologist Konrad Lorenz's work in the 1930s on imprinting. Lorenz described imprinting as the irreversible development of a preference for a social partner that was acquired during a critical

period, was found across the species, and was established prior to the preference being evident in behavior. His work demonstrated the innate tendency of young goslings to instinctively follow the first moving object encountered, typically the mother, serving to keep the goslings close to their source of protection. Images of Lorenz followed by geese – Lorenz being the first moving object they saw during their critical period for imprinting – illustrated a powerful and adaptive mechanism at work (Figure 1). Bowlby had been working with colleagues to understand the close emotional bond between child and mother, in part because he sought to explain the often devastating consequences of disrupting this bond. Based, in part, on Lorenz's work, Bowlby proposed that the young child naturally relied heavily on the presence of the mother and was disturbed by her absence, because the formation and maintenance of this close emotional bond was beneficial for safety and survival. In other words, Bowlby came to see the human infant–mother attachment as a 'special case' of imprinting, albeit with a more complex and reciprocal relationship than the ones described by ethologists. Thus, for both young goslings and human infants, maintaining close proximity to the mother facilitates physical protection as well as exploration of the environment. In particular, the human infant's connection to the caregiver gives the infant confidence to explore the environment, knowing that she is watching over him, and that he can return to her when needed. Bowlby's description of the attachment relationship between human infants and caregivers contained some unique features, shared with only a few other primate species. For humans, the function of close proximity and contact during infants' early, vulnerable years goes beyond physical safety. Human infants experience a decrease in distress through contact and soothing behavior from the primary caregiver. Partly for this reason, the attachment relationship is entwined with the early development of emotion and emotion regulation.

Figure 1 Like Konrad Lorenz and his goslings, these ducklings have imprinted to their young caregiver, and now follow her lead.

The organization of behaviors involved in human attachment relationships is also more complex and reciprocal than the systems involved in imprinting. Finally, the timeline for developing a bond between the human infant and the caregiver is relatively protracted. Imprinting in nonhuman species typically occurs during a well-defined and irreversible critical period very early in development, prior to the behaviors fundamental to imprinting. In other words, the gosling quickly imprints to the mother, which gives rise to following her. Unlike this instant connection, the human attachment bond develops over an extended and more flexible sensitive period across early development, with interactions during this period promoting attachment.

Early Social Connections – Building an Attachment Relationship

Do newborn infants have a special connection with their mothers at birth? Newborns may recognize the mother's voice from muffled sounds heard prenatally. If breast-fed, within days the infant may recognize the mother's scent and even prefer her familiar scent over that of an unfamiliar breast-feeding woman. This early recognition of sound and scent helps infants to identify their own mothers. However, in human infants, the process of forming a specific attachment relationship to a primary caregiver is an extended one, in typical situations occurring across the first year. Human infants are born with powerful tools for engaging in this relationship. In short, humans are primed for social interaction and for attachment. From the beginning, infants behave in ways that elicit nurturing and protection and that engage caregivers in delightful interactions. Infants pay special attention to human faces and voices, picking them out of a world of new sights and sounds. Around 6 weeks, infants begin to display a 'social smile,' smiling most readily in response to human faces and positive social interaction. Starting around 3 months, infants develop exquisite attunement to the behavior and responsiveness of caregivers. Prior to the 1970s, the idea that infants could be active social partners was considered a figment of mothers' imaginations. In the early 1970s, psychologist Edward Tronick developed the 'still-face' paradigm, which has since been widely used to demonstrate infants' active and

engaging social behavior starting between 2 and 3 months. In the still-face paradigm, the parent and the infant first engage in face-to-face play, but this positive interaction is followed by the parent abruptly turning away. The parent then turns back toward the infant, but maintains a neutral expression, and does not respond to the infant's bids for interaction. Tronick hoped to identify how infants would respond to mothers' breaking the rules of social interaction and also how infants would work to regain interaction. Infants are distressed when the connection is broken, and an expansive body of research has since documented infants' use of gaze and gaze aversion, reaching and other gestures, smiling, and both cry and noncry vocalizations to invite, entice, and demand a return to normal social engagement (Figure 2). These early face-to-face interactions are an important context for infants to practice interaction skills, and they also provide infants with a developing sense of self and effectiveness as they influence the behavior of their partner. Importantly, sometimes face-to-face play is synchronous, but most of the time interactions are slightly mismatched. Caregivers can help infants move from nonsynchronous interactions back to a state of synchrony, facilitating the infant's developing capacity for self-regulation (as the caregiver and the infant adjust behavior and affect) and also for relationship repair.

All of these early behaviors are instinctive, but social bids are not at first directed exclusively, or even primarily, toward the mother. Attachment relationships develop in a series of gradual transitions across the first year. Why do infants take such an extended period to develop a specific attachment? One reason may be that waiting to discern which adult figure will be most devoted to their well-being, and retaining the flexibility to become attached to that individual, regardless of biological connection, is adaptive. Another is that the cognitive and physical capabilities needed to recognize and participate in this complex reciprocal relationship take time to develop. Based on observations of infant behavior, Bowlby identified four phases in the early development of attachment relationships.

Phase 1: Preattachment

Between birth and 2–3 months, infants simply respond and orient to people, making little differentiation between their social partners. Newborn infants emit signals such as crying, grasping, and smiling to all potential social partners. Although these signals are not initially intentional, they are effective in eliciting responses. During this period, especially if caregivers are consistent in responding to infants' cries and other behaviors, patterns of interaction may start to become predictable for infants.

Phase 2: Attachment in the Making

Between 2–3 and 5–6 months, these predictable interactions, along with cognitive developments, support the infant in beginning to respond in unique ways to a primary caregiver. Where the infant previously smiled at any friendly person, the largest smiles are now elicited by this familiar caregiver, with whom the infant is developing a special relationship. The infant shows more engagement and positive emotion and is more easily soothed by this person. Near the end of this phase,

Figure 2 In the first part of the still-face procedure (a), the mother and her 6-month-old infant engage in typical face-to-face play. In the second part of the procedure (b), the mother maintains a neutral facial expression and does not interact with the infant. The infant expresses mild distress while reaching out to the mother, and as the distress escalates, the infant fusses and turns away (c). Finally, we observe the infant's delight as the mother reengages (d).

infants begin to display wariness toward unfamiliar individuals. This 'stranger anxiety' signals infants' further discrimination of preferred social partners. Although infants recognize and respond especially to their familiar caregiver, during this phase, infants are not distressed when separated from the caregiver, and thus have not yet developed a true attachment relationship. The end of Phase 2, typically around 7 months, is marked by the appearance of 'separation anxiety,' the infants' clear distress upon separation from their preferred caregiver, even when left with another familiar person.

Phase 3: Clear-Cut Attachment

Between 7 and 12 months, a clear attachment relationship with a primary caregiver emerges. Infants become distressed upon separation from that person and actively seek to maintain proximity to and contact with their preferred caregiver. Although infants will develop more than one attachment relationship if more than one person consistently responds to their needs, they first show a preference for one caregiver over the others. Attachment to a secondary caregiver is typically expressed within weeks following clear attachment to a primary caregiver. Infants may develop attachment relationships with a small number of close caregivers. However, the relationships are thought to be hierarchical, with one relationship preferred over others. Although mothers are often primary caregivers, it is important to recognize that fathers, grandparents, and nonrelative caregivers (such as childcare providers) may all become attachment figures. During this phase, physical and cognitive developments such as crawling and increased communication skills support new attachment behaviors. In particular, the infant's newly mobile status means that the infant can actively approach the preferred caregiver and follow the latter from place to place. Hallmark behaviors of the

attachment relationship are now evident, including secure base exploration, returning to the caregiver for 'emotional refueling,' seeking refuge with the caregiver when distressed, and clinging to maintain contact. Infants have a strong desire to stay close to the caregiver, who has become a source of comfort and protection, as well as delight. However, physical and cognitive advances also support a new desire and ability to explore the environment, and infants must balance these competing desires. A central tenet of attachment theory is that infants are best able to explore when the attachment figure is near and supportive, often referred to as the 'secure base' function of attachment. Infants stay fairly close to their caregiver, look back to check reactions to uncertain situations, and also to share discoveries and positive emotions with the caregiver. These things make for an easy return to the caregiver when needed. Not coincidentally, infants develop these tendencies to stay close and check parents' reactions around the same time that they are newly capable of crawling away to explore.

Infants' attachment behaviors during this phase also become 'goal-directed.' The infant can conceptualize a goal (e.g., contact with the attachment figure when distressed) and develop skills for adjusting behaviors as needed to meet this goal. For example, the infant may plan a path across the room to the caregiver, but if the caregiver leaves the room, the infant can adjust his or her path or vocalize to signal the attachment figure. The infant can flexibly use a variety of attachment behaviors, depending on the situation, to accomplish his or her goal in a particular situation.

The emergence of goal-directed behavior also indicates that infants have become representational, and consideration of the attachment relationship now must include both representation and behavior. The organization of infants' attachment behaviors reflects their internal working model (IWM), or representations of self, the attachment figure, and their interactions.

As noted previously, even during the first few months of life, patterns of interaction may become predictable to the infant. Certainly by 1 year, infants can develop representations of how the caregiver will respond to their behavior (e.g., my parent will pick me up when I am upset) and can also anticipate how the caregivers' behavior will affect them (e.g., 'being held makes me feel better'). Although the IWM in infancy supports basic means–ends connections, it will become more complex and reflective across development and continue to transform along with cognitive and social cognitive changes.

Phase 4: Goal-Corrected Partnership

Beginning around 3–4 years, children develop a basic capacity to understand that the attachment figure has goals independent from their own and to take those goals into account. The relationship transforms into a 'goal-corrected partnership,' where both partners are able to adjust their goals and behaviors with consideration of the other person's plans. With this development, children's capacities for cooperation and relationship grow.

The Need for Attachment

The formation and maintenance of an attachment relationship is a basic human need. One indication of the importance of this relationship is that its absence or severe disruption produces negative effects. In addition to Lorenz's work on imprinting, Bowlby's theory of attachment drew on the Robertsons' observations of the emotional, behavioral, and relational problems exhibited by children experiencing a long separation as a result of the child's or mother's medical care. The Robertsons documented severe declines in children not accompanied in the hospital by their caregiver; this documentation was so alarming that it led to widespread changes in hospital visitation policies. Bowlby also drew on Harry Harlow's groundbreaking (but controversial) work in the 1950s examining infant rhesus monkeys deprived of caregiver contact. Following the accidental discovery that isolated infant monkeys became dependent for comfort on cloth diapers that covered the cages of their floor and that monkeys with no contact comfort quickly withered, Harlow began a series of studies testing infants' reliance on wire or cloth-covered monkeys as a source of comfort. The infants directed attachment behaviors toward the soft, cloth-covered monkey, even when the wire monkey was the source of food. Harlow observed that the young rhesus monkeys needed to rely on the minimal comfort provided by the cloth monkey, using them as a source of security in a novel, moderately stressful environment. However, as they got older, monkeys that had been deprived of a responsive caregiver showed serious deficits in their social behavior, and especially their caregiving.

More recently, attachment theorists have examined the effects of severe early deprivation as a result of institutional rearing. One longitudinal study has followed children initially raised in institutions with very little caregiver contact, and with no individual consistently responding to their needs. These children were adopted into families in the United Kingdom at different points in their development, some before 6 months, and others not until nearly age 4. Children who experienced

early severe deprivation showed an increased prevalence of 'atypical' attachment behaviors, most notably, indiscriminate friendliness, or directing attachment behaviors toward unknown individuals. These atypical attachment behaviors were less common in children who had been adopted before 6 months of age, but they became increasingly common with longer amounts of time in the institution before adoption (at least between 6 and 42 months). This finding was independent of the physical and cognitive deficits associated with longer periods of deprivation. One major conclusion of this study has been that in the absence of opportunity to develop an attachment, children become increasingly less likely to develop typical social bonds.

That children adopted very early in life were likely to show typical social development suggests that infants are initially capable of relatively easy adjustment to a new caregiving environment. This conclusion is also supported by research on infants in foster care. Infants placed into care at ages younger than 1 year begin to consistently direct attachment behavior toward a new foster parent within 1–2 weeks of placement. For infants older than 1 year, this transition takes longer (and adjustment depends also on characteristics of the foster parent). Together, this work suggests a sensitive period for human social development. Prior to 6 months, infants seem to have little difficulty adjusting. That flexibility diminishes somewhat between 6 and 12 months, with even greater loss of flexibility after 12 months. The need to develop an attachment relationship with a caregiver during this sensitive period is so important that infants can flexibly reorganize their behavior around a new person and begin to redirect attachment behavior toward them. This is consistent with ethologists' proposal that there is an optimal window of time for developing particular capacities, and that during this time infants are especially sensitive to environmental influences on those capacities.

Attachment Across Cultures

Since attachment has strong roots in human biology, it is expected that children from all cultures, despite culture-specific child-rearing practices, will display attachment behaviors that support proximity and contact with the caregiver. In other words, the bias in infants to become attached should be universal, and a sizable body of research has been devoted to testing the limits of this claim to universality. Cross-cultural studies of attachment indicate that both attachment behavior and the development of a preferred attachment figure or figures are indeed universal and serve the same functions across a broad range of rearing environments. Still, there is enough flexibility in the organization of attachment behavior to function within a range of possible caregiving environments. Studies of attachment across cultural contexts with quite varied approaches to child-rearing confirm this notion. For example, among the Gusii of Kenya, infants are raised by multiple caregivers, including both the biological mother and a consistent nonmaternal caregiver. Although adults and infants display culture-specific forms of attachment behavior (e.g., greeting by shaking hands or clapping, rather than with a hug, as is typical in many Western cultures), infants' behavior is organized around and directed toward the primary caregivers. Further, infants demonstrate attachment to both the mother

and the nonmaternal caregiver. Children reared collectively on Israeli kibbutzim, and primarily cared for by professional caregivers, provide further support for the universality of attachment. Typically, these children have contact with their parents for several hours in the evenings. However, children spend most of the day away from their biological parents. From early infancy, parents put their children to bed in the children's house – without a parent or regular caregiver – during the night. These children also demonstrate attachment to both their biological mother and caregiver, despite their limited contact with parents. Even in these circumstances, children become attached to the person or people who consistently respond to their bids. However, compared to a group of kibbutz-reared children who slept in the family home, with access to parents at night, those who slept in the children's house showed less optimal quality in their attachment to the mother. Thus, even in caregiving contexts in which children do not have a single primary caregiver, the need for access to an attachment figure, especially during potentially stressful times, remains evident.

Individual Differences in Attachment Security

Although all typically developing infants who have an opportunity to form an attachment relationship will do so during the first year, there is some flexibility in the organization of attachment behavior. In the 1950s, Mary Ainsworth, a colleague of Bowlby, conducted extensive naturalistic longitudinal observations of infants and families in Uganda. Based on those observations, Ainsworth described great variation in how infants interacted with their caregivers. Starting even before 1 year, infants began to organize their attachment behaviors in different ways. Ainsworth continued to think about those differences, and back in the United States in the 1960s, she developed the Strange Situation Procedure (SSP), a brief, standardized laboratory paradigm to assess individual differences in the organization of attachment behavior in 12–18-month-olds. The introduction and validation of the SSP was a major advance in the study of early social development because it allowed psychologists to reliably observe, in a short period of time, the nature of the infant–caregiver relationship. The SSP involves the introduction of an unfamiliar individual and a series of brief separations from and reunions with the parent

to gradually increase distress in the infant (Table 1). Infant behaviors during the reunions indicate how the infant uses the parent to relieve distress caused by separation. In other words, how the infant organizes his or her behavior with respect to the caregiver indicates the former's expectations about the latter's willingness and ability to restore comfort and trust (Figure 3). Ainsworth's early work, in both naturalistic observations and in lab settings using the SSP, identified three categories of infant attachment. A fourth category was later identified; all four categories of attachment based on behavior in the SSP have been extensively validated.

Secure

Secure infants demonstrate an emotionally positive and trusting relationship with the caregiver in which the infant derives comfort from the caregiver's presence. For secure infants, a balance is met between attachment and exploration needs; the infant feels confident to explore and is also easily able to return to the caregiver when distressed or wary, or when the infant simply needs emotional refueling. In the SSP, the secure infant openly and confidently approaches and/or signals the parent upon reunion and thus achieves the desired proximity or contact. This contact calms the infant – both behaviorally and in terms of physiological arousal – supporting the infant's return to exploration.

Insecure-Avoidant

Insecure-avoidant infants do not seek contact or proximity during reunion with the parent. Although they may exhibit some distress during the separation, they maintain neutrality when reunited. Avoidant infants convey the appearance that they do not need the attachment figure, downplaying the importance of attachment needs, and may actually ignore the caregiver's overtures. Instead of seeking the parent, they appear to focus on exploration. Outwardly, these infants may simply seem more independent than other infants, giving the impression that perhaps little distress occurred during separation, and they therefore do not need to be comforted by the caregiver upon reunion. However, avoidant infants' physiological arousal during the separations is equal to that of other groups, suggesting that although they are experiencing distress, they defensively hide this from the caregiver.

Table 1 Episodes in the strange situation

<i>Episode</i>	<i>Events</i>	<i>Attachment behavior observed</i>
1	Researcher introduces parent and infant to playroom, and then leaves	
2	Parent is seated while infant plays	Parent as secure base
3	Stranger enters, sits, and then talks with parent	Stranger anxiety
4	Parent leaves. Stranger responds to infant, and offers comfort if infant is upset	Separation anxiety
5	Parent returns, greets infant, and offers comfort if infant is upset. Stranger leaves	Reunion behaviors
6	Parent leaves	Separation anxiety
7	Stranger enters and offers comfort	Ability to be soothed by stranger
8	Parent returns, greets infant, offers comfort if necessary, and tries to interest infant in toys	Reunion behaviors

Note: Episodes two through eight last for 3 min each, although separation episodes may be cut short if infants are extremely upset, and reunion episodes may be extended if infants need more time to calm down and return to play.

Adapted from Ainsworth MDS, Blehar M, Waters E, and Wall S (1978) *Patterns of Attachment*. Hillsdale, NJ: Erlbaum.

Figure 3 In Episode 2 of the Strange Situation Procedure (a), the infant interacts with the stranger while the mother is in the room. In Episode 5, the mother leaves the infant alone in the playroom, and we see the infant attempting to follow the mother as she is leaving the room (b). In Episode 6, although another friendly adult is in the room, the infant cannot be enticed to play with her or the toys and waits at the door for the mother (c). Finally, in Episode 7, the mother returns to the playroom and the infant signals to be picked up (d).

Insecure-Resistant

Insecure-resistant infants, on the other hand, openly exhibit anxiety about both exploration and the availability of the attachment figure. This hyperactivation of the attachment system serves to keep the infant close to the caregiver, but at the expense of exploration. These infants often become more distressed during separation than secure or avoidant infants. On reunion, infants show obvious anger and resistance to contact with the caregiver. It is characteristic of resistant infants to seek contact, but to then push away efforts to comfort. For resistant infants, the presence of the parent does not have a calming effect, and returning to exploration can be difficult.

Disorganized

A fourth group, more recently identified by Mary Main and colleagues, includes infants whose defining characteristic is that they lack a clear pattern in the organization of their attachment behavior. Disorganized infants do not integrate their behavior in a way that fits into one of the original patterns, or may show anomalous behavior within an organized pattern. These infants lack a successful strategy for resolving the distress caused by separation. This lack of strategy means that they cannot turn fully toward either the caregiver or the environment, and may thus show simultaneous or sequential contradictory behaviors, odd behaviors such as freezing or stilling in response to the caregiver's return, or disordered sequences of behavior (e.g., approaching the parent followed by dazed avoidance).

In typical, middle-class samples, a majority of children (about 60%) develop a secure attachment. However, a sizable minority of infants is classified as having an insecure attachment, either avoidant (15%), resistant (10%), or disorganized (15%). The relative distribution of these classifications differs somewhat in lower-income and clinical samples, where

there is typically a smaller proportion of secure infants. Further, although a secure attachment is normative across cultures, the distribution of the insecure categories varies. For example, compared to typical samples in the United States, infants classified as avoidant are uncommon in Israeli samples, while infants classified as resistant are uncommon in German samples. These subpopulation and cultural differences in the relative distribution of attachment classifications reflect variations in family environments, such as economic or social stressors, or cultural differences in normative socialization values and child-rearing practices.

Early Experience and Attachment Security

Ainsworth's naturalistic observations of infants and families in Uganda directed attention to caregiver sensitivity as the main source of individual differences in attachment organization. Caregiver sensitivity has been operationalized in many ways, but research across diverse social and cultural contexts confirms Ainsworth's initial observations that a secure attachment is fostered by the caregiver's accurate perception of, and prompt and appropriate response to, the infant's needs or distress. Sensitive, synchronous interactions, warmth, and support, especially as infants are developing expectations of how their caregiver will respond, predict infant security. Less sensitive and supportive care in infancy predicts insecure attachment. Caregiving that is intrusive, controlling, or hostile is linked to insecure-avoidant attachments, and caregiving that is inconsistently responsive, or unresponsive, is linked to insecure-resistant attachments. Although the way in which insecure infants organize attachment behavior does not facilitate an optimal balance between exploration and proximity, in the context of a less-supportive caregiving environment, their strategies may be adaptations that allow them to best maintain

proximity to a caregiver. For example, avoidant infants are thought to defensively hide their distress, ignore the caregiver, and turn their attention to the environment. If the caregiver has been hostile toward infant's bids for comfort in the past, infants may gradually come to understand that they can better maintain proximity to the caregiver by directing attention away from their attachment needs. Similarly, resistant infants may benefit from intensifying attachment behaviors to engage an inconsistently responsive caregiver.

Experimental intervention studies support a causal link between sensitivity and security. Multiple studies indicate that by providing support and training to improve parenting sensitivity, infant attachment security can be enhanced. Importantly, this finding generalizes to dyads in challenging ecological contexts and to infants with more difficult predispositions such as an irritable temperament. Overall, however, relations between sensitivity and security are modest (i.e., sensitivity does not explain all of the variability in attachment security), and additional predictors of security that operate independently of sensitivity, or that moderate the effects of sensitivity, should be explored.

Caregiver sensitivity is less clearly related to attachment disorganization. Rather, disorganized attachment is associated with parenting that induces fear in the infant. Disorganization is more prevalent in samples with abuse or neglect and in samples with high levels of parental depression and unresolved loss. Patterns of affective communication that result from frightened or frightening caregiver behavior (e.g., contradictory emotional cues, withdrawal) also correspond to infant disorganization.

Infant Characteristics and Attachment Security

What is the role of infant characteristics in attachment security? Early attachment researchers faced the criticism that differences in how infants respond to the SSP were simply manifestations of temperament. Proponents of temperament argued that avoidant infants are simply low in distress and relatively independent. The temperament of resistant infants, on the other hand, made them prone to high levels of distress on separation. These critics further argued that differences in temperament would impact interactions between the caregiver and the infant. However, several pieces of evidence have largely contradicted these claims. For instance, avoidant infants experience high physiological arousal during the SSP, which contradicts the notion that they are simply not distressed by the procedure. Further, avoidant infants at home tend to be fussy and show clear discomfort when separated from their caregiver. Results of interventions aimed at improving sensitivity of parents of highly irritable infants also contradict the idea that temperament determines attachment. As noted above, with sensitive caregiving, even highly irritable infants may demonstrate secure attachments. Although the precise role of temperament in attachment security is complex and not yet fully understood, there is consensus that temperament does not directly influence attachment classification.

Behavioral and molecular genetics studies continue to elucidate the role of child characteristics in attachment. Behavioral genetics research identifying the relative contributions of heredity and environment to differences in twins' attachment

classifications suggests that heredity assumes virtually no part in security of attachment. Additionally, links between sensitivity and security are not influenced by heredity. These findings are consistent with attachment theory's ethological foundations, in that inheriting fixed patterns of social behavior would negate the flexibility that infants maintain by organizing attachment behavior within a particular caregiving environment. Recent studies in molecular genetics, on the other hand, offer the conclusion that certain gene polymorphisms may make infants more prone to developing insecure attachment, particularly in the context of insensitive caregiving, or simply more receptive to caregiving influences. These studies support an emerging consensus on the critical role of gene-environment interaction in development.

Correlates and Sequelae of Early Attachment

One assumption of attachment theory is that early individual differences in security will be a source of variability in later socioemotional development. Several explanations for this have been proposed. First, IWMs are thought to contribute to enduring effects of security in the parent-child relationship. The IWM initially consists of representations of the attachment figure's availability and responsiveness. These basic representations generalize into broader ideas about the self, the attachment figure, and relationships. Further, these representations color and guide our response to new information, promoting consistency in what and how we think about self and relationships. Second, early security may be connected to later outcomes because early adjustment and behaviors support particular trajectories of personality development. For example, secure attachment facilitates exploration, and may therefore support greater autonomy in early childhood, in turn leading to better adjustment in school and in social relationships. Third, consistency in the parent-child relationship may explain outcomes associated with early security. The sensitive caregiving that initially fostered a secure attachment continues to support the child's development in other ways, either in concert with or in addition to attachment security. From this perspective, any benefits conferred by a secure attachment are contingent on continued, developmentally adapted sensitivity.

A vast body of research, some examining early correlates and others later outcomes predicted by early security, indicates that a secure attachment does indeed confer some advantages. We review a sampling of these findings with respect to relationships, emotion, and social- and self-understanding. In general, outcomes associated with a secure attachment most clearly differentiate between security and insecurity, with less consistent differences between avoidant and resistant attachment. However, disorganized attachment puts infants at the highest risk of negative developmental outcomes, including emerging psychopathology.

In infancy and early childhood, a secure attachment initiates a more affectively positive, close, and cooperative parent-child relationship. This extends also to more advanced conscience development in early childhood, perhaps a result of the desire for mutual cooperation and greater compliance. Security as a predictor of parent-child relationships beyond early childhood is less clear, and probably depends on how

caregiver behavior and dyadic processes are maintained over time. Security is also related to social competence and more positive peer relationships, especially for behavior in close friendships. Consistent with the IWM hypothesis, security also predicts more positive representations of the self in friendships. Connections between attachment and peer relationships are particularly evident in middle childhood and adolescence, as friendships take on greater developmental significance.

One function of attachment relationships is to aid infants in managing their emotional arousal, first through sensitively responding to infants' distress, and over time through fostering the expectation that the parent will be available and effective in providing support to the child. Indeed, secure infants show more adaptive strategies for emotion regulation, more adaptive displays of emotion expression, and lower physiological stress response as toddlers. Over time, secure infants become more effective in regulating their response to frustration and show lower levels of fear, anger, and distress in preschool.

Attachment security also predicts children's developing social cognition. Understanding of emotions begins to emerge during the toddler years, and attachment security is one proposed source of individual differences in early emotional understanding. The emotionally open relationship and communication of securely attached dyads supports children in understanding the causes and consequences of emotions in self and others. Security assessed in both infancy and toddlerhood predicts higher levels of understanding emotions in preschool and middle childhood. There is also growing evidence for effects of security on other areas of social cognition, such as making more positive attributions about peer behavior. Finally, security in early childhood is related to expressing a more positive and open self-concept during this period, as well as higher confidence and fewer negative self-evaluations when faced with a challenging task. In fact, security in early childhood may be especially important as children are beginning to develop ideas about their psychological characteristics.

Is Attachment Security Stable over Time?

Are secure and insecure attachments of infancy maintained into childhood, adolescence, and beyond? It is important to note that this question is complicated by shifts in how attachment is conceptualized and assessed after early childhood; we might naturally expect little consistency between a behavioral measure of attachment in infancy and a measure of attachment representations in adolescence. However, studies using the most well-validated and developmentally appropriate measures, examining stability over both short and long durations, arrive at the same conclusion. Whether the duration is a few months, or many years, sometimes attachment security remains stable and sometimes it does not. Just as security is initially forged in relationship experiences, so too may later experiences continue to alter attachment security. In fact, movement between security and insecurity is predicted by changes in the quality of caregiving that young children experience. Circumstances that alter caregiving interactions, including both inherently stressful life events (e.g., divorce, death of a family member) and nonstressful life events (e.g., job changes, birth of a new child), increase the chances of a

change in attachment security. Stressful life events, in particular, are associated with a shift toward insecurity. This effect is also apparent for children's and adolescents' own experiences. For example, adolescents who experience a major psychological stressor are more likely to decline in security over time, compared to peers who do not experience a major stressor. This capacity for change in attachment organization is positive for those who initially develop an insecure attachment. As noted above, intervention studies that increase sensitive caregiving can be effective in improving parent-child relationships. However, developmental psychologists understand less about what can move a child from insecurity to security under everyday conditions, outside of the context of therapeutic intervention. One hypothesis is that cognitive shifts in adolescence enable us to reflect on IWMs, which may provide an opportunity for change in how we think about the self and relationships.

The Attachment System in Childhood and Adolescence

The majority of attachment theory and research has focused on infancy and early childhood. Recently, though, attachment theorists have offered rich conceptualizations of parent-child attachment in light of the broader developmental changes of middle childhood and adolescence. Although many questions remain, a growing body of empirical research has begun to address the nature and correlates of attachment past early childhood. Overall, despite many changes in cognitive, behavioral, social, and regulatory capacities, connections with parents remain a major source of support across middle childhood and adolescence. The manifestation of those relationships does, however, shift to accommodate new capacities and new goals.

Middle Childhood

Middle childhood brings a decline in the frequency and intensity of attachment behavior. Greater experience and personal resources, improved cognitive understanding of time and context, and reductions in physiological arousal mean that children in this period experience less attachment distress. Additionally, children begin to take on a more active role in monitoring their own behavior and maintaining proximity to their caregiver. The experiences that a young child finds threatening (e.g., a short physical separation from the parent, or a skinned knee) may not threaten an older child; conditions requiring support are likely to be psychological threats (e.g., a fight with a friend). The nature of contact that children now seek for support may also change, with a warm supportive conversation taking the place of physical comfort. With the cognitive advances in middle childhood, the attachment relationship also becomes more internalized. Children can now easily wait to contact parents; for example, if distress occurs while the child is in school, the child can wait until they are home to communicate with the parent. This means that attachment becomes much more difficult to observe in middle childhood. Because clear physical returns to the parent are not always evident, and relational strategies become much more elaborate and sophisticated, the potential variety of behaviors that will satisfy the child's goals is much greater. Middle childhood might

be considered a transition between the relative dependency of early childhood and the autonomy typically emerging in adolescence. The parent–child attachment relationship remains central, but during middle childhood, new close relationships are developing. These ‘affective bonds’ may share some of the functions of an attachment relationship (e.g., a child may feel more comfortable with a close friend in class) but do not yet serve all of the functions of an attachment relationship.

Adolescence

Adolescence is a period of even greater transition. As adolescents prepare for adult life, it is normative and developmentally appropriate to seek and achieve greater autonomy from parents. In this process of negotiating autonomy, balancing attachment needs and exploration is still a key developmental issue. The normative transitions of adolescence (e.g., autonomy seeking, identity exploration) may themselves activate the attachment system. Exploration may be more extensive and pressing, but most adolescents still turn to parents when they are distressed. In fact, a secure parent–child relationship in adolescence may best support developing autonomy while allowing the adolescent to maintain a close connection to the parent. As adolescents become more capable of abstract and reflective thought, and taking a more sophisticated perspective, reflection on the self and relationships adds a new dimension to the IWM. Secure behavior with parents may take the form of open, full, dyadic communication, while insecure behavior may be more closed or conflictual. Adolescents’ close relationships with friends and romantic partners become new sources of intimacy and support. More than in middle childhood, these relationships in adolescence start to take on some attachment functions, and friendship quality in adolescence may facilitate relational patterns that continue into early adulthood. However, it is clear that the parent–child relationship continues to play a unique role throughout adolescent development, with psychological functioning during early adulthood reflecting the quality of parent–child relationships during adolescence.

Glossary

Dependence Dependence is determined by the extent to which an actor values the resources (or services) to be obtained in an exchange relation and the degree to which such resources (or services) are available from alternative sources.

Direct exchange When two actors engage in the mutual exchange of benefits.

Indirect exchange When actors are connected only through their exchange ties with other parties (typically called 'third' parties).

Power The potential of one actor to obtain favorable outcomes from another actor despite resistance, which is determined by relative dependence.

Social exchange This involves the more or less rewarding or costly exchange of resources or services between two or more parties.

Uncertainty The extent to which an outcome is unknown.

Social exchange theory is one of the major approaches to the study of social interaction within sociology. It conceptualizes interaction in terms of what the actors involved obtain from one another that they value, either in the form of resources or services. Research on social exchange is primarily concerned with the more or less enduring relationships that develop over time and the social structures created by these interactions. Some are short term, almost market-like exchanges. Others are long-term exchange relationships that extend over time and often grow to encapsulate a varied range of behaviors and resources. Such interactions can be embedded in groups or in networks and the actors involved can be individuals, groups, organizations, or even larger entities that engage in exchange most often through agents or other forms of representation.

The social exchange perspective on social interaction has its origins in several disciplines, but most notably sociology. Contributions to this theoretical orientation also come from psychology and anthropology. *The Social Psychology of Groups* (1959), written by John Thibaut and Harold Kelley, introduced to the field of social psychology a number of concepts and principles consistent with the parallel development of social exchange theory within sociology. In particular, their notions of behavioral interdependence, fate and behavior control, and their matrix analyses of the outcomes of linked behavioral processes were influential in future developments within this tradition. B.F. Skinner, the well-known proponent of behaviorism in psychology, also had a major influence on the early formulation of exchange theory through his friendship with and impact on the work of George C. Homans, his colleague at Harvard. Behaviorism subsequently influenced the early work of Richard M. Emerson and later the research program of Linda Molm.

Anthropologists were also influential in the development of social exchange theory through the writings of Claude Lévi-Strauss, Bronislaw Malinowski, and Marcel Mauss, among others. Early research in economic anthropology, cultural anthropology, and other subfields also contributed to the development of the study of social exchange and later work on exchange networks, reciprocity, and gift-giving. Carrier and

Carrier conducted important fieldwork in New Guinea examining the linkages between informal, culturally embedded forms of social exchange and the imposition of more formal, market-based systems of exchange. Economic transitions in various parts of the globe continue to provide fruitful venues for the study of exchange systems and the cultural and political factors that determine the nature of the transition and its economic and social effects.

Within sociology George Homans, Peter Blau, and Richard Emerson are widely viewed as the pioneers in the development of what has come to be known as social exchange theory. Homans' work derived from his interest in what he called 'elementary' or subinstitutional social behavior and his approach was developed during the heyday of Talcott Parsons' influential writings about social systems and institutional theory. To some extent, Homans' theoretical orientation was constructed as a counterpoint to the more macro-level theorizing of his colleague, Parsons. In this sense Homans was much more influenced by B.F. Skinner than by Parsons. For Homans social behavior was the bedrock of sociological theory and he argued that such behavior could be understood by examining the basic principles of human behavior that had been developed within psychology and codified in propositions derived from the work on behaviorism. This approach was criticized extensively as reductionist. For Homans the primary focus was the social behavior that emerged over time as a result of the mutual interdependence of two parties involved in direct, dyadic exchange.

Peter Blau wrote the influential book, *Exchange and Power in Social Life*, in 1964. This volume represents his major contribution to the development of the social exchange perspective in sociology and in it Blau attempts to address some of the limitations of Homans' approach, most notably, the effort to embrace reductionism. For Blau exchange theory provided a vehicle for the development of a microsociological perspective that served as a foundation for the analysis of macro-level social processes and social structures. He considered social exchange to be the "prototype of a social phenomenon and thus an elemental process or particle of social life well suited for sociological inquiry" (Blau, 1986: viii). Later he argued that

microsociological analysis and macrosociological phenomena could be bridged by various approaches indicating that social exchange processes were only one such source of the 'linkages' between levels of analysis. He decoupled these levels in his 1986 revised introduction to his path-breaking book on social exchange and power, though he spelled out a number of ways in which work at each level can be complementary or used to supplement analysis at each level.

Richard Emerson's work on social exchange theory was influenced by the work of both George Homans and Peter Blau, though his power-dependence formulation, which preceded his work on exchange, was influential in Blau's analysis of power. Emerson came to exchange theory after developing power-dependence theory in two publications that have become citation classics. In a sense Emerson's main contribution to social exchange theory derives from his unique approach to the study of power articulated in these companion papers. He developed what is known as *power-dependence* theory as an approach to the analysis of power relations that did not ask 'who' has power, but rather what is entailed in *relations* of power. His approach is now one of the standard ways in which power is understood in the social sciences today.

Briefly, power-dependence theory proposes that power is a function of a social relationship in which one actor's power is directly proportional to another actor's dependence forming a dyadic conception of a power relationship between two actors. In his 1962 piece Emerson defines power in terms of dependence. It is the potential of one actor to obtain favorable outcomes from exchange with another actor. Dependence is based on the extent to which an actor values the resources (or services) to be obtained and the degree to which such resources (or services) are available from alternative sources. The main postulate of power-dependence theory is that the power of one actor A over another actor B is equal to the dependence of actor B on A for resources of value, represented symbolically as $P_{AB} = D_{BA}$. Thus, as the dependence of actor B on A increases so does the power of actor A over B for valued resources. A reduction in dependence either through alteration in the value of what is obtained or as a result of gaining access to other sources (i.e., an increase in availability) reduces dependence and thus power inequality.

A key part of Emerson's formulation is the discussion of the ways in which power balance can be achieved in relationships and networks with power differentials (i.e., inequalities in the distribution of power across actors or positions within an exchange network). Derived from his theory of power-dependence relations, Emerson argues that power can be balanced in one of four ways. In a power-imbalanced dyadic exchange represented as (Ax:By) in which actor A with resource x has power over another actor B with resource y, power balance can be achieved if B reduces the extent to which he values the resource (x) that he receives from A in exchange for (y), or B attempts to increase the value of the resource (y) that he supplies to actor A by 'status-giving' adding some form of approval in an effort to increase the value of what he offers. These two mechanisms are referred to respectively as 'withdrawal' or value reduction and 'status-giving.'

Two additional mechanisms have implications for the network in which the dyadic exchange relation is embedded. Power can be balanced through coalition formation in which

actor B (the less powerful) locates another actor in the network with which he forms a coalition to reduce the availability of resource y to actor A by agreement. Power balance can also be altered in the Ax:By exchange relation if actor B locates another source of the resource(s) he values which typically results in network extension. In the years after Emerson's formulation was published there have been few direct investigations of these four power-balancing mechanisms (with notable exceptions such as Cook and Gillmore, 1984; Gillmore, 1987, etc.).

One of the major extensions of exchange theory was Emerson's effort to expand the theory to include connected dyadic exchange relations that form networks of exchange. Homans had focused primarily on dyads and groups of actors engaged in dyadic exchange. Blau moved beyond the dyad to groups and larger associations by expanding the size of the group in which the actors were embedded, but he did not focus on networks of actors engaged in exchange (an element of exchange theory that has become highly significant in the current decade in which there are multiple forms of computer-mediated network exchange). Emerson's approach to extending dyadic conceptions of exchange (including his own formulation of dyadic power-dependence relations) was to treat networks as connected sets of dyadic exchange relations. First, he formalized a conception of connections as positive and negative focusing on the ways in which exchange relations determine the nature of the flow of resources of value within larger networks. Later he formalized a more structural conception of power within such networks of actors connected through processes of social exchange. This formulation was developed further by Cook and Yamagishi.

For Emerson networks were composed of sets of exchange relations between actors connected in various ways that significantly determine not only the locus of power in such networks, but also the potential for coalitions to form and the nature of the flow of resources (or lack of it) between actors connected in various ways. In particular, he defined two primary types of connection between exchange relations: *positive* and *negative*. A positive connection between two exchange relations is one in which exchange in one relation facilitates or increases the rate or frequency of exchange in the other. For example, if exchange in the A-B relation increases the amount of exchange in the A-C relationship the two relations are positively connected at position A in the three-party exchange network including actors A, B, and C. If A obtains something of value from B that she can use in exchange with C the relationship is positive. If, on the other hand, obtaining a resource from B makes it less likely that she will need it from C, the relationship is negatively connected at position A. That is, the connection between exchange relations A-B and A-C is negative if exchange in the A-B relation reduces the rate, frequency or amount of exchange in the A-C relation. An empirical example, easily understood, is a dating network in which B and C compete for A's attention. Of course, there are many networks in which such connections are mixed and actors have relations of each type with a variety of other actors.

Subsequent work with Cook, Gillmore, and Yamagishi extended Emerson's formulation to apply to exchange networks and facilitated determination of the locus of power within networks of connected exchange relations. Cook and Emerson, for example, conducted experimental investigations

of several types of exchange networks that varied in size and in degree of power differentiation between the actors in the network. In addition, subsequently they varied the nature of the exchange connections, comparing networks that were positively connected with those that were negatively connected. In this empirical work based on a program of laboratory research they were able to demonstrate that changing the nature of the connections in the network fundamentally altered the distribution and the locus of power within the network. A simple finding was that positional centrality in the network (typically a five-actor network) was correlated with higher power only in the positively connected network, but not in the negatively connected network in which central actors lost power as a result of competition with other alternative sources of the resources of value for those they were connected to. Other network variants were investigated as well and this work led to a plethora of studies on the determinants of power in social exchange networks (often also referred to as *network exchange* by Willer) and several related research programs on power, network dynamics, and commitment between exchange partners. We comment briefly on some of these related research programs before identifying current research emphases within this tradition and potential future theoretical and empirical developments.

Exchange Networks and Power

The work of Emerson, Cook, and their colleagues from the 1970s through the 1990s focused primarily on the structural determinants of the distribution of power in various types of exchange networks and the dynamics of power use, including coalitions, which often altered the power balance within a network, and commitment formation (akin to coalition formation) between exchange partners as a response to uncertainty and risk in the environment for exchange. A separate major research effort building on the early work of Willer and Markovsky provides an extensive treatment of the network determinants of power. This research, while referred to as network exchange theory, originally derives from what Willer refers to as 'elementary theory,' a broader treatment of types of social interaction in which exchange is only one form. Others include coercion and conflict relations, as examples in which exchange is not typically at issue. One of the most focused subprograms in this research effort involved the extensive study of networks and a typology of connections that differed to some extent from the work of Richard Emerson and his collaborators.

The book edited by Willer, entitled *Network Exchange Theory*, is the fullest treatment of this alternative to the power-dependence formulation and exchange network theory developed by Emerson, Cook, and their collaborators. While there are some misrepresentations concerning the development and character of social exchange theory in sociology and failure to distinguish between versions of the theory developed by Blau, Homans, and Emerson, the book does provide extensive treatment of 'elementary theory' in which coercive relations, exchange relations, and conflict relations are investigated. The bulk of the volume, however, focuses on exchange relations, the structural determinants of power in a variety of networks

connected in different ways (exclusive, inclusive, null, etc.), and linkages between this approach and several other theories, especially the status theories developed by Berger et al.

One of the useful distinctions introduced by Willer and his collaborators was identification of 'weak' versus 'strong' power structures, a distinction that differentiates the type of power at stake under varying network conditions in which actors have different degrees of dependence on one another as determined primarily by the nature of the connections and the structure of the network. A key factor in determination of strength of the power at stake in a network is the extent to which actors are differentially likely to be excluded or required to be included in the exchanges among the actors connected by exchange relations in the network. A typical monopoly structure in which all actors are connected to the same actor as their only alternative is a strong power structure. In such a network power-disadvantaged actors, those in competition for the resources of value, can easily be excluded from exchange, while the monopolist (and sole provider of the resources the competitors value) must be included to provide those resources if any exchange is to occur. In such structures the exclusion principle from elementary theory and the power-dependence principle in Emerson's exchange theory make similar predictions concerning the distribution (and locus) of power in the network. The monopoly structure is maximally negatively connected to use Emerson's terminology. Weak power structures are those in which there is less competition for resources and in which there is greater inclusion required of the actors in the network for exchanges to be consummated. In Emerson's terms such networks tend to be more positively connected.

While Willer and his collaborators have produced one of the most extensive treatments of network power, several other investigators have developed useful approaches that bring in other factors not included in the formulations of Emerson, Cook, and their colleagues or Willer and his team of researchers. Two of the main contributions in this category come from Phillip Bonacich and his former student, Elisa Bienenstock, and Noah Friedkin, separately. Bienenstock and Bonacich focus on game theoretic conceptions of relations of interdependence in networks of exchange, treating exchange as a form of coalition. They produce a formula for the determination of power differences based on the concept of the 'core' and measure power as a function of the strength of the coalitions required to consummate exchange.

In contrast, Noah Friedkin takes a different approach and identifies a method for calculating the distribution of power in a network of connected exchange relations by including a more complete determination of the frequencies of exchange and their effects on the outcomes of exchange (especially the distribution of profits from exchange). He was also among the first in the exchange tradition to explicitly treat differential values in connected exchange relations and their effects on power distributions in networks of exchange. Subsequently, Molm and some of her former students have addressed this same issue.

Types of Exchange

Before specifying the major types of exchange that have been investigated we provide the underlying assumptions that underpin predictions about behavior in exchange structures. Molm

and Cook specify four key assumptions that are shared by most current variants of the theory (with the exception of the research based on elementary theory). They include: (1) Actors are motivated to increase rewarding outcomes and to avoid loss. (2) Exchange structures emerge as a result of the actors' mutual dependence on one another for valued resources. Without mutual dependence there would be no need for exchange; that is, both parties must have some reason to engage in exchange. (3) Actors engage in mutually contingent exchanges with their partners over time in a series of interactions (i.e., the theory focuses on relations that emerge over time). Finally, (4) the resources exchanged obey the law of diminishing marginal utility such that each additional unit of a valued resource is of less value to the individual, once they are 'satiated.' These behavioral assumptions derive from earlier theoretical work of Homans, Blau, and Emerson.

The earliest work on exchange focused primarily on two forms of exchange, *direct* two-party exchange, and *indirect* exchange in which parties are connected through a third party. For both Homans and Blau these were the main types of exchange under consideration. Emerson expanded his treatment of forms of exchange to deal not only with direct, dyadic exchange, but also indirect forms of exchange (e.g., generalized exchange) and what he termed productive exchange. In subsequent work, primarily the research program developed by Molm, two major forms of direct dyadic exchange were distinguished: negotiated and reciprocal exchange, which differ in the nature of the social process involved in the exchange relation. Anthropologist Ekeh also writes about the nature of the underlying differences between types of exchange (e.g., restricted vs. generalized exchange) though his discussion is generally more polemical than empirical.

The key distinctions are between direct and indirect exchange and between negotiated and reciprocal exchange. Direct exchange connects two actors in mutual exchange (which may or may not be asymmetrical in terms of power). Indirect exchange connects actors through their mutual ties with another party or parties (typically called 'third' parties). These could be considered second-order exchange connections. Two employees in an organizational unit may thus be connected through their mutual employment and supervision by a third party, perhaps a boss. Indirect ties may lead to the formation of direct ties over time as when two employees connected through mutual employment by a third party meet and form their own direct exchange relation in which they may exchange relevant information or assistance. Such forms of exchange were the cornerstone of Blau's initial interest in the analysis of exchange relations in organizations.

The second distinction which Molm's work has made prominent focuses on the social process involved in the exchange. Many direct exchanges are negotiated and the two parties to the exchange actually negotiate over the terms of trade or the exchange of resources/services of value. The transaction is consummated when an agreement between the two parties is reached. This form of exchange is common in economics as well as in social exchange and necessitates mutual agreement for completion. Often such exchanges are enshrined in contracts to minimize risk, when there is much at stake, though in many circumstances a handshake is sufficient.

But many exchanges occur without explicit bargaining or negotiation. These exchanges are referred to by Molm as

reciprocal exchange relations and they most often entail the mutual performance of services (or transmission of resources) of value over time, such that one actor initially performs a behavior of value that then is reciprocated at a later time by the recipient to create a two-party 'transaction' in which the terms of trade are not negotiated, but are implicit in the act of reciprocity. They often involve greater risk of nonreciprocity since one does not know when an exchange is initiated whether it will be reciprocated. Examples include the reciprocal exchange of gifts, dinner party invitations, or even taking turns baby-sitting, mowing lawns, or other acts of service that carry an implicit obligation of return. Failure to return the favor, gift, or service would be viewed as a violation of the norm of reciprocity, which both Blau and Emerson viewed as the hallmark of social exchange. (In fact for Emerson it was a defining characteristic of exchange, thus he did not treat it as theoretically problematic.) For Molm and for Blau this type of reciprocal exchange is distinctive of social exchange in general and is viewed as a key factor differentiating this form of exchange from negotiated forms of exchange.

In the research on power in exchange networks Molm has provided the most extensive empirical work comparing negotiated and reciprocal exchange. In studies of the differences in power use in these two types of exchange Molm demonstrates that power use is more muted in reciprocal than in negotiated exchange. The salience of conflict is stronger in negotiated than in reciprocal exchange. In addition, reciprocal acts of exchange (which are not explicitly negotiated) provide a stronger signal of trustworthiness and relational intent referred to as affective regard, in part because they carry a higher risk of nonreciprocity. Because of the inherent risk in reciprocal exchange, actors are more likely to attribute a partner's positive behaviors to personal traits and intentions, which results in the emergence of stronger positive feelings and affective commitment in reciprocal exchange than in negotiated exchange. Given that the terms of the exchange are agreed on during negotiations there is little uncertainty about reciprocity and less room for the individuals involved to gain information about their partner's trustworthiness. Attributions are thus more likely to be situational than personal in negotiated exchange.

Solidarity

Although Emerson had written about cohesion in exchange networks it was not a major focus of his empirical work. Edward Lawler and his colleagues subsequently initiated a research program that addressed cohesion, relational commitment, affective regard, and emotions culminating in the recent publication of a book that extends this line of work. Lawler and Yoon first developed a theory of relational commitment arguing that positive and frequent exchange leads to positive emotions and commitment to the relationship between the actors engaged in such exchange. Building on this basis Lawler and his collaborators extended the theory to group and organizational commitment and cohesion, investigating the conditions under which positive exchange leads to greater unit-level commitment (to either the dyad, group, or organization in which they are embedded). Different types of exchange produce varying levels of positive outcomes, and have differing levels of

joint-action (those forms of exchange that involve multiple actors to contribute in order for all actors to profit). The greater the mutual dependence of the actors involved based on the need for joint action, the more likely actors are to feel solidarity with and commitment to their exchange partners. In addition, joint activities create positive emotions, which affirm and make salient social ties, further reinforcing solidarity. Given this reasoning they predict (and find) that productive exchange produces greater solidarity and commitment (as well as positive affect) than negotiated or reciprocal exchange.

Molm and her colleagues argue that not only do negotiated and reciprocal exchange vary in terms of the risk of nonreciprocity, but they also vary in the salience of conflict and the expressive value attached to acts of reciprocity. While reciprocal exchange presents a higher risk of nonreciprocity, it is lower in salience of conflict and higher in expressive value of reciprocity than negotiated exchange. Because of these differences reciprocal exchange should produce higher levels of solidarity than negotiated exchange, which contrasts to some extent with Lawler's approach since in his view negotiated exchange involves greater perception of joint action than does reciprocal exchange and thus should yield higher cohesion.

Trust

A topic that has more recently been the focus of empirical work in the exchange tradition is work on relational trust. Cook et al. treat trust as a form of 'encapsulated interest' in which one party A trusts another party B with respect to a particular domain (i.e., A trusts B with respect to x). In this formulation the key factor is the assessment of B's trustworthiness which can be based on the extent to which A believes B cares about her reputation and/or wants to maintain a relationship with A. In exchange theory terms A may come to trust B in an exchange relationship as B demonstrates her trustworthiness in terms of competence as well as integrity and benevolence (the dimensions often differentiated in trustworthiness judgments).

Blau argued that trust in an exchange relationship might emerge over time by first taking small risks and then larger ones as the relationship develops and both partners are able to demonstrate their commitment to be trustworthy with respect to one another. This type of incremental risk taking as the basis for building trust has been explored empirically in a number of studies in experimental economics as well as in social psychology. An important article on exchange relations published by Peter Kollock noted the effect of uncertainty in exchange on the emergence of trust and commitment especially when there was risk involved and trustworthiness mattered with respect to the quality of the goods being exchanged. In his experimental setting buyers and sellers either could assess the quality of the goods being exchanged or not (in a comparison of experimental conditions that have come to be referred to as 'rice' vs. 'rubber' markets in which quality either can or cannot be easily assessed). His results clearly indicate that commitment and trust are higher under conditions of uncertainty.

Molm and her colleagues have examined how the risk associated with different types of exchange (negotiated and reciprocal exchange) affects perceptions of trust. They argue that trust should be higher in reciprocal exchange compared

to negotiated exchange, precisely because the fear of exploitation should be stronger in reciprocal exchange. When the risk of nonreciprocity exists, the act of reciprocity provides a signal of the partner's trustworthiness, thus allowing trust to build over repeated acts of reciprocity.

While the majority of studies on exchange have focused on direct exchange, more recently there has been renewed interest in generalized exchange. One of the earliest descriptions of generalized exchange is Malinowski's account of the Kula Ring of the Trobriand Islanders. Additional accounts of real-life generalized exchange are included in Bearman's analysis of the exchange of women in a 1940s aboriginal population. Yamagishi and Cook first experimentally compared two types of generalized exchange and found that network-generalized exchange promoted higher levels of cooperation than did group-generalized exchange in which the risk of free-riding was higher. They also found that the emergence of mutual trust promoted increased levels of exchange. This effect was stronger in network-generalized exchange.

In addition, Molm and her colleagues and Lawler and his colleagues (2008) have begun to include generalized exchange in their empirical comparisons of types of exchange. In a recent study Molm et al. find that network-generalized exchange produces higher levels of solidarity, perceived trust and affect than either reciprocal or negotiated exchange. They argue that it is primarily the indirect reciprocity, typified by network-generalized exchange, that produces stronger feelings of attachment and solidarity, though it is clear that such systems of generalized exchange are not easy to maintain, especially with larger groups of actors. Lawler and his colleagues (2008) compare four types of exchange: negotiated, reciprocal, productive, and generalized exchange. Their results support Lawler's affect theory of social exchange, in which productive exchange creates the strongest feelings of affect, solidarity, and cohesion, followed by negotiated exchange, then reciprocal exchange, and finally generalized exchange which creates the weakest bonds of attachment between the individuals involved in exchange. Further investigation of the fundamental differences among the various types of exchange as well as the emergence of trust in networks of exchange will certainly be significant in the development of applications of exchange theory to the world of online exchange systems. We comment on the potential for such developments in our concluding section.

Future Directions

During the past three decades there has been a great deal of theoretical and empirical development in the study of exchange relations and exchange networks, the two main parts of Emerson's original formulation. Progress has been made in the analysis of power in dyadic exchanges as well as in networks of connected exchange relations in which position in the network, access to resources of value, and the strategic use of power afforded by position are now much better understood than in the era in which Homans, Blau, and Emerson first proposed this approach to the study of social interaction and social structure. In addition, a number of topics that were only mentioned in the early work have been developed further with the formulation of a range of theoretical extensions and new

'middle range' theories of related phenomena using a basic exchange framework. Such topics include social cohesion, relational commitment, solidarity, trust, coercive power use, and how these differ across various types of exchange (from direct dyadic exchange to productive exchange and generalized exchange characterized by univocal reciprocity). What is not yet fully developed is the study of power dynamics and network change as a result of the use of the power-balancing mechanisms first proposed by Emerson and other endogenous processes that occur within exchange networks. Three promising developments in this respect can be noted.

First, there is an increasing number of simulation studies that help us understand the impact of various factors such as network size, density and range (not to mention more complex forms of connection) that cannot easily be studied experimentally or in the 'real' world. Second is the increasing use of exchange theories to analyze systems of exchange that have emerged online and are facilitated by very large networks of suppliers and consumers (such as eBay and many other companies in addition to personal network sites). In particular, the study of generalized exchange systems in which typically anonymous individuals contribute to the development of public (or semipublic) goods for the benefit of group members or those connected to the network. Finally, related to these developments is the growing use of agent-based modeling in the social sciences, which may well have important applications for the study of exchange networks and processes. Progress along this latter path will aid in the investigation of more complex networks than can be studied in the laboratory, but may also advance our capacity to model the affective, cognitive, and behavioral aspects of the actors engaged in exchange and modeled fairly simply in the earliest theories of exchange. (An exception is Molm's effort to imbue the actor in the typical exchange theoretic model with loss and risk aversion in addition to the orientation to maximize gain.)

Other promising developments include the recent growth in techniques for analyzing complex networks, some emanating from what has been called the 'new' science of networks. The merging of these techniques with exchange theories of interaction and social structure and structural change may yield further insights into rapidly growing networked forms of interaction. We need better theories of action, interaction, and structure as well as techniques for taming the large amounts of data that are being generated concerning the nature of these network connections and the types of services and goods being increasingly transacted on a global scale.

Social Loafing (and Facilitation)

S J Karau, Southern Illinois University, Carbondale, IL, USA

© 2012 Elsevier Inc. All rights reserved.

Glossary

Coactive task A task in which people work individually in the presence of others who are working on the same task.

Collective task A task in which people work individually and combine their inputs with those of others into a single group product or total.

Köhler effect A tendency for individuals to work harder collectively than individually when they are working with teammates who are moderately, but not dramatically, stronger or better able to perform the task.

Social compensation A tendency for individuals to work harder collectively than individually when they expect their teammates to perform poorly on a meaningful or important task.

Social dilemmas Situations in which behaviors that are beneficial to individuals are detrimental to the group as a whole when many individuals choose to engage in those behaviors.

Social facilitation A tendency for the presence of other people to enhance an individual's performance on a simple or well-learned tasks but to reduce it on complex or unfamiliar tasks.

Social inhibition Situations in which the presence of other people can inhibit behaviors that individuals would otherwise engage in.

Social loafing A tendency for individuals to expend less effort when working on a collective task than when working on an individual task or a coactive task.

People often work on various tasks individually while in the presence of other people. Indeed, much of the world's work is accomplished by groups of individuals who must combine their efforts into a collective product or outcome of some form. Moreover, even when individuals do work alone, it is not uncommon for this work to take place in the presence of either observers or other individuals who are also working on their own individual tasks. Thus, it is important to consider the role that social factors play in motivation. A large body of research on the phenomena of social loafing and social facilitation has documented that the presence of other people can have a significant influence on individual motivation and performance, and that this influence depends on the type of work being done and the type of other people who are present. Social loafing refers to a tendency for individuals to expend less effort when working on a collective task than when working on an individual task or a coactive task. On a collective task, people work individually and combine their inputs with those of others into a single group product or total. On a coactive task, people work individually in the presence of others who are working on the same task, but their inputs are evaluated individually and are not combined into a group product or total. Thus, research on social loafing focuses on group or collective task environments and suggests that individuals often reduce their efforts and slack off when working with others on group tasks.

Social facilitation refers to a tendency for the presence of other people to enhance an individual's performance on simple or well-learned tasks but to reduce it on complex or unfamiliar tasks. In social facilitation research, the other people present are coactors or observers rather than coworkers or teammates. A variety of mechanisms have been proposed for social facilitation. However, several prominent explanations follow the general logic that the presence of other people enhances drive (or some other aspect of motivational potential such as arousal, evaluation apprehension, or distraction) that

makes dominant responses more likely or frequent. Therefore, when other people are present as coactors or observers, performance is enhanced on simple or well-learned tasks where the dominant response is likely to be correct, but performance is reduced on complex or unfamiliar tasks where the dominant response is likely to be inefficient or in error. Social facilitation research thus considers the effects that the presence of others as coactors or observers has on individual performance, whereas social loafing research considers the effects that working on a collective task has on individual motivation.

Social Loafing

Historical Background

Although the bulk of social loafing research has been conducted within the last 30 years, it has a long and varied research tradition. In the 1880s, a French agricultural engineer named Max Ringelmann developed an interest in the efficient use of human and animal energy, as well as machinery, for performing various agricultural tasks. In what may constitute some of the first attempts at controlled experimentation in social psychology, Ringelmann asked male volunteers in groups of varying sizes to pull on a rope, tug-of-war style, as hard as possible. He used a strain gauge to measure the total pulling force. The results showed that as the size of the group increased, the total pulling force exerted was increasingly less than would have been expected by simply adding up the individual performances. The two most likely explanations for these results were coordination loss and motivation loss. Namely, the individuals may have had difficulty coordinating their efforts effectively, maybe adjusting their grip or angle while others were pulling. Alternately, they may have suffered a loss in motivation and reduced their efforts in larger groups.

It was not until the 1970s that studies finally attempted to experimentally separate motivation loss from coordination

loss. An especially influential study by Latané and colleagues cleverly isolated these two mechanisms and was responsible, in part, for stimulating a wealth of later research on motivation losses in groups. Male college students in a study depicted as examining the sensory sound dynamics of crowds were asked to shout and clap as loudly as possible, both individually and with others. The participants wore blindfolds and wore headphones that played masking noise so that they could not identify who was shouting with them on specific trials. On some of the trials, students shouted with others in actual groups, whereas on other trials they shouted in pseudo groups where they believed they were shouting with others but were actually shouting alone. Effort reductions were still evident on the pseudo-group trials, showing that a significant portion of the reduced performance in groups was due to motivation loss, as distinct from coordination loss. Latané and colleagues also coined the term 'social loafing' as a label for this individual motivation loss on collective tasks.

Current Status

To date, more than 100 studies have examined social loafing. Although most of the studies have been laboratory experiments, a number of field studies have also examined social loafing within groups or teams in a variety of settings, including sports teams, classroom project groups, and organizational work teams. Social loafing has been found on a variety of tasks, including work-related tasks, physical tasks, cognitive tasks, and evaluative tasks. The tasks studied have included rope pulling, shouting, swimming, running in a relay race, generating ideas, writing songs, navigating computer mazes, typing, selecting job candidates, identifying stimuli on a computer screen, evaluating poems and essays, working on group papers, and performing organizational tasks.

Although social loafing has been documented in the vast majority of empirical studies, a number of moderating variables have also been established. Specifically, a number of studies have shown that social loafing can be reduced or eliminated by increasing the degree to which group members' individual inputs can be identified and evaluated, enhancing the meaningfulness or personal relevance of the task, making individual inputs unique and less redundant with those of other group members, reducing group size, using incentive rewards or punishments, strengthening the cohesiveness of the group, strengthening individual members' identification with the group, and providing comparisons with competing groups.

A 1993 meta-analysis by Karau and Williams concluded that the available research evidence shows that social loafing is a fairly robust phenomenon that is moderate in magnitude and comparable in size to a number of prominent social psychological phenomena. That same meta-analysis also documented that the magnitude of the effect was smaller (but still significantly different from zero) among women than among men. The magnitude of the effect was also smaller (albeit still significant) for participants in Eastern countries such as Japan and China than for participants in Western countries such as the United States or Canada. However, only a limited number of studies have been conducted outside the United States and Canada, so additional research is needed before strong conclusions can be drawn regarding culture.

Prominent Theories

A number of scholars have advanced theories of social loafing. Four perspectives have been especially influential in the literature. First, Latané's social impact theory posits that people serve as either sources or targets of social impact (or social influence), and that the amount of social impact experienced in any social situation is a function of the strength, immediacy (i.e., physical or psychological distance), and number of sources and targets present. Thus, when individuals are working alone or coactively, the social impact of an outside source of influence (such as a manager or experimenter) is relatively strong because it is experienced directly by the individual. However, when working collectively with other group members, the social impact of a manager or experimenter is substantially reduced, because it is diffused across all group members. Social impact theory predicts that the division of social impact should follow an inverse power function such that impact decreases marginally with increases in group size. In a related viewpoint that adopts the central tenets of social impact theory, Jackson and Williams proposed an arousal reduction viewpoint in which the presence of other group members serves to reduce an individual's arousal level because these others serve as cotargets of outside social impact. Thus, individuals relax and reduce their efforts in the presence of coworkers. This viewpoint is consistent with studies in which people have chosen to wait with other people rather than alone when they expected to face a fearful situation.

Second, a number of scholars have used the concept of evaluation to explain social loafing. This perspective posits that individuals are motivated to work harder when their inputs can be evaluated, and that social loafing therefore occurs because it is typically much easier to evaluate individuals' efforts when they are working coactively rather than collectively. Specifically, individual inputs are readily identifiable when they are working on coactive tasks. On collective tasks, however, the contribution levels of each group member are masked by combining individual inputs into a group score or total.

Third, dispensability explanations suggest that individuals often do not contribute fully to collective tasks because they feel that their efforts are dispensable or unnecessary in order for the group to succeed. In a number of studies, Kerr and colleagues have found that individuals tend to free ride on the efforts of others when the group works on tasks with a disjunctive rule in which the group succeeds if any single group member succeeds in reaching a preestablished criterion. In some of these studies, these motivation losses have occurred even when each individual's performance can be easily identified by both themselves and by his or her coworker, documenting that the potential for evaluation is not always sufficient to reduce or eliminate social loafing.

Fourth, several scholars have used expectancy-value models to understand social loafing. Those models propose that individuals are most willing to work hard on tasks for which they believe their efforts will be instrumental in leading to outcomes that they personally value. These outcomes can be external and fairly tangible (such as in the case of pay or physical rewards) or internal and rather perceptual or subjective (such as feelings of achievement, enjoyment, positive self-evaluation, or belonging). This perspective suggests that social loafing

occurs because there are often potent barriers to perceived linkages between one's effort and one's outcomes when working on collective tasks, whereas fewer such barriers are typically present when working on coactive tasks. For example, when working collectively, the group's performance is determined not just by one's own efforts but by those of the other group members. Similarly, rewards will typically be distributed (perhaps unfairly) across group members rather than made available immediately and directly to the individual.

Research has provided strong evidence supporting each of these four perspectives and it appears that each viewpoint is valuable for understanding at least some of the key aspects of motivation losses. Social impact theory appears to nicely account for group size effects and to offer some tantalizing, and so far mostly untested, hypotheses regarding the strength and immediacy of influence sources. A large number of studies support the central premise of the evaluation perspective, although social loafing has also been documented in some situations where individual inputs to the collective task can be identified, in a manner consistent with the dispensability perspective. The expectancy-value perspective has been very influential in recent years, and shows some potential as an integrative viewpoint.

Motivation Gains in Groups

Most research examining individuals' motivation levels on collective tasks has focused on social loafing, as well as on moderators of social loafing. Thus, most work has focused on motivation losses in groups and on strategies for reducing or preventing these motivation losses. However, in recent years, a number of studies have started to examine the potential for motivation gains in groups. These studies have sought to identify conditions under which individuals might actually work harder on collective tasks than on individual or coactive tasks. Although several possibilities have been identified in individual studies, only two types of motivation gains – social compensation and the Köhler effect – have been submitted to detailed empirical examination across numerous studies.

Social compensation refers to a tendency for individuals to work harder collectively than individually when they expect their teammates to perform poorly on a meaningful or important task. This phenomenon was first isolated in a series of studies by Williams and Karau in which expectations for coworker performance were either inferred from interpersonal trust scores (using the reasoning that those low in trust would expect poor performance from coworkers) or were manipulated using confederates who made statements about their own effort or ability at the task. The results showed that individuals socially loafed when they expected their coworkers to perform well, but socially compensated when they expected their coworkers to perform poorly. In addition, consistent with the expectancy-value perspective, individuals did not bother socially compensating for poorly performing coworkers when the task was low in meaningfulness. Social compensation has since been replicated in a number of studies by a variety of researchers, though additional research is needed to identify the complete set of moderators and limiting conditions of the effect.

The Köhler effect refers to a tendency for individuals to work harder collectively than individually when working with teammates who are moderately, but not dramatically, stronger

or better able to perform the task. The effect is named after Otto Köhler, who likely presented the first documentation of a motivation gain within a group context in 1926. He asked athletes to lift a bar that was connected to a pulley, first individually and then in dyads. He found that athletes worked harder on the dyad tasks than on the individual task when their partner was moderately stronger than they were. No motivation gain was found when dyads were relatively equal or widely separated in ability. In recent years, a number of studies have examined the conditions under which the Köhler effect does and does not hold. A 2007 meta-analysis of 17 studies by Weber and Hertel concluded that (a) the effect was moderate in magnitude; (b) a number of moderators (e.g., task influences, performance information, and gender) influenced the magnitude of the effect; and (c) social comparison (i.e., a desire to appear favorably in comparison with one's partner) and dispensability both appeared to provide viable explanations for the effect. Because the paradigm typically used in the Köhler effect studies differs substantially from the standard social loafing paradigm (e.g., different control conditions, individuals whose inputs are often identifiable to their partners), making direct comparisons across the paradigms is somewhat difficult. Nevertheless, research on the Köhler effect clearly suggests that, under some conditions, group members who are moderately less able than their coworkers may show motivation gains in groups.

Social Facilitation

Historical Background

The simple observation that cyclists often ride faster in the presence of other cyclists inspired Norman Triplett to conduct research that led to the first published social psychology experiment in 1898. Triplett asked children to turn a fishing-reel-style crank as quickly as possible, both alone and alongside another child. He found that the majority of the children reeled the line more quickly when they worked coactively alongside another child than when they worked alone. This work initiated a wealth of research over the ensuing 110 years that has examined the influence the presence of others has on individual task performance. This research has focused on the presence of three specific types of others: coactors (individuals who are also working on the same task individually), audiences or observers (individuals who observe the individual's work or performance but do not work on the same task themselves), and other persons who are simply present in the environment but unlikely to be observing or actively attending to the individual. Research conducted during the first 50 years following Triplett's work often found that the presence of others enhanced individual performance, leading Allport to use the term social facilitation to describe these findings in a 1924 social psychology text. However, a number of studies also found the opposite, with the presence of others reducing individual performance.

Drive Theory

Due in part to conflicting results, social facilitation research was suffering from relatively slow empirical progress and conceptual stagnation when Robert Zajonc proposed a rather

ingenious theoretical resolution of the issue in 1965. This resolution focused on the concepts of drive and dominant responses. Specifically, Zajonc linked together two relevant bodies of research: (a) a large body of research on drive, individual motivation, and performance that had already established that drive, activation, or arousal serves to enhance dominant responses – those responses that are most likely to occur in a specific task environment given the individual's level of task-relevant behavioral experience; and (b) research that provided some indirect, but compelling, evidence that the presence of other people tends to increase an individual's level of arousal. He posited that the presence of others produces arousal or drive that enhances dominant responses. When working on tasks that are relatively simple or well-learned, these dominant responses are likely to be correct, thereby enhancing performance. However, when working on tasks that are complex or unfamiliar, in which the individual has not yet fully learned or mastered the requisite skills, dominant responses are likely to be incorrect, thereby reducing performance. Zajonc's drive theory account brought some crucial conceptual order to the study of social facilitation and stimulated a flurry of research activity that continues to this day, having reached its apex in the period between 1965 and 1983.

Other Prominent Theories

Several theories have been proposed as to why the mere presence of others may increase drive. Zajonc's original drive theory account suggested that the mere presence of others produces uncertainty that leads to increased drive. Distraction–conflict theory proposes that the presence of others is distracting, which produces conflicts in attention that increase drive. Finally, social monitoring theory states that the presence of others leads to uncertainty and increased drive when the behavior of those others cannot be monitored.

Although Zajonc proposed that the mere presence of others is sufficient to enhance drive, the evaluation perspective argues that mere presence alone is insufficient to create social facilitation, but that it instead activates evaluative processes that can enhance drive. Thus, the evaluation perspective argues that the presence of others increases drive because it enhances an individual's concerns with evaluation or with competitive comparisons with others. For example, individuals are likely to experience more concern with being evaluated favorably by observers when making a speech in front of an audience than when preparing for it or presenting it alone. Similarly, individuals are likely to be more concerned with having their performance evaluated or compared with that of others when working on a coactive task than when working on the same task alone. Several theories have proposed that the presence of others can increase drive through the activation of various evaluative processes. Specifically, evaluation apprehension theory states that the presence of others increases drive because people learn over time that the presence of others is typically associated with evaluation, social comparison, and/or competition. Distraction–conflict theory states that the possibility of being evaluated produces distraction that increases drive. Self-efficacy theory posits that individuals develop positive performance expectations while working on simple tasks and negative performance expectations while working on complex

tasks, and that the presence of others activates corresponding positive or negative expectations regarding performance evaluation. Finally, self-presentation theory suggests that the possibility for evaluation created by the presence of others enhances individuals' concerns with presenting themselves in a favorable light, thereby enhancing their drive and motivation in the presence of coactors or observers.

Though the mere presence and evaluation perspectives both suggest that the presence of others enhances the drive and motivation of individuals (enhancing performance on simple or well-learned tasks and debilitating it on complex or unfamiliar tasks), not all social facilitation theories assume that the presence of others always enhances motivation. For example, self-attention theory proposes that the presence of others makes individuals more self-aware and more attentive to their own performance in relation to relevant performance standards in the environment. According to this theory, on simple tasks individuals have favorable performance expectations and thus work hard in the presence of others, but on complex tasks individuals have unfavorable performance expectations and actually withhold their efforts because they have little chance of meeting the performance standard. Regarding processes other than drive or motivation, Baron has proposed an information processing version of distraction–conflict theory in which attention and information processing, rather than motivational processes, are responsible for social facilitation. He proposes that the presence of others leads to distraction and conflict in attention that requires a narrowing of attentional focus in order to accomplish the task. This narrowed attentional focus facilitates performance on simple or well-learned tasks because it directs one's attention to an appropriate, limited range of task performance cues. However, it debilitates performance on complex tasks because the task requires attention to a wider range of cues, especially when individuals have not mastered an understanding of which cues are most crucial and appropriate to attend to.

Current Status

More than 300 studies have been conducted on social facilitation. Laboratory research examining the implications of specific social facilitation theories has been especially popular, although there are a number of field studies that have examined audience effects on individual performance. A wide variety of tasks have been studied. The most common tasks have been of a physical or cognitive nature, though performance on judgmental, evaluative, and perceptual tasks has also been examined. Social facilitation effects have also been documented for a variety of animals, including rats and cockroaches. Although there is a good support for the basic notion that the presence of others can enhance performance on simple tasks and debilitate it on complex tasks, the magnitude of these effects is often rather small. Moreover, the empirical results show a good deal of variability and complexity. A 1982 meta-analysis by Bond and Titus concluded that the presence of others, on average, had small effects on performance and explained <3% of the variance in the typical experiment. They also concluded that evaluation apprehension had surprisingly little influence on the magnitude of social facilitation effects, and that studies deploying physiological measures

supported the notion that the presence of others enhances arousal only for complex tasks. Research conducted since 1982 appears to support the general existence of social facilitation, though effects are still often small in magnitude, and variability in findings still occurs across studies. In addition, research in the last 30 years has provided fairly good foundational evidence that evaluative processes are capable of creating social facilitation effects.

From a theoretical perspective, researchers have found it difficult to resolve some of the fundamental differences between theories through empirical testing. For example, one key issue concerns whether the mere presence of others is sufficient to create social facilitation or whether evaluation potential (or some other factor) needs to be activated as well. One important problem is that it is exceptionally difficult to create pure alone conditions in which other people are not present and evaluation is not possible (or at least is highly muted or unlikely). It is also challenging to create conditions in which coactors or observers are present who are unable or uninterested in evaluating the individual's performance. For example, in laboratory studies, the experimenter can easily serve as a source of both presence and potential evaluation. Indeed, Bond and Titus noted that in the alone conditions of the 241 studies they reviewed, the experimenter was actually in the same room with the participants in 96 studies, and was even directly visible to the participant in 52 of those studies. Even when individuals work on the task alone with no others present, it is typically plausible that the experimenter is interested in their performances and will be able to evaluate them at some point.

Nevertheless, there does appear to be some sound evidence for mere presence effects. In an influential 1993 literature review, Guerin identified 18 studies (out of a pool of 313) that met 12 criteria he felt were required for an adequate test for mere presence effects. Of these 18 studies, 11 found evidence of mere presence effects. In addition, despite the challenges involved, a number of studies have succeeded in developing relatively clean manipulations of mere presence and evaluation potential. For example, in a clever 1978 study, Markus asked individuals to dress in familiar or unfamiliar clothing either alone, in the presence of an attentive spectator, or in the presence of an inattentive spectator. In support of the mere presence perspective, she found that in the presence of a spectator (whether attentive or not), individuals dressed more quickly in familiar clothes and less quickly in unfamiliar clothes than they did when alone. Two 1987 studies by Harkins manipulated both the presence of others and the potential for evaluation in the same design and examined their influence on the performance of idea generation and vigilance tasks. In both studies, Harkins found that, holding evaluation constant, individuals performed better when working coactively than alone (providing support for mere presence). In addition, he found that, holding group size constant, individuals performed better when their efforts could be evaluated (providing support for evaluation potential).

Given that meta-analytic support has been found for mere presence effects in the literature broadly and that a number of well-controlled studies have documented that evaluation from an external source can increase motivation on coactive tasks, it seems reasonable to conclude that both mere presence and the potential for evaluation can create social facilitation effects.

However, research has yet to completely unravel the precise dynamics of how various sources of evaluation interact with one another, as well as with mere presence and other processes, to produce social facilitation. In addition, because most research has focused on the mere presence and evaluation perspectives, other potential processes that may be operative in social facilitation, such as self-attention, information processing, self-efficacy, social monitoring, and self-presentation, have yet to be fully explored.

Integrating Social Loafing and Social Facilitation
