A special type of event schema, called a *script*, describes a temporally ordered sequence of events that frequently occur in the world and can be used both to explain new events one encounters and to predict future consequences. Moreover, they can be used as behavioral guides. For example, 'Asking for a menu' in a 'restaurant' script that precedes parts that pertain to ordering, eating, and paying the bill. So, the determinants and consequences of an individual's request for a menu can be inferred on the basis of the additional frames of the script that are used to interpret it. Moreover, one's own decision to leave a tip at a restaurant may be based on the perception that this behavior is appropriate, as implied by the same script.

In much the same way as people use scripts to benefit their memory, they also use categories. By having background knowledge about a category, people can use that knowledge to influence retrieval, or to fill in gaps in their memory. One example is to be able to guess what ran in front of your car on the road at night. With limited perceptual information people can make assumptions that the animal may have been a deer, or an opossum based on knowledge of what animals cross the road at night, or the category of animals that cross the road at night. Each category is a memory structure made up of

conceptual entities (objects, events, concepts, etc.) that are, in some respect, similar to one another. Categories help organize the various entities that are encountered. There are several different classes of theories of how mental categories are created and represented. A threefold classification of theories was proposed by Douglas Medin. According to the classical view, mental categories are defined sets of necessary and sufficient properties. Entities either have these features or not, and therefore either do or do not belong to a given category.

According to probabilistic views, mental categories are created with reference to a set of properties, without the criteria of necessity and sufficiency. Category members vary in the number and pervasiveness of their features, leading to a graded category structure. The defining features for a category in memory are either contained in a memory representation of the prototypical member (real or not) or are derived from an average of all of the separate exemplars of the category.

The third class of theories is knowledge based. In many ways, this is similar to schema theories. Here, the organization of concepts into a mental category is based on knowledge of how the various members function in the world. In other words, entities are organized into categories in the sense that they are used in similar ways to explain things about the world. This is in contrast to the other theories which regard the presence or absence of various properties as the basis for categorization. For example, the category 'things to take out of the house in a fire' would be made of things that are combustible, easily transportable, and difficult or impossible to replace. This would include such diverse things as family members, money, photos, and pets, which do not share features that would cause them to be classified in memory together a priori except that they conform to a common goal. Further details are discussed elsewhere in this encyclopedia.

Episodic memory

Episodic memory, at the highest level of Tulving's monohierarchy, is like semantic memory in that the information is easily articulated. However, episodic memory differs from semantic memory in that the subject matter is concerned with events from a person's life rather than general world knowledge. Thus, episodic memories are localized in time and place. For example, general knowledge of traffic law is in the domain of semantic memory, whereas knowledge of a particular incident of getting a speeding ticket is in the domain of episodic memory. Episodic memories, unlike procedural and semantic memories, are more influenced by the passage of time. That is, they exhibit the classic negatively accelerating forgetting curve outlined by Hermann Ebbinghaus at the end of the nineteenth century. Three specific aspects of episodic memory – mental models, autobiographical knowledge, and emotional experience – are worth special attention. Further discussion on this is dealt elsewhere in this encyclopedia.

Whereas schemas and categories refer to general knowledge, mental models represent specific events. An early conception of mental models was made by Philip Johnson-Laird. Mental models simulate the functional relations of elements in a situation. This often involves general knowledge, possibly from schemas. For example, the statement 'the bike tire is flat' may simulate the construction of a mental model based on a spatially organized schema concerning the physical state of

an object that is a part of a bike. Alternatively, the model of a friend's story about the circumstances surrounding her wedding day might be constructed on the basis of several different schemas or scripts, each of which is applied to a different sequence of events in the narrative.

Mental models are stored and retrieved relatively independently of one another. For example, a set of related information (e.g., knowing about a group of people and the locations they are in) that refers to different situations is stored in several mental models in memory and produces interference during retrieval. This is because the related mental models interfere with one another during retrieval. However, if everything can be stored in a single integrated representation, there is no interference at retrieval. So, mental models help aggregate information in memory into single representations of unique situations.

Much of the information one receives in the world directly involves oneself as an active participant in the ongoing events. This self-knowledge, or autobiographical memory, composes a large share of the episodic information that people accumulate. Autobiographical knowledge is distributed throughout episodic memory, although it may include semantic information as well, such as knowledge of what schools one has attended. Representations of this knowledge may initially be formed at different times and stored independently of one another. Later, these separate representations are retrieved and integrated into a single autobiographical memory that describes the sequence of events that occurred over a period of days, weeks, or even years. Thus, autobiographical memories often have a constructive quality. This interpretive and constructive has systematic effects on the memories for the event. For example, these memories tend to be remembered as closer in time to major events in a person's life, such as the start of a semester, losing a job, or the birth of a child. Once formed, these representations are 'theories' about oneself and one's behavior in the events in question. More details on this topic are dealt elsewhere in this encyclopedia.

Emotion can have a powerful influence on memory. For example, memories can be primed or made more available if they refer to events that evoked the same emotion as a person's current state (called mood congruent learning). Sad people find it easier to recall sad memories and happy people find it easier to recall happy memories. In addition, memory is generally improved for events that are emotional. Emotionally neutral events are not as well remembered as emotionally intense events. For example, if someone sees a traumatic event, the person is likely to remember the specific details about it well. However, this applies to the more central parts of the event. People are not as good at remembering unrelated, or peripheral, information that was also present. Possible causes of the memory benefit could be related to how emotion is processed neurologically. Activity, especially in the amygdala, serves to enhance basic memory processes, providing better memory for emotionally salient details.

Relations among memory systems

Although episodic and semantic memories are described as different systems here, it is clear that they influence one another in everyday use. For example, semantic representations

may be formed on the basis of episodic ones and vice versa. A person who is asked directions to a restaurant might respond on the basis of an episodic memory of how that person drove there the previous day, or on the basis of more general knowledge that is not temporally localized and is not based on personal experience at all. In some instances, semantic memories may simply be episodic representations (e.g., mental models) in which situation-specific features denoting the time and place of occurrences (and of oneself as the experiencing agent) have somehow been forgotten. Consequently, the distinction between episodic and semantic memory is not as clear as Tulving's monohierarchical system might suggest.

Reminding

One intriguing aspect of memory is that when people think of one thing, they are often reminded of something similar. This reminding is often of either information that the person may know or earlier experiences that are in some way similar to the current situation. The use of free association to bring otherwise inaccessible memories into consciousness is based on the idea that what is currently being thought about can remind a person of related pieces of knowledge that are more remotely associated with it.

Spreading Activation and Priming

A popular way of describing the reminding process is spreading activation. This idea assumes that memory is a network of concepts connected through a complex of associative links. When information in the network is used in some way, those concepts that are used are energized or activated. This activation spreads along the associative pathways from each of the activated concepts to other concepts, and when this activation build up exceeds some threshold, they are activated as well.

This activation process occurs for both general and event-specific knowledge. For example, if you were in a conversation and someone brings up the topic of fire trucks, your concepts for fire trucks would become activated in long-term memory. The activation would also spread to related concepts, such as red, emergency, and Dalmatians. This activation could also spread to event-specific knowledge, such as the last time you saw a speeding fire truck, you were in your neighbor's Plymouth and the engine died in the middle of a busy intersection.

Spreading activation is largely automatic, without deliberate intention. However, it can be controlled to some extent. When related information is irrelevant, or the activation has spread for some time with no benefit to the current goals, it can be dampened, and resources can be directed elsewhere. This helps people pursue their current goals, and keep them from constantly rattling through an endless series of irrelevant associative meanderings.

The effects of spreading activation have been investigated in many experiments. In a typical study, people are asked to decide whether each of several letter strings are words or non-words. People can identify 'nurse' more quickly after seeing the word 'doctor' than after seeing the word 'bread.' Encountering

the word 'doctor' and accessing its meaning in memory caused activation to spread to the concepts related to it, including 'nurse,' thus making 'nurse' easier to identify. In other words, 'nurse' was primed by the word 'doctor.'

Explicit and Implicit Memory

Another important memory distinction is between explicit and implicit memory. Explicit memory involves conscious remembering. Recognition and recall tasks, in which a person deliberately tries to remember something, are examples of tasks that rely heavily on explicit memory. In contrast, implicit memory involves unconscious remembering. Typical tests of implicit memory test the unconscious influence of previously encountered information on an ostensibly unrelated task. For example, people might read a list of words, one of which is 'memoirs.' Later, they do a task that does not involve conscious recollection, such as a word stem completion task in which they complete a word stem such as MEM with the first word that comes to mind. People are more likely to complete the stems with words that they had seen earlier than are people who were not exposed to the original list.

Explicit and implicit memories respond to different influences. For example, explicit memory is affected more by conceptually driven strategies, imposed by a person, that help to organize the information. Conversely, implicit memory is more affected by data-driven strategies that rely on the physical properties of a stimulus, such as color or font. Some theories argue that explicit and implicit memories are distinct systems with different representations and processes. Proponents of these theories point to studies in which the two processes are put in competition. For example, suppose some people in a word-stem completion task are asked to try to complete the stems with words that they saw earlier, whereas others are asked to complete the stems with words they did not see. The differential rate of completing the stems with earlier seen items provides indices of the use of explicit and implicit memory. These indices vary with the tasks used and the conditions in which they are done.

Evidence from Amnesia

A great deal of knowledge about how memory works has come from studies of anterograde amnesics. These people have suffered some brain injury, typically due to head trauma, surgical mishaps, or chronic alcohol abuse. They have difficulty remembering new information they received after the time of their injury. (Some of the more severe cases need to be reintroduced to their doctors if they leave the room for a few minutes because they have no memory of them.) Although amnesics are unable to recollect some types of information, they retain other types quite well. For example, severe amnesics with deficits in semantic and episodic memories have largely intact procedural memories. Amnesics, who knew how to play the piano before their injury, could be taught to play a new song. When asked if they know how to play the song they would report no memory of it, yet they would be able to play it successfully if coaxed into

trying. Amnesics also show deficits in explicit memory tasks, such as recognition and recall, which require active remembering, but have similar memories to normal people for implicit memory tasks, such as word-stem completion. More information on this is dealt elsewhere in this encyclopedia.

Permanence of Memories

People encounter a great deal of information in their lifetime. They see lots of things, meet many people, read many things, and have lots of experiences. What happens to all of this information? Is all of it remembered forever? Or is it the case that once information has been lost from memory it is lost forever, and will never again be recovered and play a role in influencing behavior?

One view is that everything that is ever encountered is stored in long-term memory and remains there permanently in some form or another. These memories either can be retrieved into consciousness and/or exert an unconscious influence on behaviors and ideas throughout the lifespan. A well-known source of evidence for the permanence of memory comes from the work of the neurosurgeon Wilder Penfield. During the 1950s, he performed operations that involved cutting away part of a patient's brain in the treatment of some ailment, like epilepsy. Before actually removing part of the cortex, Penfield stimulated various areas with a mild electrical charge to determine the functions of various areas so as not to remove any vital functions. Sometimes the patient reported vivid experiences. One patient reported "Yes, sir, I think I heard a mother calling her little boy somewhere" when receiving electrical stimulation in a specific area. These experiences, because of their mundane nature, led Penfield to suggest that the electrical stimulations caused a re-emergence of previously forgotten memories from the past and seemed to suggest that everything a person had ever experienced was stored in memory, and that all that is needed is a means to get it out; which in this case, was electrical stimulation of the cortex.

However, despite this convincing argument, this is not the complete explanation. First, only about 25% of Penfield's patients actually reported some experience, and only 3–7% of these reports were sufficiently clear to suggest that the patients were actually re-experiencing a previous life event. While cortical electrical stimulation may have brought back memories, it may also have just suggested experiences. No evidence was ever collected that suggested that the reported experiences actually happened to the patients.

Other positions have been put forward in support of some version of permanent memory storage. One is Harry Bahrick's *permastore* idea. According to this view, when information is first stored in memory, there is some forgetting over time. However, at some point (usually about 3 years later), the amount of forgetting ceases and what is left over stays in a stable state over long periods of time. The information that remains is said to be in a *permastore*, or permanent storage. In one study, Bahrick studied memory for college Spanish. For the first 3 years after college, there is a drop in the amount of information remembered. However, memory remained relatively constant for the next 40 years or so.

Forgetting in a Permanent Memory System

If memories are permanent, then how could forgetting occur? Two of the more prominent reasons are the lack of sufficient retrieval cues and retrieval interference.

Retrieval cues

Although information may be stored in memory, it may be destined for some dark and dusty corner of the mind that is inaccessible. One reason for this inability is that a person does not have the proper retrieval cues. Retrieval cues are the set of properties that allow for the appropriate selection and retrieval of the memory. If these cues are not available, the memory cannot be retrieved. A common metaphor that is used to describe this is that of a library. A book may be stored in the library shelves, and if it can be gotten, all of the information in it would be available. However, if its entry in the card catalog is missing, it becomes very difficult to retrieve, and might even be said not to exist in the library at all.

One of the factors that can influence the ability to remember is the amount of processing it received at encoding. Basically, the more time and effort that a person expends processing new information through elaboration or association with previously known information, the more likely it will be remembered later. This is called the level of processing hypothesis. According to this idea, information that is processed at a deeper level is remembered better because there are more cues that can be used to retrieve it. For example, if a person were to scan a newspaper article for certain letters, it is unlikely that much would be remembered. Whereas, if a person were to read the article in detail, thinking of related stories that have been reported earlier, or to other related topics, much of the information in the article would be remembered.

A related topic is the generation effect. Basically, information that was generated by people is remembered better than information that is merely presented. This occurs because all of the processing involved in the generation of the information is somehow associated with it in memory, thus allowing for a richer set of retrieval cues to access the information. While the information generation can greatly enhance memory, emerging research reveals something even more effective. Taking an evolutionary point of view, it has been found that people who try to relate knowledge to situations involved in a person's own survival, memory for that information is greatly improved. Moreover, this improvement is particularly strong if people imagine they are trying to survive in a grassland setting (as compared to, say, a city).

An extreme example of depth of processing is what are called 'flashbulb' memories. Flashbulb memories occur in situations of extreme surprise, shock, or other events that have a strong emotional impact. Common examples of flashbulb memories are highly detailed memories of what a person was doing, who the person was with, what the person was wearing, etc., when some surprising and important news was heard, such as the assassination of President Kennedy, or the September 11 terrorist attacks. It is as though a picture of the situation had been taken, hence the name flashbulb memory. The high degree of detail encoded in them would make them highly accessible because there would be many cues to retrieve them. However,

there are other explanations for flashbulb memories, such as the idea that these are events that are retrieved over and over again. This constant usage of information, a process called overlearning, allows them to be easily retrieved. There is also some evidence that the information in flashbulb memories may be incomplete and inaccurate, but through rehearsing and talking about it people have great confidence about their memories' veracity.

In a more mundane vein, more accurate information retrieval has been shown to occur by providing the same sorts of contextual cues that were available when the information was first learned. This effect is called encoding specificity. Contextual factors that can influence memory can be just about anything, including the person's mood (as noted earlier), the room that the information was learned in, the person from whom the information was originally learned from, and so on. The effects of encoding specificity can be seen in daily life. How often have you thought of doing something when you were in one room of your home, and walked into another room to act on it and then you could not remember why you went in there. So, you return to the room in which you started and, all of a sudden, you remember why you went to the other room in the first place. This remembering presumably occurs because the room in which the original idea occurred provides a sufficient number of retrieval cues to access the information.

Retrieval interference

Another reason for forgetting things that are actually stored in memory is retrieval interference. When a large number of pieces of information about an object are acquired at different points in time, they are stored independently of one another. In some cases, the more recent information appears to block or 'bury' the earlier information, making it more difficult to recall. This is *retroactive interference*. In other cases, the earlier information makes it difficult to remember subsequent information. This is *proactive interference*. Both types of interference are more pronounced when the memories contain content information that is similar and possibly conflicting. Then, the stronger memories are typically recalled instead of the weaker ones. Thus, the weaker memories appear to have been forgotten despite the fact they still exist in memory. For example, when people move, it may be difficult after a period of time to remember some of the streets in the town they lived in previously. This is because the names of the streets in the new town interfere with the retrieval of the street names in the old town.

Evidence for the Transience of Memory

The arguments for permanent memories can be quite convincing. However, there is good reason to consider the possibility that, while some information may be retained throughout a person's lifetime, due to frequent use or strong encoding, most information is removed from long-term memory after a period of disuse. Two sources of evidence for the nonpermanence of memory considered here are reconstructive processing and misleading postevent information.

Reconstructive Processing

Reconstructive processing refers to situations where people have forgotten various details of an original set of information and substituted other pieces of information. Much of the research on schema and script usage has shown that these gaps in memory are filled in with information that is consistent with the original source of information in terms of the gist of the originally presented facts, but nevertheless, is inaccurate. Even though gaps in one's knowledge have been filled in with unoriginal information, people express high confidence that the reported information was actually presented.

However, although the schema-enhanced report did contain some reconstructed inaccuracies, the original information was retained. In such a case, the general world knowledge was used as a crutch to avoid an extensive and effortful memory search. Some memory research has shown that if people are encouraged to adopt a perspective that is different from the one originally adopted during encoding, their ability to recall the original information accurately improves. At first, this seems to run counter to the encoding specificity effects described earlier. However, in this case, people are able to access the information in memory. Rather than expending all the effort needed to retrieve that information, they choose to reconstruct the more detailed aspects of the memory by assuming various defaults for the type of situation that is being remembered. In the case of encoding specificity, the nature of the information is unavailable to the person, not the details.

Misleading Postevent Information

Other evidence that the information in memory is not permanent comes from research on misleading postevent information. In studies investigating this topic, people may watch a series of events, such as a scenario of a car accident, in a slide-show or videotape. After seeing the situation, people are presented with a description that provides misleading information. In the case of the car accident, for example, people might be asked whether one of the cars stopped before the yield sign, when in fact the sign in the scenario was a stop sign. Later, people are likely to report that the features of the postevent information were actually part of the original event. This could occur because the more recent information contains features that were never observed, but were added to the original representation after it had been formed. Or, it could occur because the more recently described features actually replaced the original features in the memory, thus modifying it forever. This second possibility suggests that information in memory will be discarded if it is superseded by other relevant and more recent information.

The question of how postevent information can affect memory is especially important outside the laboratory, for example, in legal cases involving eyewitness testimony. One problem is that over time, the information in the memory of an event may decay, be difficult to retrieve, be interfered with, and perhaps be reconstructed. The additional possibility that the information a person may encounter subsequent to an event can actually change the eyewitness's memory has enormous legal ramifications. Eyewitness testimony is often thought of as one of the most valuable sources of evidence.

However, the fragility of the content of memory questions this assumption, as demonstrated by the fact that leading statements or questions by other people could cause the eyewitness to incorporate additional and extraneous information into their memory representation, thus corrupting their memory of the event. Further discussion on this topic is found elsewhere in this encyclopedia.

False Memories

It is important to remember that memories are not infallible. Through the processes of reconstruction, misleading information, and assumptions that we make based on schemas, major changes can happen to memories. Various changes and inaccurate remembering have been studied under the category of false memories, that is, memories for things that did not happen. Such inaccuracies range from misattributing a source, believing an event has happened more recently than it actually did, and believing in an event that never actually happened, such as being abducted by a UFO, or being abused as a child. Moreover, even just imagining and reporting a made-up event will lead to the creation of false memories of that event actually happening.

Summary

Human memory is a complex system. Information entering it is subject to different types of processing depending on whether it is in short-term or long-term storage. The question of how long information that is successfully stored in long-term memory will remain there is uncertain: it could remain throughout one's lifetime, or fade away permanently if it does not get used. Information is stored in different ways in memory depending on the type of information it is (whether it is knowledge of skilled action, general world knowledge, or knowledge of one's own life events). Information stored in memory has different effects on current processing goals depending on whether it was explicitly retrieved or whether it has an influence on behavior through some implicit, unconscious process.

Glossary

Agnosia A condition in which familiar stimuli cannot be recognized, despite normal perception; agnosia for faces is known as prosopagnosia.

Amnesia Memory impairment, especially an inability to acquire new information (*anterograde amnesia*) or recall previously learned knowledge (*retrograde amnesia*).

Hippocampus A neuroanatomical structure in the mesial temporal lobe that is critical to memory.

Long-term memory Information that can be retrieved for long periods of time (days, years, decades) after initial learning; huge capacity.

Memory Knowledge stored in the brain, and the processes used to acquire and retrieve that knowledge.

Modality Any of the distinct types of sensations, such as visual, auditory, somatosensory.

Retrieval Remembering information through recall or recognition.

Temporal lobes Lobes of the brain located laterally and inferiorly, which contain many structures important for memory; on the left there is specialization for verbal information; on the right, there is specialization for nonverbal and visuospatial information.

Working memory A transient type of memory, lasting a few minutes and having limited capacity (about 7 'chunks' of information).

Introduction

Virtually all human behavior involves some aspect of memory. For example, we need memory for language, planning, decision-making, and problem-solving. Memory is important for every facet of our lives – for remembering important events and people, the facts and knowledge accumulated across the lifespan, learning new motor skills (e.g., riding a bike), as well as more mundane purposes, such as where we left our keys. Memory is not one single function of the brain with a single area dedicated to its processing; rather, virtually all areas of the brain have some role in the various aspects of memory. However, there are certain key neural regions that are especially critical to memory, and that is the focus of this article. The hippocampal complex, buried in the middle part of the temporal lobes, is critical to *acquiring new information*. Other areas of the temporal lobe are involved in *retrieving conceptual information*. Other structures such as the basal ganglia and the cerebellum are important for the *acquisition of new motor skills*. The amygdala is critical to *emotional memory*. Each of these areas is involved in a different facet of memory, and each has a prodigious capacity to acquire new information and memories.

This article aims to review the neural structures involved in memory, with a focus on adult humans. While studies of nonhuman animals have made an enormous contribution to our understanding of memory and its neural substrates, a review of such studies is outside the scope of this article. It is also important to note that the focus here is on the neural systems involved in memory, rather than the molecular or cellular mechanisms involved in memory. Therefore, the emphasis in this article is on the neural systems of the adult human brain that subserve memory.

Terms and Paradigms

Definitions and Terms

Memory is the process by which information is acquired, stored, and retrieved in the brain moment by moment. This process is believed to involve three steps: acquisition, consolidation, and storage. Acquisition is the process by which information is first brought into the brain and into a first stage memory 'buffer,' via sensory organs and primary sensory cortices. For example, when you meet a new person, the knowledge of her face is acquired by bringing the visual pattern of the face into your eyes and primary visual cortex in the occipital lobes. The second stage, consolidation, is the process by which information is rehearsed and a robust representation is created in the brain. Finally, storage is the process by which a relatively permanent 'record' or 'memory trace' is created. These records are *dynamic* so that they can be continually changed, updated, and modified over time and based on new experiences. Returning to the example of learning a new face, the visual pattern of the face would be consolidated and stored, and associations would form between the face and other important facts about the face (e.g., the name of the person, the context in which you met, how you feel about the person).

After memories have been created and stored, they must be retrieved at later times. The process of retrieval involves reactivating types of information that can form a mental image (e.g., retrieving a mental image of your house). Another form of retrieval involves reactivation of knowledge into a form that can be translated to motor output (e.g., speech, movement, autonomic activity). These different types of memory are independent concepts both theoretically and neurally. The former type, or information such as facts and events that can be brought into consciousness to form a mental image, is known as

declarative memory, while information that cannot be deliberately brought into consciousness is known as *nondeclarative memory* and typically refers to motor skills and habits. In other words, declarative memory can be ‘declared,’ in the sense that the information can be brought into the ‘mind’s eye’ and mentally inspected, whereas nondeclarative memory cannot.

There are several mechanisms of retrieval of declarative information: (1) *Recall* is the process by which information is deliberately evoked in the brain. For example, you can bring into consciousness and recall the food you ate this morning for breakfast. (2) *Recognition* is the process that occurs when one encounters material that has been previously learned, and realizes (or recognizes) that it has been previously learned. For example, when you run into a group of people, one of whom you have met earlier, you can recognize the face of person you have met earlier because it ‘matches’ the face you have learned previously. For nondeclarative memory, retrieval involves skills or habits that are not brought into consciousness, but instead, the information is retrieved through motor output. For example, the information needed for balancing and riding a bicycle cannot be expressed in words or images, but instead, is expressed through motor output.

Paradigms

The investigation of the neural substrates of memory has used many different methods and paradigms. The lesion method, or the study of the (impaired) functions of patients with focal brain damage, has been paramount to the study of memory. Exploration of the neural systems involved in memory was brought to the forefront of the field of neuroscience after a patient known as H.M. was described in 1957. After undergoing surgery to resect the medial temporal lobes bilaterally to control seizures, H.M. developed an inability to learn new declarative information about facts and events. Despite having a profound memory disturbance, patients with medial temporal lobe damage such as H.M. have otherwise relatively preserved cognitive functions – they have normal language, basic intellectual abilities, perception, and attention. Descriptions of patients with brain damage, such as H.M. and others, have elucidated many of the brain areas involved in memory, their specific functions, and the relationships between different types of memory.

The lesion method is a longstanding tradition in neuroscience and has brought about many important findings in the domain of memory. Recently, studies using functional neuroimaging techniques have corroborated and expanded on lesion studies. The two main forms of functional neuroimaging are functional magnetic resonance imaging (fMRI) and positron emission tomography (PET). These techniques are able to indirectly monitor the neural activity of healthy adults as they are performing a cognitive task. PET measures regional blood flow to areas of the brain by using radioactive tracers, while fMRI measures changes in oxygenation in the brain. Both techniques rely on the concept that increased neuronal activity in a brain region results in changes in blood flow and oxygenation in that region. Therefore, by measuring changes in blood flow and oxygenation, inferences can be made about the brain areas that are activated during a cognitive task. These methods have provided many insights regarding the neural substrates of memory, especially certain types, such as working memory.

Multiple Memory Systems in the Brain

As discussed earlier, there are multiple memory systems in the brain that are involved in different aspects of memory. Many of these systems are highly interconnected and work together to perform their various functions; however, they also function relatively independently, which can be best observed when brain damage to one system occurs.

Temporal Lobe Structures

The medial temporal lobes contain numerous structures critical to multiple aspects of memory. These structures include the hippocampus, amygdala, entorhinal and perirhinal cortices, and the parahippocampal gyrus. Specifically, the hippocampal complex, a term that encompasses the hippocampus, entorhinal and perirhinal cortices, and parahippocampal gyrus, is necessary for the acquisition of new declarative information. Other areas of the temporal lobe, including the anterior, inferior, and lateral aspects of the temporal lobes, are involved in the retrieval of knowledge from long-term memory (Figure 1).

Hippocampus and related structures

Anatomy

Anatomically, the hippocampal complex is highly interconnected with nearly all regions of the brain, including association cortices from all sensory areas as well as polymodal

Figure 1 The hippocampus (Nos. 1–3) and related structures (Nos. 4–10). Adapted from Naidich TP, Duvernoy HM, Delman BN, Sorensen AG, Kollias SS, Haacke EM (2008) Duvernoy's Atlas of the Human Brain Stem and Cerebellum, New York: Springer.

Figure 2 The neuroanatomical connectivity between the hippocampal complex memory system and various areas of the cerebral cortex. The Figure depicts ventral views of the human brain and the likely connections of the entorhinal (area 28) and perirhinal (area 35) cortices derived from nonhuman primate neuroanatomical research. This system has extensive bidirectional connectivity with unimodal sensory association areas (e.g., olfactory, auditory, visual) and polymodal association areas of the brain (e.g., prefrontal cortex, superior temporal, occipitotemporal regions). The hippocampal complex also receives input from limbic areas of the brain, including the amygdala, temporal pole, and cingulate cortex. The widespread connectivity of the hippocampal system allows it to interact with a multitude of neural systems to integrate and consolidate information.

association areas (where numerous types of sensory information are integrated) in the parietal and frontal lobes. Due to this structural arrangement, the hippocampal complex receives and influences information from virtually every area of the brain. Therefore, the hippocampal complex is ideally situated anatomically to subserve memory by creating associations that bind and integrate all modalities of information (e.g., visual, auditory, somatosensory). For example, this would allow for the association of a visual stimulus (e.g., a person’s face) with an auditory stimulus (e.g., the person’s voice) for a cohesive representation of an item or event (Figure 2 and Table 1).

Involvement in anterograde memory

The function of the hippocampal complex has been primarily elucidated through the study of patients with focal damage to this area. Patients with damage to the hippocampal complex have memory impairments specifically in the ability to learn new information, or *anterograde memory*. However, *retrograde memory*, or information learned prior to their brain injury remains intact for the most part. Thus, the hippocampal complex is critical to the acquisition of new information, but not as important for the retrieval of previously learned information. The hippocampal complex seems to play a time-sensitive, temporary role in memory, such that it is critical to the formation and short-term maintenance of memories, but long-term permanent memories are maintained and stored elsewhere. Non-mesial areas of the temporal lobe and higher order sensory association cortices are believed to be important for the storage and retrieval of long-term retrograde memories.

Involvement in declarative memory

Patients with hippocampal damage have impairments in creating new declarative memories, or memory for facts and events that can be explicitly recalled, or ‘declared.’ Declarative memory includes semantic memory, or memory for facts and information not associated with a specific event (e.g., knowing Paris

Table 1 Subdivisions of memory

Type	Characteristics
Long-term	Permanent; unlimited capacity
Working	Transient (~1 min); limited capacity (7 ± 2 chunks of information)
Declarative	Information that can be brought into consciousness; ‘declared’
Nondeclarative	Performance-based; motor output; habits; automatic tendencies
Retrograde	Previous learning; material acquired prior to onset of brain injury
Anterograde	New learning; material acquired after onset of brain injury
Verbal	Words, names, verbally coded facts; word-based material
Nonverbal	Faces, geographic routes, complex melodies; spatially based material
Unique	Information belonging to class of one; proper names
Nonunique	Information from classes larger than one; animals, fruits, tools
Retrospective	Memory for the past; what happened before
Prospective	Memory for the future; what will happen

is the capital of France), as well as memory for specific events associated with a time and place, known as episodic memory (e.g., your wedding day). Despite being unable to learn new declarative information, patients with hippocampal damage are still able to learn new skills and habits, suggesting that this type of memory is not dependent on the hippocampal complex. Memory for skills and habits, such as learning how to ride a bike or ski, is known as nondeclarative, or procedural memory. Other neural structures such as the basal ganglia and cerebellum are involved in nondeclarative memory and will be discussed in more detail later.

Lateralization

Bilateral hippocampal damage causes a global deficit in acquiring new declarative information of all modalities (e.g., visual, auditory) and of all types of material (e.g., verbal, nonverbal). However, there is lateralization of function in the hippocampal complex, which can be revealed when unilateral hippocampal damage occurs. This organization parallels the overall arrangement of the brain, such that for most individuals, the left hemisphere is specialized for verbal functions while the right hemisphere is specialized for spatial, emotional, and other nonverbal abilities. Thus, damage to the left hippocampal complex will impair acquisition of information related to verbal content, while damage to the right hippocampal complex will impair acquisition of nonverbal information such as faces and spatial locations. Normally, both the right and left hippocampi function in concert as we acquire new information. For example, when we meet a new person, we acquire both the knowledge of their face (nonverbal), as well as their name (verbal), and these pieces of information are bound together and can be retrieved upon prompting. However, after unilateral damage to the hippocampal complex, an individual may be impaired at learning new names and verbal facts, while still able to learn new faces and spatial arrangements.

Independence from working memory

Overall, the hippocampal complex has a very specific role in memory, such that it is critical to declarative, anterograde memory. Observations of patients with hippocampal damage have allowed for another distinction to be made between types of memory, as they are able to retain information for short periods of time, up to about a minute or so. For example, they are able to retain numbers (e.g., a telephone number) or spatial arrangements in their minds for short spans of time. This type of memory is called working memory and has a limited capacity (7 ± 2 'chunks' of information) and is time-sensitive. Patients with hippocampal damage are able to retain such information for about a minute; however, after this time, or if the patient is distracted, the information will be lost. Other structures such as the dorsolateral prefrontal cortex are believed to be involved in working memory (discussed in more detail later).

Future episodic memory

Humans have a remarkable ability to mentally 'time-travel.' That is, we are able to revisit our past experiences through our memories, as well as imagine future experiences and situations (e.g., your wedding day, the birth of your children, a major job promotion). Recent research has suggested that the same structures that are involved in creating memories for past experiences may also be involved in imagining and simulating future experiences. For example, patients with bilateral hippocampal damage are impaired at creating novel scenarios, such that their descriptions are fragmented and lack richness of content. This has been taken to suggest that the hippocampus may be involved in binding together the various aspects of a scenario, even imagined or future scenarios. The creation of this type of scenario requires drawing upon past experiences to guide one's representation of what might happen in the future. The hippocampus may be involved in flexibly recombining

past autobiographical information for use in novel future contexts. Functional neuroimaging studies have corroborated the idea that the hippocampus is involved in both creating memories for the past and creating and imagining the future. Other areas of the brain, including the ventromedial prefrontal cortex, are believed to be important for future thinking as well.

Updating and integrating information over time

Research has also shown that the hippocampus is important for integrating multiple pieces of information over time. Patients with bilateral hippocampal damage have impairments in updating and integrating the relationships between items and pieces of information across time in order to build a representation of a person or situation over time. For example, patients are unable to form and update associations between choices made (e.g., selecting from a certain deck of cards) and outcomes received (e.g., reward/punishment) across time, and are left to rely only on the information available at hand in that moment. Similarly, patients with hippocampal damage are unable to integrate information over time to properly build a cohesive representation of another person's moral character, and again tend to overvalue the most recent information learned when creating judgments of others. Therefore, patients with hippocampal damage often do not make advantageous decisions and appropriate judgments (e.g., about the moral character of others; or about which response is most likely to be rewarded), when multiple pieces of information must be integrated.

*Nonmesial temporal lobe**Anatomy*

Nonmesial temporal lobe structures include the lateral, inferior, and anterior regions of the temporal lobe, including the temporal pole (Brodmann area 38), inferotemporal cortex (Brodmann areas 20 and 21), and an area of transition between the posterior temporal lobe and inferior occipital lobe (Brodmann area 37; see [Figures 3 and 4](#)). These areas are involved in different aspects of memory than the medial temporal lobes; however, their functions have not been worked out in as much detail.

Retrograde memory

Earlier it was noted that patients with focal damage to the hippocampal complex typically do not have extensive impairments in retrieving previously learned information, or retrograde memory, suggesting that the medial temporal lobes are not a storage site for permanent memories. The nonmesial areas of the temporal lobe are important for retrograde memory and damage to these areas causes impairment in the ability to retrieve previously learned information. For example, Boswell, a patient whose brain damage included bilateral nonmesial temporal lobe structures, has very little capacity to retrieve any information about his past. Other than a few facts about his hometown, his parents, and his former occupation, he is unable to retrieve any other important information about his life, including about his spouse, children, or other places he has lived. However, it is rare to find focal brain damage that causes complete retrograde memory impairments, suggesting that there are other systems involved in retrograde memory. For example, higher sensory association areas have been implicated (discussed later).

Figure 3 The lateral (upper) and mesial (lower) aspects of the left (left side of figure) and right (right side of figure) cerebral hemispheres. The Brodmann areas associated with regions of the temporal lobe (38, 20/21, 37, 35/36, 28) and dorsolateral prefrontal cortex of the frontal lobe (46, 9) important for memory are marked.

Figure 4 The inferior aspect of the cerebral hemispheres (the left hemisphere is on the right side and vice versa). Area 28 corresponds to the parahippocampal gyrus, and the hippocampus itself is buried deep within this region.

Lateralization

Similar to the medial temporal lobes, and the rest of the brain in general, there is lateralization of information processing in the nonmesial areas of temporal lobe. The left side seems to be important for the retrieval of verbal and lexical information, including retrieval of nouns (names) for unique and non-unique items. The right side seems to be important for the retrieval of nonverbal information such as faces and spatial

information. However, there is some overlap in the types of information processed by the left and the right hemispheres. For example, face processing involves both the right and left occipitotemporal regions, but the roles of each side are different. The right side uses a more holistic, gestalt-based method of analysis, while the left side tends to use a more feature-based, sequential method of analysis. Therefore, profound impairments in the recognition of faces, or prosopagnosia, typically occur only after bilateral occipitotemporal damage.

Unique and nonunique knowledge

The organization within the nonmesial areas of the temporal lobe is such that there is an increasing level of specificity or 'uniqueness' in the type of information processed from the posterior-to-anterior axis of the cortex. Specifically, the posterior aspects, including Brodmann areas 20/21, 36, and 37, are associated with information acquired, stored, and retrieved at the nonunique level. For example, names of entities such as tools or animals are retrieved at the nonunique level (e.g., hammer, wrench, squirrel), but not usually at a more specific unique level (for identifying a single individual squirrel, for example). However, certain proper nouns, such as names of people or unique landmarks, must be retrieved at a more specific unique level (e.g., the White House; Michael Jordan). This type of unique knowledge retrieval is dependent on more anterior aspects of the temporal lobe, including the temporal pole, or Brodmann area 38.

Amygdala

The amygdala is a structure seated just in front of the hippocampus in the medial temporal lobes. The amygdala is broadly

involved in emotion processing and plays a key role in the acquisition and expression of emotional memories. The amygdala consists of a collection of nuclei that receive input from all sensory areas of the brain and has connections to the hypothalamus and autonomic system for controlling the body's emotional response, as well as connections to higher order processing areas such as the prefrontal cortex and the hippocampus. The amygdala interacts with the hippocampal complex to enhance declarative memory for emotionally arousing stimuli. For example, in a list-learning task, healthy adults will show enhanced memory for emotional words (e.g., 'victim') versus neutral words (e.g., 'stamp'), as well as enhanced memory for emotional parts of a story compared to the neutral parts. However, studies with a patient with a bilateral damage to the amygdala (but not hippocampus) have shown that amygdala damage reduces this enhancement of memory for emotional stimuli (i.e., the patient recalls emotional stimuli no better than neutral stimuli). Importantly, unlike patients with hippocampal damage, bilateral amygdala damage does not affect memory for the neutral stimuli, but only reduces the enhancement of emotional memory.

The amygdala and the hippocampus have distinct but complementary roles in the creation of an emotional memory. The amygdala is able to strongly and persistently influence our emotional state; however, it must function in concert with the hippocampus in order to provide context for the emotional memory. For example, patients with bilateral hippocampal damage, with intact amygdala, can be influenced and aroused emotionally by emotional stimuli, long after they are able to consciously recall the stimuli that induced this mood. After seeing an emotional film clip that induces sadness, for example, a patient may continue to feel sad even long after they can recall what caused them to feel that way. Conversely, a patient with bilateral amygdala damage, with an intact hippocampus, is able to remember the details of the film but does not retain the enduring feeling of the emotion. This suggests that the amygdala is required for the emotion associated with memory, and the hippocampus for the context, but both are required for integrating emotion and context.

Higher Order Sensory Association Areas

Each primary sensory modality (e.g., visual, auditory, somatosensory) has an area of association cortex surrounding the primary processing areas. Sensory association cortices are critical to perceiving and processing higher order information related to the various sensory modalities. Interestingly, these same areas that are important for the perception of information are also important for the memory and recall of this information. For example, sensory association cortices are important for perceiving the various aspects of the object, the color, texture, shape, sound, etc. The ability to recall these various aspects of an object is also dependent on sensory association cortices. In fact, the different sensory aspects of an item are stored separately, such that brain damage can cause selective impairments in retrieving one modality of knowledge about an object (e.g., visual knowledge) while sparing other modalities of knowledge (e.g., auditory knowledge). A selective deficit in recognizing and retrieving information, typically regarding a single sensory modality, is known as *agnosia*. For example,

patients with damage to visual association cortices can often have visual agnosia, where they are impaired at retrieving and recognizing the information about an object such as an elephant from the visual modality when seeing a picture, but can recognize and name the elephant through hearing the sound an elephant makes.

This organization has been well studied in the visual modality. It has been shown that the neural units involved in the perception of color and form are also involved in their recall. Similar organization is believed to occur in auditory association cortex, where the neural units involved in the various auditory patterns, pitches, melodies, acoustic word-forms, are involved in both the perception and recall of auditory information. Somatosensory association cortices have neural units involved in both the perception and recall of information concerning tactile information such as weight, texture, and shape.

Frontal Lobe Structures

The frontal lobes are the most anterior part of the brain and are associated with higher order cognitive abilities such as planning and decision-making. However, certain aspects of the frontal lobes are involved in memory as well.

Basal forebrain

The basal forebrain (not technically a 'frontal lobe' structure, but in the vicinity) is a bilateral set of nuclei that includes structures such as the septum, diagonal band nuclei, and substantia innominata. This area contains neurons that innervate many areas of the brain, including the hippocampal complex and areas of the cerebral cortex, using the neurotransmitter acetylcholine. The delivery of acetylcholine and other neurotransmitters, such as dopamine and norepinephrine, by the basal forebrain to hippocampus and other areas is critical to memory function. Therefore, when damage to the basal forebrain occurs, a memory deficit results. This deficit is believed to occur because of the disruption of neurotransmitter delivery to medial temporal lobe structures; however, the memory impairment caused by basal forebrain damage is notably different from the memory impairment resulting from damage directly to the hippocampal complex.

The basal forebrain is believed to be involved in binding the different modal components of a particular memory together. Different parts of a memory must be bound together and integrated to form a cohesive representation. For example, a patient with basal forebrain damage is able to acquire and store new declarative information, such as the name of a person and their face, but these two pieces of information are not properly integrated and cannot be retrieved correctly at the same time. Importantly, this binding deficit can occur in both anterograde and retrograde memories. Patients with basal forebrain damage can learn new information from one modality, but have trouble integrating relationships between modalities. The binding impairment can also affect knowledge of temporal relationships between information and events, resulting in impairments in remembering the order in which events occurred. Similarly, retrograde memories can be retrieved but the information is not bound properly and tends to contain inaccurate information. For example, a patient recalling facts

about an occupation from 10 years ago may link facts together incorrectly by saying, "I used to work on an assembly line (correct) putting metal rings on the legs of frozen turkeys (correct), at the Hawkeye Packing Plant (incorrect) in the southwest part of town (incorrect)."

Dorsolateral prefrontal cortex

As mentioned earlier, the dorsolateral prefrontal cortex (including Brodmann areas 46, 9) is involved in working memory (see Figure 3). Working memory is the ability to hold a limited amount of information in mind for a short period of time. For example, working memory is necessary for holding a phone number 'in mind,' or keeping track of geographical locations as someone gives you multistep directions to a location across town. This type of memory is critical to bridging temporal gaps so that the information can be 'worked' with or mentally manipulated for a short period of time. This ability to hold representations in mind is critical to other complex cognitive functions, such as decision-making, planning, and problem-solving. Other areas of the brain, such as the parietal lobes, which are highly interconnected with the dorsolateral prefrontal cortex, have also been found to play a role in working memory.

Studies of nonhuman animals and functional neuroimaging have played an important role in discovering the role of the dorsolateral prefrontal cortex in working memory. Single-cell recordings from monkeys in this region have found neurons that fire more during the delay between stimuli presentation and recall, suggesting that they are involved in keeping the information 'online.' Functional neuroimaging studies suggest that similar to other areas of the brain, there is lateralization of function in the dorsolateral prefrontal cortex, such that the right side is important for spatial working memory, and left side is important for verbal working memory. However, the details of this organization are still under debate and much is yet to be discovered about the neural substrates of working memory.

The dorsolateral prefrontal cortex has also been implicated in memory for the frequency of an event (how often something happens) and recency of the event (how long ago it took place). For example, answering the question 'When was the last time you talked to your mother on the phone?' would be a recency judgment, while 'How many times do you talk to your mother on the phone every week?' would be a frequency judgment. Both of these types of judgments are forms of memory that are dependent on the dorsolateral prefrontal cortex.

Basal Ganglia and Cerebellum

The basal ganglia are a set of gray matter nuclei, including the caudate, putamen, globus pallidus, and subthalamic nuclei, buried deep within the cerebral hemispheres. The basal ganglia are primarily involved in motor control and refining and executing motor movements. This structure is also involved in non-declarative or procedural forms of memory; especially those that are dependent on motor movements. The basal ganglia are important for learning and retrieval of motor skills (e.g., riding a bicycle, skiing). Another structure involved in nondeclarative memory and motor coordination is the cerebellum, a structure located posterior to the brainstem at the base of the brain.

Diseases such as Parkinson's disease and Huntington's disease cause damage to the basal ganglia, and patients afflicted

with these diseases are impaired at the ability to learn new motor skills. Importantly, patients with damage to the basal ganglia retain the ability to learn new declarative information, because of their intact medial temporal lobe function. Similarly, patients with damage to the hippocampal complex are able to learn new motor skills, although they cannot remember any other declarative information about learning these skills (e.g., where or when they learned the information). This suggests that the hippocampal system for declarative memory and the basal ganglia system for procedural memory are independent systems.

The basal ganglia, especially the caudate and putamen, are also believed to be involved in nonmotor skill learning, such as habit learning. This involves the tendency to respond the same way to repeated stimuli or situations. For example, we often take the same route home everyday, or automatically reach for the seatbelt after entering the car. These are habits and response tendencies that are engaged fairly automatically without much conscious thought.

Thalamus

The thalamus is composed of a set of nuclei located in the brainstem. While the primary functions of the thalamus are not specifically for memory, it does play an important role in memory. The areas most important for memory are the dorsomedial and anterior nuclei of the thalamus, the mammillary bodies, and their associated tracts: the mammillothalamic tract, connecting the anterior nucleus of the thalamus and the medial temporal lobes, and the ventromygdalofugal pathway, which connects the dorsomedial nucleus and the amygdala. Damage to these areas of the thalamus can also cause memory impairments because of damage to their connectivity to the medial temporal lobes. In general, the role of the thalamus in memory is not well understood. The type of amnesia associated with damage to the thalamus is similar to hippocampal amnesia, in that it typically affects learning of new declarative memories; however, thalamic lesions can also affect retrograde memories. Wernicke-Korsakoff syndrome, which is typically caused by severe, prolonged alcoholism, causes damage to the thalamus and mammillary bodies and has severe effects on memory. Anterior aspects of the thalamus are important for remembering the temporal sequence of events (i.e., knowing the order in which events occurred). Finally, similar to many of the other brain regions discussed in this article, there is some laterality of information processing in the thalamus. The thalamic nuclei on the left side seem to be specialized for verbal information, while the right side is more involved in nonverbal, spatial information.

Conclusion

The human brain has an incredible capacity to learn and store a vast amount of information, including names, faces, events, facts, and skills, and to recall this information accurately and flexibly in a variety of contexts. The importance of memory for everyday life can hardly be overestimated. Memory is involved in virtually all behaviors and cognitive functions,

including language, social interaction, decision-making, and future thinking. The importance of memory and its associated neural structures can be seen through the devastation that occurs when these areas are diseased or damaged, such as Alzheimer's disease, in which case cell death begins primarily in the hippocampus and medial temporal lobes.

The neural systems that support memory encompass numerous structures in the brain. Many of these structures are not solely dedicated to memory processing, yet each area makes a critical contribution to memory function. The detailed study of patients with focal brain damage and more recent studies using functional imaging techniques have allowed distinctions to be made between different types of memory and have broadened our knowledge of the neural structures involved in memory. It is through the use of these methods that scientific explorations will continue to discover new facets of human memory.

Mental Imagery

G Ganis, University of Plymouth, Plymouth, UK; Harvard Medical School, Boston, MA, USA

© 2012 Elsevier Inc. All rights reserved.

Glossary

Dorsal stream Functional pathway in the primate visual brain that is specialized for processing spatial attributes.

Functional magnetic resonance imaging (fMRI) A noninvasive technique used to measure regional cerebral blood flow. Unlike PET, it does not involve radiation exposure.

Multivoxel pattern analyses Analyses of functional magnetic resonance imaging data that focus on subtle differences in the spatial pattern of activation across many voxels.

Occipital A posterior portion of the cortex involved in early processing of visual information.

Positron emission tomography (PET) A noninvasive technique employed to measure regional cerebral blood flow by using a radioactive tracer.

Transcranial magnetic stimulation (TMS) A noninvasive technique used to temporarily disrupt neural processing at a cortical site by using a strong magnetic field.

Ventral stream Functional pathway in the primate visual brain that is specialized for object processing.

Voxel Volume element.

Introduction

Our sensory systems enable us to register information about the world and to perceive objects and events in the external environment. However, perceiving such entities is possible only because our brains construct sophisticated and flexible internal representations of such entities that even modern computer systems are unable to mimic. These internal representations can be activated not only by signals generated by external stimuli, during perception, but also internally, during mental imagery. Although mental imagery can occur in all sensory modalities, this article focuses on the visual modality because it is the one that has attracted the most research. When asked a question such as ‘what shape is a cat’s ears?,’ one typically visualizes an image of a cat and zooms in on regions in the image that encompass the animal’s ears to determine their shape. Mental imagery relies on the reactivation and inspection of internal representations in the absence of external stimuli. Using the language of cognitive science, visual mental imagery relies on the reactivation of representations in long-term memory to construct representations that can be further manipulated in working memory. It is important to keep in mind that visual mental imagery is more than the simple reactivation of internal representations of stimuli and events that have been experienced: in many cases, visual mental images can be parsed and recombined, enabling the extraction of novel information. The following simple exercise can provide a good example of the constructive power of visual mental imagery. Imagine the capital letters ‘j’ and ‘d’ and rotate the letter ‘d’ counterclockwise by 90° and place it on top of the ‘j.’ Most people can immediately recognize the resulting object, even though they had never used the letters ‘j’ and ‘d’ for this purpose (the resulting object is a stylized umbrella). The constructive aspects of visual mental imagery are the main reasons why it is key in many important domains, including mathematics and engineering.

Brief History

The importance of mental imagery, and especially visual mental imagery, in human cognition has been recognized for a long time, at least since the Greek philosophers. For example, Aristotle believed that it is not possible to think without mental images and that images play a key role in desire and motivation by representing a goal object. The last 40 years have seen a rapid increase in the number of studies on visual mental imagery and in the amount of knowledge available about the processes, both cognitive and neural, that underlie visual mental imagery. It is important to remember that, despite the impressive amount of research on the topic in the last few decades, virtually no research had been conducted on visual mental imagery between the 1920s and the 1950s. Indeed, during these decades, the dominating behaviorist perspective had declared the study of imagery unscientific, seen as an essentially vague and private process without external measurable correlates. After the behaviorist period, with the emergence of the new theoretical framework of cognitive psychology, the 1970s witnessed a resurgence of interest in studying internal representations and processes and in experimental investigations of visual mental imagery. Among the seminal studies on the topic were those on the relationship between visual mental imagery and memory by Paivio and on the transformation of visual mental images by Shepard and collaborators. These and other studies convincingly showed that phenomena such as visual mental imagery, and more in general questions about internal representations, could be addressed scientifically. Much work has gone into the determination of the structure and format of the internal representations underlying visual mental images, generating a lively debate. Researchers on one side of the debate (depictive theorists such as Kosslyn) put forward the hypothesis that visual mental images are analog representations and function to depict objects and scenes, that is, they represent the shape and spatial relationships explicitly by means of their internal structure: distances among points in

the image map onto distances among the corresponding points in the stimuli they represent. In contrast, researches on the other side of the debate (nondepictive theorists such as Phylyshin) postulated that visual mental images were some sort of propositional representations, not different from the general-purpose mental representations underlying other thought processes. In this view, the fact that visual mental images appear to have pictorial features introspectively is irrelevant from the perspective of information processing, pretty much like the power light on a computer is irrelevant for the operations carried out by the computer.

Using Cognitive Neuroscience to Study Visual Mental Imagery

The 'imagery debate' became very intense in the late 1970s and early 1980s. During those years, it became increasingly clear that issues about the format of internal representations, and of visual mental images in particular, could not be resolved conclusively, even using the novel empirical methods of cognitive psychology. This point was summarized in a key paper by Anderson which demonstrated that behavioral results from several visual imagery studies were compatible with both depictive and propositional accounts of visual imagery, by just tweaking processing assumptions in the accounts. In his paper, Anderson showed that given a theory defined by a group of assumptions about depictive representations and processes operating on them, one could always design a second theory that could mimic the first theory on the basis of a different group of assumptions. This proof showed that the results of behavioral experiments could not unequivocally implicate the existence of specific representation-process pairs: the characteristics of these representation-process pairs could only be uncovered conclusively by using additional, nonbehavioral types of evidence, such as neuroscientific evidence. Thus, it became clear that neural evidence is critical for constraining and understanding theories of visual mental images and, more generally, of internal representations.

The pattern of results from several behavioral studies has demonstrated robust parallels between visual mental imagery and visual perception, providing a rationale for the use of neuroscientific data: if visual mental imagery and visual perception rely on the same processes, then the neural structures supporting vision should also support visual mental imagery. This kind of logic enabled the use of neurophysiological knowledge about the visual system of nonhuman animals to guide the generation of new hypotheses about how visual mental imagery works. Indeed, until recently, most of the knowledge about the neurophysiological basis of the human visual system came from studies in nonhuman primates, assuming homology among different species. Progress in technologies for noninvasive neuroimaging and brain stimulation has enabled cognitive neuroscientists to investigate the neural basis of vision in humans and to test this homology assumption directly. Experimental results using brain imaging and stimulation techniques such as positron emission tomography (PET), functional magnetic resonance imaging (fMRI), and transcranial magnetic stimulation (TMS) have complemented data obtained from brain-damaged patients and confirmed that

the organization of the visual system in humans and nonhuman primates is very similar, especially in early visual areas. These same techniques have enabled the noninvasive study of visual mental imagery in humans.

The following sections provide a concise review of a subset of the cognitive neuroscience literature on visual mental imagery, focusing on one research topic that has received considerable attention.

Shared Neural Systems Between Visual Mental Imagery and Visual Perception

A key question is whether the neural processes engaged during visual mental imagery and perception are the same, as suggested by the cognitive psychology studies mentioned earlier. A handful of brain imaging studies, such as that by Ganis and collaborators, have quantified the overlap between neural structures recruited by visual mental imagery and perception across the entire brain, suggesting an overall overlap of over 90%. However, most neuroimaging studies on the topic have focused on the more circumscribed question of whether certain brain regions are engaged in common by visual mental imagery and visual perception. A subset of these studies is reviewed in the following section.

Role of Early Visual Cortex in Visual Mental Imagery

Several brain imaging studies have focused on the specific question of whether early visual cortex is activated during visual mental imagery. This is because early visual cortex plays a special role in visual processing, as outlined below.

Visual mental imagery and the organization of the primate visual system

The primate visual system is organized in a hierarchical manner, with the early visual cortex (visual areas V1 and V2, in the occipital lobe, also referred to as areas 17 and 18, respectively) at the bottom of the hierarchy. Area V1 receives information from the retina via subcortical nuclei (mainly the lateral geniculate nucleus) and feeds it to the rest of the visual hierarchy. The visual hierarchy itself is loosely divided into parallel processing streams, specialized for different kinds of information. The ventral stream, which runs inferiorly along the temporal lobe, is involved in shape and object processing, whereas the dorsal stream, which runs superiorly along the parietal lobe, is important for spatial cognition and action.

One key feature of early visual cortex is that it is organized topographically (or retinotopically) so that points that are close to each other in visual space are represented at nearby cortical locations, with a few exceptions. Points in this orderly representation are defined by their coordinates on two axes, referred to as polar angle and eccentricity. Polar angle is the angle between a horizontal line and the line that connects a point to the center of the visual field, whereas 'eccentricity' is the distance of a point from the center of the visual field. This topographic representation becomes weaker as one moves up the visual hierarchy, as neurons respond to larger parts of the visual fields and to more complex features of the stimuli.

V1 neurons, for instance, respond optimally to small oriented bars displayed at very specific locations in the visual field, whereas neurons in the inferotemporal cortex, much higher in the visual hierarchy, respond better to complex combinations of features (e.g., color, shape, texture, etc.) appearing nearly anywhere in the visual field. This organization suggests that the topographic representation in early visual cortex is better suited to make the spatial layout of a stimulus explicit, whereas the distributed representations used in the inferotemporal cortex are better suited at capturing and coding similarities between more complex features of classes of objects.

Another key feature of the primate visual system is that information does not flow only in a feed-forward manner, from lower to higher levels in the hierarchy. Typically, areas that receive information from a lower level area also send information to that area by means of feedback connections. Although the precise characteristics of these feedback projections are slightly different from those of the feed-forward projections, this means that areas that are high in the visual hierarchy can influence neurons in early visual areas.

These organizational features of the primate visual system have inspired neuroscience-based depictive theories of visual mental imagery such as those by Kosslyn and collaborators. At the core of these theories is the idea that visual object memories are stored in higher level visual areas (such as the inferotemporal cortex) and that the neural code used by these areas cannot represent the precise spatial layout of objects explicitly because they are not organized topographically. It is only in early visual areas, where distance in space is represented by distance on the cortex by virtue of their retinotopic organization, that the spatial layout of objects can be represented explicitly. Thus, according to depictive theories, the key process of many types of visual mental imagery is the reactivation of topographic representations in early visual cortex by means of signals from areas higher in the hierarchy. Finding evidence that early visual cortex is engaged during visual mental imagery would therefore provide support for depictive theories, which is why much research has focused on this issue.

Neuroimaging findings showing activation of early visual cortex during mental imagery

Early studies used PET to show that visual area V1 is recruited during visual mental imagery with a pattern that is consistent with the topographic organization of this area. In one study, Kosslyn and collaborators exploited the systematic representation of eccentricity in V1. They monitored cerebral blood flow (an indirect measure of neural activity in the brain) while subjects visualized letters at either a very small or at a very large size. Subjects were asked to maintain the image for several seconds and then to judge the geometric properties of the letter (e.g., whether it had any curved lines). The logic was that if visual mental imagery uses retinotopic representations in area V1, then small visual mental images should engage parts of area V1 that represent less eccentric regions of the visual field, located in increasingly posterior regions of the occipital lobe. The results were consistent with this prediction and showed stronger activation in the posterior parts of V1 when subjects visualized the letters at the small size than at the larger size. In another study, Kosslyn and collaborators used a similar rationale. During the PET session, subjects visualized objects

they had studied beforehand within boxes of different size. To ensure that subjects were actually carrying out visual mental imagery, they were asked to perform various visual judgments on the images, such as whether the right side of the studied pictures was higher than the left side. The results, again, were consistent with the predictions and with the systematic organization of eccentricity in early visual cortex.

These results were replicated and extended in subsequent studies using fMRI, a technique with a better spatial resolution than PET. Some of these studies focused on the polar organization of the early visual cortex and aimed at showing that the pattern of activation elicited during visual mental imagery is consistent with this organization. In one study by Klein and colleagues, subjects were asked to visualize narrow horizontal or vertical bow-tie shapes and the pattern of brain activation in early visual cortex was compared with that found when the same subjects actually perceived these bow-tie shapes. The results were generally consistent with the prediction that the same polar angle representation is used in perception and imagery. However, the pattern was not found in every subject, suggesting that individual differences play an important role. The polar angle representation was exploited by another study by Slotnick and collaborators that attempted to adapt retinotopic mapping methods to the investigation of visual mental imagery. In this study, the visual stimuli were thin rotating bow-tie shapes which, during the perception condition, would systematically cover the polar angle dimension. During the visual mental imagery condition, the stimuli were two thin arcs delineating the outer edges of the bow-tie shapes and subjects visualized the rest of the bow-ties. To make the tasks as similar as possible, subjects pressed a button each time a tiny red square was flashed inside the bow-tie region, which was only visualized in the visual mental imagery condition. The study also used a control attention condition. Results showed some retinotopic activation in area V1 that was not seen during the attention condition, but only in a subset of subjects. Furthermore, most retinotopic activation during visual mental imagery was in common with that observed during visual perception, suggesting that visuospatial attention processes may be an important component of visual mental imagery.

Thirion and collaborators extended these results by employing a complementary approach, referred to as 'inverse retinotopy.' With this approach, given a pattern of activation in early visual cortex, it is possible to compute the visual stimulus that would be more likely to have generated such a pattern. This approach relies on inverting the known mapping between a visual stimulus and its cortical representation. In the study, subjects either saw or visualized simple patterns and the key question was whether it would be possible to infer what pattern was being perceived or visualized on the basis of the neural signals from early visual cortex. Results showed that it was possible to determine consistently what pattern subjects were perceiving with high accuracy and in single trials, using information from areas V1 and V2. However, accuracy was much lower during visual mental imagery, and it was possible to determine which pattern subjects were visualizing only in a subset of subjects.

Overall, these neuroimaging studies generally support the claim that visual mental images of objects sometimes activate retinotopically organized areas in V1 and V2. However, the

signals observed during imagery are much weaker and variable than those found during visual perception.

It is important to note that some neuroimaging studies have failed to find activation in early visual cortex during visual mental imagery, raising the question of what factors may be responsible for these differences. This type of question can be best addressed by conducting a meta-analysis on the many studies on the topic. The most exhaustive meta-analysis carried out to date to address this question was conducted by Kosslyn and collaborators. This meta-analysis included data from 59 neuroimaging studies and the results showed that the tasks that typically lead to activation in early visual cortex during visual mental imagery involved the use of high-resolution imagery to evaluate details of mental images (as opposed to global aspects) and shape judgments (relative to spatial judgments). These two key task attributes make sense in light of the visual system organization discussed earlier. On the one hand, reconstructing the high-resolution details of visual mental images may require reactivating representations available only in the topography of early visual cortex. On the other hand, spatial judgments, unlike shape ones, may rely on representations stored in the dorsal stream that are already suited for tasks involving spatial attributes.

Virtual lesion and patient findings on the role of early visual cortex in visual mental imagery

One key question is whether the topographic organization in early visual cortex has a functional role in visual mental imagery, or even in visual perception. This question cannot be fully addressed by neuroimaging alone because the data it provides is correlational. A key objection to depictive theories of visual mental imagery is that the topographic organization of early visual cortex is functionally irrelevant. To use a technological analogy, the overall shape and type of packaging of an integrated circuit is not functionally related to the types of computations it can carry out. One way of addressing this question is to find evidence that the topographic organization of early visual cortex is needed for visual processing and for visual mental imagery. This type of evidence can be obtained from two sources: virtual lesion and patient studies, discussed in the following section.

By using techniques such as TMS, it is possible to produce transient disruption of neural processing in specific brain regions. It is well known that TMS pulses delivered to early visual cortex result in phosphenes (faint flashes) or, at higher intensities, in transient scotomas (blind regions in the visual field). Critically, the perceived location of these phosphenes and scotomas in the visual field is systematically related to the locus of the stimulation: with few exceptions, nearby stimulation sites result in phosphenes or scotomas in nearby locations in the visual field represented by the stimulated cortex. This is strong evidence that the topographic organization of early visual cortex is causally related to visual processing. Probably, the strongest evidence that early visual cortex is necessary for both high-resolution visual mental imagery of shapes and for perception is the one provided in a high-profile study by Kosslyn and collaborators. In this study, subjects first memorized a 2×2 array of stripes. The stripes in each cell of the array varied along multiple dimensions (e.g., width and length). During testing, subjects answered questions about these

dimensions. For example, they would be asked whether the stripes in cell 1 were wider than those in cell 4. In the perception condition, subjects saw the stimuli, whereas in the visual mental imagery condition, they visualized them with their eyes closed. In the experimental condition, subjects carried out the tasks after low-frequency TMS of early visual cortex for 10 min. In contrast, sham TMS was used during the control condition with the same task. Low-frequency TMS reduces cortical excitability, making it more difficult for neurons to fire. Therefore, the prediction was that this kind of stimulation would slow down both visual imagery and perception. The results supported this prediction: TMS slowed down not only response times during the visual perception task, but also visual mental imagery, providing strong evidence that early visual cortex is necessary for both.

The more extreme types of lesions are those produced by brain damage. The rationale here is similar to that for virtual lesions: if early visual cortex is necessary for visual mental imagery, a key prediction made by depictive theories, then its damage should result in impaired visual mental imagery. Although this logic may seem straightforward, in practice, the inference from brain damage to processes is complicated by several factors. First, it can be difficult to be sure that cerebral tissue is functioning normally. Second, the location of brain damage cannot be controlled experimentally, and so it is possible that damage to one area systematically affects nearby areas that may not be functionally related to the damaged area. Third, brain plasticity often leads to brain reorganization over time, complicating the interpretation of results. Fourth, in part due to some constraints in clinical settings, visual mental imagery has not been assessed thoroughly in many published studies (e.g., only paper and pencil tests were administered). A number of studies have reported disruption of visual mental imagery as a result of occipital cortex damage. Hemianopic patients are particularly useful for testing the prediction that early visual cortex is necessary for visual mental imagery. These patients are blind in parts of one visual hemifield because of damage to the visual cortex in one cerebral hemisphere, and so one can administer a visual mental imagery task in the impaired hemifield and compare performances when the same task is administered to the intact hemifield. An excellent example of such a strategy is a study conducted by Butter and collaborators in which hemianopic patients and control subjects were asked to perform a mental scanning task, an objective evaluation of visual mental imagery. All subjects were first shown four dots on a sheet of paper. Next, they were shown a second sheet containing a black arrow in the center. The task consisted in using visual mental imagery to decide whether the arrow pointed to a position previously occupied by one of the dots. The main finding was that patients with left occipital lobe damage (right hemifield problems, due to the contralateral organization of the human visual system) were more impaired in the task for dots falling in the right than in the left hemifield. The opposite pattern was found for patients with right occipital lobe damage. Control subjects made few errors and showed no effect of hemifield. Furthermore, control tasks ensured that all subjects were able to perceive the dots and the arrow. These results are consistent with those of an earlier single-patient study by Farah and colleagues. The patient examined in this study had the occipital lobe in one hemisphere removed,

resulting in a reduction of the horizontal extent of visual images by half, after surgery. As the vertical extent of the visual images was unchanged, the finding suggests that the loss of half of the horizontal meridian may have caused the horizontal 'shrinking' of the extent of visual images.

The patient literature also has some cases that, *prima facie*, seem to be inconsistent with the claims made by neuroscience-based depictive theories. In some of these cases, pervasive damage to area V1 that results in blindness appears not to disrupt visual mental imagery abilities. One such patient was described by Chatterjee and Southwood. Despite becoming cortically blind after a stroke that damaged her early visual cortex bilaterally, this patient was able to carry out many visual imagery tasks, including answering questions about the shape of capital letters and common animals. Interestingly, she also anecdotally reported using visual mental images in school classes she attended after becoming cortically blind. This is not the only such case in the literature, although generally, the tests of visual mental imagery have been rather minimal. However, so far, there have not been conclusive cases showing that complete destruction of early visual cortex leaves high-resolution visual imagery of shapes intact. First, the vast majority of studies did not measure response times, making it difficult to determine whether there was at least a decrease in processing speed, which could suggest the use of compensatory strategies not based on visual imagery. One such strategy could be to rely on motor representations instead of visual ones, for example, to answer questions about the shape of letters or objects. Second, in many cases, it is hard to verify that there are no spared V1 or V2 portions that could still support visual mental imagery. Given that visual mental imagery typically engages much smaller portions of early visual cortex than visual perception, the damage may have to specifically include all these portions to produce impairments in visual mental imagery. Third, many visual mental imagery tasks may be carried out using higher level visual cortex because they do not involve generating the types of high-resolution images supported by V1 and V2, as already mentioned and as discussed in more detail in the next section.

One final point worth mentioning is that some of these cortically blind patients report having vivid visual mental images. These introspective reports are not necessarily problematic for neurally inspired depictive theories of imagery because the introspective feeling of having a vivid mental image may not depend on early visual cortex and it may not correlate with actually being able to use these visual mental images. Only rigorous testing could tell whether patients reporting vivid images of this type can actually extract information from these images. A situation analogous to this is the introspective feeling most of us have of being able to perceive every detail of the visual world despite the fact that objective tests reveal that we only encode a few visual details.

Higher Level Visual Areas in the Ventral Stream and Visual Mental Imagery

As described earlier, higher level visual areas in the ventral stream receive information from retinotopically organized early visual cortex and process object attributes such as shape, texture, and color. Object representations in these areas are

distributed, as shown by Haxby and collaborators in humans, but they also show some degree of segregation. For example, Kanwisher and colleagues have shown that patches of cortex in the lateral fusiform gyrus are more responsive to pictures of faces than to pictures of other object categories, whereas cortical patches in parahippocampal cortex respond more strongly to pictures of buildings than other objects. To some extent, this general organization has also been observed for visual mental images of objects, as summarized below.

Neuroimaging findings

The pattern of spatial segregation of object representations in the ventral stream has been used to test the similarity between the representations engaged by visual mental imagery and visual perception. The general logic of most neuroimaging studies has been to determine whether brain regions engaged in visual processing of certain objects are also engaged when visualizing the same objects. The findings of numerous studies have supported the notion that visual mental imagery engages a subset of the same brain regions engaged by visual perception. For example, a seminal study by O'Craven and colleagues reported that visual mental imagery of faces engages a portion (about 17%) of the brain volume in the ventrotemporal cortex that is engaged when somebody actually perceives a face. A similar pattern was found in the perception and visual mental imagery of buildings. Importantly, and consistent with observations in early visual cortex, the activation found during visual mental imagery was weaker than that observed during visual perception of the same stimuli, possibly reflecting the more diffuse organization of feedback connections. These results were later confirmed by similar studies, such as those by Ishai and colleagues.

More recent studies have used variants of multivoxel pattern analyses to examine this issue in more detail. The rationale of multivoxel pattern analyses in this context is that, even if visual perception and visual imagery activate a region in common, there could still be systematic differences in the spatial pattern of activation within this common region that could be indicative of differences in the recruited neural populations. A recent study by Stokes and collaborators used this strategy and examined the similarity of the spatial patterns of activation elicited by visualizing and perceiving two letters in the lateral occipital cortex. Results indicated that in some ventral stream regions, such as the left anterior lateral occipital cortex, subtle differences in the spatial pattern of activation elicited by seeing different letters were similar to those elicited when visualizing such letters. Thus, it was possible to discriminate above chance between the visualized letters by using a classifier trained on the data from the perceived letters. Another study by Reddy and colleagues extended these findings by using four object categories (face, food, tools, and buildings). Results showed above chance discrimination among object categories by using activation in the ventral-temporal cortex both in the visual perception and imagery conditions. Furthermore, a classifier trained on the perception data was able to classify the visual imagery data above chance (in fact, as well as could be done by using a classifier trained on a different visual imagery subset). This indicates that the representations used by visual imagery and perception in higher level visual cortex are quite similar. Furthermore, classification rates on visual mental imagery data

were at chance when using information from early visual cortex. This is not entirely surprising, in light of the section on early visual cortex, because the task did not require inspecting high-resolution shape information and only involved deciding if the previous stimulus had the same color as the current one (and the few stimuli used in the task, e.g., 'apple' and 'banana,' were very different in color).

Single neuron findings

Multivoxel spatial analyses still look at the scale of single voxels, which is much larger than the scale of single neurons. Therefore, it is still possible that nonoverlapping neural populations of neurons could be recruited within the same voxels by visual categorization and visual mental imagery. The only technique that enables us to examine single neuron activity in humans is that of the invasive intracranial recordings in patients with epilepsy. One study by Fried and collaborators that compared visual perception and imagery directly examined the activity of single neurons in the medial-temporal lobe. In the study, subjects studied picture pairs and then imaged them, cued by one of the two auditory tones. The main result was that the vast majority of neurons that were recruited by both visual perception and imagery had similar stimulus selectivity. A follow-up study recorded single neuron data in the medial-temporal cortex when subjects watched video clips and when they visualized them later on. Most neurons responded to a small subset of the clips watched by the subjects and, critically, the pattern of selectivity was similar during visual mental imagery of the same clips. These findings are rather sparse, but they suggest that the similarity between the processes engaged by visual perception and visual mental imagery may hold down to the single neuron level.

Patient findings

The neuroimaging data just described and showing that visual perception and mental imagery of objects engage similar neural populations in the ventral stream suggest that damage to some of these neural populations should result in parallel deficits. Consistent with this prediction, the literature has reported cases in which brain damage results in domain-specific deficits in both visual perception and mental imagery. For instance, some patients with deficits in face recognition also exhibit problems in visualizing faces. Indeed, 14 of the 28 cases with object agnosia described in an early review by Farah showed parallel visual perception and visual imagery deficits. For most of the remaining cases, imagery was either not tested or not tested rigorously. These parallel deficits can be explained by assuming damage to ventral stream regions that store long-term memories needed both during object categorization and imagery. However, the picture is complicated by the fact that there are also cases in which impairments in object categorization are not accompanied by corresponding problems with visual imagery, for instance, a case described by Servos and collaborators. One potential explanation for these cases relies on the observation mentioned earlier that visual perception typically recruits larger volumes of cortical tissue than visual imagery in the ventral stream. Some of the nonoverlapping regions recruited by visual perception are likely to be the key for processes such as figure ground segregation that are

necessary for perception but not visual mental imagery. Thus, damage to these nonoverlapping regions could lead to dissociations in which a patient is impaired at object categorization but still able to perform visual imagery. There are also a few cases with the opposite pattern of impaired visual imagery and spared perception, possibly reflecting damage to frontal and parietal regions that may be providing feedback inputs necessary for visual mental imagery.

Summary and Conclusion

Our understanding of visual mental imagery has made enormous progress because of three concurrent developments over the last several decades. First, theories of visual mental imagery could build upon knowledge about the neural basis of perceptual and motor systems. Second, progress in behavioral and neuroscientific methods enabled the field to avoid relying entirely on introspection when studying visual mental imagery. These novel methods showed that imagery can be studied objectively, like any other entity in science: like many particles in theoretical physics that cannot be seen directly visual mental images have consequences that can be objectively assessed. Third, the birth and growth of computer science provided a new set of conceptual tools. These constructs enabled researchers to begin characterizing imagery, mental processes, and representations rigorously. The theories that relied on such conceptual tools were sufficiently well defined that they could be mapped to the brain and lead to testable predictions.

Despite such progress, our understanding of visual mental imagery is still in the early stages and there are many unanswered questions. Some of the explanations put forward to account for potential contradictions in the literature will need to be addressed empirically in a direct manner, ideally by using hypotheses generated by neurally inspired computational theories. Given the great progress made in the last two decades, we are optimistic that future work using the tools of cognitive neuroscience and cognitive science will resolve many of the currently open issues in the field.

Glossary

Human factors engineering Also known as applied experimental psychology or engineering psychology, human factors engineering is the systematic study of the role of human capabilities and limitations and their influence on the performance of engineered systems, such as high performance aircraft or military command and control centers.

Naturalistic decision making The ability of experts to make rapid and accurate decisions by employing intuitive and often unconscious cognitive processing.

Posttraumatic growth The experience of personal growth following a traumatic experience; increases in courage, capacity for love, or other positive traits following a potentially life or well-being threatening experience.

Posttraumatic stress disorder A maladaptive response to a highly stressful event or sustained period of stress exposure, characterized by reliving the event, impaired social behavior, and exaggerated autonomic nervous system reactivity.

Psychological resilience Ability to recover from stress and adversity, to remain strong when things are tough; buoyancy.

Situational awareness The ability of a person to perceive key elements of a complex situation, understand what these elements mean, and make accurate projections about what is likely to occur in the near future. Thought to be a critical component of tactical decision making.

History

The psychologist Herman Ebbinghaus once remarked “psychology has a long past, but only a short history.” Although Ebbinghaus did not have military psychology in mind when he said this, he well could have. Even a casual reading of ancient texts such as Homer’s *Iliad* and the *Odyssey* or Sun Tzu’s *The Art of War* reflects the critical importance of understanding human nature in planning, executing, and recovering from war. Psychology emerged as a formal discipline distinct from philosophy and biology in the late nineteenth century. By the twentieth century, military psychology emerged as a formal subdiscipline. Based on suggestions from noted psychologists including E. G. Boring, Ernest Hilgard, and Carl Rogers, the American Psychological Association (APA) reorganized in 1945 and included the Division of Military Psychology (Division 19) among its first group of formal subdivisions. In 2003, Division 19 changed its name to the ‘Society for Military Psychology’ to reflect its growing international composition. Today, the membership of Division 19 represents a cross-section of both the profession and science of psychology, counting among its ranks clinical, experimental, industrial–organizational, social, and engineering psychologists. Moreover, uniformed and civilian psychologists serve the military in virtually all nations. In short, military psychologists are united by their object of focus – the military – and not by traditional lines of disciplinary nuance, and the discipline of military psychology is international in scope.

War has historically driven advances in science. Noted military historian Robert H. Scales argues that every major war since 1900 has been associated with dramatic development in different scientific disciplines. World War I was critically influenced by chemistry. Physics dominated World War II. The Cold War was associated with rapid developments in information technology. The Global War on Terror may

ultimately rely on psychology and related behavioral and social sciences, insofar as ‘winning hearts and minds’ relies more fundamentally on knowledge and understanding of human behavior and culture, compared to traditional wars that were dependent on the successful application of kinetic energy to achieve victory.

Taking a closer look at the role of psychology in warfare, one can trace the field of psychological testing directly to World War I. Previous wars did not require much from soldiers in terms of aptitude or special skills. In contrast, weapons employed in World War I were increasingly sophisticated and required soldiers to be able to read and write in order to learn how to operate weapons systems and other equipment. For example, aircraft were first deployed in battle in World War I, and military trainers quickly learned that aviators required high intelligence in order to successfully fly and navigate the airplane and to operate weapons systems while doing so. This gave the impetus to develop, in the United States, rapid and efficient ways of classifying soldiers, and it led to the Army Alpha Examination. Over 2 millions soldiers were screened with this test before the close of the war.

World War II saw the continued development of increasingly sophisticated aptitude tests. The General Classification Test (GCT) was based on a subset of four of Thurstone’s primary mental abilities and was used to place recruits into four general classifications related to aptitude to learn. By 1960, the GCT had evolved into the Armed Forces Vocational Aptitude Battery (ASVAB), which is still in use. Besides psychological testing, World War II is credited with giving rise to applied experimental psychology, especially what has come to be known as human factors engineering or engineering psychology. In World War II, aviation, in particular, began to test the limits of human performance. Aircraft were faster, maneuvered more quickly, had increasingly sophisticated weapons and communications systems onboard, and the complexity of the cockpit

increased exponentially. Psychologists were needed to aid engineers in designing aviation and other complex military systems in such a way as to maximize the user's ability to optimally operate the system.

One can also look to war and its influence on clinical psychology. Concepts of battle fatigue, combat stress, and posttraumatic stress disorder (PTSD) grew directly from observations of the effects of combat stress on soldier adaptation. Formally labeled as a psychopathology by the American Psychiatric Association following the Vietnam War, PTSD continues to receive considerable attention amidst the conflicts of the twenty-first century. Research into the causes of PTSD and other combat-related stress reactions has significantly increased psychology's understanding of stress in general, and informed modern methods of treatment including both pharmacological and psychological based therapies.

The conflux of large numbers of people united in a common mission, highly stressful operating conditions, and increasingly complicated technological systems continue to have a major influence on the general science and profession of psychology. However, military psychology in its present form cannot be understood or appreciated without consideration of both its past and its history.

Industrial–Organizational Psychology

The US military selects hundreds of thousands of enlisted members and officers for service each year. Military members serve in hundreds of occupational specialties and conduct a variety of missions around the globe. With its daunting human resource management needs, the military relies heavily on industrial–organizational (I–O) psychology for efficient and effective recruitment, selection, training, performance assessment, and organizational development.

Since World War I, I–O psychologists have advanced cognitive ability testing to meet professional, practical, ethical, and legal standards and considerations. The ASVAB is administered to all applicants for enlistment. The ASVAB comprises ten subtests (work knowledge, paragraph comprehension, arithmetic reasoning, mathematics knowledge, general science, electronics information, auto information, shop information, mechanical comprehension, and assembling objects) with various reliable and valid combinations used for determining enlistment eligibility and job assignment. In addition to a paper-and-pencil version, a computerized adaptive testing (CAT) version is also available.

Because the overwhelming majority of military members are enlisted personnel (rather than officers) who enter service as labor force novices, there is a well placed emphasis on enlistment screening using cognitive ability measures. However, testing and selection efforts are extended to special applications such as more 'select' populations of officers and for subgroups of military personnel assigned to critical roles (e.g., special operations forces, pilots, recruiters, etc.). In addition to general cognitive ability measures, spatial, psychomotor, and perceptual aptitudes are tapped as are personality or temperament, interests, and attitudes.

Of course, in addition to developing reliable and valid predictors, I–O psychology has also tackled the criterion

domain. Based on job analysis, performance measures including hands-on tests, rating scales, and paper-and-pencil job-knowledge tests have developed and revised through the years. By understanding the so-called criterion space, I–O psychology has furthered the appropriate matching of predictors and criteria. For example, cognitive aptitudes are excellent predictors of general and core technical proficiency, whereas non-cognitive measures (e.g., temperament and biodata) predict performance dimensions involving effort, discipline, and leadership.

Between selection and performance comes training. The US military has been heralded as the world's largest training and education institution. From basic military skills indoctrination and inculcating technical skills, through high fidelity simulation, training is a comprehensive and critical enterprise for the military. Based on task analysis and sound learning principles and techniques, psychologists have contributed to training effectiveness and skill mastery. Training progressed from classroom lecture to computer-aided instruction, then on to computer-based training and intelligent tutors, and beyond. The military has been a pioneer in distance learning and realistic training. In addition to training technical skills such as marksmanship and equipment operation and repair, military personnel are trained in such soft skills as leadership and decision making; and they are trained to operate as a crew or team. Military training research and application not just encompasses content and delivery platform but aims to enhance motivation to learn because of its relationship to knowledge acquisition and training transfer and hence training effectiveness or outcomes.

The above discussion has highlighted the *Industrial* or 'I' side of I–O psychology with its overlap with experimental psychology and psychometrics. However, the *Organizational* or 'O' side of I–O psychology is also important to the military. The attitudes of youth and their influencers toward the military provide invaluable information for military recruitment efforts. Job satisfaction and other work related attitudes, motivation, individual performance, and retention are affected by organizational and leadership dimensions. The 'O' side of I–O psychology has its origins within social psychology, which is discussed as it pertains to the military within the section below.

Social Psychology

Military members are organized into teams and units of varying size; therefore, social structure is vital to the military context. Thus, group identification and processes such as socialization, unit cohesion, morale, and esprit de corps are important to military effectiveness. Effective leadership, in turn, is critical to group processes and functioning. Since World War II and the four-volume *American Soldier* series, social psychology has proven its value to understanding and shaping the military.

Upon entry into the military, members begin forming a group identity. In addition to customs and rituals, newcomers learn and are encouraged to adopt the core values of their particular service. The US Army espouses seven such values – loyalty, duty, respect, selfless service, honesty, integrity, and personal courage – that intentionally form the acronym

'LDRSHIP.' Social psychology considers such elusive constructs as climate, culture, cohesion, and commitment and relates them to work attitudes and performance. For example, organizational commitment, which comprises affective, continuance, and normative components (or wanting to, needing to, and moral obligations to be part of the organization) are linked to employee behaviors such as performance and retention. Further, commitment can be influenced by organizational support and leadership processes.

Morale, the emotional bond that holds the group together and is a function of cohesion and esprit de corps has been recognized as critical for combat effectiveness since World War II. More recently, to inspire cohesion across military functional branches, a warrior ethos has been identified and championed to unite members across occupational divides.

The principles of social psychology have also been invoked to smooth misunderstandings and tensions among diverse personnel subgroups based upon minority status, gender, and sexual orientation. Harassment and discrimination are not common but are quite disruptive to military readiness. Social psychology has been at the forefront of race relations and gender integration in the military. Today and in the future, the military does and will struggle with the inclusion and acceptance of members from diverse race, ethnic, gender, religious, cultural, and sexual orientation backgrounds.

In addition to military structure, function, and culture, military families represent another social construction that is critical to military effectiveness. Traditionally, the military comprised predominately single men who served for short terms. Today, however, military members have families and are expected to make the military a career. Family issues and the challenges of separation and mobility are important considerations for morale and retention. Spouse employment and children's transitions and disruption are issues that affect morale, retention, and effectiveness. Since the advent of the All Volunteer Force in 1973, there exists a social contract between members and the military. Quality of service and quality of life are critical for recruiting, performance, and retention, as well as overall military readiness and well-being.

Applied Experimental Psychology

Advances in the technology and practice of war continue to tax human capabilities. High performance aircraft, modern ground vehicles, and highly complicated command and control systems challenge the operator's ability to react in time to threats, withstand g-forces, and process volumes of critical information quickly enough to enable accurate and timely decision making. Basic experimental psychology, with its emphasis on carefully controlled experiments in artificial laboratory environments, proved inadequate to inform engineers and developers on how to design systems that people could safely and effectively operate. These considerations were instrumental in the rise of applied experimental psychology during and in the years immediately following World War II. Also known as human factors engineering, ergonomics, and engineering psychology, this area of study includes topics of sensation and perception, cognition, decision making, design of displays and controls, biomechanics and physiology, stress

and workload, automation and human-computer interaction, selection and training, and social factors. More importantly, it focuses on how these factors interact with engineered systems (aircraft, vehicles, weapons, etc.) to maximize soldier performance.

Cognition and Decision Making

Applied cognition is a major area of interest within military applied experimental psychology. Modern weapons and communication platforms are exceedingly sophisticated and can provide masses of data to the operator. In turn, the operator must perceive and understand this information in order to make timely and effective decisions. The construct of situational awareness (SA) represents a major area of research and development in understanding battlefield cognition. The most widely accepted SA model was developed by Mica Endsley. This model maintains that there are three levels of SA and each builds toward an individual's ability to make timely and accurate decisions in a challenging setting. Level I SA is perception, or the ability to accurately sense key elements of a given situation. For example, an infantry soldier may enter a village and notice debris in an unusual place. Level II SA refers to comprehension, or the ability to infer meaning from what is perceived. The infantry soldier may infer that debris could be set up to slow vehicles or force them to take another route. The highest level of SA, Level III, involves making accurate predictions about what may happen in the near future. In the case of the infantry soldier, he may infer that an ambush is likely to occur if vehicles are diverted from their planned route and into a route where the enemy has prepared an assault. The three levels of SA are viewed as necessary components of consistently effective decision making. Considerable research exists linking SA to improved decision making in a variety of military situations, for both individuals and teams.

Another area of cognition of importance to the military is the role of intuition in tactical decision making. Many times, military personnel involved in tactical situations such as fire-fights do not have sufficient time to invoke deliberate, controlled processing in reacting to the situation. This is also true in other domains, such as fire and police service, where operators are apt to lose control of the situation, that is, let the fire get out of control or let the criminal escape if they stop to critically evaluate all potential options for action. The concept of naturalistic decision making (NDM) has emerged to explain how people come to make effective decisions in such circumstances. According to this model, with time and exposure to many different tactical scenarios (in training and on the job), people develop a complex and diverse set of scripts that may be rapidly invoked when encountering similar situations. Thus, an expert infantry soldier may respond to an attack on his convoy by pattern matching a script to the nuances of the present attack. This can occur rapidly and without apparent tapping of conscious decision making processes. After such an action, soldiers may report that they 'acted on instinct' and may have difficulty articulating why they responded as they did in that particular situation. According to the NDM approach, therefore, decision making based on the automatic processes can be quite effective. Interestingly, the NDM approach conflicts with a separate body of literature of heuristics and

cognitive biases, which suggest that such intuitive responses are often in error. However, the two approaches may be more complementary than not.

Sensation and Perception

Applied experimental military psychologists investigate how vision, audition, touch, and the vestibular system respond under the conditions encountered by military personnel, including sleep deprivation, extreme heat or cold, high altitude, strong g-forces, and other stressful environments. For example, how many hours may a soldier go without sleep before vigilance is adversely impacted? Or how do g-forces affect visual perception? Sound localization and speech perception are of vital concern to the military. Recently, military psychologists have begun investigating ways of using the sense of touch to communicate in conditions where vision and audition are severely limited. Signal detection theory is a key construct in this area of military psychology. This approach, which focuses on the ability of an operator to correctly detect a target stimulus under distracting conditions, has wide applicability across a host of practical situations. Will the operator of a radar system correctly identify a target as friend or foe, and will the operator then make the correct decision to engage or not? Both intrapersonal and technological factors that improve the ability to make correct decisions are vital to the success of modern military operations.

Controls and Displays

Broadly speaking, human factors engineering investigates the role of the human operator in a larger system. The complexity of modern military systems requires them to be congruent with human capabilities and constraints. Controls and displays must be easy to read and operate. A modern military tactical operations center may contain dozens of computers and displays, collectively making available thousands of bits of information to the commander and his or her staff. Information must be filtered so that only the most critical and time-sensitive pieces of information are presented to the commander. Controls should be optimally positioned and adhere to well-established principles of ergonomic design. In short, military workspace must be designed with the human operator in mind. A weapons system that is too complex or unresponsive to work is of little value on the modern battlefield.

Stress and Workload

The military operates under conditions unthinkable to civilians. Task and environmental stressors combine with the potential of loss of life or serious bodily injury to play a major role in human performance under the challenging conditions of combat. Infantry soldiers may carry well over 100 pounds of equipment into battle. They may perform in nearly continuous operations for several days at a time with little or no sleep. Military psychologists study psychological and physiological reactions to such stress in order to develop training programs and operational procedures to allow the soldier to maximize performance under the most trying circumstances. Toward this end, they study the effects of fatigue and sleep

deprivation, work overload and under load, life stress, and environmental and a host of other stressors on soldier performance.

Human-Computer Interaction and Automation

Many complex military tasks are now executed by computers. Naval aviators do not assume control of their aircraft, for example, until it has departed from the deck of the aircraft carrier. Semiautonomous and even fully autonomous weapons systems are under development. What are the effects of decreasing the human's role in operating such systems? A growing body of research on factors that affect how humans interact with automated systems exists. Topics include the reliability of the automation, trust and mistrust, workload, and training. Does the operator of a remotely controlled aerial vehicle, stationed half way around the world from the theater of operations, derive the same degree of pride and satisfaction in performing missions that a traditional fighter pilot would? How does one train differently for operating such systems versus operating traditionally piloted aircraft? Work must be optimally distributed between the automated system and the human. Too much responsibility for the automated system and the human may disengage. Too much responsibility for the human, and their performance may degrade.

Summary

Soldiers do not fight in the laboratory. Traditional, laboratory-based experimental psychology yields findings high in internal validity but low in external validity. Military psychologists must carefully weigh the tradeoff between the two, but they are ultimately more concerned with how experimental manipulations play out in the real world. For this reason, military psychologists tend to be at the cutting edge of methods and procedures relevant to understanding human behavior in its natural context.

Clinical/Counseling Psychology

Given the psychological demands of military life and missions, mental health professionals are essential personnel. Across the world, thousands of psychologists in uniform prepare, support, and care for military members and their families through the stresses and strains of combat, peacekeeping, and humanitarian operations. Licensed clinical and counseling psychologists serve within the military mental health system as commissioned officers in all branches of military service. They are called on to assist service members and their families with regard to life skills such as anger management, conflict resolution, coping with loss and grief, substance abuse, parenting, parent/child communication, relationship issues, and marriage enrichment. Such counseling support is not unique to the military; however, the military lifestyle is associated with unique demands. Military mental health professionals are familiar with the military lifestyle and are prepared to support soldiers, sailors, marines, and airmen through deployment, combat, reintegration, relocation, and separation. They serve in military hospitals and clinics in the United States and

overseas as well as aboard aircraft carriers, in special operations units, and in combat theaters.

In addition to routine mental health screening prior to service entry, military personnel are screened prior to deployment and upon return so as to identify those 'at risk' for further evaluation. Although the severely mentally ill (e.g., those with a diagnosis of psychosis or other debilitating psychiatric condition) are ineligible for service, deployment can take its toll on mental health on even well-adjusted people. Sleep disturbances, depression, suicidal and homicidal ideation, and PTSD are among the problems that require detection, if not prevention, monitoring, and treatment. And, with better body armor and other protective equipment, many more soldiers survive wounds that would have killed those fighting in earlier wars. This creates additional challenges for clinicians who specialize in neuropsychology, and cognitive and physical rehabilitation.

Given the challenges and stress associated with military service, proactive mental health training is common practice. Such psychoeducation serves to mitigate problems and promotes good mental health. Resilience and stress inoculation training help prepare military members for the psychological demands of combat and aim to sustain the well-being of deployed service members. Military members receive training in relaxation, deep breathing, progressive muscle relaxation, and guided imagery. Service members are trained to identify their own signs of stress as well as stress among their peers and subordinates. Training is also aimed at reducing the perceived stigma of mental health disorders and treatment. Routine mental health screening and individual and group based training and early intervention are the key for the high risk military population, with access to weapons, who tend not to seek or follow through with care.

Typically, clinical and counseling psychologists work within the military's medical community and offer such therapeutic services as behavioral therapy, psychotherapy, and even medication. However, clinical psychologists also more directly support commanders who lead combat and other operations including survival, evasion, resistance, and escape (SERE) and psychological operations (PsyOps). Clinical psychologists are also providing interrogation and detention support with special attention to human dignity and rights. The umbrella term for this mission-oriented subdiscipline is 'operational psychology.'

Military psychologists in clinical and operational roles face unique ethical challenges. As military officers and licensed psychologists, clinicians have dual responsibilities – to the unit and to the soldier-patient – that occasionally conflict. Among the issues that clinicians grapple with is whether to return a service member with a mental health problem to combat. Furthermore, maintaining clear and professional boundaries and ensuring confidentiality and informed consent are more challenging in the military than in civilian life. Likewise, the widely publicized abuses of Iraqi prisoners of war at Abu Ghraib question the ethical limits of the role of military psychologists in interrogations.

Given the stressors from combat, peacekeeping operations, high operational tempo, and the home front, a focus on mental health is imperative. Clinical and counseling psychology offer an invaluable discipline to address the diagnosis, treatment, research, training, and operational support needs of the

military across the spectrum of missions and environments to enhance mental fitness in deployment and garrison environments alike.

Recent Developments

Just as the two World Wars of the twentieth century fueled the development of psychology both as a profession and as a science, the Global War on Terror continues to energize contemporary developments in the discipline. This should come as no surprise, for, as discussed earlier, war pushes people to their limits. And as the nature of warfare evolves, so does the psychological science that supports the understanding of soldier adaptation and performance.

For example, social psychologists are developing a science of mortality salience that seeks to understand the impact that the realization of one's own mortality has on a variety of outcomes. Because soldiers routinely operate in settings where death and severe injury – including their own – is likely, then knowing how this awareness affects behavior is critical. Many interesting findings have emerged from this line of research. Activating an awareness of one's own mortality through experimental manipulations is associated with several outcomes. When this awareness is induced, for example, people may become more willing to engage in life-threatening behaviors. While this would likely be dysfunctional in civilian society, on the battlefield, this could encourage soldiers to engage the enemy. Other studies show that increased mortality salience may, in some persons, increase their motivation to volunteer for military service. Religious people may become more intensely so under the threat of death. People with good self-regulation skills respond with fewer death-related thoughts following mortality salience activation. There even is evidence that following mortality salience activation, people may experience short increases in physical strength.

Military psychologists are also now developing methods and procedures to systematically study leadership in situations where lives are on the line. Thomas Kolditz defines *in extremis* leadership as "giving purpose, motivation, and direction when there is eminent physical danger, and where followers believe that leader behavior will influence their physical well-being or survival." Findings suggest that effective *in extremis* leaders do not react to danger with normal distress reactions. Studies of special weapons and tactics teams, mountain climbing guides, leaders of jungle expeditions, parachute teams, and combat leaders suggest they share seven characteristics: inherent motivation for the task or mission, a learning orientation, a sense of shared risk, a common lifestyle with followers, competence, the ability to develop trust from their followers, and loyalty to the organization. Knowing how to select, train, and develop effective *in extremis* leaders may pay dividends not only in mission performance but also in the improvement of the adaptability of their followers.

The widely reported increases in maladaptive reactions to combat exposure such as PTSD and suicide are driving innovations in screening, treatment, and prevention of these disorders. Mental health research, consulting, and practice are being conducted in real time and in vivo, and broad support is being offered throughout the deployment cycle. The advances in

routine screening and training, and also peer, leader, and organizational support are working to reduce the stigma of seeking mental health care and continuing the same.

At the same time, the challenges of combat has increased interest among psychologists in understanding what factors and processes allow some – in fact most – soldiers to actually grow from their experience. The emerging field of positive psychology provides a theoretical framework to examine this phenomenon. Positive psychology focuses on positive states, positive traits, positive institutions, and positive social relations. It is interested in what allows people to flourish, even in the face of substantial challenges. For example, the concept of posttraumatic growth (PTG) refers to positive consequences of having survived a traumatic event. Recent research suggests that PTG is a more common sequel to combat trauma than PTSD, yet, surprisingly, it garners just a fraction of the attention. Other research suggests that personal character strengths such as courage, persistence, teamwork, honesty, self-regulation, and the capacity to love are linked to successful performance and adaptation among soldiers.

Based on positive psychology principles, the US Army is adopting a program called Comprehensive Soldier Fitness (CSF). Under the CSF program, a diagnostic metric was developed to assess soldier resilience in five domains – physical, emotional, social, family, and spiritual. Moreover, a variety of evidence-based interventions are being developed to provide soldiers with the tools needed to improve themselves if they are weak in a given area. Just as a soldier may seek help from a strength coach to improve performance in pushups or sit-ups, these interventions allow soldiers to build resilience in other domains. For example, the Penn Resiliency Program, a 12-lesson program originally designed to improve emotional resilience in children, has been adapted for use among soldiers. Outcome studies suggest the intervention has effects that last up to 2 years. A major desired outcome of the CSF is to encourage soldiers to utilize psychological services with a view of strengthening resilience or fitness, versus to ‘treat’ pathology. This approach could have significant implications in healthcare beyond the military, if successful.

Cultural psychology and related disciplines are also seeing innovations as a result of the Global War on Terror. In addition to war fighting, military members are increasingly asked to engage in other missions (e.g., nation building, security and stability operations) that require cultural expertise and political savvy. Such missions require social, emotional, and cultural competencies – or relationship skills that traditionally have not been the core areas of concentration in military education, training, or development. As language and cultural education and training are stepped up, civilian social scientists, including psychologists, are lending their expertise to military efforts at home and alongside deployed combat teams. For example, the Human Terrain System embeds teams of social scientists with brigades in Iraq and Afghanistan to coach the military commanders and units on patrol with regard to interaction, negotiation, and communication.

Advances in digital technology and related technical disciplines are also reflected in state-of-the-art military psychology. Breakthroughs in nanotechnology will soon lead to chameleon-like camouflage for both uniforms and systems. This development is motivating new research into the human visual

system as well as technologies that may be designed to defeat such camouflage. Microcomputers can now be mounted on individual soldiers, giving them far better command and control information than is commonly available in vehicles or housed in tactical operations centers just a few years ago. Today, a soldier on the battlefield can communicate instantly across echelons within the theater of operations, as well as around the world. This raises a plethora of questions about how soldiers, their superiors, and political leaders can handle such real-time and high-volume information.

These developments have social implications. For many years, it was accepted as a fact that soldiers who could directly hear or touch each other would fight more bravely and persevere better in combat than those who were socially isolated. Hence, soldiers were grouped into battle buddies, fire teams, squads, platoons, etc. This social organization was necessary to channel information in a hierarchical organization, but also ensured that soldiers maintained close proximity with each other. But the digitally equipped modern platoon (30–35 soldiers) has the communications ability and firepower to occupy the territory that an infantry battalion (500–600 soldiers) did in World War II. Now, soldiers communicate by radio or digital texting. Work is underway to better understand how this may affect morale. Moreover, the hierarchical system of command and control that evolved through the millennia may be obsolete with the advent of these technologies.

Conclusion

To tell someone that you are a military psychologist conveys little about what specialty of psychology you ascribe to. Clinical, social, industrial-organizational, and experimental psychologists all contribute to the field of military psychology. Indeed, the development of psychology as a general discipline was and continues to be closely linked to the special demands brought on by the evolution of warfare. Just as the race to place humans on the moon led to a plethora of scientific and technical discoveries with applications across society, warfare might necessitate paradigm shifts in how psychologists conceive of human nature. Perhaps it is a sobering comment on the human species, but without warfare, many innovations in science – including psychology – would never have occurred.

The Mind–Body Problem

D E Presti, University of California, Berkeley, CA, USA

© 2012 Elsevier Inc. All rights reserved.

Glossary

Behaviorism The notion that behavior can be completely described and understood solely in terms of objectively observable phenomena, without any need to consider internal, subjective experiences.

Dualism The notion that two irreducibly distinct domains of discourse and analysis, the physical and the mental, are needed to completely describe reality.

Explanatory gap The difficulty in making a coherent connection between external, objective phenomena and internal, subjective experience.

Identity theory The notion that mental phenomena are in some way identical to physical states of brain physiology.

Mentalism The notion that only mental experience is irreducibly real and all else (including the physical world) is derivable in some way from mental experience.

Panpsychism The notion that some kind of subjectivity, mentality, or consciousness permeates the universe and is an intrinsic property of all phenomena.

Physicalism The notion that only physical phenomena are irreducibly real and mental phenomena must be accounted for entirely in terms of the physically described properties of matter, energy, etc.

Physical An aspect of reality describable in terms of mathematical properties ascribed to coordinates in space–time: mass, energy, trajectories, forces, field strengths, etc.

What Is the Problem?

All that we know comes to us by way of our mental experience – our thoughts, feelings, and perceptions. We will call this collection of internal, subjective mental experiences ‘mind.’ The term ‘consciousness’ is also used in this context. By consciousness we here mean the capacity to be aware – aware of mental processes such as thoughts, feelings, perceptions (visual, auditory, olfactory, gustatory, tactile), mental images, and one’s sense of self. To have consciousness (by this definition) is to have some kind of awareness of what it is like to ‘be’ a particular person, or an animal, or an organism, or (who is to say at this point?) a thing. We can consider these characterizations of mind and consciousness to be working definitions for the purposes of engaging in scientific dialogue.

Much discussion can go into defining the words ‘mind’ and ‘consciousness,’ and misunderstandings sometimes occur because people are using the words in different ways. By the definition used here, one would be conscious during wakefulness, lose consciousness upon falling asleep, and regain consciousness upon waking. The recall of dreams would indicate the presence of some level of awareness or consciousness. Lucid dreaming occurs when there is a kind of full awareness while dreaming, even though the person is asleep. General anesthesia, as used for surgery, would produce loss of consciousness. Coma would presumably be associated with the absence of consciousness. In all these conditions, there are variations in the level or the quality of awareness.

One also hears about unconscious mental processes. By this we mean processes that take place out of awareness, but that have the capacity to enter awareness under suitable conditions. Otherwise, by our definition, such processes would not be mental, but would be physiological processes that could never have a subjective quality. Thus, there may be mental processes happening during sleep that are generally unconscious; dreams would often fit into this category. When a

dream is remembered upon awakening, or when lucid dreaming takes place, there is consciousness of the dream. Clearly, our operational definitions of mind and consciousness are very closely related, since to be part of ‘mind’ by this definition, there must be either awareness or the possibility of awareness. As a result, one often finds the two terms used interchangeably. This may be fine most of the time, except that confusion can arise in discussing unconscious mental processes, such as non-lucid, nonremembered dreams, and repressed memories. The key feature in all these phenomena is that consciousness and mental processes are irreducibly subjective, first-person experiences.

It is sometimes said that studying the mind is beyond the scope and methods of science, that subjective phenomena are not suitable for scientific study. Is this so? The origin of the word ‘science’ is knowledge, to know. It has come to mean the collection and organization of knowledge about the world (nature, the universe) that leads to some sort of ‘explanatory understanding.’ The method of science is fundamentally to collect data through observation and experiment. This is guided by the formulation of questions and hypotheses, and further deepened by theoretical frameworks of ‘explanation’ and ‘understanding’ that endeavor to connect observations together in ever richer networks. Based on these established criteria for science and the scientific method, there is no reason why the investigation of mental experience cannot fall under this rubric. As will be discussed later in this article, this may be facilitated by methods for carefully observing subjective phenomena.

A vast amount of empirical data, accumulated especially over the last two centuries, suggests that our mental processes (our mind) and our awareness (our consciousness) are intimately related to the material substance of our body and in particular of our brain. The great pioneer of the contemporary science of mind, William James (1842–1910), stated it clearly in his 1890 book *The Principles of Psychology*:

If the nervous communication be cut off between the brain and other parts, the experiences of those other parts are non-existent for the mind. The eye is blind, the ear deaf, the hand insensible and motionless. And conversely, if the brain be injured, consciousness is abolished or altered, even although every other organ in the body be ready to play its normal part.

Thus, damage to the brain is associated with specific changes in mental functioning. In addition, certain chemical substances (psychoactive drugs such as stimulants, sedatives, psychedelics, and so forth) that enter the brain are associated with specific effects on mental processes. And the neural activity of the brain – as measured by imaging technologies such as electroencephalography (EEG), functional magnetic resonance imaging (fMRI), and positron emission tomography (PET) – is correlated in specific ways with perceptions, emotions, and other mental processes.

That there is an intimate relationship between mind and body is unquestioned. However, just how this relationship is manifest – how it is that the physical processes taking place among the ions, molecules, and cells of the brain and body are related to the subjective experiences of the mind – is a deep mystery. This is the so-called mind–body problem and some say it constitutes the greatest question in contemporary science.

The Mind–Body Problem in the Context of Western Science

To better understand why it is sometimes said that the study of the mind is outside the scope of science, it is instructive to look at the historical trajectory of modern science, at least as it developed in Europe, beginning around the time of Copernicus. The publication of *On the Revolutions of the Heavenly Spheres* by Nicolaus Copernicus (1473–1543) in 1543, the astronomical observations of Johannes Kepler (1571–1630), the observations and writing of Galileo (1564–1642), culminating in the publication of his *Dialogue Concerning the Two Chief World Systems* in 1632, and, finally, the development by Isaac Newton (1643–1727) of a comprehensive description of motion that applied equally to celestial and terrestrial phenomena, published in his *Mathematical Principles of Natural Philosophy* in 1687 provided a powerful framework of organization for a multitude of observations. Concepts of space, time, matter, and energy were central to this description and, together with mathematical equations describing dynamical interactions, a system of stunning explanatory power was in place. In the nineteenth century, James Clerk Maxwell (1831–1879), building upon the work of Michael Faraday (1791–1867) and André-Marie Ampère (1775–1836), developed an elegant mathematical description of electricity and magnetism in terms of electromagnetic fields, further expanding the explanatory and predictive power of physical science. And, at the beginning of the twentieth century, Albert Einstein (1879–1955) again expanded the explanatory framework by formulating the special and general theories of relativity and describing matter, energy, and gravitation with awesome beauty and predictive power. This mathematical framework of physical science, as developed from Galileo to Einstein, is often referred to as ‘classical physics.’

It was found in the early years of the twentieth century that classical physics failed when its dynamical equations were applied to describing the behavior of atoms. To deal with the observed properties of photons, electrons, atoms, and molecules, it was necessary to develop an entirely new physical theory with new physical concepts and new dynamical equations: quantum mechanics. A large number of physicists at the beginning of the twentieth century made substantial contributions to this truly revolutionary undertaking: Max Planck, Albert Einstein, Niels Bohr, Louis de Broglie, Werner Heisenberg, Erwin Schrödinger, Wolfgang Pauli, Max Born, and Paul Dirac among them. Nearly a hundred years later, quantum mechanics continues to provide a profoundly successful description of the measurable properties of matter. Like classical physics, quantum physics is built upon an elegant mathematical framework. Indeed, the search for aesthetically elegant mathematical formalism has been a driving force in the development of physical theories of nature, from Newton to Maxwell to Einstein to quantum mechanics to contemporary attempts to extend physical theory into new domains via multidimensional string theories.

Quantum mechanics also profoundly changed the ontological status of physical theory. In classical physics, the objects of analysis and the properties of physical systems are conceived as having an existence independent of observation. The properties of matter and energy are inherent qualities of the universe that can be fathomed by our observations, but are not in any way dependent upon observations. In quantum physics, interaction is crucial to defining the properties of a system, and the interaction we humans have as observers plays a new and critical role that was unanticipated in classical physics. Because of its possible relevance to the mind–body problem, we will return to a discussion of quantum physics later in this article.

Concepts from the physical sciences (here, physics and chemistry) provide the foundation for the biological sciences. Living organisms are understood as particular configurations of molecular components, having specific properties of stability, information storage, energy generation, and replication. From atomic and molecular chemistry to biological macromolecules to cell physiology to organisms, the framework of physical science as pioneered by Newton provides an elegant organizational explanatory structure. To this is added the conceptual framework for understanding the diversity of living organisms, as articulated by Charles Darwin (1809–1882) in *On the Origin of Species* in 1859. Today, it is understood how Darwin’s ideas operate even at the level of the molecular components of living cells. Extending the framework of the physical and biological sciences to nervous systems, the human brain, and human behavior, the field of neuroscience now presents as a system of great explanatory potential.

All of this is about observation and description of what is understood as an objective external physical reality. We humans, together with our brains, are understood as having evolved within this physical reality. Mind, mental experience, consciousness, and subjectivity are left out. It is accepted that somehow, at this point in our evolutionary history, we have developed a capacity that allows us to be privy to observing and deeply analyzing our own place in the world. However, this conscious mental experience seems not to be explicable in

any coherent way in terms of physical processes. This disconnection between subjective, mental experience and the observations and explanatory scenarios of physical science has been around at least since the time of Galileo.

Early on, René Descartes (1596–1650) struggled with this disconnect and came to the conclusion that mental experience and the physical world may not be explicable one in terms of the other, or unifiable in any way, and that two irreducibly distinct domains of reality would be necessary. Descartes called the two domains *res cogitans* and *res extensa* and speculated that they would interact with one another within the human body, for example. This reasonable stab at making sense of subjectivity has been termed dualism, referring to the dual domains of the mental and the physical. Indeed, classical physics, as developed following Descartes by Newton and others, is built on this foundation, focusing on the physical and, from the very beginning, excluding the mental. It is a kind of external, outsider perspective on nature, one that has sometimes been called a ‘god’s-eye’ view of the universe or a ‘view from nowhere.’

Such an exclusion of the mental from the scope of the explanatory framework of science could be seen as unsatisfactory, for why should we not ask that our science provide a unified understanding of our entire world, one that includes both objective physical reality and subjective mental phenomena? How to accomplish this is a central aspect of the mind–body problem. It may be that because mentality has been excluded from our physical science from the beginning, attempting to make sense of subjectivity within this framework has seemed difficult. Indeed, this explanatory gap between the mental and the physical has been called the ‘hard problem’ of consciousness research.

Attempts to Bridge the Gap

Cartesian dualism is one approach to bridging the explanatory gap by defining the gap to be primary and insurmountable, thus positing two separate domains of reality. Dualism sets a metaphysical frame within which the phenomena of our observations are organized. Another framework is to attempt to reduce physical phenomena to mental experience in some way. This has been termed mentalism or idealism. Here, only mental experience is irreducibly real and matter must be explained in terms of mind. Within Western philosophy, one of the foremost exponents of this perspective was George Berkeley (1685–1753), who wrote that ‘esse is percipi’ (to exist is to be perceived), arguing that it is perception that is irreducibly real, and objective physical reality is some kind of an abstraction from this. Certainly there are components of truth here, since it is the case, as stated at the beginning of this chapter, that everything we are able to know does come to us by way of our mind and consciousness. Thus, in a fundamental way, all there is for us is mental experience, and one might imagine a science of mind based upon a deep analysis of mental experience. The philosophical tradition of phenomenology, as developed in the twentieth century by Edmund Husserl, Martin Heidegger, Maurice Merleau-Ponty, and others, stresses the importance of first-person experience in addressing the nature of the mind.

Contemporary Western science, however, takes as its underlying metaphysical framework that of physicalism, sometimes called physical materialism. In physicalism, only the physical is irreducibly real and mental phenomena, including consciousness, must ultimately be understood completely in terms of physical processes. Here, by physical, we mean describable in terms of mathematical properties ascribed to coordinates in space and time: mass, energy, trajectories, forces, field strengths, and the like. Physical phenomena are what are described by the dynamic equations of classical and quantum physics.

There exist various approaches to describing the mind within physicalism, each of which has been articulated and critiqued extensively by numerous philosophers over the years. There is ‘behaviorism,’ which posits that whatever mental experience is, it can be completely represented by observable behaviors, making any reference to mentality unnecessary. Behaviorism dominated the experimental study of human psychology, at least in the United States, for a good part of the twentieth century. There is ‘identity theory’ and there is ‘functionalism,’ which hold that mental states are somehow identical to physical states of brain physiology or functional activity. There are various notions of ‘emergent properties,’ sometimes described by terms such as ‘higher-order interpretation’ and ‘supervenience.’ However, in none of these cases have scenarios been articulated that even begin to describe how it is that subjective mental experiences are identical to or emerge from physical properties of the brain. It is simply assumed that this will come in time, with more and more research into the structure and function of the brain. Philosopher Karl Popper (1902–1994) has referred to this notion as ‘promissory materialism.’

Confidence in the physicalist approach derives from the awesome success of physics, chemistry, and molecular biology in explaining so much of the world. The successes of this approach are indeed stunning, contributing to the achievement of great technological sophistication: jet airplanes, lasers, MRIs, rocket ships, computers, genetically engineered organisms, atomic bombs, and cell phones, to name a few examples. A significant number of contemporary scientists comment that we may be close to grasping the whole shebang, from the origin of the universe to the evolution and operation of the human brain and mind. That there is still little clue as to exactly how to understand mentality within this framework is no deterrent for its advocates, for such a string of past successes can only presage every kind of future success in this area. This has led to a kind of dogmatic belief (rather than a working hypothesis) within contemporary neuroscience that whatever the mind is, it is necessarily a function of physical processes in the brain and nothing more. Sometimes the words ‘brain’ and ‘mind’ are used almost interchangeably and some neuroscientists are prone to referring to the ‘measurement of mental processes’ with various brain-imaging technologies, rather than making the more accurate reference to the measurement of ‘neural correlates’ of mental processes.

Physicist John Wheeler (1911–2008) and others have speculated that the concept of information is at the core of our conception of reality, a notion Wheeler calls ‘it from bit.’ Taking off from this, philosopher David Chalmers has discussed the idea that whatever the psychophysical laws

connecting mind and brain might be, the concept of information is key, and that somehow the physical and mental may be conceived as objective and subjective perspectives on information. Connecting a particular measure of information to nervous system physiology, neuroscientist Giulio Tononi has proposed that awareness is related to what he calls ‘integrated information.’ This latter phenomenon finds its physical expression in the complexity of interactions between neurons, and in the human brain includes active communication between widespread areas of the cerebral cortex. In this conception, loss of consciousness or awareness during sleep, general anesthesia, or coma would be related to a loss of integrated connection between cortical neurons. Simpler nervous systems would also be associated with less integrated information, corresponding to a simpler capacity for conscious awareness. Although this provides an attractive neurobiological framework in which to understand different levels of awareness, it still says nothing about how subjectivity comes about. We are still faced with the question of how to bridge the explanatory gap.

That little or no progress has been made on resolving the explanatory gap from a physicalist approach has been a factor in conceptualizing the mind–body connection as an aspect of a larger domain of synthesis. This idea has been articulated in one form or another by a number of folks over the last several centuries. Among the approaches that share something akin to this are neutral monism, dual-aspect theories, panpsychism, panexperientialism, and others. Philosophers have dissected and analyzed these various views and discussed their similarities and differences. What they share is some sort of pre-eminent existence of domains of mentality and of physicality (akin to dualism), but now, and very importantly, conceptualized as parts of a larger synthesis. Alfred North Whitehead (1861–1947), for example, has taken this perspective to a high level of development, in which reality is described as being constructed by processes termed ‘actual occasions’ that possess both physical and mental aspects. As interesting as these metaphysical frameworks are, thus far none have been widely appreciated as offering enough to grasp on to, something that gives an experimentally testable picture of the underlying ‘*unus mundus*,’ to use the alchemical term meaning ‘one world.’

The lack of ideas about how to make sense of mentality in terms of brain processes has even led some to declare that the mind–body problem is fundamentally unsolvable, in that the capacity to discern this connection, to span the gap, may be beyond our intellectual capacity. It has been said that it might be like attempting to teach a dog about quantum physics; a dog simply lacks the cognitive apparatus to grasp the necessary concepts. And so it perhaps is for humans and the explanatory gap. Perhaps so; but really, is it possible to make such claims with any degree of confidence? What would have been the predictions of physicists a century or two ago about many things we take for granted today? It sometimes seems to be the case that philosophers, scientists, and other scholars of today believe that our historical moment is especially privileged and that we somehow have gotten a handle on the way things are that is almost as good as it can get. While it is the case that our current scientific story does work very well for many things, such an egocentric view seems quite shortsighted!

Among the other important issues related to the mind–body connection is the problem of what kind of causal efficacy mental states have. We have the experience that our will is free, that our subjective thoughts and feelings can and do have effects on our actions in a very direct way. Naturally, the nature of the connection between mind and body is central to addressing this issue in a meaningful way. Many contemporary scientists, if they bother to think about the question of free will at all, consider that our experience of free will must be illusory. Such beliefs have important implications in issues of ethics and criminal justice, for example.

Toward a Revolution in the Mind Sciences

The history of science has been punctuated with revolutionary shifts of paradigm or explanatory framework. Such a shift occurred in the period extending from Copernicus to Newton. Before and after this period, the scientific understanding of the universe was very different. Another revolutionary shift occurred with Einstein and the relativity theory. After Einstein, space and time were no longer considered absolute and invariant frameworks in which the physical processes of the universe took place, but were interconnected and malleable, could warp and bend, and have beginnings and endings. A third revolution in physics occurred with the introduction of quantum mechanics, after which matter, at least at the atomic level, is no longer represented as moving along well-defined trajectories, but in terms of potentialities. Measurement, probing, or other interaction seems to be required to impart a kind of definiteness to what is otherwise described as a distribution of probabilities or potentialities.

In biology, Darwin initiated a revolution when, after spending decades carefully observing biological phenomena, he provided a grand conceptual framework for understanding diversity among living organisms in terms of variation and natural selection. The Darwinian revolution took on additional momentum in the twentieth century when, with a growing knowledge of biochemistry, the quest for understanding the molecular basis of life took center stage. Of particular interest was the great mystery of heredity, how the information needed to construct a living cell was stored and transmitted from one generation to the next. In a lecture delivered in 1932, Niels Bohr (1885–1962), one of the physicists who founded quantum mechanics, speculated that perhaps the laws of physics and chemistry, as then currently understood, might be inadequate for describing the fundamental nature of living organisms. However, Bohr saw this not as a reason for pessimism, but rather its opposite; for just as the analysis of matter at the atomic level had precipitated the discovery of the new physical laws of quantum mechanics, so perhaps the pursuit of the molecular basis of life would entail the discovery of new laws of nature. What could be more exciting than that?

Bohr’s lecture was inspirational to Max Delbrück (1906–1981), a young physicist who heard it at the time, and went on to become one of the pioneers of the yet-to-be-founded scientific field of molecular biology. Delbrück was one of the first to consider that genetic information in organisms was somehow stored in large molecules, and went on to develop experimental techniques to investigate the molecular basis of heredity,

using bacteria and viruses. The ideas of Bohr and Delbrück were further elaborated in a widely read little book, *What is Life?*, published in 1944 by another one of the founding physicists of quantum mechanics, Erwin Schrödinger (1887–1961). Especially by way of Schrödinger’s book, the idea that new laws of nature might be discovered in the quest to understand the molecular basis of life was inspirational to a number of scientists in the early days of molecular biology.

The scientific revolution begun by Darwin achieved culminating moments with the molecular description of deoxyribonucleic acid (DNA) in 1953, the description of the genetic code within the following decade, and more recently, the sequencing of the human genome and the genomes of an increasing number of other organisms. At least thus far, Bohr’s speculation that new laws of nature might be discovered in the quest to understand life has not panned out. Increasingly sophisticated descriptions of the molecular basis of heredity, and other biochemical and biophysical processes underlying life at the cellular and molecular level, have been developed without needing to invoke any new laws of nature. Indeed, contemporary molecular biology has seen a series of triumphs in the application of a reductionist physicalist framework, leading to a richer understanding of the nature of life. Still, within this framework, some great mysteries remain, perhaps the most notable of which are the emergence of life from nonliving matter and the mind–body problem.

As stated earlier, the history of science has been punctuated with revolutionary shifts of paradigm or explanatory framework. If any place is now poised for such a shift, it may be the science of the mind. Contemporary science has reached an impasse in tackling the explanatory gap and some philosophers and scientists interested in the mind–body problem are open to an expansion of our scientific framework for there to be substantial progress toward a richer understanding of the mind–body connection. Perhaps the new laws of physics about which Bohr, Delbrück, and Schrödinger speculated will be found in connection with attempts to more deeply understand the nature of the mind. In any case, our scientific understanding of the nature of reality has always been an evolving enterprise and who is to say what the next phase will involve. William James, writing in 1892 about the scientists who would one day more fully illuminate the mind–brain connection, said that “the best way in which we can facilitate their advent is to understand how great is the darkness in which we grope, and never to forget that the natural-science assumptions with which we started are provisional and revisable things.”

At the time when James wrote this, classical physics was still strong, but was, unbeknownst to him, on the verge of going down for the count as the premier explanatory framework for understanding nature. Within a few years (although after James had died) quantum mechanics displaced classical physics as the fundamental description of nature. And quantum physics may indeed contain the seeds of an expanded framework of physical theory that provides a place for mentality or consciousness in a way that classical physics may never be able.

How might this be so? Thus far in the biological sciences, while quantum mechanics is assumed to be necessary to explain the stability of atoms and molecules, quantum-mechanical effects have not (yet?) been appreciated as playing any central role in our conceptual understanding and

description of living systems. For example, when describing the signaling between nerve cells taking place at synapses, neurotransmitter molecules, receptor proteins, reuptake transporters, and so forth are described as if they were solid objects of matter that could in some sense be visualized as microscopic billiard balls knocked around by the forces of electrostatic interaction and thermal diffusion.

However, quantum mechanics posits that measurements are necessary to turn the characteristics of a system from potentialities into well-defined properties. Some physicists argue that some sort of additional framework, beyond what is described by the equations of quantum mechanics, is necessary to specify the measurement. Bohr referred to this as the ‘free choice of experimental arrangement’ and it may be a place to at least begin a discussion of how mentality is connected with the rest of the physical universe. An important implication is that mentality need not be identical to, be derivable from, or somehow emerge from the physically described properties of matter, as it is in the various approaches of physicalism. Instead, mentality may interact with the physical system in some way to fully define its properties. It is a concept that may fit within an expanded dual-aspect-like framework. However, thus far it has been difficult to specify what might be the next steps in describing such a framework, since quantum physics itself says nothing about the structure of the mental domain, if that is what it is. The implications of this so-called quantum-mechanical measurement problem are hotly debated among physicists who are interested in what quantum physics has to say about the nature of reality and our ability, through experiment, to acquire knowledge about reality.

Toward an Empirical Science of the Subjective

Something not generally discussed in the context of philosophical or neurobiological discussions of the mind–body problem is the idea that in order to move forward, we may need to develop methods to more deeply investigate the mind on its own terms. William James articulated this in his classic 1890 text *The Principles of Psychology*, wherein he laid out a threefold approach to the study of the mind: (1) behavior, (2) neural correlates of behavior, and (3) direct study of mental phenomena themselves, stating that “introspective observation is what we have to rely on first and foremost and always.”

Just as progress in astronomy and cosmology has depended strongly upon the implementation of ever more powerful telescopes of various kinds, and progress in cellular and molecular biology has employed ever more powerful microscopes and microscopic probes of various kinds, it seems reasonable that greater progress in the science of the mind will benefit from more refined methods of observation of mental phenomena. Some argue that because we are all intimately familiar with the mind, refined observation of mental experience is second nature to everyone. After all, are we not experiencing thoughts, feelings, and perceptions all the time? Nonetheless, introspectively carrying out careful observation of mental processes is a difficult business at best and requires years of practice, just as learning how to make other kinds of scientific observations requires extensive training. We can each of us look at the sky at night, be aware of the phases of the moon and the movement

of the planets, be awed by the countless number of stars, but this does not qualify us to make the kind of refined observations that have led to our current cosmological understanding of the universe.

Refined introspective observation and analysis benefits from stable and highly focused attention, something that does not come easily to most people. Our attention is generally moving about quite actively from one thing to another. Contemplative practitioners associated with various religious and spiritual traditions have for millennia been developing refined introspective methodologies, to better observe and understand mental experience. It was in part this potential of sharing ideas about the nature of the mind and how it could be investigated that motivated the Dalai Lama of Tibetan Buddhism to first propose, in the 1980s, that cognitive scientists and Buddhist contemplatives engage in a dialogue that might be of benefit to both traditions. These dialogues rapidly broadened to include neuroscientists and physicists and have become annual events, leading to the generation of new experimental research at the interface of contemplative practice, psychology, and neuroscience. However, the task of bringing the highly refined methods of mind observation into the domain of contemporary cognitive science is much more difficult, due to the rigors of the training involved.

Conclusion

We assume that the mind and consciousness have developed according to principles of biological evolution: that whatever mental experience may be, it has evolved in intimate concert with brain and body physiology and is an essential part of how our body engages with the physical world. It certainly could be the case that a capacity for conscious awareness might give us (and other creatures that possess such awareness) an enhanced ability to analyze and integrate information and that such an ability would facilitate survival and reproduction in a complex environment. Since brain processes are intimately connected with mentality, it makes eminent sense to continue to advance the study of brain function at the molecular, cellular, and systems levels as one program of investigation of the mind–body connection. This includes continued development of experiments to elucidate neural correlates of mental experiences. Perhaps it will be that a far more complete understanding of mind will come solely from an analysis of the already known and yet-to-be discovered molecular, cellular, and systems properties of the brain and the body. Perhaps a physicalist metaphysics will provide a framework sufficient to adequately address the mind–body connection. Perhaps even, as some have argued, the Cartesian linguistic distinction of ‘mind’ and ‘matter’ sets up a disconnect that predisposes us to certain limitations in the way we conceptualize the mind–body problem. Are the explanatory gap and the seemingly special and irreducible nature of first-person subjective experience somehow artifacts of this distinction?

However, it also makes sense to be attuned to phenomena that do not readily fit within the explanatory structure of brain function as currently understood, for such phenomena may point the direction to an expanded framework for

understanding the mind–body connection. These would include, but are not limited to, some aspects of near-death experiences, especially reports of out-of-body experiences and of clear awareness during periods of sensory deprivation and minimal brain activity; mystical, transpersonal, or transcendental experiences, some spontaneous, some facilitated by shamanic processes such as the ingestion of certain powerful plant or chemical preparations; experiences suggesting some kind of survival of mental information after the death of the body; other phenomena grouped broadly under the heading of anomalous (telepathic communication, remote viewing, and precognition, for example). Some of these phenomena are very difficult at best to study under laboratory conditions. Moreover, there is widespread belief in Western science that many of these phenomena simply cannot be real and it is fashionable to dismiss them as mere pseudoscience. Such attitudes are in part tied to an apparent lack of theoretical explanation within current physical theory. Additionally, many who are dismissive are remarkably unfamiliar with the evidence that does exist concerning some of these phenomena. As many of these phenomena are widely reported across cultures and across millennia, it may be that an expanded science of the mind will be unable to continue to ignore them. Ultimately, one hopes that the self-correcting nature of the scientific enterprise will foster the development of frameworks to encompass whatever is empirically justified.

We began with an operational definition of the mind as the collection of our mental experiences and of consciousness as our capacity to be aware of these mental experiences. As pointed out earlier, these operational definitions of mind and consciousness are very closely related, since to be part of the ‘mind’ by this definition, there must either be awareness or at least the possibility of awareness. It is possible that empirically we will be brought to a place where more nuanced definitions of mind and consciousness are needed, perhaps incorporating transpersonal and transcendental aspects. Biological evolution has had several billion years to refine the processes of life, and it is likely that the extent of connectivity and interaction within the web of life is much more complex than we presently imagine. This may include aspects of the mind–matter relationship that are as far or farther beyond our present scientific description as contemporary theories of mathematical physics would have been to Newton. Moving toward the next level of insight concerning the mind–body connection may entail honoring how little we presently know and openness to radically new perspectives.

Glossary

Affordances Affordances is a term introduced by James J. Gibson indicating that the observation of an object determines an immediate and automatic selection of those of its properties that allow one to interact with it. The affordances are not the visual aspects of the object, but the *pragmatic opportunities* that the object offers to the observer.

Canonical neurons Canonical neurons are a specific class of neurons of the monkey ventral premotor cortex that discharge during motor act execution and in response to the presentation of 3D objects. Typically they show congruence between the motor act, the code (e.g., precision grip), and the physical properties of the observed object (e.g., small object).

Mirror neurons Mirror neurons are a distinct class of neurons found in the monkey premotor cortex and IPL that discharge both when the monkey execute a given motor act or observes the same motor act performed by another individual.

Motor act Unlike the term movement that describes a displacement of body parts, motor act indicates movement with a goal.

Motor cortex Motor cortex is defined as that part of the frontal lobe that lacks the layer containing granular cells. Its electrical stimulation, at low threshold, elicits discrete movements of contralateral body parts.

Potential motor act Potential motor act is defined as the activity of a motor neuron triggered by sensory stimuli and not accompanied by an overt motor response.

Voluntary movement Voluntary movements are manifestations of a centrally generated intention to act. The way in which intention is generated is irrelevant for the notion of voluntary movement. It may result from bodily needs such as hunger or thirst, or from higher order deliberations based on one's own beliefs and desires. What accounts for voluntary movements is that the individual has a goal and that this goal determines movements leading to its achievement. Unlike for reflexes, in voluntary behavior, stimuli do not determine a motor response, they only *set the occasion* for it. According to their needs, animals may or may not respond to the same stimulus.

Introduction

In the early 1990s, Giacomo Rizzolatti and his coworkers Luciano Fadiga, Leonardo Fogassi, and Vittorio Gallese discovered a distinct class of neurons in the monkey premotor cortex that discharge both when the monkey performs a goal-directed motor act and when it observes a similar motor act done by another individual. These neurons were called 'mirror neurons.' There is now evidence that the mirror neurons of the monkey's premotor cortex represent a particular case of a more general mechanism, the 'mirror mechanism,' that is present also in other species of animals, including humans. The mirror mechanism operates as follows: it transforms the visual representation of an observed motor act into a representation of that motor act in a motor format. Because the observing individuals know the outcome of their motor representations, the mirror mechanism provides them with a *direct* knowledge of what the others do.

The functional role of the mirror mechanism is not unique but changes according to where it is located in the brain. At present, there is evidence that it plays a role in the recognition of songs in birds, in understanding motor acts in monkeys and in recognition of motor acts, intention, emotions, and phonemes in humans.

The Mirror Mechanism in Monkeys

Anatomical and Functional Organization of the Parieto-Frontal Areas

The encephalon of primates, and humans in particular, is characterized by the enormous increase of the cerebral cortex. A large part of this increase is due to the development of the 'association areas' and, among them, of the posterior parietal lobe. The classical view of the functional role of the association area and of the posterior parietal lobe, in particular, was that they 'put together' information coming from different sensory modalities. Perception would be the consequence of this 'putting together.'

A series of studies carried out by Vernon Mountcastle and Juhani Hyvarinen in the 1970s radically modified this view. These authors recorded single-neuron activity from the inferior parietal lobule (IPL) in awake macaque monkeys and assessed their responses to sensory stimuli and during motor behavior. The results showed that many parietal neurons respond to sensory stimuli and often to stimuli from different modalities (e.g., visual and somatic stimuli). However, a large number of neurons discharged in association with motor acts performed by the monkeys. A recent analysis of the organization of IPL has shown that the IPL is organized according to a motor

scheme. Neurons located rostrally (areas PF) discharge in relation to mouth actions; neurons located centrally (PFG and PG) fire mostly in association to hand and arm movements; finally those located caudally are related to eye movements. The sensory, unimodal and polymodal, responses are linked to the body parts that are motorically represented in a given area. Thus, the basic organization of IPL is not sensory, but motor, with the sensory and association responses inserted in a motor scaffold.

Congruent with this new view of IPL organization are anatomical data showing that there is no such a thing as a large multipurpose association area, but that cytoarchitectonically different parietal areas (Figure 1) have specific connections with premotor areas and form, together with these areas, a series of circuits coding different types of motor behaviors. Here we will discuss the functional properties of three of

these circuits, AIP/PFG-F5, VIP-F4, and LIP-FEF (frontal eye field), all endowed with the mirror mechanism.

AIP-PFG-F5: The Hand Grasping and Manipulating Circuit

The functional properties of this circuit have been investigated by Sakata and Rizzolatti and their coworkers. Sakata and his colleagues recorded the neural activity from area AIP in monkeys trained to grasp different objects requiring specific types of grip. They found that there were neurons responding to the mere vision of the objects, others discharging during the motor acts directed toward objects, and, others that became active both during the mere vision of an object and during an action on it (visuomotor AIP neurons).

Rizzolatti and his coworkers recorded the activity of neurons from area F5. They found that virtually all neurons of this area discharged in association with hand motor acts (e.g., grasping, holding, manipulating). Many F5 neurons also discharged when the monkey observed an object. These visual responses were present not only if the monkey subsequently grasped the observed object, but also when it had to release a lever following object presentation. This finding indicates that the discharge was not related to grasping preparation. As in area AIP, the majority of these visuomotor neurons (also called 'canonical' F5 neurons) were selectively activated by the presentation of objects of a certain size, shape, and orientation. The visual specificity was congruent with the motor specificity.

What can be the explanation of the behavior of AIP visuomotor and F5 canonical neurons? The explanation is that every time a three-dimensional (3D) visual stimulus is presented, these AIP and F5 neurons transform their visual affordances (action possibilities) into 'potential motor acts,' that is into a possible motor act. This potential motor act may be executed or not. Thus, potential motor acts give individuals the freedom to choose whether to respond to a stimulus or to hold it in memory. Their discharge does not represent a command to act.

F5 and AIP Mirror Neurons

While the observation of a 3D object is sufficient to trigger AIP visuomotor and F5 canonical neurons, the observation of a *motor act* (i.e., a goal-directed movement) is necessary to trigger *mirror neurons* (Figure 2). These neurons are located in the premotor cortex (area F5) and in two areas of IPL (AIP and PFG). However, because most studies of the basic properties of mirror neurons have been carried out on F5 neurons, we will deal mostly with these neurons.

Like all neurons in F5, mirror neurons discharge during the execution of specific motor acts such as grasping, tearing, or holding. In addition, they fire when the monkey observes another individual (human or monkey) performing the same motor act. They do not discharge in response to mere object presentation.

What is the function of mirror neurons? Why are they activated during the observations of actions done by others? To address this issue, one must solve first a preliminary problem: what do the parieto-frontal mirror neurons encode when they discharge during voluntary movements?

Before doing this, one has to have clear in mind that what is recorded in extracellular single-neuron studies is the neuron

Figure 1 A lateral view of the monkey brain showing some parieto-frontal circuits. The main cytoarchitectonic feature of the frontal motor cortex is the absence of granules (agranular frontal cortex). This cortex is formed by the primary motor cortex (F1 or M1) and by various premotor areas. Some (areas F2, F4, F5, and F7) are located on the lateral cortical surface. Two (F3 and F6, not shown in the figure) are located on the medial cortical surface. F means frontal. The parietal areas located on the cortical convexity (upper panel) are indicated according to the terminology of von Economo (PF, PG, PFG; P means parietal). The areas located inside the intraparietal sulcus can be seen by opening this sulcus (lower panel). AIP, anterior intraparietal area; LIP, lateral intraparietal area; MIP, medial intraparietal area; PEip, intraparietal PE; VIP, ventral intraparietal area; V6A, an extrastriate visual area.

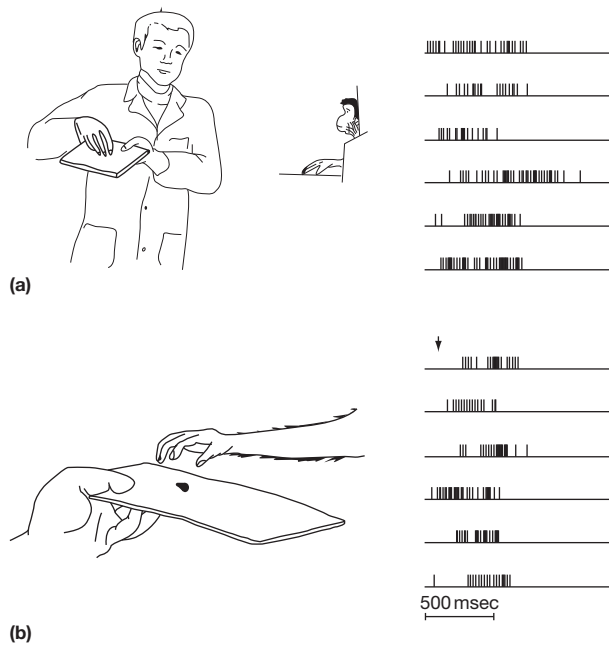

Figure 2 F5 mirror neuron. Upper panel: neuron's responses during the observation of grasping movements done by the experimenter; Lower panel: responses of the same neuron during monkey grasping movements.

output. This is (obviously) true both for action execution and action observation. Thus, a way to assess which information is carried out by a mirror neuron when activated during action observation is to establish what this neuron encodes during agent's own motor act execution.

There is evidence that most motor neurons of F5 encode *motor acts* (see definition above) rather than *movements*, that is, body parts displacements without a specific goal (e.g., finger flexion). Crucial evidence in this sense has been recently provided by Umiltà et al. These authors recorded single neuron in monkeys trained to grasp objects using two different types of pliers: 'normal pliers,' which require hand closing to grasp an object, and 'reverse pliers,' which, in contrast, require hand opening for the same purpose. The results showed that F5 neurons discharge, in both conditions, during the same phase of grasping regardless of whether, in order to achieve the goal, the hand has to be opened or closed (Figure 3).

It is clear from this experiment that the mirror neurons of F5 code the *goal* of the observed motor act. They give an immediate knowledge to the observer on what the agent is doing.

The functional properties of IPL motor neurons seem to be similar to those of F5 neurons: the goal of the executed motor acts is the parameter that IPL neurons that fire during the execution of motor acts encode.

Recently, a single-neuron study investigated the effect of the spatial relations between agent and observer, comparing the responses of F5 mirror neuron to motor acts performed within the reach of the monkey (peripersonal space) or outside its reach (extrapersonal space). The results showed that many F5 mirror neurons are differentially modulated by the spatial location of the observed motor acts. Some neurons are selective for actions executed in the monkey's peripersonal space, whereas others prefer extrapersonal space stimuli. These

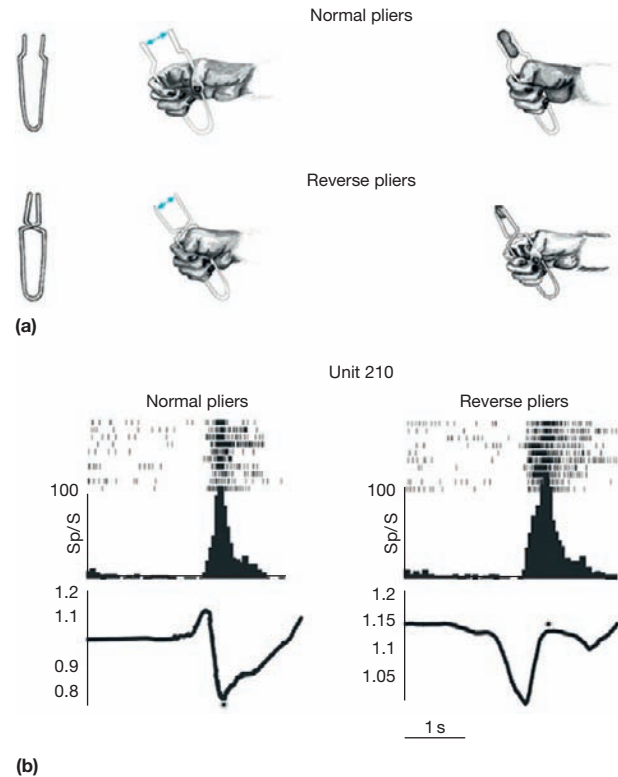

Figure 3 F5 neurons code the goal of a motor act. Upper part: schematic illustration of the used experimental paradigm. (a) normal pliers and (b) reverse pliers. Lower part: activity of a neuron recorded in area F5. Rasters and histograms illustrate the neuron's discharge recorded during grasping with normal pliers (left) and reverse pliers (right). Both rasters and histograms are aligned with the end of the grasping closure phase (asterisks). The traces below each histogram indicate the instantaneous hand position recorded with the potentiometer and expressed as function of the distance between the pliers handles. Trace down indicates that the hand closes and the distance between handles decreases, while trace up indicates that hand opens and the distance between handles increases.

findings indicate that mirror neurons may encode the goal of others' motor acts in the observers' centered spatial framework, thus providing the observer with critical information for organizing their own future behavior in cooperation and/or competition with the observed individuals.

Motor Goals and Motor Intentions in PFG/AIP-F5 Circuit

The properties of parieto-frontal mirror neurons described up to now indicate that their activity reflects what is going on 'now' and 'here.' However, there is evidence that parietal and frontal mirror neurons are involved in encoding not only the observed motor acts but also the entire action of which the observed motor act is a part. Fogassi and colleagues trained monkeys to grasp objects with two different motor intentions: to place them into a container or to bring them to their mouth. After training, IPL grasping motor neurons were studied in the two conditions. The results showed that more than 60% of grasping neurons discharged with an intensity that varied according to the action in which the motor act was embedded ('action-constrained' motor neurons). This finding implies that

IPL is constituted of chains of neurons in which each neuron encodes a given motor act and is linked to other neurons that are selective for subsequent motor acts. Together these neurons form a motor chain that encodes a given action (e.g., grasping-for-eating).

A striking result of this study was that many of 'action-constrained' motor neurons have mirror properties. When tested in the two conditions described above, the majority of them were differently activated when the observed motor act belonged to one action or another ('action-constrained *mirror* neurons'). This finding indicates that IPL mirror neurons not only describe what the observed individual is doing (e.g., grasping), but also, thanks to IPL chained organization, allow the observer to predict *why* the individual is doing it. In other words, they allow the observer to recognize the agent's motor intention.

VIP-F4: The Hand Reaching Circuit

Area VIP is located in the fundus of the intraparietal sulcus. It receives visual projections from components of the dorsal visual stream. There are two main categories of neurons in VIP: purely visual neurons and polymodal (somatosensory and visual neurons). Polymodal neurons have somatosensory and visual receptive fields that lie in register. A visual receptive field in front of the face, for example, is associated with a tactile receptive field on the face. Recordings demonstrate that many neurons in VIP are encoded in body part-centered coordinates.

Area VIP neurons appear to encode the first step in the construction of peripersonal space. The area in which this process becomes fully expressed is area F4. Neurons in area VIP have been recently discovered by Ishida and colleagues. These authors recorded from VIP neurons that respond to stimuli presented in the peripersonal space. They assessed then the distance at which the neurons ceased to respond. At this point the experimenter entered into the extrapersonal space and moved a stimulus around his face. The results showed that these neurons started to fire again. A good correspondence was found between the location of tactile and visual receptive field on the monkey face and that of the experimenter.

Motor responses were not studied by Ishida and colleagues. One has to keep in mind, however, that area VIP is strictly connected with area F4, where also peripersonal space is encoded and whose neurons discharge during reaching movements. It is very likely therefore that neuronal responses in VIP although elicited by visual stimuli are, at least in most cases, not visual responses in the strict sense, but potential motor acts directed toward specific space sectors or specific body parts.

The demonstration of mirror neurons in VIP is of great interest because it shows that neurons endowed with the mirror mechanism may encode body-directed, and not only object-directed, motor acts (F5 mirror neurons), thus opening fascinating possibilities for understanding how individuals encode the body of others.

LIP-FEF: The Circuit of Eye Movement

The two main areas that control the saccadic eye movements are area LIP and the FEF. Area LIP is located in the posterior

part of the lateral bank of the intraparietal sulcus. It receives a direct input from many extrastriate visual areas and from the temporal lobe. It is richly connected with the FEF. Electrical stimulation of LIP evokes saccadic eye movements. The threshold for evoking saccade is, however, higher than that of FEF or the superior colliculus. This finding indicates that LIP, although involved in processes leading to saccade generation, is more distant from eye movement generating centers than the last two structures.

Single-neuron recording showed that nearly all LIP neurons respond to the presentation of visual stimuli. Their receptive fields are typically large and coded in retinal coordinates. Some LIP neurons discharge stronger to complex visual stimuli than to unstructured light stimuli. Many LIP neurons discharge before saccadic eye movements. Pure movement-related neurons are rare. The majority of LIP neurons with saccade-related activity discharge also at the presentation of visual stimuli.

FEF is a cortical visuomotor center involved in the genesis of saccadic eye movements. Electrical stimulation of FEF even at low intensity produces contralateral saccades.

The electrophysiological properties of FEF have been extensively studied. These studies showed that, schematically, FEF neurons can be subdivided into three major classes: neurons that respond to visual stimuli, neurons that have movement-related activity (movement neurons), and neurons that have both visual and movement-related activity.

Visual neurons respond vigorously to stationary light stimuli. Their receptive fields are large, varying from a few degrees to an entire quadrant of the visual field. Movement neurons fire during ocular saccades. Most of them discharge before movement initiation. Visuo-movement neurons have both visual and movement-related activity. They discharge to visual stimuli in the absence of saccades, but they fire also during purposive eye movements made in darkness. There is a continuum of visuo-movement cells, from neurons in which visual activity predominates to neurons in which movement activity predominates. Association of visual stimulus and eye movements produce the strongest discharge.

LIP Mirror Neurons

There is some evidence that there is a population of neurons in LIP that are endowed with a mirror mechanism. Shepherd and colleagues found that there are LIP neurons that discharge both when the monkey looked in the neuron-preferred direction and when it saw another monkey looking in the same direction. Interestingly, they also found another set of LIP neurons that discharged when the recorded monkey looked toward a certain direction but whose discharge was, in contrast, suppressed when the observed monkey looked in the same direction. The authors suggested that LIP mirror neurons contribute to the sharing of observed attention and might play role in imitative behavior.

The Mirror Mechanism in Humans

There is a large amount of evidence that several human cortical areas possess the mirror mechanism. This evidence comes from studies using noninvasive techniques (PET, fMRI, TMS, EEG,

MEG) and, more recently, also from single-neuron recordings. The mirror mechanism is present in the areas of the parieto-frontal circuits, in the insula, cingulate cortex, the hippocampus, and supplementary motor cortex.

By using single-subject fMRI analyses, evidence has been recently provided that there are also other cortical areas (e.g., SI, SII) that become active during action observation and action execution. It might be, however, that these activations outside of mirror circuits reflect additional mechanisms (e.g., internal models) that are triggered by the mirror mechanism. These activations, not properly due to the mirror mechanism, would enrich the information about other individuals' behavior that the mirror mechanism provides.

Human Parieto-Frontal Circuits with Mirror Properties

The human mirror parieto-frontal circuit mostly studied is the one coding grasping motor acts. This circuit is formed by two main nodes: the IPL including the cortex located inside the intraparietal sulcus and the inferior sector of the precentral gyrus plus the posterior part of the inferior frontal gyrus (Figure 4). It is likely that there is another parieto-cortical circuit formed by the superior parietal lobule and the dorsal premotor cortex. It has been suggested that this dorsal circuit contains the mirror mechanism for the observation–execution of reaching movements.

What does the grasping mirror circuit code? In accord with early findings, a series of more recent fMRI studies provided strong evidence that the human mirror parieto-frontal circuit encodes the goal of observed motor acts. Gazzola and colleagues instructed volunteers to observe video clips in which either a human or a robot arm grasped objects. In spite of differences in shape and kinematics between the human and robot arms, the parieto-frontal mirror circuit was activated in both conditions. These results were extended by Peeters and

colleagues who investigated the cortical activations in response to the observation of motor acts performed by a human hand, a robot hand, or using different tools. They found bilateral activation of a network formed by intraparietal and ventral premotor cortex regardless of the acting effector. Most interestingly, the observation of tool actions produced a specific activation of a rostral sector of the left anterior supramarginal gyrus, suggesting that this sector specifically evolved in *homo sapiens* for tool use.

Further evidence for goal encoding by the parieto-frontal mirror circuit was obtained in an fMRI experiment in which two aplasic individuals, born without arms and hands, and control volunteers were asked to watch video-clips showing hand actions. All participants also performed actions with their feet, mouth and, in the case of control volunteers, hands. The results showed that the parieto-frontal mirror circuit of aplasic individuals that was active during foot and mouth movements was also recruited by the observation of hand motor acts that they have never executed but whose motor goals they could achieve using their feet or mouth.

An important issue is how we understand actions that are not present in our motor repertoire. An fMRI study addressed this issue. Two types of actions performed by humans, monkeys, and dogs were shown to volunteers. They were biting and oral communicative actions (speech reading, lip smacking, barking). The results showed that the observation of biting, regardless of whether performed by a man, a monkey or a dog, determined the same activation foci in the IPL, in the pars opercularis of the IFG, and the adjacent precentral gyrus. The left rostral parietal focus and the left premotor focus were virtually identical for all three species, while the right side foci were stronger during the observation of actions made by a human being than by an individual of another species. Different results were obtained with communicative actions. Speech reading activated the left pars opercularis of IFG;

Figure 4 Later view of human brain. The figure shows the areas (in color) that form the human parieto-frontal grasping mirror circuit.

observation of lip smacking, a monkey communicative gesture, activated a small focus in the pars opercularis of IFG; observation of barking did not produce any frontal lobe activation.

These results indicated that actions made by other individuals could be recognized through different mechanisms. Actions belonging to the motor repertoire of the observers are mapped on their motor system. Actions that do not belong to this repertoire are recognized essentially on visual basis. It is likely that these two different ways of recognizing actions have two different psychological counterparts. In the first case, the motor activation translates the visual representation into a 'personal knowledge' (see Merleau-Ponty), while this is lacking in the second case.

Mirror Mechanism for Encoding Movements

Unlike monkeys, humans are endowed with the mirror mechanism also for movements that are not goal-directed. Evidence for this was originally obtained with TMS experiments. Various studies showed that the observation of others' movements, even when devoid of a goal, results in an activation of the muscles involved in the execution of those movements. Further support for the existence of this movement-related mirror mechanism comes from EEG and MEG studies showing that the observation of movements without a goal desynchronizes the cortical rhythms recorded from motor areas.

Recently it has been shown that coding the goal of an observed motor act or the movements that form it depends on the content of the observed behavior. Cattaneo and colleagues recorded motor-evoked potentials (MEPs) to TMS from the right *opponens pollicis* (OP) muscle in participants that were observing an experimenter either opening and closing normal and reverse pliers or using them to grasp objects (see Section on 'F5 and AIP Mirror Neurons'). The observation of tool movements (i.e., opening and closing without grasping anything) activated a cortical representation of the hand movements involved in the observed motor behavior. In contrast, the observation of the tool-grasping action activated a cortical representation of the observed motor goal, irrespective of the individual movements and the order of movements required to achieve it. This duality of coding is probably one of the major factors that allows human beings to learn by imitation.

Imitation

Although the term imitation has several definitions, there are two main senses in which it is most commonly used. The first defines imitation as the capacity of an individual to replicate an observed motor act; the second defines imitation as the capacity to acquire, by observation, a new motor behavior and to repeat it using the same movements employed by the teacher. In both cases, imitation requires the capacity to transform sensory information into a motor copy of it.

There is clear evidence that the mirror mechanism is involved in imitation in the first sense, that is, to replicate immediately an observed motor act. In an fMRI experiment, volunteers were tested in two main conditions: 'observation' and 'observation-execution.' In the 'observation' condition, participants were shown a moving finger, a cross on a stationary finger, or a cross on empty background. The instruction was to observe the

stimuli. In the 'observation-execution' condition, the same stimuli were presented, but, this time, the instruction was to lift the finger, as fast as possible, in response to them. The crucial contrast was between the trials in which the volunteers made the movement in response to an observed action ('imitation') and the trials in which the movement was triggered by the cross (a nonimitative behavior). The results showed that the activation of the mirror mechanism and in particular of that located in the posterior part of IFG was stronger during 'imitation.'

More complex appears to be the mechanism involved in imitations learning. In this case, imitation, as suggested by Byrne, appears to result from the interaction of two distinct processes: (a) segmentations of the action to be imitated into its individual elements and their transformation into the corresponding potential movements of the observer and (b) organization of these potential movements into a temporal and spatial pattern that replicates that shown by the demonstrator. A study of Buccino and colleagues on learning to play chords on guitar showed that the first step of imitation learning is achieved through the mirror mechanism, while the second one is mostly due to the activity of the prefrontal lobe and in particular of area 46 that memorizes and recombines the motor elements in the new pattern.

Intention Understanding

As discussed in the previous sections, the sight of motor acts done by others produces, in the observer, the activation of cortical motor areas involved in the organization of the observed motor acts. This activation is at the basis of understanding 'what' the observed individual is doing. There is now evidence that, besides understanding motor acts, mirror mechanism is also involved in understanding 'why' a motor act has been performed, that is, the *intention* behind the observed motor acts.

Convincing evidence in this sense has been provided by an fMRI study by Iacoboni et al. In this study, there were three conditions. In the first one (called 'context'), the volunteers saw some objects (a tea-pot, a mug, a plate with some food on it) arranged as if a person was ready to drink the tea or arranged as if a person had just finished to have his breakfast; in the second condition (called 'action'), the volunteers were shown a hand that grasped a mug without any context; in the third (called 'intention'), the volunteers saw the same hand action within the two before and after breakfast contexts. The context and the different grip shapes suggested the intention of the agent, that is, grasping the cup for drinking or grasping it for cleaning the table.

The results showed that in both action and intention conditions there was an activation of the mirror parieto-frontal circuit. Crucial was the comparison between intention and action conditions. This comparison showed that the understanding of the intention of the doer determined a marked increase in activity of the right frontal node of the parieto-frontal mirror grasping circuit.

In line with these findings are the results of a more recent fMRI study based on the repetition suppression paradigm. This study confirmed the involvement of the frontal node in motor intention understanding and, in addition, also showed that the parietal nodes activity underlies this capacity.

Taken together, these data clearly show that the intentions behind the actions of others can be recognized by the mirror mechanism. They do not imply, of course, that intention of others cannot be understood using other more cognitive ways (see Frith and Frith), but they suggest that the mirror mechanism (see monkeys data) is most likely the most basic neural mechanism for intention understanding from which other aspects of understanding others evolved.

Recognizing Emotions

Up to now we discussed the neural mechanisms that enable individuals to understand actions without an obvious emotional content. In social life, however, it is equally important to recognize the emotions of other people. As discussed for 'cold' action, it is reasonable to admit that emotions can be understood in two ways: one based on sensory information provided by others' emotional behaviors and successive mentalizing; the other on a direct mapping of the observed behavior on the motor structures that, when active, produce, the observed emotion in the observer.

These two ways of recognizing emotions are experientially radically different. With the first, the observer understands the emotions expressed by others, but does not experience them. He deduces them. A certain facial or body pattern means fear, another happiness. Different is the case for the direct matching mechanism. In this case, the recognition occurs because the observed emotion triggers the experience of the same emotion in the observing person. It is a 'first-person' recognition.

What is the evidence for this type of action understanding? There are two sets of data that indicate the existence of this mechanism. Wicker and colleagues carried out an fMRI study aimed to find out whether the same cortical sites that show activation during the experience of disgust, also show activation during the observation of faces expressing it. In this study, volunteers were subjected to an fMRI experiment consisting of two sessions. In the first session, the participants were exposed to unpleasant and pleasant odors; in the second session, they watched a video showing the facial expression of people sniffing an unpleasant, a pleasant, or a neutral odor.

Among other structures, the exposure to smells determined activations in the insula and the anterior cingulate. The most important result, however, was the finding that the same foci that were activated within the insula and the anterior cingulate by the exposure to disgusting odorants were also activated by the observation of facial expression of disgust. The anatomical colocalization of the active foci strongly suggests that the insula contains neural populations that becomes active both when individuals experience disgust and when they see it in others.

Similar results were obtained also for pain. Singer and coworkers conducted an fMRI experiment in which the participants were either subjected to a mildly painful electric shock applied by electrodes located on their hand or asked to watch while the same electrodes were fastened to the hand of a loved one. The results showed that the same sites of the anterior insula and of the cingulate cortex became active in both conditions, thus showing that both direct pain experience and its evocation are mediated by a mirror mechanism similar to that found for disgust.

Language

There is disagreement on whether the human speech has its evolutionary roots in gestures or animal calls. Yet, nobody denies that speech is something more than a mere collection of curious sounds. This was clearly demonstrated by Liberman, who showed that one could not build an efficient communication system by simply using tone combinations. According to Liberman, the unique property of speech is its capacity to elicit the motor representation of the heard sound in the listener.

There is evidence that this capacity has a precise neural correlate. In a TMS experiment, the left hemisphere speech motor centers were stimulated and MEPs were recorded from the tongue muscles in volunteers instructed to listen carefully to acoustically presented verbal and nonverbal material. The stimuli were words and bitonal sounds. In the middle of words, there was either a double 'f' or a double 'r'. 'f' is a consonant that, when pronounced, requires virtually no tongue movements, whereas 'r' is a consonant that, in contrast, requires, marked tongue muscle involvement to be pronounced. The results showed that listening to words containing the double 'r' produced a significant increase of MEPs amplitude recorded from tongue muscles compared to listening to bitonal sounds and words containing the double 'f'.

Similar results were obtained using the same technique and recording MEPs from a lip muscle and a hand muscle in four conditions: listening to continuous prose, viewing speech-related lip movements, listening to nonverbal sounds, and viewing eye and brow movements. Compared to viewing eye and brow movements, listening to and viewing speech enhanced the amplitude of MEPs recorded from the lip muscles. All of these effects were seen only in response to stimulation of the left hemisphere.

Taken together, these data indicate that in humans, in addition to the mirror mechanism transforming observed movements into potential movements, there is a further system transforming heard phonemes in the corresponding motor representation of the same phoneme. There is no doubt that this mechanism plays a fundamental role in language learning.

Mirror Mechanism and Autism

Over the last few years, electrophysiological and brain imaging experiments showed that individuals with autistic spectrum disorders (ASD) have an impairment of the mirror mechanism, suggesting that the social isolation typical of patients with ASD may result from this deficit. There are two versions of this theory. The early version suggests that the deficit concerns the mirror neurons as such (single mirror neuron hypothesis). As a consequence, the observation of motor acts of others does not activate the mirror mechanism in individuals with ASD in a way comparable to that of neurotypical (NT) individuals. Because of this impairment, individuals with ASD present deficits in understanding action, intention, and emotion of others. The type and severity of the deficit depend on the location of the impaired mirror mechanism.

A more recent version of the relation between ASD and mirror mechanism (mirror neuron chain hypothesis) is based on the discovery in the parietal and premotor cortex of the monkey of neural chains mediating specific actions. As described

above, these neural chains are formed by specific sets of neurons ('action-constrained neurons') that code motor acts forming a specific action. Parietal and frontal motor chains become also active when an individual observes a motor act done by others, provided that the observed motor act is part of a specific action (e.g., grasping-for-eating, but not grasping-for-moving). In virtue of this mechanism, the observer may understand the intention of the acting individual from the very beginning of the observed action (first motor act) and hence understands his/her motor intention.

Recently, the existence of this chained organization has been demonstrated also in humans. Cattaneo et al. tested NT and ASD children during the execution and observation of actions. They found that, during the execution of a given action in NT children, there was activation of the muscles involved in the final motor act of an action as soon as the action started. Similarly, during the observation of an action done by another individual, there was activation of the muscles that the observer would have used if executing that action. In contrast, children with ASD, although able to execute the tasks, failed to express their motor intention in advance to the final motor act. Most interestingly, the observation of actions done by the others did not 'enter' in their motor system, the muscle involved in final motor act being not activated. The authors proposed that the basic deficit in ASD resides in a connectivity impairment that prevents the organization of intentional motor chains. This impairment is responsible of abnormal motor action organizations as well as understanding of others' intention.

Additional evidence in favor of a deficit of the chain-based mirror mechanism in ASD is provided by a recent study in which the authors tested the capacity of NT and ASD children to report the goal of the observed motor act, that is, *what* the actor was doing and the intention underlying it, that is, *why* the actor was doing it. The results showed that children with ASD are able to recognize individual motor acts with the same error rates as TD children, but they fail to understand the intention behind them when contextual information is absent.

A General Overview

In conclusion, the mirror mechanism is a general mechanism that transforms the visual representation of an observed motor behavior in an analogous representation in a motor format. The specific role of the mirror mechanism depends on the functional properties of the neural circuit in which it is located. The mirror mechanism located in the parieto-frontal circuits on the lateral brain convexity transforms the sensory representation of motor acts into a motor representation of the same acts. Its function is to give the observer a direct understanding of the seen motor behavior. The mirror mechanism located in the insula and rostral cingulate transforms an emotion observed in others into a visceromotor pattern analogous to that present when an individual feels that emotion elicited by natural stimuli. It gives the observer a direct feeling of others' experience.

The mirror mechanism plays also a role in imitation, in imitation learning, and in translating the speech sound into the motor pattern responsible for the emission of the same

speech sound. Preliminary evidence suggests that the mirror mechanism might also be involved in the understanding of the meaning of verbal material.

Although this list of the functions mediated by the mirror mechanism may seem to be rather long, actually it is only preliminary. Considering the generality of the mirror mechanism, it is very plausible that future research will demonstrate its presence in other species besides birds, monkeys, and humans and its involvement in other functions besides those discussed here.

The Conceptual Foundations of Gene Theory

For thousands of years, at least since the beginnings of agrarian culture, human beings have recognized that the traits of offspring resemble, in a predictable manner, those of their parents and that this relationship holds true for both animal and plant species. It is in this agrarian past that modern genetics has its origins. Mendel's discovery that this parent-offspring predictability followed reliable statistical laws is one of the landmark discoveries in modern science. Yet, the rule-like regularity with which phenotypic traits get passed from one generation to the next has also led to one of the greatest debates in the history of science – the nature-nurture debate. The crux of the dilemma stems from the fact that while patterns of inheritance are reliably observed and can, with statistical estimations extending from Mendel's initial calculations, be predicted with some degree of accuracy, the process or mechanism through which this statistical regularity occurs has remained a mystery.

The genesis of contemporary gene theory is found in early scientific attempts to resolve the unknown process, which generated these statistical regularities between parent and offspring traits. Contemporary gene theory was born out of an era when the Newtonian mechanical universe was the dominant paradigm of science (or natural philosophy, to which science was then referred). This worldview held that the universe and all of its subsidiary features, such as plant and animal life, functioned via the mechanical interactions of discrete and independent objects, be they atoms, molecules, or as in the present case, genes; causes were considered to be singular (i.e., there was one and only one actual cause for an event) and deterministic. Further, the explanation for most complex events was thought to be found through a process of reducing the objects involved down to their most fundamental and atomistic dimensions and then delineating the deterministic transactions among those atomistic components. Within this philosophical backdrop, contemporary gene theory derived its key principles:

1. Genes must be discrete causal agents 'located' in the germ cells. This principle is derived entirely from the Newtonian assumptions of linear, singular, and deterministic causes. Indeed, it was a completely assumed *a priori* 'given.' The only empirical observations related to this principle were the basic, observable aspects of sexual reproduction.
2. Genes behaved statistically 'as if' they contained independent and unique causal information, which additively combine to form the adult organism, although there were no formal tests of this assumption. The logic being that if our atomistic and additive conceptualization is true, then the statistical properties of the organism would follow certain parameters; the statistical properties do follow these parameters; therefore, our conceptualization of the gene is true. Philosophers of science refer to this logical fallacy as 'affirming the consequent.'

3. Because traits are predictable from the statistical estimations of Mendel and then later Fisher, both of whom did not include terms representing either development or environmental variation, it was further asserted that the causal information contained in genes was effectively isolated and independent of external influence (either biological or ecological).

These key principles, variations of which are referred to as the central dogma of molecular biology, soon became codified into the methodological operations of quantitative genetics. At its inception, and indeed, until only very recently, the gene, seemingly so concrete and definitive a structure, was nothing more than a hypothetical construct in a statistical equation. Even with the discovery of the unique and highly functional structure of deoxynucleic acid (DNA) by Watson and Crick, a little more empirical light was shown on the subject than simply having a molecule with the kinds of properties through which the hypothetical gene might work. It has only been in the last decade or so that molecular biology has developed the methodological tools for inducing segments of DNA to synthesize proteins and thereby identify a 'biological gene' as opposed to a 'statistical gene' or what Moss refers to as a D-gene (for DNA) rather than a P-gene (for phenotype inferred). It is worth noting that molecular biology has, within just a few short years of reliably observing the action of genes, abandoned the central dogma of genetics as untenable. In fact, work in stem cell biology takes contextual influences on gene synthesis to be foundational.

Traditional Quantitative Behavioral Genetics

One of the key, and perhaps most damaging, outcomes of the historical development of the gene concept is that not only did the assumptive base underlying the central dogma become codified into the methodology of the discipline, but also this once hypothetical construct became reified in the statistical equations of quantitative geneticists and subsequently divorced from empirical observation. As evidence for this, we note that there is not a single published study using a 'genetically informed design' in which a biological assessment of any kind has been undertaken. There are no actual genes to be found in the methods section of quantitative behavior genetics studies. Because of this empirical divorce, quantitative behavior geneticists have persisted in their Newtonian belief of the hypothetical gene, even when their molecular biology counterparts have abandoned the idea.

As a result, quantitative behavioral genetic studies explicitly measure neither sources of environmental variance (shared or unique) nor genetic variance. Indeed, it is only the dependent variable that is actually explicitly measured. It is true that the zygosity of each twin pair is measured as an indirect measure of the sequential structure of DNA, but this is not the same

as genetic variance. The use of zygosity as a surrogate index of genetic variance is only valid if one adopts a preformationist concept of a genotype. It is assumed that there is a limited phenotypic range about the prescribed genotypic potential through which environmental factors can influence the ultimate phenotypic outcomes.

This preformationist conceptualization is inherent in the fundamental equations of quantitative behavior genetics. It is explicitly assumed that phenotypic variance is an additive function of genetic, common environmental, and unique environmental factors. Algebraically, this is represented as

$$P = h^2 + c^2 + e^2$$

where P is the observed variance in some phenotypic trait, h^2 the proportion of variance due to genetic factors, c^2 the proportion of variance due to common environmental influences, and e^2 is the proportion of variance due to unique environmental experiences. Given that the DNA sequences in monozygotic twins are identical, it is assumed that monozygotic twins should have identical genotypes and in the absence of environmental influences they should have identical phenotypes. As the genomes of dizygotic twins have on average only half of their DNA sequences in common, sans environmental influences, they should on average share about 50% of their phenotype. Using this preformationist logic, the proportion of genetic influence can be inferred from the discrepancy of phenotypic correlations between monozygotic and dizygotic twin pairs:

$$h^2 = 2(r_{mz} - r_{dz})$$

Environmental influences common to both twins in a twin pair, such as having the same parents, are estimated then as the difference between the monozygotic correlation and the proportion of that correlation that is due to putative genetic factors.

$$c^2 = r_{mz} - h^2$$

Finally, environmental factors that are unique to each member of a twin pair is simply the residual term.

$$e^2 = 1 - h^2 - c^2$$

It is clear from this set of equations that genetic variability is inferred from the relative degree of phenotypic similarity in monozygotic and dizygotic twins. This is not the same thing as observed genetic variability.

Moss makes this important distinction by referring to genetic variance inferred from phenotypic similarity as P- genes and observed genetic variance as D-genes. The critical point is that P-genes are not informative about DNA and that D-genes are largely not informative with respect to phenotypes. In fact, basic cellular biology texts make this point "...the relationship between genotype and phenotype is very obscure.structural similarity between proteins does not necessarily imply [DNA] sequence similarity".

As such, when the authors of this article state that genetic factors account for the majority of increased variance in perceived adolescents, they do not really mean genetic factors, what they really mean is that the discrepancy between the monozygotic correlations and dizygotic correlations has

increased. This is an interesting finding and could potentially lead to important insights into developmental processes, but the limited attribution of this finding to statistical genetic effects restricts further analysis. If structural sequences in the genome were isomorphic to genetic function and more importantly to protein function, then the inferred genetic variability assumed by behavioral genetic models might be more instrumental. However, genes, rather than being static structural entities, are dynamic processes. What is important is not solely their nucleotide structure, but also their linear spatial location in the genome, their spatial location in the intranuclear environment, their individual temporal patterns of expression, and the patterns of expression and inhibition across the entire genome. Moreover, gene expression is far from a straightforward process. It is highly dependent upon complex genetic regulatory networks as well as extracellular factors. Gottlieb identified no less than 16 empirical studies demonstrating behavioral/environmental factors affecting gene/protein expression. Moreover, a single gene is capable of synthesizing more than a single protein, which has severe consequences for relating genes to phenotypic outcomes as compared to the assumption that there is a one-to-one relationship between genes and proteins. Thus, knowledge of the gene sequence itself, without the developmental conditions differentiating when a given protein might be synthesized, provides little information about how gene sequences relate to proteins, let alone complex behaviors such as perceptions of adolescent-parent relationship quality.

Given this more dynamic, integrative systems understanding of gene expression, the conceptualization of the structural genotype as a set of special instructions guiding development then is in direct conflict with empirical findings. Structural sequences of DNA have no independent developmental information. It is only in the context of developmental transactions of gene-gene and gene-environment (broadly defined) regulatory networks that the genome takes on any developmental salience. This completely undermines the utility of inferring genotypic variation from the relative phenotypic correlations of monozygotic and dizygotic twins. When the authors of this article refer to proportions of variance due to genetic factors, they are really reporting variance due to both genotypic and epigenotypic variance. The latter term coined by Waddington to describe the "...organizers and organizing relations to which a piece of tissue will be subject to during development..." (cited by Van Speybroek, 2002, p. 69).

Indeed, in studies of some of the strongest behavioral candidates based on heritability estimates, such as schizophrenia and major depression, we find that actual genetic variability is not significantly associated with behavioral variability with effect sizes of <1% of covariance. Another purported benefit is to use behavioral genetic models to identify genetic predispositions or risks for developing various disorders. However, since there is such a disparate relationship between genetic mechanisms and observed phenotypes, this use of behavior genetic findings also has to be taken with caution. In a recent review of data regarding adult chronic disorders such as hypertension and diabetes mellitus, which are generally thought to be reflective of genetic predispositions, Gluckman and Hanson found that they are more highly related to prenatal environmental experiences than to statistically estimated genetic

susceptibility. So, the empirical literature seems to suggest, much as developmental biologists, experimental embryologists, and developmental psychobiologists have suspected, that the presence of a high heritability estimate provides little information about the relationship between actual genes and behavior.

A Developmental Systems Perspective on the Role of Genes in Development

Developmental psychobiology, which has close historical ties with both comparative psychology and experimental embryology, was also impacted by the methodological limitation surrounding a pivotal construct that no one had ever empirically measured. Chiefly, in the absence of an empirical gene, the field could only indirectly infer an alternative view of the role of genes in development. Because of the experimental tradition of developmental psychobiology, the arguments that ran counter to the central dogma of genetics, such as those made by Gottlieb, were derived from a much stronger logical position. A large portion of this entire body of empirical literature comprises studies which provide counterfactual evidence to the central tenets of behavioral genetics.

One of the strongest of these arguments against the central dogma of genetics is drawn from experimental findings supporting the norm-of-reaction concept. The norm-of-reaction concept is a relatively old concept in the field of embryology, which states that phenotypic variability is restricted in a population because the developmental ecology of a population is relatively homogeneous (i.e., normalized) and that under conditions of increased ecological variability, there would be an associated increase in phenotypic variability. This is in stark contrast to the reaction range concept, which posits genetic limits on phenotypic variability with a limited range of variance due to environmental conditions. A central idea is that there is substantial phenotypic plasticity latent in the genome and that it is the developmental ecology that serves as the limiting or normalizing source of phenotypic variance rather than the genome.

There are several classic empirical examples of this effect, notable is the difference in wing morphology in several species of *Drosophila*. As was the case for the *Drosophila*, differential temperature during embryonic development is a key extragenetic mechanism for affecting phenotypic outcomes. Temperature has been shown to directly impact not only broad morphological outcomes Kaplan & Phillips, but also molar developmental processes, including heterochronic differences in development, as well as intracellular processes such as rates of diffusion, enzyme-induced protein activity, and gene expression. Early experimental work on the pluripotency of cell lines also provided counterfactual evidence to the central dogma.

Yet, the field was largely in the position of arguing what genes could not logically do rather than what they in fact did; a much less appealing case. This developmental-oriented theoretical perspective differed from the standard central dogma perspective on a number of levels. On a substantive level, based on empirical observations, genes are considered to be participatory components of a much broader biopsychosocial system. Genes were likely important factors in the

development of phenotypic traits; remember there had not been any empirical investigation of a biological gene, but they could not serve as the reductive prime cause. As such, it was inferred that the gene could have no independent causal influence and rather worked through causal interactions among variables in an integrated hierarchy. Further, phenotypic development has been shown to be highly probabilistic rather than deterministic, a result of the continual dynamic transactions across the development of biological, psychological, and ecological variables.

The Impasse Between Genocentric and Developmental Systems Perspectives

On a much deeper level, the theoretical perspective of Gottlieb and his predecessors stood in stark contrast to the Newtonian worldview. Theirs was a perspective in which causes were multiply determined and where multiple causal events could lead to the same outcome; a perspective in which the idea of a deterministic cause was untenable; where hierarchical systems, like organisms, were determined by the dynamic patterns of relationships among their parts rather than by the additive attributes of their constituent parts. The argument between developmentally oriented theorists and the central dogma-oriented perspectives of many behavior geneticists was played out without either side having empirical knowledge of an actual biological gene. So, both sides based much of their conceptualization on indirect inferences. And, while the counterfactual experimental evidence of developmental psychobiologists was particularly condemning for the central dogma perspective, which was on much weaker logical footing, there was no methodological framework for laying out the developmental- and systems-oriented postulates of developmental psychobiology. As such, concepts such as emergence, integrative levels, probabilistic epigenesis, and horizontal and vertical coactions were relegated by opponents to being little more than descriptive heuristics.

Contemporary Molecular Behavioral Genetics

It is almost common knowledge among biologists and philosophers of biology...that the classical molecular gene concept is not sufficient any longer in the face of the complex interactive processes being reported by molecular biology.

(Neuman-Held, 2001, p. 69).

Neuman-Held and others also point out that since the end of the twentieth century, the very notion of just what a gene is has changed. It is no longer sufficient to speak of 'the' gene; the term has come to mean different things to different people. The term gene is now understood to be shorthand for several different kinds of units. It may be that 'gene' is not so much an identifiable *thing* as it is a *process* involved in binding DNA to other factors which act together in polypeptide production. At its inception, and indeed, until only very recently, the gene, seemingly so concrete and definitive a structure, was nothing more than a hypothetical construct in a statistical equation. Even with the discovery of the unique and highly functional

structure of deoxynucleic acid (DNA) by Watson and Crick, a little more empirical light was shown on the subject than simply having a molecule with the kinds of properties through which the hypothetical gene might work.

However, it is now understood that there is no explanation in attributing a trait, behavioral or structural, to genetics in light of what converging current research from several disciplines indicates. Many behavioral scientists, behavior geneticists, and evolutionary psychologists seem to be unaware of these recent developments in our understanding of genetics as Gottlieb and others have pointed out. It turns out that there is no information in the genome to be triggered or nurtured by the environment, though this is the current consensus in the behavioral and much of the biological sciences. This has been consistently and reliably demonstrated empirically in data from a large number of studies which give us a new picture of the role of genes in development in general. "For instance, genes are not informational in the way supposed, nor do they initiate or direct ontogeny, there is no such thing as a genetic programme, and there is no straightforward 'unfolding' relation from genotype to phenotype."

It is now known that genes do little more than code for the many different proteins that go into making up living things; the proteins are themselves incorporated into the ever-changing molecular and cellular structure and physiology that is an individual organism. Genes participate in turning reactions on or off, they function as catalysts. Similarly, they really operate by participating in the timing of important chemical events. When the default schedule is followed, certain interactions inevitably occur. "There is no need for genes to encode and control those interactions directly. Instead, they follow from the laws of physics, geometry, topology – laws of great generality."

In this context, it is useful to recall the distinction between the genotype and the phenotype. The genotype is the actual genetic code, the genetic blueprint that influences every cell of our bodies. As all cells trace their beginnings to a single daughter cell, the genotypes of each cell must be identical. The result of how those genes express themselves is the phenotype, but there is no direct relation here. It is not the case that the genotype codes for the phenotype. While all cells have the same genotype, some become bone cells, some blood cells, some skin cells. Human beings possess some 256 different types of cells. These different cells arise as a result of epigenetic forces acting upon the genes to cause them to express themselves in different ways (e.g., "Cellular differentiation is a classic example where epigenetic phenomena have a critical role"). Genes express themselves in the context of a field of internal and external forces which impinge upon them. It is known that in addition to a cell's own internal chemistry, genes can be switched on and off by signals from other cells and from other aspects of the environment, including positional information, referred to earlier in this article. "The path linking genes or molecules to the expression of behavior is long and complex... There are innumerable ways genes can influence development, physiology, and the nervous system to affect behavior. Further, the genome has a dynamic relation with behavior, and each influences the other through complex regulatory mechanisms." The relation between genetics and behavioral phenotypes is extremely indirect. Thus, two strains

of inbred mice, C57BL10J and A/J, differ substantially in their aggressive behaviors, not a result of their inheriting aggressive or nonaggressive genes, but rather the result of their sensitivity to stimulation, a biological factor that is indeed an inherited trait, much as myopia is in human beings. The title of a review of T. C. Schneirla's writings reflected this: 'A long way from genes to behavior'.

The field of molecular biology has learned a great deal about the functioning of genes in the past few decades, exploding a number of ideas we now see to be myths. These include the notion that single genes affect single traits – eye color for example. While some single gene/single traits are known to exist, the common mode is for genes to act in concert with others. What a gene does, then, is very much influenced by which other genes are being turned on or off at any particular time during development. In other words, genes do their work along with other genes, rather than individually. The developmental process, then, is not a predetermined one, but, rather, a probabilistic one. Put another way, "Since it has become evident that genes interact with their environment at all levels, including the molecular, there is virtually no interesting aspect of development that is strictly 'genetic,' at least in the sense that it is exclusively a product of information contained within the genes."

Genes and Development

A common question, whether implicitly or explicitly posed, in theoretical papers regarding genetics, evolution, and development, asks what the role of biology is in shaping development. Such questions take the form of hypotheses regarding the relation between a given allele and trajectories of behavioral outcomes such as adolescent smoking or the heritability of attachment or the findings of fMRI studies correlating age-related declines in spatial abilities with changes in regional neural metabolism during a spatial memory task. In the case of evolution, if the research questions posed are even reasonably empirically testable, they tend to be framed in the form of the constraints that evolution places on behavioral development. Alternatively, evolutionary perspectives simply articulate putative adaptive explanations for developmental phenomena. In all of these situations, there is an underlying assertion that development is subsidiary to evolutionary trajectories and biological factors. In other words, ontogeny is a function of phylogeny and behavioral development is shaped by the organism's biology. From this perspective, biology is the fundamental and guiding force that drives individual differences in developmental trajectories of behavior.

However, a relational holistic position takes a dramatically different perspective on the relations between biology, evolution, and psychological development. From this perspective, development is an active system of processes superordinate to biology and evolution. Thus, it is not that the gene or evolution explains development, but that the developmental system explains the functioning of both the gene and the evolution. From this perspective, it is the developmental system that integrates biological functions into coordinated patterns which support behavior. It is the process of development that shapes biological organization and provides a temporal context

for biology–behavior–ecology interrelations. So, the question really is how does development shape biology and the relation of genes and neurons with behavioral outcomes in a given environmental context?

In endorsing this relational holistic position, we believe that the focus of study in psychology should be on the pattern of interrelations between biological structure, psychological states, and ecological contexts. A clear characterization of development, be it biological or behavioral, is that organisms are initially comprised of relatively undifferentiated biological and behavioral features which over time become increasingly differentiated and reintegrated into a coherent biological and behavioral system. It is the probabilistic epigenetic and self-organizing principles of development within a dynamic ecological context that shape the process of differentiation and integration which characterize a given individual's genetic, neurological, and behavioral attributes, rather than the other way around.

As early as 1929, Woodger made a very important distinction between the study of development in the form of embryogenesis and the study of genetics. The study of development has, as its focus, the patterns of biological and behavioral differentiation within a single organism over time. This notion of development is echoed in the recent work of Nesselroade and colleagues (e.g., see also Nesselroade & Molenaar, this volume) emphasizing the importance of methods for the study of intraindividual variability. However, the study of genetics has, as its focus, the pattern of differences in attributes between organisms at a given point in time. In relating the two sciences, Woodger stated that even at the turn of the twentieth century, the source of individual differences in patterns of differentiation were sought both in the nucleus and in the cytoplasm of the germ cells, yet these attempts were unsuccessful. But despite the consistent lack of empirical support for the genesis of developmental differentiation in the physical attributes of the germ cells, it is an assumption that has yet to yield. However, what has consistently been demonstrated empirically from experimental embryology at the turn of the twentieth century to contemporary molecular genetic studies is that the physical attributes of the cell, including protein formation and structure, are a direct result of developmental transactions of the biological aspects of an organism and the environmental context of that organism. As Woodger put it

The cells of a given developing embryo are internally related to one another in the sense that the rate and plane of division, at least, of a given cell, depend upon its relations to the neighbouring cells, and hence on its position in the whole. . . . At a certain period of development the cells of an embryo undergo intracellular elaboration depending partly on their mutual relations, and partly on their intrinsic properties so that the latter may be the same in all cells, [and] which of them are realized in a given cell will depend upon its relations to the whole, which will of course differ from place to place. (p. 384)

And so it would seem that nearly 90 years of empirical findings suggest that rather than searching for the source of intraindividual differentiation in interindividual differences, we should perhaps be looking for the source of interindividual differences in the patterns of intraindividual differentiation. The sequencing of the human genome has not yielded the

scientific fruit for behavioral science that many leading behavioral geneticists envisioned, as we discussed earlier. Rather, there has been a realization among cell biologists that genes do not carry biological or developmental information, and that they have the capacity to differentially respond to environmental and developmental signals originating at multiple levels of biosocial organization. As a result, there has been a resurgence of interest in epigenesis as a developmental process and of epigenetics as a mechanism through which genes and contexts transact through development.

While the concept of epigenesis originated in biology, with respect to behavioral development, the usefulness of *probabilistic* epigenesis was recognized and promoted throughout the twentieth century by psychologists such as Zing-Yang, Gilbert Gottlieb, Susan Oyama, and T. C. Schneirla, though Schneirla never specifically employed the term epigenesis in his writings. Probabilistic epigenesis has gained support from an exciting set of developments in contemporary science subsumed under the rubric of 'dynamic systems theory and relational developmental systems theory' in which complex developmental processes are understood as composed of interrelations among many active system components of the whole developmental system. The implication of this position is that in a dynamic and changing environment, rather than genes specifying a particular developmental outcome, be it structural or behavioral, *every outcome is an emergent result of the transaction between genes and their cellular, organismic, ecological, and temporal contexts*. This view of epigenesis is epitomized by recent discoveries in biology that even identical genomes in extremely similar environments do not always follow the same developmental pathways. Ko and colleagues studying enzyme activity in bacteria found that despite identical genomes and extremely uniform culture conditions, individual cells developed different levels of enzyme activity and grew into colonies of different sizes. Ko's studies showed that cell state in bacteria is determined not only by genotype and environment. Rather, "Changes of state can occur spontaneously, without any defined internal or external cause. By definition, these changes are epigenetic phenomena: dynamic processes that arise from the complex interplay of all the factors involved in cellular activities, including the genes" (Solé and Goodwin, 2000, p. 63).

In an impressive review of developmental processes shaping biological phenotypes, Rudel and Sommer have identified ten basic developmental principles that can adequately describe biological development. What is perhaps most intriguing about these principles is how few of them are genocentric. In fact, nearly all of them involve either epigenetic factors or epistatic genetic regulation.

Molecular Behavioral Genetics

Over the last decade, there has been substantial advancement in behavioral genetics as a result of being able to incorporate genes and their functions into traditional behavioral outcome studies. Three assessment techniques in particular have been quite valuable. The first quantitative trait loci (QTL) is a method for producing genetic maps of nucleotide sequences and comparing differences in a parent sample to those of an offspring sample

and correlating those differences to phenotypic outcomes. This technique is primarily aimed at identifying chromosomal regions in which heterogeneous allele distributions are associated with phenotypic variance. QTL provides a starting point for later molecular genetic analyses to link mechanisms of genetic expression to endophenotypes (neural mediators of behavioral outcomes). For example, QTL analyses have pointed to several candidate genes that appear to be associated with key socioemotional and behavioral outcomes. Foremost among these include the DRD4 gene and 5-HTT genes. The DRD4 gene is the dopamine D4 receptor gene and has been associated with a wide array of behaviors, including ADHD, externalizing behavior, and dimensions of temperament, including activity level and impulsivity. The 5-HTT gene is one of a series of serotonin transporter promoter genes that have been associated with more internalizing disorders as well as temperamental negative affect and anxiety. That these two genes have been associated with this broad array of behavioral outcomes is not surprising, given the well-known roles of dopamine and serotonin in molecular neuroscience and psychopharmacology, giving credence to the initial relationships demonstrated via QTL analyses.

However, a second key methodological technique, single nucleotide polymorphism (SNP), has demonstrated a more complex relationship between genetic variation such as those seen with DRD4 and 5-HTTLPR. SNPs are a more targeted analytic approach in which variance in the allele of a specific gene is correlated with variance in behavioral outcomes. The DRD4 gene, for example, has a 48 base pair variable number tandem repeat (VNTR) in exon 3. These repeats range in number from 2 to 11 and there is significant variance across individuals in the number of repeats. The DRD4-7r is a 7 repeat allele and seems to be less responsive to dopamine molecules (xxx) and seems to be associated with the array of behavioral outcomes described previously. Interestingly, but not surprising to many developmental psychobiologists, the association with behavioral outcomes is highly context-dependent. Caspi et al first described the strong influence of behavioral context on gene-behavior relationships in their landmark study showing that a variant of the 5-HTT gene was associated with adult depression, but only in the context of elevated life stressors. Similarly, we see this pattern of gene X environment interaction or as more recently referred to as gene X environment interplay.

The role that genes play in behavioral development across the life span is a perennial source of enthusiasm and controversy in psychology. Driven by the remarkable progress in molecular genetics research over the last decade, this discourse has reached yet another watershed for developmental science. Indeed, the focus of debate has moved away from the traditional nature-nurture controversy to a broad acceptance of gene-environment interactions or interplay. As such, the manner in which genes and environments mutually effect each other and how their interplay conjointly influences behavioral trajectories is the overarching question driving contemporary gene-environment research. For instance, there is a growing recognition that genes do not necessarily code for any specific phenotypic outcome, but rather play an interdependent role in the potentialities of a phenotypic dimension. Recent research trends incorporate the growing recognition that genetic effects

need to be considered at an appropriate level of analysis and that they are participatory components of a dynamic, integrated biopsychosocial system. There is also a growing recognition that structural features (i.e., nucleotide sequences) are of less consequence than the functional synthesis of proteins. No more profound finding has emerged from the plethora of molecular genetic research than the dissolution of the dogma of a one-to-one relationship between a given nucleotide sequence and the resulting protein. The same gene can synthesize different proteins, depending on the spatial and temporal context of the synthesis process. This has led to much greater recognition of the probabilistic epigenetic approach to gene functioning, as well as the adoption of a norm-of-reaction (as opposed to the more traditional reaction range) concept in relating genotype to phenotype. Finally, with the ability to measure genetic effects directly, there has been a marked increase in our understanding of the consequences of ecological effects on the functional genome. This has moved gene-behavior research toward a more dynamic and transactional model of gene-environment interplay.

Glossary

Autonomy The capacity to govern oneself according to one's own reasoning.

Disequilibrium The first part of stage transition in which the equilibrium or balance achieved at a particular stage is disturbed by a cognitive conflict.

Heteronomy The subordination of the self to an external authority, law, or source of influence.

Intentionality The child's ability to take into account intentions and motives in making judgments of praise and blame.

Longitudinal study A method that assesses the same individuals over time.

Perspective or role-taking stages Stage that describe the ability of children to take the view of others and to coordinate different viewpoints.

Structural wholeness The assumption that a cognitive developmental stage is characterized by an organized pattern of reasoning that underlies particular content considerations of moral choices and values.

Transformational model A model of stage development in which the lower stages are integrated by the higher stages.

A Historical Overview

Introduction

How humans develop from impulse-governed infants to morally responsible adults has been a question of perennial concern and debate since the time of ancient Greece. Socrates, for example, believed that one's morality developed through rational inquiry into the nature of the good. He, therefore, challenged the youth to question the morality of the status quo, a practice that led to his being sentenced to death. Aristotle, on the other hand, emphasized the role of habituation in forming virtue. In his view, individuals learn how to be moral much the way apprentices learn their craft.

In the first half of the twentieth century, the discussion of moral development took a more radical turn as psychoanalytic and behavioral psychologists called into question the very notions of universal morality, character, and virtue. The most significant of all research at this time was Hartshorne and May's landmark study of deception, self-control, and service. They indicated that moral behavior does not depend on an individual's character or virtue but is a function of influences operating in the situation. Following Hartshorne and May, the psychological study of morality, as it has traditionally been understood, practically ceased, until the cognitive developmental approach of Piaget and Kohlberg took hold in the 1960s and 1970s. That approach dominated the field of psychology well into the 1990s. At the turn of the century, evolutionary psychology, neuroscience, and cultural anthropology have challenged the foundations of the cognitive developmental approach. On the other hand, Turiel's domain theory and Blasi's investigations into the moral dimensions of the self have refined and enlarged the scope of the cognitive developmental approach.

Psychoanalytic Theory

Psychoanalytic theorists take their definition of what is moral from the norms and values of the existing culture. They describe the operation of becoming moral as the internalization of those cultural norms and values in the superego through a process of

parental identification, which according to Freud, culminates in the resolution of the Oedipal conflict at age 5 or 6. In their research, they typically look for correlations between early childhood parenting and behavior, and between the arousal of guilt and behavior. This paradigm presents the essence of moral functioning as following one's conscience in order to avoid guilt. Given the irrational nature of the superego, psychoanalytic theorists are concerned not only that cultural standards are upheld but also that the superego does not become excessively punitive.

Social Learning Theory

Social learning theorists tend to equate morality with societal norms and more broadly with other-oriented or altruistic actions. Like the psychoanalytic theorists, they maintain that individuals become moral through the internalization of those societal norms. In place of processes of parental identification, however, social learning theorists, such as Bandura, attempt to demonstrate that norms are acquired not only through external rewards and punishments but through observational learning and intrinsic reinforcement. Children are, in this view, initially motivated to satisfy their own needs and desires. They are then shaped or socialized by environmental mechanisms to find satisfaction in socially approved and other-oriented actions. The test of a person's morality is thus whether she or he will adhere to a social norm or perform an altruistic action without the expectation of a reward or punishment.

Cognitive Developmental Theory

Cognitive developmentalists reject the assumption shared by psychoanalytic and social learning theorists that morality can be equated with culturally relative standards. Taking an explicitly philosophic stance, they maintain that morality is a process of adjudicating conflicting claims on the basis of universally recognized principles of justice and benevolence. Cognitive developmentalists see moral development as occurring through a sequence of stages in which individuals reason about moral

problems in progressively more adequate ways. In contrast to psychoanalytic and social learning theorists, who view the child as being passively formed by environmental forces, cognitive developmentalists picture the child (and later the adolescent and adult) as developing a personal moral perspective through interacting with the environment.

Piaget's Theory

The Moral Judgment of the Child

The study of moral development as we know it today drew its initial inspiration from Jean Piaget's seminal study, *The Moral Judgment of the Child*; it is the fifth of a series of books that Piaget published at the beginning of a highly productive career. Developmentalists either have focused directly upon these studies to elaborate, refine, and confirm their conclusions or, like Kohlberg, have used Piaget's ideas and methods as a springboard for their own theories. *The Moral Judgment of the Child* is subdivided into three empirical parts and a fourth theoretical part in which Piaget contrasts his views on moral development and education with those of other theorists, most notably, the great French sociologist Emile Durkheim.

Heteronomy and Autonomy

In the first part of *The Moral Judgment of the Child*, Piaget examines the ways in which children from the ages of 3–12 understand and apply the rules of marbles and hopscotch, the most popular children's games in French-speaking Switzerland. Piaget believed that by studying children at play, he could penetrate into their own moral world, a world that they were attempting to understand and control on their own terms. Feigning that he had forgotten the rules of the game, he asked the children to teach him and let him play with them. He then proceeded to ask the children about the various shots in the game and how to determine the winner. All the while, he played the game as seriously as he could, letting the children beat him to sustain their sense of superiority but making an occasional good shot to avoid being dismissed as incompetent. Having determined children's 'practice of the rules,' Piaget proceeded to inquire into their consciousness of the origins of rules by asking such simple questions as Can you make up a new rule. Would it be all right to play like that with your pals. Have people always played as they do today.

Piaget found that young children (usually under the ages of 8) typically believed that adults made the rules and the rules could not be changed. On the other hand, older children (usually over the age of 9) readily believed that they with their peers were authorized to make and change rules. Piaget theorized that children's belief in the creation of rules by adult authorities reflected a quasi-mystical, heteronomous respect for the rules, while older children's belief in their own power to make rules reflected a secular, autonomous respect. As is most evident in the final section of his book, Piaget's perspective was deeply influenced by Durkheim, whose views on the sociology of religion and moral education were highly influential at that time. According to Durkheim, respect for rules could be generated only if the rules were regarded as emanating from a power superior to the individual. Durkheim's historical studies led him to postulate

that religion and morality were originally undifferentiated and that all rules were regarded as sacred because of their divine origin. With societal evolution, rules became secularized, but, retained their power to elicit respect because of their transcendent, societal origin. In Durkheim's view, rules elicited respect only if they were seen as issuing from a superior, quasidivine being. Individuals, therefore, had to look beyond themselves to the collective being of society as the authority behind the rules.

Piaget's entire book may be regarded as an effort to respond to Durkheim by showing that children develop an alternative, autonomous morality through cooperative peer relationships. Unfortunately, his preoccupation with Durkheim's view seems to have foreclosed his exploration of other types of moral reasoning, types later uncovered in Kohlberg's research. What Piaget's analysis loses in breadth, it gains, however, in depth by juxtaposing moral heteronomy with moral autonomy.

Egocentrism

Piaget found that children at the heteronomous stage flagrantly but unwittingly broke the very rules that they regarded as sacred and immutable. Piaget explained this paradox as a function of childhood egocentrism. This term should not be confused with egoism or selfishness; it simply connotes children's inability to distinguish their subjective perspective from the perspective of others. As Piaget and others have noted, egocentrism is a salient characteristic of children's speech and play. For example, when telling stories or making requests, young children typically fail to take the needs of their listeners into account. They seem to assume that their listeners know what they are talking about. Similarly, when young children play with one another, they tend to parallel play or play as individuals in the company of others.

Although young children tend to behave in egocentric ways, there is considerable debate over whether their egocentrism should be regarded as a stage of cognitive immaturity. Some research indicates that very young children are capable of altering their speech and actions to meet the needs of others, and Piaget himself had noted that even adults can be egocentric in expressing their opinions. There are other studies, however, that have reconceptualized the egocentrism construct to consist of a stage of perspective or role taking in turn influences concepts of the self, friendship, groups, and morality.

Overlooked in this debate, as Youniss has noted, is the relational dimension of the egocentrism construct. Piaget consistently maintained that the unequal relationship that children have with adults fosters egocentrism by encouraging children to submit to the adult authority. On the other hand, the equal relationship that exists among peers encourages children to consider their perspective in making reasonable decisions through mutual agreement. Piaget's relational perspective on moral development leads to the radical conclusion, elaborated in a provocative study by Youniss, that peers, not parents, play the decisive role in promoting moral development.

Intentionality

In the next section of the book, Piaget examined children's modes of moral evaluations with a focus on the origin of children's awareness of intentionality. The best known of his

queries asks who was the naughtiest, a child who knocked over 15 cups accidentally or a child who broke 1 cup in an act of disobedience. Piaget found that children below 8 or 9 years old typically based their judgments of culpability on the extent of material damage. The older children, however, recognized the moral relevance of the intentions of the actors. Conceding that objective responsibility may largely be a function of the way in which parents respond to children's clumsiness, Piaget observed that his own young children made spontaneous judgments of objective responsibility, even though he and his wife were careful not to punish or blame their children for unintentional damage. Furthermore, Piaget found that when considering cases of stealing and lying, younger children tended to make judgments of objective responsibility that their parents would be very unlikely to make. For example, the younger children regarded lying as saying something untrue, whether or not the misstatement was made intentionally. The mere violation of moral rule was a sufficient determinant of guilt. As in his discussion of egocentrism, Piaget attributed young children's failure to differentiate moral from physical laws (moral realism) and intentions from consequences partly to their immature thinking and partly to authoritarian child rearing practices.

The Two Moralities of Childhood

In the third section of the book, Piaget studied children's conception of punishment and distributive justice. Although his data indicated that development generally proceeds from heteronomy to autonomy, the many exceptions to this pattern suggested that heteronomy and autonomy are not sequential stages but two irreducible types built on different relational foundations. For example, Piaget found that young children see expiatory punishment as fair only in the adult-child relationship, whereas, in the child-child relationship, children at all ages favor what Piaget called punishment by reciprocity, that is punishment aimed solely to make the transgressor aware of the undesirable consequences of his or her misdeed.

Post-Piagetian researchers, as indicated, have tended to view sociomoral development in a more cognitive and less relational framework than Piaget. Although this may have led many researchers to underestimate the effects of constraint and cooperation on sociomoral problem-solving, it also led to important breakthroughs in the study of such topics as perspective-taking and intentionality. Furthermore, in the case of moral development, the cognitive developmental focus has led away from the two morality hypothesis to a unitary process of stage development.

Kohlberg's Theory

The Moral Domain

When asked to give his views on moral development and education, Lawrence Kohlberg was fond of citing Socrates' response to a similar request at the beginning of Plato's *Meno*: "You must think I am very fortunate to know how virtue is acquired. The fact is, far from knowing whether it can be taught, I have no idea what virtue really is." Kohlberg, like Socrates, did not believe that one could address questions of moral psychology and

education without first attempting to define in a philosophically justifiable way the nature of morality. Yet in the mid-1950s, when Kohlberg began his dissertation research on moral development, social scientists paid little if any attention to the philosophical presuppositions of their work.

Kohlberg was particularly distressed by the claim prevalent in social learning research and psychoanalytic theory that moral development reduces to the internalization of the rules and practices of one's society. Having become involved in the Hagganah's effort to smuggle European Jewish refugees into Israel following the Holocaust, Kohlberg was committed to an understanding of morality that transcends the status quo and provides a rational basis for responsible social criticism. He also questioned the assumption that morality can be reduced to culturally relative norms and values. Such an assumption, based on observed cultural differences, blurs an important distinction between morality and custom or social convention. Moral norms and values, such as prohibitions against causing physical injury, concern the rights and welfare of individuals in any societal arrangement. Customs or conventions (e.g., table manners), on the other hand, concern socially imposed rules that provide a certain order and decorum but are not recognized as obligatory in the same sense as moral norms.

In addition to differentiating morality from custom, Kohlberg also distinguished morality from personal and religious values or the right from the good. Underlying the distinction between the right and the good is a recognition that what is right or moral is obligatory, whereas what is good is left to individual choice, as long as it is in harmony with what is right. Kohlberg used this distinction to argue that moral education could be undertaken in public schools without violating the separation between church and state or without indoctrinating personal values.

Following up on Kohlberg's philosophical attempt to delineate the moral sphere, Turiel and his colleagues have proposed that morality, convention, and personal values comprise three conceptual domains, each with its own developmental trajectory. Their research indicates that even very young children are capable of distinguishing moral violations from violations within the other domains. Such findings confirm the wisdom of Kohlberg's effort to base his research on a carefully defined conceptualization of morality, even as they call into question whether he consistently distinguished the moral from the conventional in some of his stage descriptions.

The Moral Judgment Interview

Kohlberg's definition of morality as justice, his emphasis on studying the development of moral reasoning, and his aim of charting moral development throughout the life span led him to construct a semiclinical moral judgment interview. His original interview posed ten hypothetical moral dilemmas drawn, not from familiar episodes in the world of children (as were Piaget's) but from challenging problems in the world of adults. Kohlberg regarded the Heinz dilemma (slightly abbreviated here) as his best:

In Europe, a woman was near death from a special kind of cancer. There was a drug that could save her but the druggist was charging twice as much as the sick woman's husband, Heinz, could raise.

Heinz pleaded with the druggist, but the druggist said, "No, I discovered the drug and I'm going to make money from it." Heinz has exhausted all other alternatives, should he steal the drug?

The Heinz dilemma puts subjects in the uncomfortable position of having to decide between his wife's claim to life and the druggist's legally sanctioned claim to property. The point of the interview is not to identify subjects' action choices but to examine the ways in which they justify their choices; therefore, interviewers are instructed to ask subjects to present, elaborate, and clarify their arguments.

Levels and Stages

Kohlberg's current theory describes a sequence of six stages grouped into three levels: the preconventional level (stages 1 and 2), the conventional level (stages 3 and 4), and the postconventional level (stages 5 and 6). As the labels indicate, the levels are determined by the perspective taken on the moral expectations (rules, roles, norms, and values) of the conventional social order. The word 'conventional' connotes simply what is commonly accepted and should not be confused with Turiel's use to mean a non-moral custom. At the preconventional level, conventional expectations are seen as external to the self. The obligation to follow such expectations comes not from their intrinsic worth or their place within the social fabric but from the mere fact that they are commanded or that noncompliance is punished. At the conventional level, conventional expectations are internalized. Conventional expectations are respected because individuals value their membership in society and want to be regarded as upstanding members of their communities. At the postconventional level, conventional expectations are subordinated to general, foundational principles. Conventional expectations are critically appraised according to such principles from a prior to society perspective, that is from the perspective of a moral agent aware of basic rights and values that all societies should recognize.

Like the levels, the structural core of the stages depends upon what Kohlberg calls the sociomoral perspective of the subject. At stage 1, individuals are, to use Piaget's term, egocentric: they fail to differentiate their perspective from others, particularly those in authority who are valued for their superior size and power. As a consequence, those at stage 1 believe that rules are to be obeyed for their own sake or for the avoidance of punishment, which is seen as inevitable. For example, children at this stage often state that Heinz should not steal the drug simply because stealing is wrong or because his theft will be punished. At stage 2, individuals are aware that individuals have concrete wants and desires and that such wants and needs can come into conflict. It is right to pursue one's interests as long as others are not prevented from pursuing theirs. Individuals at this stage sometimes justify Heinz's stealing simply by appealing to his wife's need or to the presumption that anyone in Heinz's situation would not want their wife to die or would automatically do what was necessary. They will likewise justify Heinz's not stealing by noting that the risk of punishment may not be worth it. Conflicts of interest are to be settled by making deals. For example, Heinz should steal the drug for his wife in return for what she has done for him or because he may need a favor from her sometime.

At stage 3, individuals take a third-person perspective and view themselves and others not only as individuals, but also as members of relationships or small groups. They seek to uphold shared expectations for good behavior and value sympathetic and prosocial motives. For example, subjects will argue that Heinz should steal the drug because he loves her or because he is her husband. On the other hand, they will also argue that Heinz should not steal because stealing is selfish or takes advantage of the druggist who works hard. At stage 4, individuals assert that the social system and respecting of laws and legal processes are necessary for maintaining social order. Just as they see the need for consistency in society, they also see the need for developing individual character and respecting the dictates of conscience. At this stage, individuals sometimes maintain that Heinz should not take the law into his own hands by stealing. They will, however, also maintain that stealing may be justified in response to an idealized natural law that is higher than the human law.

At stage 5, individuals take a prior-to-society perspective and judge the moral worth of rules and values insofar as such rules and values are consistent with more fundamental considerations such as liberty, the general welfare or utility, human rights, and contractual obligations. They typically argue that Heinz should steal the drug because the right to life is more basic than the right to property. At stage 6, individuals take a procedural or dialogical perspective on decision-making. What is right is what would be freely chosen by all interested parties who take one another's point of view into account and who respect others as equal and autonomous persons. Those at this stage make explicit appeals either to a procedure for adjudicating claims or to universal, regulative principles of justice.

The empirical status of stage six is uncertain. Although stage 6 continues to be listed in the table of stages, the current scoring manual provides only criterion judgments through stage 5 because no stage 6 examples were found in the longitudinal sample. The current formulation of stage 6 is embedded with the contractarian tradition in moral philosophy extending from Rousseau and Kant to Rawls and Habermas. Such a formulation and the fact that the few examples of stage 6 cited by Kohlberg come from individuals with philosophic training suggest that stage 6 may not be a psychological stage but a philosophical position.

Reliability and Validity

At the very heart of cognitive development theory are the assumptions of invariant stage sequence and structural wholeness. The test of invariant sequence is whether individuals develop through the stages in ascending order without skips or reversals. The test of structural wholeness is whether individuals respond to different kinds of moral dilemmas by using the same or adjacent stage reasoning. These assumptions have guided efforts over the years since Kohlberg's dissertation to refine the stage description and methods for scoring the interviews. The early definitions and procedures for scoring were based on moral content, that is, the moral concerns and values typically associated with a particular stage. For example, a simple statement of concern for law and order was scored as stage 4. At the 10th year of Kohlberg's longitudinal study, problems of regression and stage heterogeneity across the

different dilemmas called the cognitive developmental assumptions of Kohlberg's theory into question. Case analysis indicated that regressions were occurring because content, like the law and order concern, was being coded as stage 4 regardless of its meaning in the larger context of the interview. Kohlberg thus revised both his stage definitions and his scoring method to focus on structure rather than on content. Because the structural scoring method required far greater interpretive judgment than the earlier method, interrater reliability suffered for a time, prompting critics to challenge the empirical foundation of the theory.

In response, Colby, Kohlberg, and their colleagues developed the present Standard Issue Scoring Manual, which supplements the structural scoring process by providing over 700 prototypes (criterion judgments) of common responses to nine dilemmas. Stage scores are assigned by matching arguments in the interview to these criterion judgments. This new method achieves high interrater reliability (from 88% to 100% agreement within a third of a stage) by eliminating much of the subjectivity in the structural coding method, while, nevertheless, providing guidance for distinguishing content from structure.

The case for the validity of the measure is based on how well longitudinal data support the major theoretical assumptions of invariant sequence and structural wholeness. Three major studies, of US males, of Turkish males from rural and urban areas, and of male and female adolescents from an Israeli kibbutz, were used to determine the validity of the construct. All of the studies show that development proceeds through an invariant sequence. There were no instances of stage skipping or stage reversal within the limits of measurement error (determined through test-retest instability). All of the studies also indicate that development proceeds as a structured whole. Individuals generally respond to different dilemmas using one or two adjacent stages (e.g., at stages 2 and 3). Cases in which three stages are used are infrequent (<10%). The data thus support Kohlberg's major theoretical claims as well as the adequacy of the methodology.

Cross-Cultural Validity

Longitudinal studies in Turkey and Israel and cross-sectional studies in over 25 Western and non-Western countries, which include populations from both urban and traditional folk societies, generally support the universality of the moral stages. Although content differences were found and stage development in folk societies rarely got above stage 3, the interview responses were generally codable with the new manual and the pattern of the sequential stage development and structural wholeness was similar to that of the US longitudinal sample.

New Directions

The Defining Issues Test

The Defining Issues Test (DIT) was developed by Rest as an alternative to the moral judgment interviewing and scoring procedures for individuals at or above a 12-year-old reading level. It presents participants with stage prototypic responses to six moral dilemmas and asks them to rate and then rank

their preferences. Although the DIT has been widely and successfully used as a proxy for the clinical moral judgment method (it correlates moderately well with the Kohlberg measure), it is an important measure in its own right. The DIT measures individuals' comprehension of and preference for moral arguments. Finding considerable rating and ranking heterogeneity in the DIT and charging that Kohlberg's scoring procedures have tended to smooth over significant stage irregularities, Rest and his colleagues have proposed that a moral schema model of development may be more adequate than Piaget and Kohlberg's transformational or displacement stage model. Support for the schema model comes not only from DIT research but also from studies indicating considerable stage heterogeneity when comparisons are made between standard and nonstandard moral dilemmas and between hypothetical and real-life dilemmas. Furthermore, most post-Piagetian psychologists, influenced by cognitive psychology, prefer a more differentiated and incremental approach to development. The evidence favoring the holistic, transformational model comes from production tasks, like the moral judgment interview, which is designed to assess the moral reasoning competence and to facilitate the interpretation of discrete ideas into a more comprehensive framework.

Early Childhood Development

Kohlberg's longitudinal sample begins with 10-year-olds because the original intent of his research was to build upon Piaget's work. The nature of his moral dilemmas would have precluded his starting much earlier because they were specifically designed to describe how individuals develop the capacity to resolve moral problems in the adult world. Yet, such dilemmas emphasize the limitations of children's thinking (as is evident in the punishment and obedience description of stage 1). Returning to Piaget's method of presenting children with familiar problems, Damon demonstrated that the sociomoral conceptions of young children (ages 4–9) in the areas of distributive justice, friendship, and authority develop through surprisingly varied and sophisticated developmental levels. For example, in describing the development of children's resolutions of distributive justice problems, Damon described a six-level sequence in which children based their judgments on the following sequence of considerations: their own desires, strict equality, merit, equity, and combinations of merit and equity that best serve the common good.

More recent work by Kochanska suggests that the precursors of conscience develop in toddlerhood when children demonstrate a capacity for understanding rules and a willingness to comply with them. Conscience develops in the preschool years and later as children monitor others' thoughts and feelings in relation to their own and develop the emotions of shame and guilt.

Gender and Development

Gilligan has since the mid-1970s charged that Kohlberg's stage theory is biased against women because it describes the justice and rights orientation favored by males, while it neglects the care and responsibility orientation favored by females. She attributed the one-sided orientation of Kohlberg's

approach to his embeddedness in the Western male philosophical and psychological traditions, his all-male sample, and his use of hypothetical moral dilemmas, which were better suited to males, who preferred abstractions, than to females who preferred context. Originally, support for Gilligan's critique came from several studies showing women's moral judgment scores were, on the average, lower than those of men. Yet, reanalyses of those studies indicated that once adjustments were made for education and occupation, differences between men and women disappeared. Gilligan has, nevertheless, persisted in her claim that an alternative theory is needed to describe women's moral voice. She maintains that Kohlberg has overlooked the dynamics of relatedness and interdependence, dynamics that require a radically new approach to moral psychology.

In spite of the popularity of Gilligan's criticism, there is little evidence to support the view that men and women follow radically divergent development paths. On the other hand, Gilligan's analyses suggest that men and women may have somewhat different moral concerns and sensitivities.

Culture and Morality

Drawing on anthropological research, Shweder argues that although individuals across cultures share similar moral concepts, individuals adopt culturally diverse ways of thinking and valuing. Shweder believes that Kohlberg and Turiel's approaches to moral development fail to articulate distinct ethical systems, which characterize different cultures. Shweder identifies three different ethics: autonomy, community and divinity, which have their own views of the person and their own kind of moral reasoning.

Moral Judgment and Moral Action

In an effort to organize the literature on moral action and to integrate relevant research in areas other than cognitive moral development, Rest has proposed that the internal processes leading to moral action be divided into four sequential components or phases: (1) interpreting the moral situation, (2) formulating the moral ideal, (3) choosing a course of action in the light of one's moral and nonmoral values, and (4) executing one's choice.

The process of moral action begins with a perception that one is in a situation that is likely to require a moral response. Feminist ethicists have pointed out that key to this perception is what Weil and Murdoch have called attentiveness and what Noddings has called engrossment, a sensitive openness to and focused awareness of the needs, thoughts, and feelings of others. Their analyses as well as the studies of Eisenberg and Hoffman among others point to the critical role that empathy plays in motivating individuals to become involved and in providing information about the source of the other's distress and how it may be alleviated.

The second phase involves the reasoning and decision-making process that result in a moral judgment or in the determination of a moral ideal. The cognitive developmental approach has dominated the research in this area; yet, it has only identified deep structures of moral reasoning. Such structures do not directly predict behavior or action choices, yet, the

stages of moral judgment have been shown to be related to delinquency, altruism, resistance to the temptation to cheat, the clinical performance of medical interns, participation in the Berkeley Free Speech Sit-in, and a willingness to disobey in the Milgram experiment. In most studies, the higher one's moral stage was, the greater the likelihood that one would perform the putatively moral action.

In the third phase, individuals ascertain the extent to which they feel personally responsible for acting on their moral choices at the second phase. For example, many of those who participated in the Milgram experiment admitted that it was wrong to administer painful shocks, but nevertheless, believed that they did not have a responsibility to quit the experiment because they were following the instructions of the psychologist in authority. Blasi's research indicates that as individuals develop, they experience themselves as more autonomous, that is, as more personally responsible for their values, decisions, and actions. Judgments of responsibility, while related to cognitive moral development, appear rooted in the processes of identity and personality development. Colby and Damon found that moral exemplars could be characterized less by a high stage of moral reasoning than by the centrality of moral commitments to their sense of identity.

In the fourth phase, moral aims become moral deeds. Many personality variables play a role at this phase. For example, research by Krebs and Kohlberg indicated that stage 4 subjects with high ego strength were better able to resist the temptation to cheat than stage 4 subjects with low ego strength. Research by Haan showed that defenses and coping and self-assertion strategies play an important role in the way in which individuals interact in game-simulated moral situations. Recent studies by Oser and Weil suggest that moral action in the political realm requires specific organizational competencies.

Promoting Moral Development

Cognitive developmentalists generally explain stage change as the result of the disequilibrium brought about by experiences that are not readily assimilated within a person's existing cognitive structure. Such experiences are thought to lead to cognitive conflict, which in turn leads to the construction of a new stage. Experimental and educational research suggest that experiences fostering moral development provide at least one of the following conditions: (1) exposure to a higher stage of reasoning, (2) exposure to a conflicting opinion (at the same stage as one's own), and (3) perspective taking.

Relatively little attention has been paid to the role of families in promoting moral development. This is partly due to the research showing that moral development is not confined to early childhood as Freudians among others had posited but continues into adulthood. The lack of attention to the family may have also been influenced by Piaget's belief that the parent-child relationship tends to foster a heteronomous morality. There is a growing body of research, however, that indicates that the parenting style and the nature of family discussions play a significant role in stimulating moral development. Baumrind, for example, has found that the most effective parenting is neither authoritarian nor permissive, but authoritative. Authoritative parenting combines a high level of parent and child communication with control and

realistic demands. Focusing on family discussions, Power has identified that the patterns most conducive to moral development blend cognitive challenges with affective support.

Considerable research has been conducted on educational applications of moral development theory. The most widely used approach based on cognitive developmental theory is the discussion of moral dilemmas. Hundreds of studies have found that moral discussions led by a teacher-facilitator employing Socratic questioning techniques promote modest (about a third stage) but significant stage change.

Kohlberg, Higgins, and Power have developed a more radical moral educational strategy, the just community approach, which builds on Piaget's view that moral autonomy is fostered under conditions of equality and reciprocity. Just communities consist of a relatively small group (from 30 to 90) who take a core of courses together and who make and enforce their rules with their teachers in a direct participatory democracy. Research in the United States and Europe (e.g., by Oser) indicates that the just community approach not only promotes the development of moral reasoning but also nurtures the students' sense of responsibility and agency.

Key to the 'just community' approach is an emphasis on building a positive moral culture. This culture has been described in terms of the extent to which norms and values expressive of a relatively high stage of fairness and group solidarity are shared and upheld by members of the program. A positive moral culture appears to provide both a motivating and a disequilibrating context for moral development. Students are attracted to a democratic group that they perceive as genuinely caring. At the same time, students are challenged by membership in a group with high expectations for responsible behavior.

The EQUIP program for juvenile and adult offenders, which Gibbs and Potter devised, also emphasizes the importance of building a positive moral culture. The key to EQUIP is identifying and addressing cognitive distortions that trap individuals in immature ways of thinking and behaving.

Conclusion

The study of moral development emerged in the early 1960s as the seminal cognitive developmental studies of Jean Piaget

and Lawrence Kohlberg and captured the attention of developmental and social psychologists. The initial phase of cognitive developmental research focused on the description of stages of reasoning from childhood through adulthood. The current phase of research seeks to understand the relationship between moral reasoning and moral behavior by exploring dimensions of the self as well as the social environment.

Glossary

Compassion It is an emotional state in which the emotional capacities of empathy and sympathy are linked to an active desire to alleviate another's suffering.

Empathy It is an affective and cognitive response that stems from the apprehension of another's emotional state. The affective response is similar to what the other person is feeling. The cognitive response is the intellectual identification with the feelings of another.

Guilt feelings These are painful feelings of regret that are aroused when the actor causes or believes to have caused a transgression and accepts responsibility for violating internalized norms.

Happy victimizer It is a phenomenon in which young children expect a moral perpetrator to be happy, even though they understand the validity of the moral rule.

Moral emotions These are self-evaluative and other-oriented emotions, evoked by the individual's

understanding and evaluation of the self or by an affective response to the emotional state of the other.

Moral judgments These are making decisions and evaluations that are moral (i.e., based on internal principles).

Pride These are positive emotions that are generated when the self resists moral temptations and acts in accordance with obligations and responsibilities and/or if one is responsible for a moral action.

Respect It is a positive emotion of esteem for a person in his or her quality as a human being.

Shame It is a negative feeling that is evoked by the experienced wrongness of the aspects of one's being.

Sympathy It is a feeling of concern for the other stemming from the apprehension of another's emotional state, but it is not the same feeling as the other person may experience.

For centuries, psychologists and philosophers have debated on how to frame the role of moral emotions in human morality. Recently, this question has experienced a renaissance. Although the issue is far from resolved, there is a consensus that moral emotions and ordinary moral concepts are linked. For example, moral emotions, such as compassion or guilt feelings, are recognized as influencing a person's understanding of the prescriptive nature of the norms of fairness and caring. Therefore, developmental researchers have called for an integrative approach to the study of moral emotions and moral cognitions, as well as their emergence in human moral development.

Although moral judgments are assumed to be at the core of morality, it is also claimed that moral emotions help children and adolescents anticipate the outcomes of sociomoral events and adjust their moral action tendencies accordingly. Thus, moral emotions can serve as motives for morally relevant action. Moral emotions such as sympathy represent a genuine orientation toward the other's welfare; conjointly with moral cognition, they are important to the early development of moral action tendencies. Obviously, the relationship between moral emotions and moral action is complex. Thus, feelings of guilt do not necessarily prevent the violation of moral rules. Rather, their presence following a moral violation indicates moral awareness. This awareness of personal responsibility has been interpreted as an indicator of the beginnings of the moral self.

The aim of this article is to review selected current theory and research on central moral emotions such as guilt and shame in childhood and adolescence. We focus on the framework of the happy victimizer research paradigm, because most of the recent developmental research on moral emotions has

been conducted within this framework. Furthermore, we discuss relations between moral emotions and social behavior. Additionally, we describe educational approaches to enhance the development of moral emotions.

Defining Moral Emotions

Moral emotions are considered to be a key element of human moral experience. Typically, they are linked to the interests of society or other people. Developmental researchers have defined moral emotions as self-conscious or self-evaluative emotions, because they are evoked by the individual's understanding and evaluation of the self. Moral emotions may play an important (influential) role in why individuals adhere or fail to adhere to their own moral standards. Psychological theories on morality have described emotions such as guilt, shame, and compassion and also positively charged emotions such as pride as a quintessential part of children's emerging morality, because these emotions genuinely express the moral orientation of internalized norm orientation. Tangney et al., distinguished between self-conscious moral emotions (guilt, shame, embarrassment, and moral pride) and other-focused moral emotions (righteous anger, contempt, disgust, elevation, and gratitude).

Guilt has been defined as a painful feeling of regret over wrongdoing. Thus, guilt feelings indicate the self's awareness that he or she has acted in a morally wrong way and takes responsibility for his or her actions. They create desires to punish the self or to recompense. Shame has been defined as negative feeling evoked by the experienced wrongness of the

aspects of one's being. In contrast to guilt, ashamed people focus on devaluing and degrading aspects of the entire self, and it is often associated with the desire to undo the aspects of the self and/or self-destructive behavior. Embarrassment has been defined as a less intense form of shame. Compassion is defined as cosuffering. It describes an emotional state in which the emotional capacities of empathy and sympathy are linked to an active desire to alleviate another's suffering. It is viewed as the key component in what manifests in the social context as altruism, because compassion is seen to motivate care-taking behavior.

Positive moral emotions such as pride have been relatively neglected in research on moral emotions. Mascolo and Fischer define pride as an emotion generated by appraisals that one is responsible for a moral outcome. Moreover, researchers discussed other-oriented empathy as a morally relevant emotional process with both affective and cognitive components. Although empathy/sympathy is considered an important moral emotion, it is not being discussed in this article since it is being discussed elsewhere in this Encyclopedia. Finally, several researchers have considered respect as a moral emotion. Respect has been defined as a positive feeling of esteem for a person in his or her quality as a human being.

The idea that emotions are self-conscious and include evaluations shows that moral emotions are complex. Emotions such as guilt or sympathy are based on an understanding of the other person's circumstances and/or one's own internalized moral standards and constitute the basic motive in situations calling for moral actions. Thus, several researchers have argued that moral emotions are inevitably intertwined with cognitive moral processes. A strict distinction between cognition and emotions seems therefore not necessary in the concept of moral emotions.

Theoretical Model of Moral Emotions

Moral emotions such as guilt feelings indicate that the self feels committed to a norm. Thus, researchers have interpreted the existence of moral emotions as an early precursor and antecedent of the development of the moral self. Developmental research has supported the argument that moral emotions such as guilt feelings are the primary motive in situations calling for moral actions. They motivate reparative behavior, such as apologies, and they restrict immoral, aggressive behavior. However, if moral emotions are not anticipated, it is likely that cognitive moral complexity will be used strategically to achieve personal goals. Thus, understanding emotions in the context of moral conflict is important if we are to understand how young people resolve the conflicts that occur inevitably in everyday life.

An understanding of complex moral emotions, such as guilt feelings or shame, is assumed to emerge around the age of 6–8 years. The understanding of guilt feelings requires complex cognitive abilities, namely, the integration of the understanding of a moral rule's validity with the understanding that other's evaluation of the self depends on the self's own actions. Developmental studies support the conclusion that emotions in the context of moral conflict are a salient feature of children's experience of rule violations and that they help children

to increasingly differentiate their moral judgments from other social judgments. From a motivational perspective, moral emotions such as guilt, shame, or embarrassment indicate that the self feels committed to a norm. Thus, researchers have argued that moral emotions provide an early foundation for the development of the moral self.

In an effort to address more completely the development of moral emotions, Malti and Keller devised an integrative theoretical model that connects research on the development of moral emotions with the moral self. According to this model, the development of moral emotions and the emerging moral self entails sociomoral knowledge about persons, interactions, and norms. Cognitively, the self increasingly comes to understand the world of others by participating in social interactions. Affectively, the moral self is characterized by an empathic sharing of the consequences of its actions on others. Based on this idea, Malti and Keller have proposed that moral emotions develop sequentially: when children first learn to *distinguish* between the perspectives of the self and others, the self becomes aware that moral transgressions have negative consequences for others. However, the self does not take these consequences into account, thus leading to the happy victimizer phenomenon. The happy victimizer phenomenon describes the fact that young children attribute positive feelings to a moral transgressor in order to achieve a personal goal, although they understand the rule to be valid. In the second step, when children learn to *coordinate* the two perspectives, they realize that transgressions not only have negative effects on others but also give rise to the moral emotion of guilt, shame, or embarrassment (the unhappy victimizer). As a third step, a generalized third-person perspective is developed. This perspective helps to establish a self-evaluative system that determines how one ought to treat others to establish and maintain relationships built on trust. Feelings of guilt or shame emerge when the person violates this trust (unhappy moralist). This moral self has positive moral feelings, such as pride, provided it acts in accordance with its obligations (happy moralist). This perspective typically develops in adolescence.

This sequential developmental model assumes both normative developmental trends and individual differences in moral emotions. For example, although many children shift from positive to negative emotion attributions during middle childhood, it has also become clear that the attribution of positive feelings remains well into adolescence.

Moral Emotions Research

The sequential developmental model provides a conceptual framework for developmental research on moral emotions. A central approach to the study of moral emotions has been to study the emotions that children and adolescents expect will follow from various (im)moral acts. Thus, research on moral emotions has frequently employed in the happy victimizer paradigm to investigate the attribution of emotions to hypothetical victimizers following rule violations. Children and adolescents are typically presented with scenarios in which a protagonist violates a moral rule (e.g., pushing somebody off a swing or stealing sweets) in order to achieve a personal goal and asked to attribute emotions to the protagonist or

self-as-protagonist. Such emotion attributions generally have a strong cognitive component, because they require a basic understanding of the conflict, specifically the protagonist's situation and actions and the related consequences for the self and others. The LOGIC study in Germany was one of the first attempts to use this paradigm to obtain information on the development of moral emotion in children and adolescents. It revealed a gap in children's cognitions and moral emotion attributions, the latter lagging behind the former. Around 7 years of age, children seem to show a change in emotion attributions to transgressors by switching from a 'happy victimizer' or positive attribution to an 'unhappy victimizer' or the attribution of negative or guilt feelings. The observed decrease in the happy victimizer phenomenon signals an important developmental transition in children's moral emotion attributions. This transition involves the child's understanding that immoral conduct makes a transgressor feel sad, guilty, or remorseful. The previous developmental literature on moral emotions, as a whole, likewise shows that feelings such as guilt emerge in middle childhood. However, sympathy appears very early in life.

Despite impressive empirical evidence for the happy victimizer phenomenon and developmental change, studies in the happy victimizer tradition have revealed some inconsistencies. For example, Keller, Lourenço, Malti, and Saalbach have shown that moral (i.e., negative) emotion attributions also depend on perspective: Children attributed negative emotions more frequently and earlier to the self-as-victimizer than to a hypothetical other victimizer. Additionally, studies with adolescents indicated that individual differences in self-attributed emotions continue to exist. Thus, the empirical picture is not being resolved completely.

Furthermore, moral emotions as assessed in happy victimizer research mostly relied on children's and adolescents' verbal reports so far, whereas a few studies used nonverbal methods to elicit shame or guilt feelings. Most of these few studies have been conducted with early childhood samples. For example, Kochanska, Gross, Lin, and Nichols observed reactions to mishaps in 33- and 45-month-old children to assess guilt feelings. In general, however, very few studies have used observational measures to assess spontaneously occurring emotions in moral conflict situations, particularly in middle childhood or adolescence (for an exception, see Arsenio and Killen, 1996). Thus, we do not know to what extent, if any, spontaneous emotions differ from self-reported emotions in the context of moral conflict. Some difference is likely, however, because self-reported emotions are more likely than spontaneous emotions to be intertwined with cognitive processes and reflections.

Researchers have offered different explanations for the happy victimizer phenomenon. For example, some researchers have interpreted the phenomenon as resulting from a lack of social-cognitive competence. Various social-cognitive prerequisites for the development of moral emotion attributions have been considered in research, such as an interpretive theory of mind or an understanding of mixed emotions. In contrast, other researchers have explained the happy victimizer phenomenon in terms of a motivational moral deficit. Accordingly, young children do not necessarily lack the social-cognitive prerequisites to act morally, but rather are not motivated to act upon moral rules. More empirical research is needed, particularly on the

relation between moral emotions and social-cognitive development, to rule out one or the other explanation of the phenomenon.

The majority of research on the development of moral emotions has focused on guilt, shame, and empathy/sympathy. Within the framework of the happy victimizer paradigm, guilt and shame are seen as an important indicator of moral development, because they point out a person's internalized knowledge about a moral norm. In contrast, very few studies have investigated positively valenced moral emotions such as pride. Among the few, Tracy, Robins, and Lagatutta found that children can recognize praise by age 4 years and that pride recognition improves from age 3 to 7 years. Krettenauer and Johnston investigated if positively valenced emotions such as pride and negatively valenced emotions such as guilt differentially relate to adolescent's moral choices in prosocial and antisocial situational contexts. The authors found that positively valenced emotions were more closely related to moral choice in prosocial contexts (helping, donating), whereas negatively valenced emotions such as guilt were more important for antisocial contexts (stealing, cheating). Given the importance of both negatively and positively valenced moral emotions in the development of human morality, future studies that systematically investigate developmental differences and similarities among these different types of self-evaluative emotions are warranted.

Taken together, it has become clear that research in the happy victimizer tradition has provided valuable information on how children anticipate negatively charged emotions in interpersonal-moral conflict situations. This research has almost exclusively focused on hypothetical moral conflict situations. But what role do moral emotions play in real-life contexts of transgression? Although moral emotions are not specifically addressed in the literature on narrative development, a recent line of research has begun to investigate how young people make meaning of their own emotional and social experiences in real-life situations involving moral conflicts. Because narratives represent contextualized social interactions, it is likely that moral emotions are different for narratives of real-life situations than for hypothetical scenarios. Moreover, real-life situations are more complex than hypothetical situations because, in addition to the moral considerations, perpetrators must justify their own transgressions by referring to their own goals.

In a recent study by Gutzwiller-Helfenfinger et al., children's narratives describing their interpersonal conflicts, including emotional aspects of their own moral transgressions, were explored. The findings indicated that the emotions constructed in the course of these real-life narratives differ from the emotions generated in the context of hypothetical transgressions. In the narratives, all self-evaluative emotions mentioned spontaneously were negative. In contrast, emotions attributed in the interview part covered a broader spectrum, including happiness and positive self-evaluative emotions.

In summary, the emphasis placed on moral emotions in the study of morality has been highlighted in recent theoretical and empirical developmental work, and promising first steps toward systematic empirical analysis have been taken. So far, most published studies have focused primarily on a particular negatively valenced moral emotion such as guilt feeling. Future research needs to investigate more systematically the

development of other moral emotions (e.g., shame, pride), as each of these emotions may follow a distinct developmental trajectory. It also still remains unclear what the varying relations among different types of moral emotions are. For example, are empathy and guilt related over the course of development, or do they develop independently from each other? Longitudinal studies may be particularly well suited to address this and related questions in future research. Psychological research is also needed in order to elaborate how different assessments of moral emotions (e.g., self reports vs. observation) may influence this developmental process, and how contextual features (e.g., hypothetical vs. real-life moral conflict situations; culture) interact with the normative developmental trajectories of various moral emotions. Finally, future research is needed to better understand the various relations between moral emotions with moral cognition and social-cognitive development.

Moral Emotions and Social Behavior

The idea that emotions in the moral domain are linked to morally relevant behavior seems to be uncontroversial in the developmental literature. Emotions signal those aspects of the social interaction that are worth acting upon. Thus, scholars have pointed to the need to investigate the neglected role of moral emotions in the genesis of interindividual behavioral differences. The question how moral emotions impact children's and adolescents' social behavior is of great significance for developmental and clinical psychologists, because it may help us gain further insight into the moral deficiencies as well as the strengths of aggressive and prosocial young people. Several studies have elucidated the role of moral emotions in causing (mal)adaptive behavior. These studies are reviewed selectively in the next section.

Moral Emotions and Aggressive Behavior

Developmental research has investigated the relation between moral emotions and aggressive behavior in the happy victimizer experimental paradigm. Some studies have documented a negative relation between aggression and the attribution of positive emotions to a moral transgressor. In contrast, other studies have revealed no such association. One of the reasons for this lack of consistency might have been that children do not spontaneously identify with the hypothetical victimizer. As outlined earlier, Keller and colleagues showed that children's emotion attributions to themselves in the role of the hypothetical victimizer are perceived as personally more obligatory. There is empirical evidence that self-attributed moral emotions are negatively relevant to immoral, aggressive behavior in adolescence and in childhood.

In a recent meta-analysis of 45 studies with 7,762 participants, Malti and Krettenauer analyzed the overt impact of moral emotions as assessed in the happy victimizer paradigm on aggressive behavior. This study documented a robust significant association between moral emotion attributions and aggressive behaviors. Moderation of these effect sizes by the type of moral emotion attribution indicated that self-attributed moral emotions showed larger effects than emotions attributed

to hypothetical characters when predicting aggressive behavior. Taken together, these findings underscore the value of considering emotional processes in explaining immoral, aggressive action tendencies. The findings have mostly relied on cross-sectional, correlational evidence so far. Thus, future studies with longitudinal and experimental designs are needed to validate and extend this productive line of research.

Moral Emotions and Prosocial Behavior

Developmental researchers consider the experience of self-evaluative emotions (in particular guilt) as an important indicator of a person's readiness to comply with rules. The experience of self-evaluative emotions indicates that a moral norm has been internalized and thus has the potential to predict morally relevant, prosocial behavior. In accord with this theoretical notion, developmental studies have supported a positive relationship in children between different measures of sympathy (i.e., behavioral or physiological reactions, and self- and other-reports) and prosocial behavior. Despite the ample empirical evidence for a positive relation between sympathy and prosocial behavior, a meta-analysis by Eisenberg and Miller revealed that the relation is rather modest in strength. Researchers have therefore argued that a further analysis of the moderators of prosocial behavior is needed. Among these factors are other moral emotions besides empathy.

Research on moral emotions other than empathy and prosocial, adaptive behavior has been surprisingly rare, even though the role of two of the moral emotions (empathy and guilt) in prosocial behavior has been acknowledged. Gummerum, Keller, Rust, and Hanoch showed that preschool children with high levels of guilt feelings also shared more attractive stickers in a prosocial dilemma situation. Malti et al., found that guilt feelings were related to prosocial behavior in 6-year-old children. In a study with adolescents, Krettenauer and Johnston did not find evidence for a relation between moral emotions (particularly guilt) and self-reported prosocial behavior. Further studies are needed to continue this promising research avenue.

Educating Moral Emotions

To date, there are no evaluated educational approaches that systematically promote various moral emotions in young people. Yet, there are numerous educational approaches that focus on the development of empathy in children and adolescents. These programs are most commonly listed under social and emotional learning programs (SEL), moral and character education programs, or Positive Youth Development programs. The underlying assumption of SEL programs is that empathy is a protective factor that promotes young people's psychosocial adjustment, and helps them overcome risk factors for maladjustment, particularly aggression and immoral behaviors. Similarly, character education and Positive Youth Development programs aim to promote empathy and caring in young people, since they are considered key assets to adaptation and social responsibility. Studies demonstrate that empathy can be taught effectively through school-based programs. Today, there are numerous evidence-based programs providing

systematic classroom instruction that enhances children's and adolescents' ability to be empathic, take the perspectives of others, and behave prosocially.

Most of these programs focus on the cognitive component of empathy (i.e., perspective-taking skills). Thus, many programs share the methods typically utilized by programs that aim to promote moral reasoning and cognitive moral skills, such as group discussions about moral issues. In the future, it will be important to also give children the opportunity to develop the affective components of moral development by experiencing self and other's multifaceted feelings in everyday moral situations. Researchers have argued that emotional experiences in real-life situations can be meaningfully used as a basis for children's moral learning. It is therefore important to raise educators' awareness of real-life moral conflict situations as a resource for moral education. In line with Oser's conception of learning from moral mistakes, educators can help inculcate children's sociomoral sensitivity by discussing specific conflict situations and the emotions they invoked in the child – as victim, perpetrator, bystander, and/or observer.

Another family of programs specifically addresses the problem of bullying and aggression. These school approaches aim not only to establish rules for tackling specific instances of bullying, but also to promote empathy (see also the Roots of Empathy program).

The developmental studies center provides a list of research-based social and emotional learning programs for children and adolescents. The mission of the nonprofit CASEL (collaborative for academic, social, and emotional learning) organization (www.casel.org) is to promote the establishment of evidence-based social and emotional learning (SEL) programs as an essential part of education. One of the many well-known prevention programs is second step, a violence prevention program that integrates academics with social and emotional learning. Adolescents learn social skills such as empathy, emotion management, and cooperation. The effectiveness of SEL programs has been documented by evaluation studies. Strengths of effects vary as a function of program type, program characteristics, and participant characteristics. Improvement has been shown in empathy and prosocial behavior.

Summary and Future Directions

Moral emotions are a central dimension of human morality and of key importance for (im)moral action tendencies. In this article, we selectively reviewed literature on some key issues in the moral emotions area that have emerged in both developmental research and applications. Moral emotions are an umbrella term, and its definitions have been correspondingly broad. A commonly shared feature of these definitions is that these emotions are described as self-conscious or self-evaluative emotions, because they are evoked by the individual's evaluation of the self. Feelings of guilt and shame have been considered key indicators of affective moral development. Likewise, positively valenced self-evaluative emotions such as pride have been described as morally significant. Additionally, other-oriented emotions such as empathy/sympathy have been considered moral emotions. A theoretical model of moral emotions was presented and it describes how emotions

attributed to protagonists in interpersonal-moral conflicts develop. Research on moral emotions in the corresponding happy victimizer research tradition was selectively reviewed. This research has described how various moral emotions such as guilt develop in childhood and adolescence. Most of this research has focused on emotions attributed in the context of hypothetical transgressions. More recent research has begun to investigate emotions in the context of real-life moral conflict. As moral emotions are considered to play an influential part why individuals adhere or fail to adhere to their own moral standards, research on the link between moral emotions and pro- and antisocial behavior was described. This research has been predominantly focused on cross-sectional relations and selected moral emotions such as empathy and guilt. Longitudinal studies on various moral emotions and pro- and antisocial behavior is needed next. Additionally, it was shown that theorists have begun to analyze the relationship between moral emotions and social-cognitive development. However, not much research on this relation has been conducted so far. Future research on the relationship between various moral emotions and dimensions of social-cognitive development, such as an interpretive theory of mind or an understanding of second-order beliefs, is therefore needed. Finally, a number of educational approaches have addressed the promotion of moral emotions in children and adolescents. These programs, which are frequently classified under social and emotional learning, are often school-based and focus on the promotion of a particular moral emotion, mostly empathy/sympathy. Promising advances have been made in integrating research and practice. Future efforts at integrating research and educational practices in the area of child and adolescent moral emotions are needed.

Glossary

Achievement motive A capacity to derive pleasure from mastering challenging tasks.

Affiliation motive A capacity to derive pleasure from having close, harmonious relationships with others.

Extrinsic motivation Externally regulated, controlled form of goal pursuit.

Incentive Affectively charged stimulus that elicits goal-directed, motivated action.

Intrinsic motivation Internally, autonomously regulated goal pursuit.

Mastery goal A goal that aims at improving one's competence or performance level relative to one's previous performance.

Motivation Affectively charged state that energizes and directs action aimed at the attainment of a reward (or avoidance of a punishment).

Motivational congruence State of alignment between a person's implicit motives on the one hand and explicit goals and values on the other.

Motive A stable disposition to seek a particular type of reward and experience its attainment as pleasurable. Stable personality disposition to experience particular types of incentives as pleasurable.

Performance goal A goal that aims at demonstrating one's competence relative to others or a social norm.

Power motive A capacity to derive pleasure from having physical, social, or emotional impact on others.

Self-determination The autonomous setting and pursuit of a goal.

Introduction

The term *motivation* characterizes an affectively charged state that energizes and directs action aimed at the attainment of a reward or avoidance of a punishment. For instance, a food-deprived bear experiences hunger (*affectively charged state*) and therefore orients its attention and behavior toward cues in its environment that signal the availability of food (*directing function* of motivation). The hungrier it is, the more vigorously, quickly, and frequently it will go after berries, honey, and prey (*energizing function* of motivation). Here, the reward is food, and obtaining sufficient amounts of it will satisfy the bear's hunger and thus end this particular motivational episode.

In this case, the affectively charged state at the core of the motivational state was due to deprivation – the bear had not eaten for a long time and the body's nutrient levels had to be replenished. Still, the bear had to be sensitive to suitable cues in the environment that signaled the availability of food – so-called incentives – and ignore many other cues. This highlights an important principle in motivation science: goal-directed behavior is a joint product of the individual's internal need (hunger in this case) and situational incentives (food-related cues) that allow the expression of this need. This also means that individuals with a stronger need become more motivated by the same incentive cue than individuals with a weaker need. Thus, individual differences in transient as well as enduring motivational needs are important for motivation. Conversely, some incentives are more 'incendiary' and luring than others, with the former eliciting more motivation than the latter in individuals with similar motivational needs. In extreme cases, high incentive value can even beat motivational need, as when people ignore signs of satiety after a full meal

and cannot resist the lure of an ice cream box or a bag of potato chips.

The fact that the bear ceases its search for food after it has gorged itself on berries and honey, that it has actually stopped being motivated to seek food, highlights another important principle of motivation: it is dynamic. A specific episode of motivated behavior is set in motion by the interplay of an internal need and the presence of suitable external incentive cues and persists until the individual reaches the desired reward. Motivation for pursuing the reward then stops and the individual is free to engage in other motivational pursuits. For instance, a person who was hungry and in single-minded pursuit of food will be free to think of and do other things once the craving for food has been stilled by eating a full meal.

Motivation also guides learning of reward-predictive signs and behaviors that are instrumental for obtaining a reward. For instance, the bear from the above example may learn to associate a certain patch of the woods or a particular smell therein with the taste of mushrooms and berries, because both can be found on a specific type of soil with its characteristic look and scent and both signal that food can be found with high likelihood here. And it may learn to carefully pluck the berries from the bush with its snout without getting pinched by the thorns. The more motivated the bear is, the quicker it will learn both the food-predictive signs and effective food-gathering behavior.

While the above examples only involved motivational needs and processes that all higher species share (such as hunger and feeding, and also dominance, affiliation, sexual reproduction, etc.), there is an important distinction between animals and humans: only the latter can set and pursue abstract goals, goals that are rooted in a person's culture, that can be verbally communicated to and coordinated with other

humans, and that have the capacity to override and suppress more biologically based forms of motivation. For instance, people can set and pursue diet and fitness goals that make them forsake food and leisure time that their bodies may crave but that provide them with a sense of meaning and purpose, sometimes even at the expense of hedonic pleasure. There is thus a fundamental difference between verbally mediated, conscious forms of motivation, represented by the goals people set and pursue in their daily lives, at home and at work, and the types of motivation humans share with other animals and that do not necessarily require language or consciousness for their proper enactment (e.g., eating, drinking, social closeness, dominance, sex). Both types of motivation can effectively guide behavior, but for different reasons: biologically based motivation, because it ensures the attainment of pleasurable, rewarding, and ultimately survival-enhancing goal states; and culturally based goal pursuits, because they enhance social coordination and provide human lives with a sense of meaning.

Motivational dispositions and processes are most frequently studied from the perspective of biopsychology, social psychology, and personality psychology. Biopsychology, using animals as research subjects, allows the experimental manipulation of brain areas assumed to be involved in motivation across mammalian species and studies the effects of these manipulations on behavioral markers of motivation. Social psychology studies the effect of situational factors on human motivation, as assessed through questionnaires, cognitive processes, and behavioral observation, and is interested in drawing conclusions about general features of motivating stimuli and contexts as they apply to all people. Personality psychologists are interested in individual differences that make people respond differently to the same types of incentives. Individual differences in motivational dispositions and processes are most frequently assessed through questionnaire measures, although indirect measures (such as content coding of verbal material) and cognitive-process measures are also employed. Affective and social neuroscience, an emerging new field that cuts across the three previously mentioned research approaches and that uses brain imaging methods in combination with behavioral and questionnaire data in human subject populations, rapidly provides new approaches and opportunities for studying motivational dispositions and processes.

Approach and Avoidance Motivation

A fundamental distinction in the psychology of motivation is the one between approach motivation (aimed at the attainment of rewards) and avoidance motivation (aimed at the avoidance of frustrations and punishments). The latter can be subdivided into active avoidance, characterized by active execution of instrumental behavior aimed at moving away from a punishment (such as running away from a predator if it is still some distance away), and passive avoidance, characterized by the behavioral inhibition of behavior in order to avoid a punishment (such as being very still when a predator passes by in the vicinity).

Based on the distinction between approach and avoidance motivation, Jeffrey Gray developed reinforcement sensitivity theory, a biopsychological model that incorporates three basic systems presumed to underlie any motivated behavior.

(1) A behavioral approach system (BAS) that energizes behavior aimed at the active attainment of learned and natural rewards as well as attainment of stimuli indicating safety or nonpunishment. The BAS is essential not only for active approach motivation, but also for active avoidance motivation, because it facilitates behavior aimed at reaching rewarding safety. It is associated with the brain's mesolimbic dopamine system, a key structure for motivated behavior. (2) The fight-freeze-flight system (FFFS) generates behavior aimed at the avoidance of imminent learned and natural punishers as well as experiences of intense frustration. This system is associated with the periaqueductal gray, the medial hippocampus and the amygdala and is essential for escape and defensive aggression. (3) The behavioral inhibition system (BIS) gets involved when an individual's approach and avoidance goals are simultaneously activated, that is, when both the BAS and the FFFS are equally engaged. Once BIS gets activated, premature action tendencies elicited by either the BAS or the FFFS are inhibited and the individual is instead put into an enhanced cognitive-processing state that allows him to collect more information to resolve the current approach-avoidance conflict in one direction or the other. This might, for example, be the case in situations in which an animal tries to reach available food in an area where a potential predator is present. The septohippocampal system represents the neuroanatomical basis of the BIS. Behaviorally oriented animal studies provide ample support for the validity of Gray's model, as do neuroimaging and behavioral studies with normal and clinical human populations.

Another theory about the neurobiological basis of approach and avoidance motivation was suggested by Richard Davidson. Research on victims of strokes and other accidents that scar the brain's tissues links differences in the location of a stroke to differences in subsequently experienced symptoms of depression. Specifically, strokes in the left but not the right frontal cortex are responsible for diminished positive affect. Looking at normal, healthy individuals, Davidson found that the induction of positive mood was associated with increased left frontal cortex activity while the induction of negative mood was connected to higher right frontal activity. Moreover, he also found that differences in left versus right frontal activity relate not only to transient emotional states but also to enduring differences in personality traits. People with habitual higher left frontal cortex activation under resting conditions characterize themselves as more extraverted, outgoing, and emotionally positive, while people with higher right frontal cortex activation describe themselves as more prone to anxiety, mood swings, and negative emotionality. Davidson therefore concluded that positive affect, either as a state or as a trait, is associated with left frontal activation and negative affect with right frontal activation. However, the frontal cortex is not itself the seat of affective states or dispositions; rather, it exerts inhibitory control over subcortical affect generators such as the amygdala, and research has shown that this is the reason why differences in frontal cortex activation are associated with differences in positive and negative affect.

The relationship between cortical asymmetries and motivation was further elaborated by Eddie Harmon-Jones who contended that higher left frontal activity is not necessarily related to more positive affect per se but rather to increased approach motivation. He found that negative emotional states, such as

anger, can also be associated with elevated left frontal cortex activity. More specifically, trait and state anger as well as behavioral aggression, although all representing negative affect, are associated with greater left than right prefrontal activation. Harmon-Jones argues that anger is an approach-related affective state that occurs if the way to a cherished goal or reward is blocked and the obstacle can be removed. He therefore argues that it is more accurate to link left frontal activity to approach motivation and right frontal activity to avoidance motivation than to positive or negative affect *per se*.

Other neurobiological models of motivation also assume the existence of separate systems for approach and avoidance motivation, but postulate additional systems that can help make behavior flexible beyond reflex-like responding to rewards and punishers. There is evidence for the existence of an additional impulse-control system that can restrain the impulsive, stimulus-driven effects of approach and avoidance motivational systems on behavior and bring behavior under the guidance of analytical thinking, the setting of deliberate plans and goals, and verbal self-instructions or instructions from others. The impulse-control system enables humans to delay gratification of motivational needs for extended periods of time (e.g., being able to sit through a lecture despite feeling hungry) and appears to be associated with the neurotransmitter serotonin.

More recent theories of motivation emphasize the interaction between motivational states and cognitive processes. For instance, Julius Kuhl's personality systems interaction (PSI) theory links functional properties of positive and negative affect to four cognitive processing systems. According to PSI, positive affect activates an intuitive behavior control system that is specialized in executing automatic, well-established behavioral programs and is functionally similar to Gray's BAS. If intuitive behavior runs into trouble and is no longer adaptive, positive affect is reduced. This in turn switches off the intuitive behavior control system and instead activates a cognitive system dedicated to analytical thinking and the careful crafting of behavioral plans and strategies. Negative affect, on the other hand, facilitates object recognition in the service of a thorough analysis of unexpected events and situations, a function that is similar to Gray's BIS. When the environment matches one's expectations, on the other hand, negative affect is decreased, which in turn switches off object recognition and activates a system called extension memory, a broad network of knowledge about the world and the self. Thus, in PSI, high or low positive or negative affect is functionally related to distinct cognitive processes and motivational states.

Despite obvious differences in all these theoretical accounts to approach and avoidance motivation, with some being more concerned with the neuroanatomical basis, others with hemispheric differences or the role of affect and cognition, there is extensive empirical evidence for each model and it seems possible that they may 1 day be integrated into a comprehensive theory of the generation and regulation of approach and avoidance motivation.

Implicit Motives

Whereas approach and avoidance motivation characterize general behavioral trends toward rewards and away from

punishers, motives define the specific types of incentives individuals strive for. A motive is a capacity to experience a specific type of incentive as pleasurable. Motives drive, orient, and select behavior that aims at obtaining motive-specific incentives and satisfying the motivational need. For instance, a person with a strong food motive has a particularly well-developed capacity to relish the taste of food. When this person's food motive is aroused (i.e., if she feels hungry), she will act in such a way as to find a food source, prepare, and eat the food, thereby satiating her appetite. Motives are implicit in the sense that they are rooted in specialized brain systems developed over evolutionary time spans, operate outside of a person's conscious awareness and therefore have to be assessed indirectly, such as by content coding of verbal material. Such indirect motive measures predict a large array of motivational phenomena, ranging from physiological and neural responses to incentive stimuli, to economic success and political action, but frequently fail to overlap with people's explicit declarations of their motivational needs and goals.

Three motives have received particular attention from researchers over the past 60 years: these are the need for achievement (*n Achievement*), a capacity to derive pleasure from the autonomous mastery of challenging tasks; the need for affiliation (*n Affiliation*), a capacity to derive satisfaction from establishing, maintaining, and restoring positive relationships with others; and the need for power (*n Power*), a capacity to enjoy domination and having an impact on others or the world at large.

Individuals high in *n Achievement* strive to do something better for their own sake, simply for the intrinsic satisfaction of doing something better. The incentive to do better is strongest when the task at hand is of moderate difficulty. If a task is too simple there is little challenge in doing it better. On the other hand, if a task is extremely difficult and therefore has a very low probability of being completed, then the likelihood of failure is very high and this makes it almost impossible to do better. Moderately difficult tasks therefore provide achievement-motivated individuals with the best opportunity of improving a skill or competency. In the workplace, individuals high in *n Achievement* frequently try to improve their personal performance and meet or exceed standards of excellence. This can have positive results, such as when employees surpass self-imposed standards, accomplish something new and make long-term plans for their career. For managers, however, a high level of *n Achievement* can lead to negative side-effects such as micromanaging, offering little positive feedback to subordinates, expressing impatience with poor performers, and a higher focus on goals than people.

Individuals with a high *n Affiliation* learn social relationships more quickly, engage more often in dialogue with others, and maintain their connections with other people via letter writing, telephone calls, personal visits, etc. Organizational leaders with a strong affiliation motive experience a need to maintain close, friendly relationships with others. As a result, such leaders avoid confrontation, look for ways to create harmony, avoid giving negative feedback, with a general focus on people rather than on performance. While an aspiration to be liked and accepted might not conform well to the demands of most managerial positions, this characteristic is indispensable for success in positions in which a person is responsible for integrating employees.

The way in which the implicit power motive manifests itself varies widely across people, socioeconomic classes, professions, cultures, regions, and, in some circumstances, gender. With few exceptions, most societies are ambivalent about individuals' desire to dominate others. For this reason, individuals with a high *n* Power must find socially acceptable outlets for satisfying this need by, for example, participating in highly competitive or high-risk sports, choosing influential occupations, collecting prestigious possessions, and seeking recognition in small groups. In leadership contexts, *n* Power is differentiated into socialized and personalized power. A manager with a high need for personalized power seeks to be strong and influence others by being coercive, even ruthless, wanting to control or manipulate others, and focusing on reputation maintenance rather than management of subordinates. Leaders with a high need for socialized power strive to help people feel strong and more capable. In other words, this type of leader strives for power in order to empower others. This individual's leadership behavior is characterized by coaching and teaching, being supportive to subordinates, involving others in the decision-making process, with an overall focus on the group instead of on the self.

Explicit Motivation: The Self-Concept, Goals, and Values

In contrast to implicit motives, which influence motivation and behavior nonconsciously, individuals' explicit, language-based self-concept, values, and goals afford conscious modes of behavioral regulation. The self-concept represents an individual's mental image or perception of 'the self,' encompassing the temporally stable self-knowledge of this particular individual (e.g., one's personality attributes, knowledge of one's skills and abilities, one's occupation and hobbies, and awareness of one's physical attributes), including her or his attitudes, affective preferences, values, goals, and life story. In other words, the self-concept is viewed as a system of affective-cognitive structures providing coherence for the individual's self-relevant experiences. It refers to the sum total of an individual's beliefs about his or her own personal attributes. It is made up of self-schemas, that is, knowledge structures that guide the processing of self-relevant information and determine how people interpret new information and organize past experiences in their memories. A person's self-concept is complex, dynamic, and may change over time.

It is important to note that the self-concept is not restricted to the present. Conceptions of the self in the future are called 'possible selves.' They represent individuals' perceptions of what they might realistically become, what they would very much like to become ('ideal self'), and what they are afraid of becoming ('feared self'). In other words, an individual's repertoire of possible selves can be viewed as the cognitive-affective manifestation of enduring goals, aspirations, fears, and threats. Possible selves are cognitive links between the present and the future, specifying how individuals may change from what they are now to what they will become. That is, if a current self-concept is challenged or supported, it is often the nature of the activated possible selves that determines how the individual feels and what course the subsequent action will take. Possible selves thus function as incentives for future behavior and allow

comparisons of present and desired future states, providing a frame of reference for the assessment and evaluation of current goal attainment.

Personal goals have been defined as personally meaningful concerns, projects, or strivings people pursue and try to attain in their everyday lives. Similar to motives, goals are relevant to the regulation of behavior. However, unlike implicit motives, they are verbally represented, conscious, and measurable by self-report. Personal goals are subjectively meaningful representations of anticipated end-states delineating what a person wants to achieve, maintain, or avoid in his or her current life situation. Individuals actively derive personal goals from their self-concepts and then plan and engage in activities directed toward goal attainment. The process of goal setting and planning focuses on intention and acquisition of knowledge, and helps to organize resources. The implementation of goals depends on how much a person is committed to a given goal, particularly when the going gets tough. Research shows that people who are not strongly committed to a goal may actually miss opportunities to enact the goal and, when faced with challenges and setbacks on the way toward the goal, may abandon it altogether. In contrast, individuals who feel firmly committed to a goal are better at utilizing opportunities to realize it (a case of chance meeting the prepared mind) and, when they encounter difficulties, will step up their efforts to attain the goal or seek alternative ways to realize it. Successful pursuit and implementation of personal goals in turn provides individuals with a sense of meaning in life, with greater life satisfaction, and with emotional well-being, although the latter effect depends on the fit between a goal and the person's implicit motives (see next section).

Only rarely are goals represented mentally in a purely abstract, verbal format. Most goals entail imagining a 'possible self' realizing the goal. A crucial element of any goal is the mental image of approaching and attaining it. Goals are particularly effective regulators of behavior when the person can conjure up representations of the self achieving them (e.g., imagine your 'self' graduating, buying a car, trying hard to get a job, etc.). In other words, a goal will have a stronger impact on behavior to the extent that an individual can personalize it by building a bridge of self-representations between one's current state and one's desired or hoped-for state.

Central, overarching human goals are often referred to as values. Although there does not exist a common definition for the term, most scholars agree upon the following five aspects regarding values: a value is a subjective belief that pertains to desirable end states (goals) or behaviors, that transcends specific situations, that guides the selection or evaluation of behavior, people, and events, and that is ordered by importance relative to other values to form a system of value priorities.

Similar to 'possible selves' and goals, values are defined as desirable end states. They serve as guiding principles for the lives of individuals (personal values) and social groups or society as a whole (social values). Implicit in this definition of values are the following: that they serve the interests of some social entity; that they can motivate action, giving it direction and emotional intensity; that they function as standards for judging and justifying action; and that they are acquired through unique learning experiences of individuals

or groups. Other goal-related constructs such as 'personal strivings' and 'life tasks' may be seen as expressions of values in specific life domains.

The content of a distinct value is heavily determined by the motivational goal this value expresses (e.g., the value 'helpfulness' represents the goal to preserve and enhance the welfare of others). Values represent, in the form of conscious goals, responses to three universal requirements with which all individuals and societies in all cultures must cope: needs of individuals as biological organisms, requisites of coordinated social interaction, and requirements for the smooth functioning and survival of groups. From these three universal requirements, a number of motivationally distinct types of values can be derived: power, achievement, hedonism, stimulation, self-direction, universalism, benevolence, tradition, conformity, and security. For example, the value 'conformity' stems from the desire for smooth interaction and group survival. This value expresses the goal to restrain impulses and inhibit actions that might hurt others.

Taken together, the self-concept, personal goals, and enduring values provide humans with conscious, explicit routes for regulating their goal-directed behavior in harmony with the demands and affordances of the sociocultural context they live in and with ways to experience their pursuit of incentives as meaningful and rewarding.

Interactions Between Implicit and Explicit Levels of Motivation

The simultaneous existence of an implicit and an explicit level of motivation, represented by individuals' implicit motives on the one hand and their explicit views of themselves, their values and their goals on the other, raises the question of how these two levels interact with each other to shape thought, feeling, and behavior. Hundreds of studies conducted over several decades have consistently shown that measures of implicit and explicit motivation within a given domain have little statistical overlap with each other. This means that, for instance, a person with a strong implicit achievement motive can have explicit goals and values that do not emphasize achievement and, vice versa, that a person with low implicit achievement motivation can strongly endorse explicit achievement values and be firmly committed to a host of achievement goals. In both cases, implicit and explicit levels of motivation are incongruent with each other, and such motivational incongruence can give rise to problems. Motivationally incongruent people experience less satisfaction with life and less emotional well-being. They are also more prone to develop symptoms of psychosomatic illness. In contrast, people who endorse values or pursue goals that are congruent with their implicit motives (e.g., a person high in implicit achievement motivation who pursues many achievement goals in her daily life) report overall better life satisfaction, emotional well-being, and fewer psychosomatic symptoms.

Because motivational congruence and incongruence can have profound effects on well-being, researchers have started to look for factors that can help people achieve higher congruence between their implicit motives and their explicit values and goals. Dispositional factors that are associated with

high motivational congruence include a strong sense of self-determination, being tuned to one's bodily sensations, the ability to quickly overcome negative affective states, and being able to verbalize one's perceptions quickly. But people can also increase their motivational congruence strategically by vividly imagining a potential goal before committing to it, because imagination helps translate the verbal content of the goal into the nonverbal format in which implicit motives process information.

Learning and Performance Goals

Research on achievement motivation in classroom settings and educational contexts has focused on the difference between performance goals and mastery goals: while performance goals describe the desire to appear competent compared to others, mastery goals emphasize the acquirement of competence through successful mastery of tasks. Carol Dweck and others have provided extensive evidence that performance goals can be hurtful for all but the most accomplished learners, because having to prove one's ability to others makes one vulnerable to the negative social consequences of failure, and fear of failure in turn undermines one's performance. Mastery goals, in contrast, promote learning and motivation, because one's current performance is not compared to others' performance, but only to one's own performance, and success and failure are only diagnostic of whether one has succeeded in improving one's skill level, not one's standing in a social hierarchy.

Andrew Elliot has argued that learning and performance goals can be further differentiated by considering a person's motivational orientations, that is, whether someone is primarily concerned with *approaching* a desirable outcome or whether someone is driven by the objective of *avoiding* aversive outcomes. The interplay between learning and performance goals on the one hand and approach and avoidance on the other has led Elliot to first propose a trichotomous achievement goal framework in which the performance goal construct was divided into performance-approach and performance-avoidance goals. The former describes the striving toward the goal to perform better than others, that is, to pursue a normative approach goal, and is associated not only with more persistent, absorbed, and efficient goal striving, but also with greater test anxiety and unwillingness to cooperate with others. Performance-avoidance goals are about not wanting to perform worse than others and are associated almost exclusively with negative outcomes such as distracted and disorganized learning, anxiety, and impaired performance.

In a later version of the theory, Elliot also divided mastery goals into approach and avoidance goals, with mastery-approach goals reflecting the desire to master a task and mastery-avoidance goals representing the desire to avoid making a mistake or performing worse than previously. Mastery-avoidance goals are grounded in fear of failure and low self-determination, that is, a low desire for autonomy and choice. An analysis of parenting styles showed that parents of mastery-avoidant children tended to give a lot of negative feedback concerning the child as a person (e.g., 'you are not a good person') as opposed to a specific behavior (e.g., 'you did

not put a lot of effort into completing this task') and to create a family climate characterized by worrying. Consequently, the pursuit of mastery-avoidance goals is predictive of disorganized studying and worry-proneness among children. Interestingly, parental socialization practices appear to be unrelated to the development of mastery-approach goals, perhaps because an active approach toward mastering one's environment is inherent in human nature and therefore does not need to be reinforced externally. Performance-approach goals were linked to parents' conditional approval of children (e.g., 'you have to do well in school to make me happy') and positive feedback by fathers that focused on their children's overall personality rather than just on the positive outcome of the task. This type of person-focused feedback by parents also facilitates children's adoption of harmful performance-avoidance goals.

To summarize, research in classroom and learning contexts shows that people benefit from mastery goals, particularly when they are approach-oriented, because they allow to focus on gradual improvement of one's skills, and suffer when they pursue performance goals, particularly when they are avoidance-oriented, because they induce harmful social comparisons.

Self-Determination Theory and Basic Needs

When people believe that a particular behavior will reliably lead to the desired consequences and they also feel capable of performing that behavior, they will experience intentionality and a sense of personal causation. To account for the diverse effects goals have on affect, cognition, and behavior, Ed Deci and Richard Ryan argued that intentional behavior is regulated along a continuum from autonomous (self-determined) to controlled by intrapersonal or interpersonal forces. They also distinguish between intention and choice: while choice refers to autonomously initiated intentional behaviors that reflect intrinsic motivation, intentional behavior can also be at the other end of the spectrum and be executed for reasons extrinsic to the person, thus reflecting extrinsic motivation (e.g., when a soldier executes an order given by a higher ranking officer). The autonomous and controlled ends of the self-determination continuum also differ in the sense of a person's inner endorsement of his or her actions. For example, an anorectic person refusing to eat is not showing autonomous intentional behavior as the intention contains a strong element of compulsion. When controlled intentions motivate behavior, people feel they are 'pawns' to the desired outcomes.

According to self-determination theory, all humans are propelled by three basic needs, namely the needs for competence, autonomy, and relatedness. These needs are seen as essential for psychological growth, self-esteem, integrity, and wellness. Intrinsic motivation is facilitated to the extent that a person's needs for autonomy and competence are supported; their suppression leads to extrinsically motivated forms of behavior. For example, imposing deadlines for the completion of an interesting task is being perceived as controlling and will therefore decrease intrinsic motivation, as is receiving certain types of rewards. Also, self-awareness, that is, seeing oneself through the eyes of others, or ego involvement (e.g., when the task is evaluative of a person's abilities) will lead to controlled regulation of behavior, which is associated with low persistence and

task enjoyment. In contrast, having the opportunity to choose between different tasks or being supported in one's autonomy by teachers and parents will lead to an increase in intrinsic motivation and thus to high persistence, task enjoyment, and qualitatively superior outcomes.

Although extrinsic reasons for action often undermine intrinsic motivation, extrinsically motivated behaviors can become autonomous via internalization. People can introject external reasons; that is, they can 'swallow' the reasons without really digesting them. But they can also accept them and identify with them if they think they are reasonable and valuable, or, in the best case, they can actively integrate them with their own sense of self. Thus, extrinsic reasons for behavior are not always at odds with autonomous regulation, provided that a person can internalize in some way the external reasons for behavior. Research shows that internalization of external values and regulations is effective in social contexts that support autonomy.

Since its formulation, self-determination theory has been successfully applied to various contexts, including sports, politics, and psychotherapy. However, it has also drawn some criticism because it fails to account for the fact that extrinsic rewards can also boost creativity, motivation, and performance in the laboratory and many domains of life.

Conclusion

Motivation is a unifying term for a diverse group of phenomena and constructs that are all related to goal-directed behavioral regulation. A fundamental rift exists between implicit motivation that automatically directs behavior toward incentives and away from disincentives without requiring conscious awareness and explicit motivation, a uniquely human form of self-regulation that is rooted in a person's ability to verbalize her or his sense of self, to adhere to culturally transmitted values, and to set and pursue personally meaningful goals. Another fundamental distinction is the direction of motivation: whether it fuels approach to rewards or avoidance of aversive stimuli. This distinction is valid both at the levels of implicit and explicit motivation and is manifested, for instance, in the types of mastery and performance goals people pursue in academic contexts. Finally, behavior can be motivated extrinsically, such as when pressure is exerted on a person to perform a certain task, or intrinsically, such as when a person feels strongly motivated to perform a task. A thorough understanding of motivational phenomena thus requires a multidimensional approach to their assessment and conceptualization.

Glossary

Central pattern generator Network of neurons responsible for generating properly timed rhythmic output.

Closed-loop control Mode of control consisting of a reference mechanism (standard of correctness) against which feedback from the ongoing or completed response is compared to generate error.

Coordinative structures Group of muscles constrained to act as a functional unit, also called synergy.

Degrees of freedom The least number of independent coordinates needed to describe the positions of the elements of a system.

Dynamics Branch of sciences that deals with changes in systems, expressing their existing and evolving states.

Feedback Information from sensory receptors that monitor the state of the body and the external environment.

Feedforward Information used prior to executing a particular act, with the main advantage that the human movement system is prepared in advance of the movement and tuned to processing response-produced information.

Motor programs Central representation of movement containing abstract movement commands.

Open-loop control Mode of control that does not make use of error information but, instead, prepares instructions for actions in advance, without modifications on the basis of feedback.

Synchronization Phenomenon that refers to the (mutual) attraction of limb movements or body parts, often resulting in phase and frequency synchronization.

Motor control is a relatively young discipline of scientific inquiry that attempts to describe and explain how movement is accomplished with special reference to concomitant postural adjustments. It focuses on the organization and control of the motor apparatus. Moreover, it seeks to understand how sensory processes converge with action. Different sources of sensory information have to be integrated to generate purposeful movements. This field of study has theoretical as well as practical relevance. Movement is at the heart of everyday life and the inability to move severely limits our capability to interact with the environment. Therefore, a better understanding of skilled performance in daily activities, sports settings, artistic contexts, and the workplace is desirable. This body of knowledge can be applied to the organization of practice or therapeutic intervention with the ultimate goal to improve performance or restore movement disabilities resulting from accidents, stroke, neurodegenerative diseases, etc.

The study of motor control has a pronounced interdisciplinary flavor. It is an interface between the neurosciences, biophysics, engineering, kinesiology, and the behavioral sciences. The neuroscientific perspective unravels how the brain and spinal cord bring about movement. With the development of imaging techniques, the brain structures involved in human motor control and their functional role have become apparent (see [Figure 1](#)). The biophysical/engineering and kinesiological perspective seek to understand the physical principles to which the human body in action, consisting of limb segments with pendular characteristics and springlike muscles, obeys. More recently, computational approaches have received increasing attention (see section 'Representations for Actions'). The behavioral perspective attempts to describe and explain observable movement behavior and the various manipulations that affect it, leading to inferences about the design of the control system. Increasingly, these perspectives are merging into a unified approach for understanding human movement behavior.

How Does Movement Take Place?

Movements such as reaching, grasping, and typing are so embedded in everyday life that one hardly thinks about how these actions are accomplished. We only learn to appreciate how complex this process really is when confronted with the consequences of pathology. Control of movement is an interplay with the various forces of nature. On the one hand, movers exploit these forces to produce skillful actions (e.g., ground-reaction forces, elastic forces, interaction torques), generated through the spring-like properties of muscles attached to segments that are connected to each other. On the other hand, living beings continuously fight against gravitational forces for their survival. Limbs have similarities to levers, designed to overcome these forces. Standing up against the laws of gravity, which takes several months in the newborn, is a primary accomplishment with survival value. As one grows older, it also becomes a limiting factor. Control of posture deteriorates in older individuals, sometimes resulting in falls.

Motor control research attempts to describe and explain movement as a complex combination of external and internal forces. On the one hand, mutual interactions between the mover and the (external) environment are a central focus of study. Action often leads to changes in the environment, and changes in the environment bring about modifications in action. On the other hand, because the human body consists of a kinematic chain of interconnected body parts, various interactions exist among the respective segments. Even within a limb, interactions among the joints can be identified which are governed by various types of torque.

For voluntary movement to take place, three elements are minimally required: muscles, a signaling system that makes muscles contract, and a system of sensors that provides information about the state of movement. Many centers in the brain are activated before, during, and after movement execution.

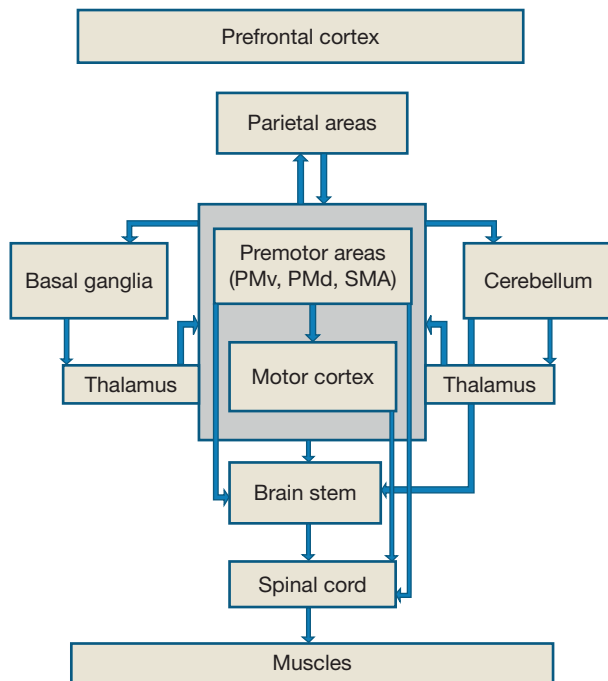

Figure 1 Rudimentary sketch of brain areas involved in motor control.

Among them are various subcortical and cortical structures working together to control the final outputs from the brain to the spinal cord (see [Figure 1](#)). An important question refers to how the information is encoded by these high-level systems, which are apparently far removed from the detailed peripheral events in the muscles. It appears that coding of movement represents a continuum ranging from abstract/goal-directed to specific. The parietal cortex is a critical neural site for abstract encoding whereas the (pre)motor areas are important for more specific movement-related encoding (see [Figure 1](#)). E. Evarts, who pioneered the recording of activity of single cells in the brain of awake animals, provided a major impetus to understanding the role of the motor cortex. He argued that activity of the nerve cells in the motor cortex was primarily related to the amount and pattern of muscular contraction rather than to the displacement that was produced by the contraction. Evarts also hinted at the tuning of the cortical cells to movement direction and this feature has been investigated intensively in subsequent years by Georgopoulos and colleagues. They proposed that cells have a directional preference even though they are only 'broadly tuned' to movement direction. Movement in a specific direction is then represented as a weighted sum of the directions signaled by a population of cells in the motor cortex (the population coding hypothesis). The motor cortex is an important brain structure because it resides close to the final motor output. What happens next? Neural information from higher levels is relayed to motor neurons whose cell bodies are located in the spinal cord and whose axons terminate on the muscle fiber membrane. At this site, neural events are translated into mechanical energy by generating a contractile force in the muscles. The properties of these muscles constrain the calculations of the central nervous system: the combination of muscle lengths and tensions are interdependent with the velocity of muscle shortening or lengthening.

Before information converges to provide input into the motor cortex, many brain areas play a role in providing information about the properties of objects to interact with as well as the trajectory that needs to be planned in view of the spatial requirements. In this context, the discovery of mirror neurons in the beginning of the 1990s has constituted a breakthrough. Rizzolatti and coworkers from Parma discovered neurons in the premotor cortex (and later also in the inferior parietal cortex) that not only fired when a monkey reached out for food but also when he observed another monkey or human performing a similar action. Apparently, the monkey mirrored the intentions of the observed other onto his own action repertoire. This provides a neurophysiological basis for action imitation and understanding that is of considerable importance for human development and (imitation) learning. Current research is primarily directed at unraveling the brain regions involved in the human mirror neuron system and at exploring its role in the broader context of social interactions.

[Figure 1](#) shows a schematic overview of the principal brain areas involved in movement control. This flow chart may leave the impression of a strict hierarchy in which a strict distinction is made between cognitive, perceptual, and motor areas. However, Cisek and Kalaska recently challenged this hierarchical perspective, suggesting that these different modules are closely interconnected. Neural processing is thought to be continuous rather than organized in distinct serial stages.

General Control Modes

A key issue that has dominated thinking in motor behavior since its inception concerns the locus of movement control. Competing ideas on this matter have formed one of the most persistent controversies throughout the history of motor control. On the one hand, the peripheral viewpoint argues that movement is controlled via some combination of feedback from the muscles and joints and the vestibular, auditory, and visual systems. The central perspective, on the other hand, assumes that commands are structured in advance and that feedback is not essential to produce patterned movement. These perspectives can be exemplified by two distinct modes of control, known as closed- and open-loop systems. These form extremes on a continuum.

Closed-Loop Systems

Closed-loop systems (like home-heating techniques), usually consist of three parts. A central feature is the reference mechanism, which represents the goal of the system or something to be achieved (e.g., the thermostat setting). Information from the environment is gathered to determine the value that the system seeks to regulate (actual temperature in the house), and this information is relayed to the reference, termed feedback, thereby closing the loop. Comparisons between a desired and actual state give rise to error detection. The executive level, informed about errors, takes action to reduce the error toward zero (e.g., the heater is turned on). Granted that slowly graded responses may be controlled in a closed-loop fashion, one is prompted to ask how very fast (ballistic) movements are produced.

Open-Loop Systems

In contrast to closed-loop control, strictly open-loop systems do not contain the feedback cycle and are not directed at nullifying error. Commands are structured in advance and are executed without regard to the effects they have on the environment. The major advantage of such a system is that it can act quickly, as it does not have to process incoming information. Its drawback is that it cannot adjust to changing environmental circumstances unless one steps away from strictly open-loop control.

Representations for Actions

In the past decade, the conventional open–closed control debate has waned and attempts have emerged to combine these control modes into a more comprehensive framework. On the one hand (and similar to centralists), the so-called motor systems perspective, backed by the information-processing approach, assumes that movements are centrally represented. Movement commands, specified in rather general or abstract terms, are responsible for output organization. This perspective does not strictly adhere to open-loop control as feedback is argued to play a role, depending on the type of task involved. Experimental observations showing invariant temporal relations between the muscle contractions underlying movement, despite variations in overall speed, are argued to be consonant with this viewpoint.

Conversely, the dynamical approach sets out a different strategy by minimal reliance on representations or central prescriptions for explaining order and regulation manifest in motor behavior. Instead, it is argued that order in action emerges as an *a posteriori* fact, or as a necessary consequence of the way the system is designed to function. The key question becomes what can be explained in movement organization ‘for free’ (i.e., through universal biophysical laws) before burdening the central nervous system with computational and control problems. This approach is characterized by an emphasis on processes of self-organization, a feature inherent to complex biological and physical systems. The interplay of forces and mutual influences among the components of a system, tending toward equilibrium, is largely held responsible for order in movement. Dynamics refers here to a more recent approach at the interface between mathematics and the sciences that is concerned with a description of changes in systems, their existing and evolving states. This perspective is committed to applying a rather universal language for describing systems in which multiple components become collectively organized. It recognizes rhythmic movement as a cornerstone for a theory of coordination.

Computational motor control approaches have lately become more prominent and they provide new insights into the previously mentioned open- and closed-loop control modes. Central in this notion is the idea of ‘optimal control’ implying that (1) minimization of costs and (2) maximization of rewards, drive the performer. Based on experience, the nervous system is involved in the formation of an internal model of the human body in interaction with the environment by relating motor commands to their outcomes. A key component of the optimization problem is the processing of feedback from

the sensory receptors. In addition, another source of information is ‘internal’ because it arises from these internal models that monitor the motor output and predict their sensory consequences. The latter feedback loop is faster than the former one (based on sensory input), allowing very rapid adjustments. Thus, three problems need to be resolved: (1) the sensory consequences of our motor commands need to be accurately predicted (system identification), (2) these predictions need to be combined with actual sensory feedback to form a belief about the state of our body and the external environment (state estimation), (3) based on these beliefs, the gains of the sensorimotor feedback loops have to be adjusted to maximize performance (optimal control). How a performer finally moves is based on expected rewards and the cost he/she accepts to pay.

Although opposite schools of thought have initiated lively debates on major control issues in the past decades, this clash of doctrines has created the opportunity to appreciate the benefits of various modes of control which can be explored by the mover in response to the huge variety of existing task dimensions and environmental constraints. This paves the road for conceiving hybrid models of human motor behavior. Next, evidence for central and peripheral contributions to motor control will be discussed. This description goes beyond the formerly made sharp distinction between closed- and open-loop systems.

Central and Sensory/Perceptual Elements in Motor Control

Central Contributions to Motor Control

This perspective suggests that central commands are mainly responsible for organization of movement. To strengthen this argument, various sorts of evidence have been collected to demonstrate that patterned movement can occur in the absence of peripheral feedback. Under conditions of feedback deprivation through deafferentation (severing the sensory nerves that carry information into the nervous system), monkeys have been shown to walk and climb, mice to display grooming patterns, and birds to sing even though portions of the song are eliminated by denervating one side of the vocal apparatus, etc. This has led some to argue that movement is mainly controlled via centrally stored movement commands, often called programs.

A motor program can be defined as a central representation of movement or skill. It has been a cornerstone of motor control theories that are inspired by the information-processing framework. Although the program is generally considered to be represented centrally, where exactly it resides remains obscure and medical imaging has not been able to resolve this matter. Task features may be an important factor in this respect. For example, in the case of learned movements, looking for a program in a well-defined location within the central nervous system might not be fruitful, as it may consist of several nodes that are widely distributed in the nervous system involving many interconnected brain areas. On the other hand, programs for certain inborn rhythmic behaviors, such as locomotion, swimming, and scratching, have a more circumscribed location, taking the form of a network of

neurons (called a neural oscillator or central pattern generator (CPG)), responsible for generating properly timed rhythmic output. Timing of these repetitive movements is then regulated by intrinsic properties of the central nervous system. For example, the CPG for locomotion in certain animals is located in the spinal cord. CPGs drive the spinal motoneurons (innervating muscles) by rhythmically raising and lowering their membrane potentials, causing them to fire in bursts. The excitability of the CPGs is governed by locomotor centers in the midbrain and brain stem.

Although CPGs are mainly invoked for the generation of inborn interlimb cyclical actions, they may be critically involved in, or form the basis of, learned movements. S. Grillner, a pioneer in CPGs, has proposed that these are made up of networks of smaller unit generators that may be of use in learning new motor acts that are far removed from locomotion. Think, for example, about the leg action in the breast-stroke: Leg propulsion is accomplished by extending the hip and knees while dorsally flexing the ankle to maximize grip on the water. This is a difficult matter for the beginning swimmer because there is a natural tendency to flex and extend all joints simultaneously. It is reminiscent of the tight cooperation among joints that is already evident in the kicking movements of the newborn in supine position. With practice, the ankle joint is dorsally flexed while extending the other joints, referring to a recoordination of parts of the locomotor synergy.

Whereas CPGs were previously assumed to consist of a well-defined assemblage of neurons, functionally distinguishable from others, recent work with invertebrates suggests that they may not be immutable functional entities. Instead, neurons from different circuits can be reconfigured into a new circuit that enables a different function. This selective dismantling of preexisting networks, and the building of new ones, provides us with important clues for a better understanding of the mysterious but enormous flexibility in motor coordination that can be found across the animal world. Additional research is required to demonstrate similar phenomena in the vertebrate nervous system where the neural networks are inherently more complex.

Sensory/Perceptual Contributions to Motor Control

Even though the nervous system is capable of issuing stored motor commands without reference to peripheral feedback, this does not imply that feedback is unimportant for goal-directed motor performance and learning. As mentioned previously, some have argued that birdsong is represented centrally. However, when birds are reared from an early nestling stage without experience of their own species-specific song, the learned contributions to development of the normal song template become evident. These observations point to the important role of auditory experience in species-specific song development. Similarly, even though CPG networks can produce patterns of interlimb coordination in the absence of afferent information, it is equally the case that afference plays a critically important role in normal locomotion for grading the component movements to specific environmental contingencies, such as unexpected obstacles or irregular surfaces.

Research on deafferented humans clarifies the role of sensory information in human motor control. Two patients,

showing severe loss of somatosensory modalities following episodes of sensory polyneuropathy, have been investigated intensively by scientists in the United Kingdom (Marsden et al., 1984) and in Quebec (Teasdale et al., 1993). Although these patients can perform many skillful activities with the help of visual information, they experience difficulties in producing fine manual skills, such as feeding, writing, and fastening buttons. Moreover, their recovery from unexpected perturbations during movement production, takes longer than in control subjects. Interlimb and intralimb (intersegmental) coordination is disturbed as well. These observations point to the important role of sensory afferents in motor control. Thus, whereas the peripheral and central viewpoints are incompatible at their polar extremes, their reconciliation is no longer a matter of doubt. The question can now be rephrased as to 'how central commands and sensory information cooperate to produce skilled action.'

Several sources of sensory information play a determining role in movement regulation: proprio- and exteroception. Proprioceptors provide information about body position in space, joint angles, and the length and tension of muscles. It is information about our own (proprio) movements. Exteroceptors inform us about the spatial coordinates of surrounding objects and the environment. When contacting surfaces and objects, tactile information is also of critical importance to drive our actions. This allows us to hold a glass of water without letting it slip from our hand. A reciprocal relationship exists between sensory information and movement. Sensory information allows movement to proceed correctly as it tells the mover about the state of the body and environment; conversely, movement allows us to sense and perceive. For example, when holding a pen between your fingers for some time, you will experience a loss of sensation of the pen, and its presence fades from consciousness until you move your fingers again, informing you that the pen is still there. In addition to the important role of sensory information in movement, it is also critically involved in the maintenance of posture.

Sensory information and postural control

A variety of receptors contribute to the maintenance of posture. The vestibular apparatus in the inner ear contains receptors sensitive to deviations from the vertical and, more general, to the orientation of the body in space. In addition, receptors in the muscles (e.g., muscle spindles, golgi tendon organs) and joints (e.g., Ruffini endings, Pacinian corpuscles) provide information about muscle stretch, degree of muscle tension, and angle positions. Great effort has been spent in studying these ingenious receptor devices; nevertheless, their modes of operation are still a matter of debate. The muscle spindle is particularly interesting for movement control and has, perhaps, been studied most extensively. It signals changes in muscle length as well as rate of length changes. Sometimes these changes occur abruptly, giving rise to an immediate response.

For example, when standing upright in a driving bus that suddenly stops, one tends to fall forward, resulting in a stretch of muscles in the lower leg (e.g., gastrocnemius, soleus). This results in contraction of these muscles to maintain equilibrium. This response is initially mediated by the stretch reflex, which originates in the muscle spindle and causes muscles to increase tension (although not sufficient) soon after detection

of muscle lengthening. It is an example of a fast closed-loop control mode. Another negative-feedback servomechanism originates in the golgi tendon organ, which senses force rather than muscle elongation, resulting in the reduction of force. Postural control is not only an end but also a means to an end in that it participates in almost any action. When lifting the arm, leg muscles will be activated before onset of arm movement to secure body equilibrium during this focal act. Thus, posture can be regarded as a background upon which a picture of voluntary movement is 'engraved.'

In addition to these muscle-specific sensory devices, vision is a very dominant receptor system in the control of posture and movement. Close your eyes when balancing on one leg, and you will realize that visual information is important for postural equilibrium. Vision also provides information about the position and movements of objects in the environment, leading to decisions for action. But, it is a far richer source of information in that it also tells us about our own movements in relation to the environment (also called exproprioception, as distinguished from extero- and proprioception). When the observer moves in the environment or when an object moves with respect to the observer, changes in the optical array occur, called optical flow. Thus, visual environmental information (e.g., texture, gradients, surface of objects) flows past us as we move around. For example, the rate at which trees and houses become larger and pass by as we drive a car down a road, tells us about our speed and the time at which upcoming objects will be contacted (time-to-contact). Sometimes vision can be so powerful that it overrules the proprioceptive information. As such, the human system is not only capable of integrating different sources of sensory information but also of giving different weights to these sources based on their reliability at a certain time.

Formal evidence for the powerful effects of vision in motor control has been provided by Lee and Aronson in a 'moving room' experiment. Subjects stood on a stationary floor surrounded by walls that could be moved back or forward together. When moving the wall a few centimeters toward or away from the subject, a loss of balance occurred. Apparently, moving the wall changed the optical array that was used as a source of information for postural control. The changes in the visual array were inappropriately interpreted as a loss of balance and produced a compensatory response, that is, moving the wall toward the subject induced the illusion of falling forward. The subject compensated with a backward movement, resulting in a disruption of posture.

Sensory/perceptual information and movement

Role of sensory information before movement

Information about the environment is gathered before actions are planned and executed. When throwing a ball, information is obtained about the location of the target to be hit and the position of the limbs and body. When enough time is available, such information processing may occur at a conscious level. In other cases, as in suddenly avoiding obstacles, decisions for action need to be made so fast that time-consuming processing stages are omitted. For example, information derived from optical flow patterns enables the identification of important external temporal events (the time-to-contact objects), which can be used to control motor activity in

humans and animals. This time-to-contact information is argued to derive directly from the rate at which retinal images of an object change in reference to their image size. It allows precise timing of actions without much conscious processing. This is supposedly the way humans accurately strike the takeoff board and initiate the long-jump when running up the trackway. With the latter examples, the distinction between use of information prior to and during action has become blurred.

Role of sensory information during movement

Ongoing movements can also be adjusted on the basis of incoming information that is fed back to a reference, as long as these movements proceed slowly enough. Examples of such control in human motor behavior are found in continuous tracking tasks such as driving an automobile, flying a small airplane, etc. While driving an automobile, for instance, a major goal is to keep the vehicle on the right track without approaching the road borders too closely. This environmental information is used to guide steering behavior through a series of corrections. The motor system is directed at nullifying error in these tracking tasks. Because the brain is a predictive organ, error detection and correction are implemented very quickly.

Role of sensory information after movement completion

Sensory information can also be processed after movement has taken place, particularly when movements are performed rapidly. After completion of a golf swing, the information produced by this response (response-produced feedback information; e.g., the way the ball was hit, the sound produced at contact) is compared to some reference of correctness, providing information about the degree of success obtained. Any discrepancy between the actual (what is) and expected (what should be) states leads to error detection and decisions for error correction that can be of use for the following trial. When the moving proceeds slow enough, such comparisons can also take place during movement production and may lead to corrections that occur very rapidly, particularly when well-developed internal models of sensory information are available.

This comparator function is hypothesized to reside predominantly in the cerebellum because central motor commands, as well as somatosensory, vestibular, and visual reports from the periphery, converge in this structure. One hypothesis concerning the mode of operation of this comparison process contends that signals are sent to certain neural centers, ahead of the response, to ready the human movement system for upcoming motor commands and for the receipt of feedback information. This advance information is also called corollary discharge (a related term is efference copy), and represents an example of feedforward control. In contrast to feedback, feedforward control refers to sending information ahead of time to prepare for upcoming sensory information or for planned motor commands. Prediction has the advantage that incoming information undergoes facilitated processing. Evidence for this viewpoint comes from experiments showing different sensory experiences in the case of passive or active movement production. As indicated previously, feedforward control is a cornerstone of computational models of motor control.

Movement Constraints: Computational Simplification

Degrees of Freedom and Control of Movement

Considering all movements that can in principle be generated at one joint through various muscle combinations and reflecting on the numerous ways to combine the movements of many joints, our ability to control all these muscles for the purpose of goal-directed behavior is rather remarkable. Indeed, an enormously rich configuration of neuromuscular assemblages is theoretically conceivable in the human motor apparatus. This was coined the 'degrees-of-freedom problem (df)' by the Russian physiologist Bernstein. Roughly defined, df refers to the number of independent states or variables that must be controlled at the same time. The df problem can be conceptualized at various levels of the movement apparatus (e.g., muscles, joints, motor units, neurons). How the control and coordination of several limb segments acting together are accomplished, has become of major interest.

There are various ways to address the df. For example, one can maximally exploit the biomechanical properties of the motor apparatus such as the length-tension characteristics of muscles or the external forces that act on movement (e.g., gravity). Another (related) way is to conceive of 'efficiency' or 'cost' as a dominant criterion for shaping action. For example, it has been proposed that the minimization of torque or mean squared jerk (the first time derivative of acceleration) is a primary efficiency constraint. Third, movement organization can be simplified by invoking larger units of behavior, such as preexisting synergies or reflex patterns, as discussed next.

In attempting to perform more than one motor task concurrently, limitations emerge that constrain our capability to perform different limb movements at the same time. Think, for example, about patting the head while rubbing the stomach simultaneously. A tendency for one movement to impose its pattern of activity on the other or a mutual synchronization of both action patterns becomes evident. Such constraints are common experience and are not limited to motoric dual-task performance. The study of these limitations is a long-standing issue in experimental psychology. I will limit the discussion to the particular case of discrete and continuous motor task coordination.

In a study on bimanual aiming tasks (pointing to different locations in space), Kelso and coworkers (1979) showed that the laws governing unimanual performance do not necessarily apply to multilimb action. In order to better appreciate their findings, it is necessary to first elaborate on one of the most fundamental laws in motor behavior. When aiming with the arm at a certain target, more time is needed when the distance to be covered increases, or, when the target becomes smaller. This can be put in a formal mathematical relationship, known as Fitts' law: $MT = a + b[\log_2(2A/W)]$, where MT is movement time, a and b are empirical constants, A is amplitude of the movement, and W is target width. A combination of the latter two variables provides an indication of task difficulty. If the index of difficulty is increased, the movement will be performed at lower speed. Hence, there is a speed accuracy trade-off. This is a powerful law in that it generally holds for a variety of aiming tasks, irrespective of whether one aims for a glass with the hand, types a keystroke with the finger, or positions the foot on the accelerator.

Given the strength of this lawful relationship for single effector performance, Kelso and collaborators wondered what would happen when making a short pointing movement to a wide target with one hand together with a long movement to a small target with the other hand. In the case of individualized control of the limbs, Fitts' law would predict both movements to be completed in different overall times because of their differential degree of difficulty. The findings, however, proved otherwise: the slow movement was sped up and the fast movement was slowed down, resulting in a rescaling of the movements toward a common underlying temporal structure. This was interpreted as evidence for a coordinative structure, that is, interlimb control by means of a group of muscles constrained to act as a functional unit. These findings do not invalidate Fitts' law which was only conceived for unilimb motions. The point is, however, that the laws governing multilimb actions are not necessarily linear extrapolations of those applicable to unilimb action. In other words, the whole is more than or is different from the sum of its parts. Please note that such constraints refer to the default state of the movement system. Practice allows these constraints to be overcome and musicians are a nice example of differentiated manual performance.

Interlimb interactions equally appear in discrete and cyclical movement production. The latter often display features of oscillators. The theoretical and experimental basis for this work was laid down by Von Holst some 50 years ago during his investigations of the coordination of fin movements in anesthetized fish species. Two important principles of coordination were discovered, which have relevance for many species (including humans). First, each fin pattern tended to maintain its own frequency or speed of natural oscillation, referred to as the maintenance tendency (*Beharrungstendenz*). Such intrinsic frequencies are interdependent with the lengths and masses of the segments to be moved, that is, smaller segments (such as the human arm) are likely to display higher frequencies than larger segments (such as the leg). Second, Von Holst observed a tendency for one fin movement to impose its frequency on another, or for both fin movements to mutually affect each other. This (mutual) attraction was called the 'magnet effect' (*Magnet effect*), often leading to a 1:1 temporal relationship between fins. These principles demonstrate that coordination arises as a result of the interplay between competitive and cooperative tendencies. Moreover, they exemplify how various modes of coordination are accomplished by lower centers through the combination of a few elementary principles. This reduces computational complexity through minimization of the degrees of freedom.

When humans perform cyclical limb movements simultaneously, similar phenomena can be observed. Although this does not necessarily imply that the basic modes of operation are the same in both types of species, it is noteworthy from an evolutionary perspective that some general principles of coordination arise within the animal world. When making horizontal finger or elbow movements in both upper limbs simultaneously, a strong tendency emerges to synchronize the output patterns in a temporally compatible fashion (1:1 frequency ratio), similar to the magnet effect. Both arms are either flexed or extended simultaneously (in-phase), or one arm extends whereas the other is being flexed (antiphase) (see [Figure 2\(a\)](#)). In-phase coordination is associated with the

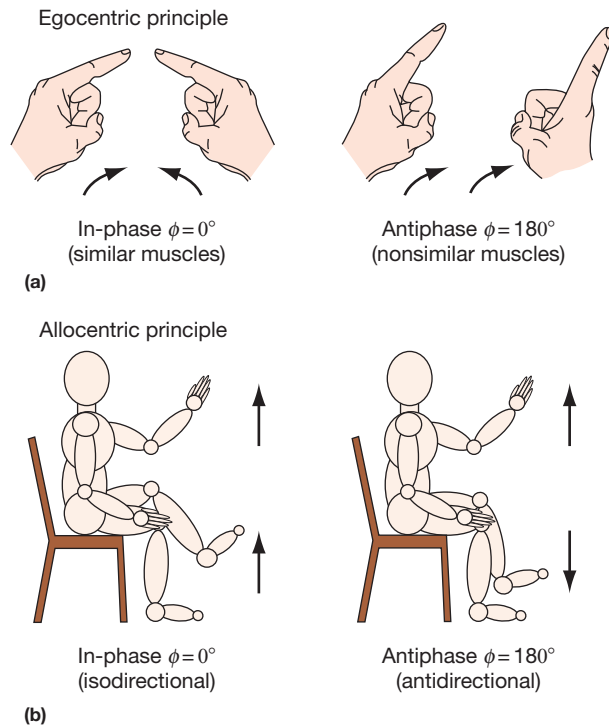

Figure 2 Basic coordination constraints: the egocentric, and allocentric principles. (a) The egocentric principle refers to a preference for mirror symmetrical movements, which involves activating homologous muscle groups simultaneously. (b) The allocentric principle refers to a preference for moving the limbs or limb segments in the same direction in extrinsic space. Φ = relative phase. Reproduced from Swinnen SP (2002) Intermanual coordination: From behavioural principles to neural-network interactions. *Nature Reviews Neuroscience* 3: 350–361, with permission from Nature Reviews Neuroscience.

simultaneous activation of homologous muscle groups whereas antiphase coordination requires the simultaneous activation of nonhomologous muscle groups. This refers to the egocentric constraint. Phase refers to the point of advancement of the signal within a cycle, ranging from 0° to 360° . By subtracting the phase angles of both limbs, one obtains the phase difference or relative phase which provides a signature of the mode of interlimb coordination. Applied to the previous examples, in-phase refers to 0° and antiphase to 180° relative phase. Alternative coordination modes, such as moving the limbs 90° out-of-phase with a 1:1 frequency ratio or producing a pattern with a 3:2 frequency ratio, are more difficult to accomplish and often require substantial learning to attain comparable degrees of stability.

With respect to coordination of nonhomologous limbs or segments (e.g., ipsilateral hand and foot), the most preferred and stable pattern is characterized by moving both limbs in the same direction in extrinsic space, that is, both limbs are moving up and down simultaneously (isodirectional, $\Phi = 0^\circ$) (see Figure 2(b)). Conversely, movements in different directions, that is, one limb moves up whereas the other moves down (antidirectional, $\Phi = 180^\circ$), are perceived as being more difficult to sustain, particularly at higher movement frequencies. This is referred to as the allocentric constraint, denoting a general preference for performing movements in the same direction in

extrinsic space, irrespective of the muscle combinations. The compelling impact of this constraint can be experienced when making cyclical clockwise circular motions with your right leg from a seated position and suddenly drawing the number '6' with your right arm. The anticlockwise motion during drawing '6' results in a sudden shift from clockwise to anticlockwise motion in the lower leg, resulting in isodirectionality.

This directional constraint is also evident during coordination of the homologous limbs, even though it is subordinate to the egocentric constraint. More specifically, coordination patterns of the upper limbs that involve simultaneous activation of the same muscle groups and isodirectional movements in extrinsic space are more accurate and stable than any alternative patterns. Preferred neuromuscular and perceptual aspects could underlie these basic coordination constraints. In this respect, an interesting parallel can be drawn with visual perception, in which mirror image symmetry on the one hand and perceptual grouping of isodirectional stimuli on the other hand are more salient than alternative symmetry or grouping principles. The type of coordination pattern that performers will ultimately produce is task-specific and context-dependent. Recent medical imaging studies have shown that the perceived differential difficulty between the aforementioned bilateral or ipsilateral coordination modes is also associated with differential brain activity, that is, the more difficult mode requires a greater recruitment of neural resources in cortical (temporoparietal and premotor areas, see Figure 1) and subcortical structures (cerebellum, basal ganglia, thalamus) than the easier mode.

Overall, the previously mentioned observations point to a fundamental tendency for frequency and phase synchronization that is evident during the production of various coordination patterns. Stability during in-phase and antiphase coordination is easily obtained and does not require much practice in adults, that is, both are intrinsically stable coordination modes. Advocates of the dynamical systems perspective refer to these modes as 'behavioral attractors.' The important behavioral implication is that alternative coordination patterns tend to converge to or are biased by these attractors, thereby inducing errors in performance.

Thus, we have identified synchronization as a fundamental organizational property governing interlimb coordination and resulting in the exploitation of a restricted range of preferred interlimb relationships. It is now easier to appreciate the nature of errors or the interference that subjects experience when attempting more difficult or incompatible coordination patterns, such as in musical performance. In summary, research on interlimb movements points to the necessity for investigating coordination as a distinct type of control problem with its own lawful modes of operation. In a more general way, global behavior of biological systems cannot always be understood by investigating its elemental units, because interactions among the units are responsible for emergent properties at the macroscopic level that cannot be directly deduced from knowledge of the individual components.

Significant Units of Motor Control

Research on coordination has prompted an animated discussion about the significant units of movement to be controlled

by the human motor system. The viewpoint has gained acceptance that cooperating groups of muscles, constrained to act as a functional unit, are preferably recruited. These are also referred to as muscle collectives, coordinative structures, or synergies, as discussed earlier. This mode of control has a number of advantages. First, it provides an economical solution to the aforementioned df problem in that a limited set of preferred modes of movement organization become apparent. Second, computational complexity is reduced, as these muscle synergies constitute not only the external language of movement but also the internal language of the central nervous system. Although the synergy perspective provides a fruitful and economical way to theorize about the organization of action, it should not be taken to imply that individual muscles, or even motor units, cannot be controlled individually, or that a release from the constraints imposed by these coordinative structures would be impossible. This latter issue will be discussed later.

What evidence has been advanced to support the control of muscle groups by the central nervous system? The strong tendency to synchronize patterns of motor output in the limbs has already been reported. Another line of evidence is provided by the appearance of complete or fractionated reflex patterns in voluntary movement. For example, the tonic neck reflex, which arises in neck proprioceptors, gives rise to body and limb movements through a series of internally triggered reactions. The asymmetric tonic neck reflex, induced by turning the head sideward, is characterized by extension of the limbs on the side of face orientation and flexion on the other side. The symmetric neck reflex causes the upper limbs to flex and the lower limbs to extend when bending the head forward (ventriflextion) whereas the reversed pattern occurs when bending the head backward (dorsiflextion). As head movements also activate the inner ear receptors, these patterns often operate together with labyrinthine reflexes. Reflex patterns can be elicited rather easily in newborns or children with cerebral dysfunctions, but more careful observation reveals that they are also evident in the skillful performances of athletes. For example, attention to head position often induces major improvements in somersaults because it triggers the correct limb or trunk responses. These empirical observations are corroborated by experimental work that has shown actions in accordance with the tonic neck reflexes to confer additional strength. Thus, inherited reflex patterns appear to be part of the behavioral repertoire and become integrated with voluntary movement. This viewpoint is not incompatible with a programming notion of movement control. Central commands may help orchestrate the possible role of these muscle synergies in movement and may incorporate fractions of it into the overall plan of action.

Acquiring New Patterns of Coordination

In the previous section, synchronization was emphasized as a key organizational feature in movement coordination. However, this may also constitute an obstacle whenever differing or incompatible limb movements have to be performed together, such as in playing two different rhythms on the piano. Tapping rhythms with the fingers is not difficult when fingers move in synchrony (1:1), or when tapping in one finger is an integer

multiple of the tapping rate in the other (2:1, 3:1). But, when the timing relationships are less compatible (3:2, 5:3), achieving the same degree of consistency in tapping rate is much more difficult. Degree of temporal incompatibility between the movements marks task difficulty.

Luckily, the human motor control system can overcome or eliminate natural or preferred response tendencies to generate new task-specific forms of coordination. Therefore, it is as important for a theory of coordination to identify the restricted range of interlimb interactions as to provide insights into the way patterns of activity can be differentiated within a highly interconnected neural system, that is, to de- and recompose coordination patterns. The latter is not only a matter of selecting the appropriate action patterns, but also of inhibiting or repressing unwanted or excessive motor activity. Shaping new forms of coordination requires a release from the constraints imposed by intrinsic muscle synergies to meet the general principle of minimal expenditure of energy.

Recoordination of action patterns sets in at an early age. In the newborn, reaching toward a visual target is initially accomplished by a tight coordination of elbow, wrist, and finger extension. This coordinative pattern evolves into a more differentiated organization of the joint movements in which the fingers can be flexed in anticipation of grasping an object while the arm extends; this is an example of intralimb coordination. Sometimes, the overruling of constraints is easily accomplished. At other times, it requires considerable practice as expert athletes, dancers, musicians, etc. testify. Intention and the deployment of attentional strategies are helpful to stabilize otherwise unstable patterns of coordination. Moreover, the use of conceptualisation strategies, instructional means to promote task integration, and/or visual transformation procedures, has been gaining increasing attention of late. Thus, the manner in which actions are conceptualized and represented affects the amount of interference observed. Complex tasks that are seemingly difficult to perform can become easy when familiar events or symbols are called upon. These cognitive strategies serve as binding rules to generate meaningful gestalts. For example, it is generally difficult to produce a 90° out-of-phase finger tapping pattern but learners may catch the trick when referring to a sound made by a galloping horse. Experimental evidence supporting the role of conceptualization processes has been obtained by Franz and coworkers during the simultaneous production of semicircles with both hands. When you perform these geometrical forms in front of you in the air from left to right and back, such that the overall pattern gives rise to a full circle, performance is easy (Figure 3(a), left part). When the semicircles start and end far apart but approach each other in the middle (like a 90° rotated X symbol), performance is much more difficult (Figure 3(a), right part). Both tasks are similar in their relative phasing but differ in familiarity of the symbols that are brought to mind to conceptualize both limbs' subtasks into a meaningful 'gestalt.' Whereas the latter example refers to relatively spontaneous behavior, conceptualization strategies can also be imposed. Binding rules are also critical when performing complex polyrhythms (e.g., a 3:2 or 5:3 frequency ratio). Polyrhythms can be performed successfully when the subtasks become integrated into a common temporal structure in which the taps of the slower limbs are integrated into those of the faster limb. Perhaps the advantage of such

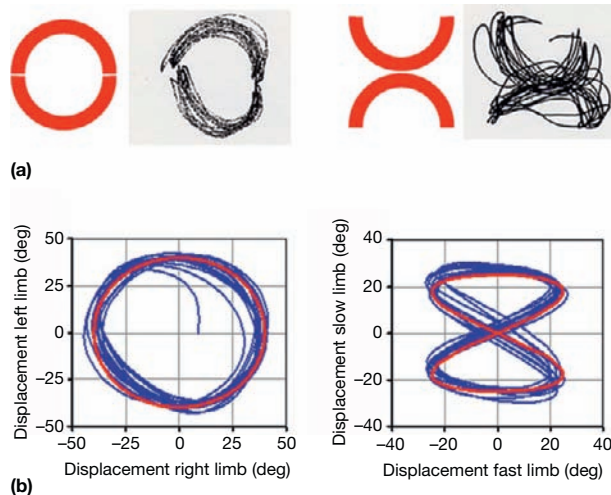

Figure 3 Examples of conceptualization processes or visual transformations that promote task integration. (a) Participants are required to draw semicircles in front of them with both arms. They move in the air from left to right or vice versa. One task (left) requires starting and ending both fingers together in space whereas there is maximal separation in the middle of the trajectory. The other task (right) starts and ends with both fingers separated but the trajectories meet in the middle. When the resulting global pattern is represented by a circle (left), performance is more successful than when a less familiar pattern is generated (right), in spite of the similar relative phasing patterns in two-dimensional space for both tasks. The template is shown in red and actual performance in black. (c) Difficult relative-phasing patterns can be produced and acquired more easily when performers receive real-time augmented feedback displaying their displacements in an integrated fashion. Participants perform cyclical forearm movements in the horizontal plane while the Lissajous figures are represented on a screen in front of them. The left arm motion is presented in the ordinate and the right motion in the abscissa. Examples of patterns with a 1:1 (left) and 2:1 (right) frequency ratio in which one limb lags 90° with respect to the other. Mathematically generated ideal templates are shown in red, actual performance across a 15-s trial is indicated in blue. Reproduced from Swinnen SP and Wenderoth N (2004) Two hands, one brain: Cognitive neuroscience of bimanual skill. *Trends in Cognitive Sciences* 8(1): 18–25.

binding rules is that attention is no longer divided across the subtasks but is focused on the gestalt.

Instructional aids can also be employed to reduce coordinative complexity by provision of a simplified visual representation of the task.

For example, coordination between the limbs can be displayed more directly by a single integrated signal instead of two separate signals representing each limb. When plotting the displacement signals of each limb online during performance in an orthogonal fashion (i.e., a Lissajous figure), difficult coordination patterns become 'graspable' (Figure 3(b)). This type of augmented feedback provides direct information about the nature and quality of coordination and has been used successfully in the context of learning new bimanual coordination patterns.

In summary, the human motor system is plastic and adaptive to overrule coordination constraints. Abstract binding or visual transformation rules can help to overcome these

constraints by enslaving the sensorimotor networks. This is consistent with a hierarchy in control with higher level abstract and lower level muscle- or effector-specific codes.

Motor Control Flexibility and Goal Accomplishment

Writing a computer program that is sufficiently generic for the analysis of various data sets is more elaborate than for one particular data set. Creating an adaptive program or any other device to meet general-purpose requirements is indeed a thorny problem. Flexibility and adaptability are interesting properties of the human motor control system, favoring goal-appropriate behavior through various means. For example, when brushing your teeth, you can move your arm or your head or you can explore various ways to combine them. This is often referred to in the literature as motor equivalence.

Response equivalence is not unique to humans but can also be found in lower mammals as shown in conditioning studies. For example, a sheep is initially trained to lift his left foot off a grid floor at the sound of a tone that signals an impending electrical shock. When the sheep is subsequently forced to lie down with its head on the grid floor, it will now lift its head and shoulders from the floor when the tone sounds. Apparently, the animal has not learned a stereotype response but a goal-directed action, that is, it does whatever is needed to avoid the shock.

At least two types or levels of movement flexibility have received attention. One type concerns adjustments to environmental circumstances through a rescaling of certain movement variables without affecting the basic structure of movement. A second type of adjustment is more invasive and occurs very fast. The former one may be more preplanned through evaluation of initial conditions, whereas the latter may appear rather suddenly during movement, or whenever attainment of action intentions is in danger.

Goal Accomplishment Through Adjustable Parameter Specification

A favorite example to demonstrate that movement can be performed under a variety of circumstances without affecting its basic structure is that of handwriting. Handwriting skill is also a classic case for advocates of programmed control. If you do not believe that movements can run off in a clocklike (programmed) manner once initiated, try this: Write the words 'motor control' at normal speed but try to omit the horizontal bar in the letters 't.' Although you intend to do so before movement initiation, modifying this particular aspect is difficult unless you slow down considerably. It leaves the impression that this action happens beyond voluntary control. But granted these strokes seem to be almost rigidly strung together into one unit, what evidence is there in favor of motor output flexibility? Suppose that you write the word 'skill' under different circumstances and with different overall sizes and speeds. The basic question is whether each variation constitutes a different movement or another version of the same movement structure. Current evidence tends to support the second case. Figure 4 shows the vertical acceleration patterns generated for writing the word skill on a digitizing board positioned

Figure 4 Vertical acceleration patterns produced for writing the word 'skill' on a digitizer positioned horizontally, with 45° inclination, and vertically. On the Y-axis are shown the acceleration patterns. Note that the time basis in graph (a) is different from those in graphs (b–d). Both upper traces differ from each other in letter size, as shown on the right. Letter sizes in (c–d) are also different from (a) although total duration is similar. Reproduced from Swinnen SP (1994) In: Ramachandran VS (ed.) *Encyclopedia of Human Behavior*, vol. 3, pp. 229–243. New York, NY: Academic Press.

horizontally (small and large size), with 45° inclination, and vertically (as in writing on the blackboard), respectively.

As shown in the figure, the word skill is written in different overall sizes: the word presented in graph (a) is two to five

times smaller as the words in graphs (b)–(d) (see Figure 4). The total duration for the smallest word is half that needed for writing the larger words. Leaving aside these parameter differences, similarities among these variations are apparent. They reflect existing task constraints as well as the individual's particular writing style. Thus, although the absolute values of peak accelerations and decelerations differ among these written words, the general form of these acceleration patterns is very similar even though this word has never been written before under these varying conditions. However, the forms are not exactly the same and this is due to the unique way movement commands unfold on every attempt in view of contextual requirements. It reminds us that each movement is unique and is never made in exactly the same way as before.

The consistencies or invariances across variations are noteworthy when realizing that the particular set of muscles used is unique for each example (due to shifts in writing posture, differential gravity effects, writing size, etc.). Consequently, the same program is run off using entirely different muscle groups and with variations in overall size and timing. Whatever is represented in this motor program must be coded in rather abstract terms. Accordingly, a one-to-one relationship between the program and movement does not exist; rather, programs govern all movements that belong to the same class. Schmidt therefore uses the term 'generalized motor programs.' Recent medical imaging studies support the idea that some brain activations are effector-dependent (such as those in the primary sensorimotor cortex) whereas others are effector-independent (such as in the left parietal and premotor cortex). The separation of invariant features and adjustable parameters represents an economical account to human movement production in that movement can be tailored to particular environmental demands without compromising on its basic features.

Goal Accomplishment Through Response Reorganization: Evidence for Motor Equivalence

In contrast with the previous example, the preservation of the movement goal in the face of disturbances can also result in a more invasive reorganization of control. When environmental circumstances impede ongoing movement, the intended goal can often be accomplished by means of short latency but set-dependent responses. Short latency refers to the rapid character of these responses; set-dependence refers to their dependence on the performer's intention. Speech control research has illustrated motor equivalence although it has also been observed in fine precision grip movements and target-directed arm movements. There is mounting evidence that rapid reorganization of movements involved in speech is possible to achieve articulatory goals. For example, when upward movement of the mandible is impeded in the process of saying something that requires a labial occlusion (as in p or b), the upper lip increases its downward movement within 50–60 ms to achieve the articulatory goal. It is a case of feedforward control. These movements are unique in that they differ from voluntary responses that have much longer latencies. But they are also distinct from reflexes in that they are more adaptive in meeting the subject's goal and intentions. These short-latency responses indicate that higher level parts of the control system are

relatively unconcerned with the specific contribution of sub-systems as long as the intended goal is met.

All together, these observations indicate that what is represented as a result of learning is not muscle specific but consists of a rather abstract formulation of movement goals. By specifying general action goals or intentions at the highest levels and leaving the movement details to be fitted later in the process of organization at lower levels, the central nervous system is capable of producing the same effect over and over again, but never in exactly the same way. This is motor equivalence.

Summary

Recent concerns for the df problem on the one hand and for motor equivalence and output variability on the other hand illustrate that organizational and purposive issues in movement form basic tenets in motor control theories. This will eventually lead to a better understanding of the ingenious mechanisms that characterize the human motor control system and will promote the development of appropriate learning settings to improve skilful behavior and to help restore movement disabilities.

The field of motor control has increasingly attracted the attention from a large umbrella of widely different subfields of science. It generates research at an accelerating pace and is marked with interesting discoveries that will ultimately result in the establishment of a solid body of knowledge on the functioning of the central nervous system and the great diversity of actions it generates. However, it is also a challenging area to work in for the practicing scientist in that information from various areas of research has to be brought together.

Near-Death Experiences

B Greyson, University of Virginia, Charlottesville, VA, USA

© 2012 Elsevier Inc. All rights reserved.

Glossary

Autoscopy The experience of seeing a hallucinatory image of one's body in external space.

Cardiac arrest A sudden, complete cessation of the heartbeat and cardiac function, causing blood to stop circulating through the body.

Deathbed vision A vision or other experience that a dying person may have in the minutes, hours, or days before his or her death.

Ego boundary The normal psychological delineation of the self from everything that is not the self.

Extrasensory perception (ESP) The acquisition of information about an external event or object in some way other than through any of the known sensory channels.

Hallucination A subjective perception that appears to be real but is generated by the mind rather than by any corresponding external stimulus.

Mind/brain problem The philosophical problem of the interrelationship between the mind and the brain.

Neurotransmitter A chemical that transmits neural signals across a synapse between a neuron and another cell.

Out-of-body experience (OBE) An experience in which one's center of consciousness seems to be in a spatial location outside one's physical body.

Rapid eye movement (REM) Sleep a sleep stage in which dreaming occurs, characterized by rapid eye movements and a waking-like EEG.

Introduction

Near-death experiences (NDEs) are profound and sometimes life-changing experiences reported by people who have been physiologically close to death, as in cardiac arrest or other life-threatening conditions, or psychologically close to death, as in accidents or illnesses in which they feared they would die. The characteristic transcendence of ego boundaries, including a sense of separation from the physical body and experience of cosmic unity, leads many near-death experiencers (NDErs) to interpret the event in spiritual or mystical terms.

Experiences of altered consciousness on the threshold of death can be found in the folklore and writings of most cultures and have been described sporadically in the Western medical literature since the nineteenth century. The phenomenon was first described as a discrete syndrome in 1892 by Albert von St. Gallen Heim, a Swiss geology professor who was motivated to collect accounts after he himself had a profound experience while falling from a mountain in the Alps. However, the term *near-death experience* and its acronym *NDE* were not coined until 1975. Extensive research since then suggests that NDEs are reported by 12–18% of cardiac arrest survivors (between 1600 and 2400 Americans each year).

Early research into NDEs was predominantly retrospective, raising the question of the reliability of the experiencer's memories. However, studies comparing NDE accounts from the same experiencers on successive occasions varying from days apart to 20 years apart have found no indication of embellishment or other distortion over time; and more recent research has placed greater emphasis on prospective studies.

Phenomenology of NDEs

Raymond Moody, who coined the term *near-death experience*, used it to refer to an ineffable experience on the threshold of

death that may include feelings of peace and cessation of pain; a sense of being out of one's physical body and watching events from an out-of-body perspective; a sense of movement through a dark tunnel or void to another realm; seeing an unusually bright light that may be experienced as a 'being of light'; a panoramic life review; meeting other nonphysical beings, including deceased acquaintances; a border or point of no return; and a return to the physical body, followed by profound changes in attitudes and values and elimination of the fear of death.

The most common features of NDEs can be grouped into four components. Cognitive features reflect changes in thought processes, including distortions in the sense of time, acceleration of thought, a life review or panoramic memory, and a sense of revelation or sudden understanding. Affective features reflect changes in emotional state, including a sense of peace and well-being, joy, a sense of cosmic unity, and an encounter with a brilliant light that seems to radiate unconditional love. Paranormal features include purported psychic phenomena, such as extraordinarily vivid physical senses, extrasensory perception, precognitive visions, and a sense of being out of the physical body. Transcendental features include apparent otherworldly phenomena, such as travel to a mystical or unearthly realm or dimension, an encounter with a mystical being or presence, visions of deceased or religious figures, and a border beyond which one cannot return to earthly life.

NDEs are reported both by individuals who had been pronounced clinically dead but then resuscitated, and by individuals who, in the course of accidents or illnesses, merely feared that they were near death. Some individuals who actually do die are able to describe 'deathbed visions' in their final moments, or speak and act in ways that suggest they are having visions, which bear some similarities to NDEs. Although all elements of the NDE can be reported by individuals who merely believe themselves to be near death, an encounter with a brilliant light, enhanced cognitive function, and positive

emotions are more common among individuals whose closeness to death has been corroborated by medical records.

Many of the experiential features of NDEs are typical of those of mystical experiences occurring in other settings: a sense of cosmic unity or oneness, transcendence of time and space, deeply positive mood, sense of sacredness, noetic quality or intuitive illumination, paradoxicality, ineffability, transiency, and persistent positive aftereffects. However, typical NDEs differ from classical mystical experiences in three respects: the accent on individual identity, such as in the life review and encounters with deceased relatives; the relative clarity of events; and the lower frequency of the experience of union, which is a defining characteristic of mystical experience.

Aftereffects of NDEs

NDEs can permanently and dramatically alter an individual's attitudes, beliefs, and values. Aftereffects most often reported from long-term follow-up studies, including interviews with significant others, include increases in spirituality, compassion and concern for others, altruistic behavior, appreciation of life, sense of connection to others, belief in postmortem existence, sense of purpose, and confidence and flexibility in coping with life's vicissitudes; and decreases in fear of death, interest in materialism, personal status, and competitiveness. Although decreased fear of death usually increases suicidal risk, NDEs paradoxically express stronger opposition to suicide than comparison samples, primarily on the basis of increased transcendental beliefs and sense of meaning and purpose in life.

This transformative aspect of NDEs has not been reported in connection with the various fragmentary experiences that are sometimes compared to NDEs, such as the 'dreamlets' induced by hypoxia or other abnormalities of blood-gas concentrations, or experiences reported by patients receiving temporal lobe stimulation. Moreover, the transformative features associated with NDEs differ from those associated with the experience of coming close to death but not having an NDE. For example, although most individuals who come close to death express greater appreciation for life, those who did not have NDEs often become more fearful of death and less flexible in coping with stressors.

Psychological Models of NDEs

How can these phenomena best be understood? Psychological speculations have attributed NDEs to defense mechanisms, depersonalization, wishful thinking, retroactive confabulation, and expectation, although these psychological models are not supported by empirical evidence, and some have been rebutted by what evidence we have. One such explanation suggests that NDEs are products of the imagination, constructed from personal and cultural expectations to lessen the threat of death. However, individuals often report experiences that conflict with their specific religious and personal expectations of death. Specific knowledge individuals had about NDEs previously does not influence the details of their own experiences: people who have not known about NDEs describe the same kinds of experiences as do people who are familiar with them,

and experiences that were reported before 1975, when the term NDE was coined, do not differ from those that occurred after that date. Furthermore, children too young to have received substantial cultural and religious conditioning about death report the same kinds of NDEs as do adults; some cases have been reported to have occurred before the child could have acquired significant language skills.

Although there are some cross-cultural variations in the content of NDEs, these may reflect simply the experiencers' difficulty processing and expressing an experience that is largely ineffable. At this point it is unclear whether cultural beliefs influence the actual experience itself, or merely its recall and retelling, or the investigators' collection of the accounts. There seems, in short, to be an underlying core experience that is inevitably cast in the images, concepts, and symbols culturally available to the individual.

Since religion addresses fundamental human concerns such as death and dying, one might speculate that religious orientation or religiosity might influence NDEs. One view of the NDE is that it represents essentially a religiously inspired illusion. However, several studies in the United States and in other cultures have failed to find associations between religion or religiosity and subsequent NDEs, although they have found that an individual's belief system influenced the *interpretation* of the experience.

Another psychological model attributes NDEs, with their dark tunnel, a bright light, and transition to another realm, to memories of birth. However, newborns lack the visual, spatial, or mental capacities to register memories of birth experiences. Furthermore, many NDEs do not contain the features of a tunnel or a light, and many other common features of NDEs are not accounted for by this model. Finally, claims of out-of-body experiences (OBEs) and of passing through a tunnel to another realm are equally common among persons born by normal vaginal delivery and those born by Caesarean section, whose birth would not include any 'tunnel' analogy.

Researchers have identified very few personal traits or variables that can predict who will have an NDE or what kind of NDE a person may have. NDEs are indistinguishable from other survivors of close brushes with death in terms of age, gender, race, intelligence, neuroticism, extroversion, trait and state anxiety, history of mental illness, or relevant Rorschach measures. However, some studies have suggested that NDEs tend to be good hypnotic subjects, remember their dreams more often, and are adept at using mental imagery, and tend to acknowledge significantly more childhood trauma and resultant dissociative tendencies than others. It is not clear whether these distinguishing personal traits are the results of having had an NDE or whether people who already have those characteristics are more prone to have NDEs when they come close to death.

Comparison of NDEs to Psychopathological Conditions

As noted above, retrospective studies of NDEs have shown them as a group to be psychologically healthy individuals, who do not differ from comparison groups in measures of mental health. The percent of psychiatric patients reporting NDEs is comparable to that found in the general population, suggesting that mental illness itself bears no association with NDEs.

Psychiatric patients who have been close to death report more psychological distress than those who had not; however, among those patients who had come close to death, those who reported NDEs report less psychological distress than those who did not. Thus, NDEs seemed to have a protective effect against, rather than to cause, psychological distress. Despite this evidence of mental health among NDErs, NDEs and their aftereffects have been compared by some authors to several psychopathological conditions.

Depersonalization involves feelings of detachment, strangeness, and unreality, which some have compared to the perceptions in NDEs. However, in depersonalization, the feeling of one's own reality is lost, whereas NDEs are described as being vividly real; depersonalization is usually unpleasant, in contrast to most NDEs; and depersonalization involves an emotional detachment from the body but not a perception of actually leaving the body. Depersonalization does not include the hyperalertness and mystical consciousness seen in NDEs, and it differs from NDEs in its age and gender distribution.

NDEs have been compared with *dissociation*, the separation of thoughts, feelings, or experiences from the normal stream of consciousness and memory. Symptoms of dissociation are more common among NDErs than among individuals who have come close to death without NDEs, but they are still within the range of the normal population and much lower than in clinical dissociative disorders. The dissociative symptom profile of NDErs is suggestive of a normal psychophysiological response to stress, a shifting of attention from the physical environment to an altered state of consciousness, rather than a pathological type of dissociation or a manifestation of dissociative disorder.

Related to dissociation is *absorption*, the ability to screen out the external world and focus attention either on selected sensory experiences or on internal imagery, and *fantasy proneness*, characterized by frequent and vivid fantasies, hallucinations, intensely vivid sensory experiences, and eidetic imagery. Empirical data regarding absorption and fantasy proneness among NDErs have been equivocal. A relationship between fantasy proneness and NDEs might suggest that NDEs are fantasies, or it might instead reflect an ability to enter more readily into altered states in which the ordinary relationship of consciousness to brain activity and the external environment has changed.

Among the psychological and biological responses to trauma is *posttraumatic stress disorder (PTSD)*, which involves a biphasic pattern of reliving the trauma through intrusive memories, alternating with avoidance of reminders and numbing. NDEs can in some cases lead to PTSD-like symptoms of intrusive recollections of the event, recurrent dreams of the event, diminished interest in previously important activities, estrangement from others, and a sense of foreshortened future. The incidence of PTSD-like symptoms among NDErs is higher than that among survivors of close brushes with death without NDEs, although it is within the normal range and far below that seen in clinical PTSD. The NDErs' profile of moderate elevation of intrusive (though not distressing) thoughts, images, feelings, and dreams, but no elevation of avoidant psychic numbing, behavioral inhibition, or counterphobic activities, is typical of a normal response to stress rather than of PTSD.

NDEs have sometimes been compared to *autoscopy*, seen in a variety of brain lesions. However, in NDEs the observing self or point of perception is experienced as outside the physical

body, and the subject sees his or her own inactive physical body; in autoscopy, the observing self remains inside the body and sees an apparitional 'double.'

NDEs also are superficially similar to psychoactive substance-induced hallucinations, but are generally more complex than the mental imagery induced by drugs, are more often endowed with personal meaning, and usually occur in the absence of psychoactive substances. Although schizotypal personality disorder can include cognitive and perceptual distortions, it requires a pervasive pattern of interpersonal deficits that is not seen in NDEs. NDEs can be differentiated from brief psychotic disorders by their acute onset following a stressful precipitant, and by the experiencers' good premorbid functioning and positive exploratory attitude toward the experience.

Physiological Models of NDEs

There have been numerous attempts to explain NDEs in terms of conventional biochemical or neurobiological mechanisms, based on known or hypothesized changes in the neurochemistry of the brain brought on by the conditions accompanying a close brush with death and leading to abnormal neuroelectric activity in critical brain areas, usually the temporal lobes. However, as researchers have learned more about the variations and complexities of the conditions under which NDEs can occur, there has been a noticeable move away from attempting to find a single common mechanism underlying all NDEs and toward a multifactorial interpretation. It should be noted that these hypothetical neurobiological mechanisms, for which there is little if any empirical evidence, may suggest brain pathways through which NDEs are expressed or interpreted, but do not necessarily imply causal mechanisms.

Hallucinations

Because NDErs report events that others around them cannot see or experience, some have regarded NDEs as elaborate hallucinations produced either by medications given to dying patients or by metabolic disturbances or brain malfunctions as a person approaches death. However, many NDEs are recounted by individuals who had no known metabolic or organic malfunctions that might have caused hallucinations. And although some drugs may occasionally induce experiences that bear superficial similarities to NDEs, comparative studies have shown that patients who receive medications in fact report *fewer* NDEs than do patients who receive no medication. Such findings suggest either that drug-induced delirium, rather than causing NDEs, in fact inhibits them from occurring or that delirious patients tend not to recall their experiences upon recovery.

As for metabolic causes of hallucinations, organic brain malfunctions generally produce clouded thinking, irritability, fear, belligerence, and idiosyncratic visions, quite unlike the exceptionally clear thinking, peacefulness, calmness, and predictable content that typify the NDE. Visions in patients with delirium are generally of living persons, whereas those of patients with a clear sensorium as they approached death are almost invariably of deceased persons. Patients who were febrile or anoxic when near death report fewer NDEs and less elaborate experiences than do patients who were not.

Altered Blood Gases

One physiological model attributes NDEs to decreased oxygen (*hypoxia*) or to a complete lack of oxygen (*anoxia*), which is often the final common pathway to death. However, NDEs also occur without anoxia or hypoxia, as in nonlife-threatening illnesses and near-accidents. Furthermore, the experiential phenomena associated with hypoxia are only superficially similar to NDEs. 'Dreamlets' occurring during the brief periods of hypoxia-induced unconsciousness induced by rapid acceleration in fighter pilots, for example, share with NDEs tunnel vision and bright lights, floating sensations, pleasurable sensations, brief fragmented visual images, and (rarely) a sense of leaving the body. In contrast to NDEs, these 'dreamlets' include visions of living people but never dead people, and no life review or panoramic memory. NDEs do not include typical hypoxic symptoms, such as myoclonic convulsions, retrograde amnesia for events prior to unconsciousness, automatic movements, memory effects, tingling in extremities and around the mouth, confusion and disorientation upon awakening, and periawakening paralysis. Hypoxia or anoxia generally produces idiosyncratic, frightening hallucinations, and leads to agitation and belligerence, quite unlike the peaceful NDE with consistent, universal features. Furthermore, the few published studies of blood gases in people near death have shown that those who have NDEs do not have lower oxygen levels than those who do not.

Another possible model suggests that elevated carbon dioxide levels (*hypercarbia*) may contribute to NDEs. However, the NDE-like features that have been reported in hypercarbia, such as a sense of leaving the body, bright light, dark void, memory revival, and sense of peace, are rare and isolated. Furthermore, there have been reports of NDE in patients in whom carbon dioxide levels were not elevated. Finally, if anoxia and hypercarbia played an important role in NDEs, NDEs should be much more common than they are in patients with cardiac arrest.

Neurotransmitters

NDEs have been speculatively attributed to a number of neurotransmitters in the brain, most frequently endorphins or other endogenous opioids released under stress, although other models have implicated serotonin, adrenaline, vasopressin, glutamate, and dimethyltryptamine. At this point, such models are speculative and none has been tested.

However, endorphins produce pain relief and a sense of well-being that persists for hours, whereas the peace and cessation of pain in the NDE are brief, often only a few seconds. Furthermore, the release of endorphins fails to account for many other important components of NDEs, such as the OBE, seeing deceased persons, a life review, and the transformative effects.

A more intriguing model has been proposed based on a putative neurotransmitter that in fact is not known to exist. Ketamine, an anesthetic agent that selectively occupies *N*-methyl-D-aspartate (NMDA) receptors, can at subanesthetic doses produce feelings of being out of the body, and can produce other experiences that resemble NDEs, such as travel through a dark tunnel into light, believing that one has died, or communing with God. It is plausible that a ketamine-like endogenous neuroprotective agent – which has been

hypothesized but not yet found to exist – may be released in conditions of stress, acting on NMDA receptors.

However, unlike the vast majority of NDEs, ketamine experiences are usually frightening and involve bizarre imagery, and patients usually express the wish *not* to repeat the experience. Most ketamine users also recognize the illusory character of their experience, whereas NDEs are almost always convinced of the reality of the experience. Many important features of NDEs, such as seeing deceased people or a life review, have not been reported with ketamine. Furthermore, ketamine typically exerts its effects in an otherwise more or less normal brain, while many NDEs occur under conditions in which brain function is severely compromised.

REM Intrusion

In one recent study, an association was suggested between NDEs and 'rapid eye movement (REM) intrusion,' the intrusion into waking consciousness of thought processes typical of REM or dream sleep. NDEs and REM intrusion share common elements of seeing light and feeling alert to the surroundings while the body seems passive. However, the interpretation of this association is questionable, as the post hoc estimation of 'REM intrusion' was perfunctory and possibly biased, and comparison groups were quite dissimilar. In fact, NDEs report the same amount of 'REM intrusion' as does the general population, whereas the comparison group in that study reported about one fourth the 'REM intrusion' of the general population. Data arguing against the contribution of REM intrusion to NDEs include many features, such as fear, that are typical of 'REM intrusion' but rare in NDEs; the frequent occurrence of NDEs under general anesthesia and other drugs that inhibit REM; and the transformational aftereffects of NDEs.

Neuroanatomical Models of NDEs

NDEs have also been speculatively linked to a number of anatomic locations in the brain, most often the right temporal lobe, although various neuroscientists have also suggested involvement of attention-control areas in the frontal lobes and elsewhere, the somatosensory body maps in the parietal lobes, the thalamus, the hypothalamus, the amygdala, the hippocampus, and Reissner's fiber in the central canal of the spinal cord. The brain region most often implicated in NDEs has been the *temporal lobes*, based on purported similarity of NDEs to temporal lobe seizure phenomena. However, NDE-like phenomena are almost never seen in temporal lobe seizures, and electrical stimulation of the temporal lobes may elicit fragmented bits of music, isolated and repetitive familiar scenes, hallucinated voices, fear or other negative emotions, or bizarre, dream-like imagery, in addition to a wide range of somatic sensations that are never reported in NDEs. Initial reports of NDE-like phenomena induced by transcranial magnetic stimulation of the temporal lobes turned out to be quite unlike NDEs in their detail, and even those could not be replicated and have now been attributed to suggestion.

OBEs, in which a person's consciousness is experienced as separated from the physical body, are a frequent feature of NDEs, being reported by between 50 and 80% of experiencers. Abnormal activation of areas of the temporal lobes may

produce alterations in body perceptions, and recent neuroimaging studies have linked OBEs to the temporal–parietal junction (TPJ). However, in those studies, the TPJ was only a region of statistical ‘mean overlap’ of individual lesions that were actually distributed much more widely, and in many subjects the seizures were in different brain regions that did not involve the TPJ or could not be localized at all.

Even if the TPJ were involved in the production of at least some OBEs, that part of the cortex would probably not be producing them. Both seizure activity and direct electrical stimulation of a brain region typically disrupt whatever patterns of neuroelectric activity would otherwise be going on there; thus, it could explain the failure of the normal integration, but not the production of an integrated altered state such as an OBE. Moreover, the vast majority of patients with temporal lobe seizures do *not* experience OBEs. Thus localized abnormal activity in the brain is not only not *necessary*, but also not in general *sufficient* to produce an OBE.

Even if OBEs were associated with a certain region of the brain, that would not account for complex perception or thought processes at a time when the abnormalities in brain functioning would ordinarily abolish consciousness. To equate OBEs with pathological ‘body illusions’ ignores the complexity of their physiological, psychological, and phenomenological aspects.

Multifactorial Explanations

Despite the questionable foundations for assertions that NDEs are similar to experiences associated with abnormal temporal lobe activity, anoxia, hypercarbia, ketamine, or endorphins, several multifactorial theories, based on these foundations, combine these putative causes at will to account for whatever constellation of features is observed in any given NDE. Even if supporting data were found for some of these physiological models for NDEs, correlating a brain state with an experience does not necessarily imply that brain states cause the experience; the brain state may alternatively allow access to or simply reflect the experience, an interpretation favored by some researchers who have investigated neurophysiological models of NDEs.

NDEs in Anesthesia and Cardiac Arrest

The most important problem with current psychophysiological theories of NDEs is that mental clarity, vivid sensory imagery, a clear memory of the experience, and a conviction that the experience seemed more real than ordinary consciousness are the norm for NDEs, even when they occur in conditions of drastically altered cerebral physiology under which current neuroscientific models of the mind deem such phenomena impossible. In short, our current physiological models do not explain the enhancement of mental functioning at a time when the brain is grossly impaired, as it is under conditions such as general anesthesia and cardiac arrest.

NDEs that occurred under *general anesthesia* typically include such features as OBEs that involved watching medical personnel working on their body, an unusually bright or vivid light, meeting deceased persons, and thoughts, memories, and sensations that were clearer than usual. Unconsciousness

during anesthesia is associated with a distinct EEG frequency shift, spatial distribution, and decoupling of rhythms across the brain; this consistent pattern of brain electrical activity confirms the disabling of awareness under anesthesia according to our current neurophysiological understanding. Likewise, blood flow, glucose metabolism, and other indicators of cerebral activity under general anesthesia show that, although sensory pathways remain relatively unimpaired, they no can longer ignite the cooperative network interactions generally believed necessary for conscious experience.

Reports of NDEs in *cardiac arrest*, like those that occur with general anesthesia, typically include vivid or even enhanced sensation, thinking, and memory formation, despite cerebral functioning shutting down within seconds. In cardiac arrest, there is instantaneous cessation of blood flow, and oxygen uptake in the brain plunges swiftly to zero. EEG signs of cerebral ischemia are detectable within 6–10 s, and progress to flat-line EEGs within 10–20 s, reflecting the absence of any cortical activity. Cardiac arrest leads rapidly to the three major clinical signs of death – absence of cardiac output, absence of respiration, and absence of brainstem reflexes. Nevertheless, many NDEs have been reported in conjunction with well-documented cardiac arrest. In fact, the incidence of NDEs in cardiac arrest is ten times greater than that in other serious cardiac incidents.

Of course, even with a flat-lined EEG there still could be undetected brain activity in *subcortical* brain regions, as the EEG detects only activity common to large populations of neurons in the cerebral cortex. However, the type of brain activity that is thought necessary for conscious experience is detectable by EEG, and it is indisputably abolished both by anesthesia and by cardiac arrest. In cardiac arrest, even neuronal action potentials, the ultimate physical basis for coordination of neural activity between widely separated brain regions, are rapidly abolished. Moreover, cells in the hippocampus, essential for memory formation, are especially vulnerable to the effects of anoxia, making it implausible that NDEs in cardiac arrest can be accounted for by a hypothetical residual capacity of the brain to process and store complex information under those conditions.

It has been suggested that some NDE features may occur not during the actual episodes of brain shutdown, but just before or after, when the brain is still more or less functional. However, unconsciousness produced by cardiac arrest characteristically leaves patients amnesic for events immediately preceding and following these episodes, in contrast to the extreme mental clarity associated with NDEs. In addition, the confusional experiences occurring as a person is losing or regaining consciousness do not have the life-transforming impact so characteristic of NDEs. Moreover, a substantial number of NDEs contain time ‘anchors’ in the form of verifiable reports of events occurring during the period of brain shutdown itself, such as circumstances occurring in conjunction with resuscitation procedures in the hospital while the patient was comatose.

Implications of NDEs for the Mind–Brain Problem

Although NDEs can occur in a wide variety of conditions in which the person is clearly *not* near death, many such experiences clearly *do* occur when the brain is severely impaired.

Thus, NDEs raise questions about the common assumption in neuroscience that consciousness is the product of brain processes, or that mind is merely the subjective concomitant of neurological events.

The idea that mind and brain are not identical is not inherently unscientific. Although it contradicts the assumption of many psychologists and neuroscientists that brain produces mind, or indeed is the mind, the direction that physics has taken in the last century justifies ample caution when it comes to making assumptions about the scope and the fundamental character of consciousness and its relationship to the physical world.

The evidence from enhanced mental function, accurate out-of-body perception, and some visions of the deceased during NDEs fundamentally conflicts with the conventional belief that brain processes produce consciousness, and supports the alternative view that brain activity normally serves as a kind of filter, selecting material that is allowed to emerge into waking consciousness. On this latter view, the relaxation of the filter under certain poorly understood circumstances may lead to drastic alterations of the normal mind/brain relation and an associated enhancement of consciousness.

Enhanced Thought Processes

Perhaps the most important of these features, because it is so commonly reported in NDEs, is the occurrence of normal thought processes, and even enhanced mental activity, at times when the mind/brain identity model would expect such activity to be severely diminished, if not impossible. NDEers often describe their mental processes during the NDE as remarkably clear and lucid and their sensory experiences as unusually vivid, surpassing those of their normal waking state, as if the mind had been freed from the distractions and limitations of the physical brain. Indeed this mental clarity, vivid sensory imagery, a clear memory of the experience, and a conviction that the experience seemed more real than ordinary consciousness are the norm in NDEs, even when they occur under conditions of drastically altered cerebral physiology. Moreover, the closer people are to death physiologically, the more likely they are to report such enhanced mental functioning. People who have NDEs during cardiac arrest almost invariably retain vivid memories of their experience that change little with the passage of time, despite the fact that memory under such conditions is ordinarily seriously impaired. In contrast, most patients with temporal lobe epilepsy have no memory afterward for what happened during a seizure.

Another example of enhanced mental functioning during an NDE is a rapid revival of memories, often called a 'life review.' In contrast to the isolated and often just single brief memories evoked during cortical stimulation of the temporal lobes, memories revived during an NDE are frequently described as being an almost instantaneous 'panoramic' review of the person's entire life.

Out-of-Body Experiences

About half of all NDEers report having viewed their bodies from a different point in space, and many are able to describe accurately what was going on in the vicinity of their physical

body, such as resuscitation attempts, while they were ostensibly unconscious. Many such reports of accurate perception during NDEs are not simply vague or general statements but contain very specific details unlikely to have occurred by chance.

Additionally, some experiencers report that, while out of the body, they became aware of events occurring beyond the reach of their ordinary senses even if they had been conscious. Some of these accurate perceptions included unexpected or unlikely details. There are also well-documented examples of blind individuals, including those blind from birth, who experienced during their NDEs accurate quasi-visual perceptions of objects and events. Many of these apparent out-of-body perceptions had been reported to someone else *before* being verified by independent researchers.

It has been suggested that some of these apparent out-of-body perceptions may be retrospective imaginative reconstructions attributable to a persisting ability to hear, even when unconscious. However, claims that adequately anesthetized patients retain significant capacity to be aware of their environment, let alone to hear and understand, have not been substantiated. There is no convincing evidence for adequately anesthetized patients having any explicit, or conscious, memory of events during the surgery – other than patients who have reported such memories in connection with an NDE. It is implausible that memories of complex sensory experiences occurring during general anesthesia could have been acquired by the impaired brain itself during the period of unconsciousness.

Partial awakening during surgical procedures does occur in less than 1% of general surgical procedures, usually attributable to insufficient anesthesia, but these awakenings are altogether different from NDEs, and generally extremely unpleasant, frightening, and painful. The partial-awakening experiences are typically brief and fragmentary, and primarily auditory or tactile, and not visual; for example, the patient may report hearing noises or snippets of speech, or briefly feeling sensations associated with intubation or with specific surgical procedures. Explanations of NDEs involving sensory awareness during anesthesia are even less credible when, as commonly happens, the sensory channels involved in the reported experience have been deliberately blocked, such as when visual experiences are reported by patients whose eyes were taped shut during the surgical procedure.

It is conceivable that some accurate apparent OBE perceptions may be retrospective imaginative reconstructions attributable to expectations about what was likely to have occurred. However, studies in the United States and in the United Kingdom specifically examining that possibility show that patients who reported leaving their bodies during cardiac arrests described their resuscitations accurately, including idiosyncratic and unexpected details, whereas cardiac arrest survivors who had not reported leaving the body made numerous errors in regard to equipment and procedures when asked to describe their resuscitation.

Although some of the reports of accurate perceptions of events at a distance from the body depend on the experiencer's testimony alone, many cases have been corroborated by independent witnesses. A recent review by Jan Holden of 93 reports of potentially verifiable out-of-body perceptions during NDEs found that 92% were completely accurate, 6% contained some

error, and only 1% were completely erroneous. Even among those cases corroborated to the investigator by an independent informant, 88% were completely accurate, 10% contained some error, and 3% were completely erroneous. The cumulative weight of these cases is inconsistent with the conception that purported out-of-body perceptions are nothing more than hallucinations.

Encounters with the Deceased

Many NDErs report that, during the time they seemed to be dying, they met deceased relatives and friends. Some of these visions may be due to hallucinations or to expectations of or wishes for reunions with deceased loved ones. However, although NDErs often perceive deceased people with whom they were emotionally close, consistent with the expectation theory, in one-third of the cases the deceased person was either someone with whom the experiencer had a distant or even poor relationship or someone whom the experiencer had never met.

Moreover, some experiencers on their deathbeds see, and often express surprise at seeing, a recently deceased person of whose death neither they nor anyone around them had any knowledge, excluding the possibility that the vision was a hallucination related to the experiencer's expectations. In some cases, the person seen died at the time of, or immediately before, the vision, allowing no possibility for the experiencer to have learned of the death. Reports of these cases, in which the dying individual sees someone recently deceased but thought to be still living, are scattered throughout the literature; but there are enough of them to warrant giving them serious attention.

Furthermore, in some cases the deceased person seen was someone whom the experiencer had not even known. Recently published examples of this type of case include a man who reported encountering his biological mother, whose photograph he had never seen because his father had remarried after her death when he was an infant; a child who reported encountering a brother she was unaware of, who had died before her birth; and a man who encountered a stranger whom he later recognized as his biological father from a photograph he had not previously seen, whom his mother had never married, and whom he had never known.

Summary

Although NDEs have been reported for centuries, they have become more prevalent as modern technology has allowed us to bring people back from the brink of death and indeed to blur the boundary between life and death. These technological medical advances have increased the number of reported NDEs, which are important to behavioral scientists for three reasons. First, NDEs precipitate pervasive and durable changes in beliefs, attitudes, and values. Second, they may be confused with psychopathological states, yet have profoundly different effects requiring different therapeutic approaches. Third, clarification of their mechanisms may enhance our understanding of consciousness and its relation to brain function.

The extensive research on NDEs over the past three decades has focused primarily on their epidemiology, their

psychophysiological correlates, and their effects on the lives of experiencers. Aftereffects most often reported include increases in spirituality, compassion, and concern for others, altruistic behavior, appreciation of life, sense of connection to others, belief in postmortem existence, sense of purpose, and confidence and flexibility in coping with life's vicissitudes; and decreases in fear of death, interest in materialism, personal status, and competitiveness. Studies of NDErs have shown most of them to be psychologically healthy individuals, who do not differ from comparison groups in measures of mental health. NDEs share some features in common with dissociation, depersonalization, PTSD, and hallucinations, but also differ from those conditions in significant ways.

Despite the research focus on mundane aspects of NDEs, the main reason that these experiences generate interest among the general public is that they seem to provide evidence that consciousness can function independent of the human body. NDEs commonly include a number of features challenging the conventional assumption that consciousness is solely the product of brain processes, or that mind is merely the subjective concomitant of neurological events. These features include enhanced cognitive function in the presence of demonstrable brain dysfunction, accurate perceptions from a visual perspective out of the physical body, and apparent encounters with deceased spirits. Although some of these visions of the deceased may be attributed to expectation and wishful thinking, that explanation cannot account for cases in which the deceased person seen was not known or expected to be dead.

The theoretical challenge of NDEs lies in asking how complex consciousness, including thinking, sensory perception, and memory, can occur under conditions in which current physiological models of mind deem it impossible. This dilemma is most apparent in NDEs that occur under conditions of general anesthesia and/or cardiac arrest. Scientific discussions of the mind-brain problem, to be responsible intellectually, must take these data into account.

Negotiation

P J Carnevale and Y K Kim, University of Southern California, Los Angeles, CA, USA

Published by Elsevier Inc.

Glossary

Best alternative to negotiated agreement (BATNA) The outcome if there is no agreement in negotiation, a useful reference for evaluating the merits of offers and possible outcomes.

Concession-making Reducing one's demands or offers, that is, changing one's proposal so that it provides less benefit to oneself.

Contending Attempting to persuade the other negotiator to make a concession, or an attempt to resist a similar effort by the other negotiator.

Integrative potential The degree to which a mutually beneficial agreement exists.

Issue A topic under consideration in negotiation that requires a joint decision by negotiators. An issue entails two or more options, which are called 'alternatives.' A negotiation over a single issue is referred to as 'distributive'; a negotiation over more than one issue that entails different priorities across the issues is referred to as 'integrative.'

Limit The offer level at which a negotiator refuses to concede beyond, also known as reservation value; sometimes limit is the BATNA, which is often identical with the status quo, that is, the situation that would have obtained if negotiation had never taken place.

Offer A proposal on an issue or a set of issues for an agreement, for a possible settlement, also known as demand.

Problem-solving Trying to locate and adopt options for settlement that satisfy both parties' goals or aspirations.

Strategy A plan of action that specifies broad objectives and the general approach that should be taken to achieve them. Some strategies must be translated into more specific *tactics*, for example, a problem-solving strategy is reflected in the tactic *provide truthful information*.

Win-win agreement The outcome of a negotiation that satisfies the major aspirations of all parties involved, also known as an integrative agreement.

The General Negotiation Paradigm

The behavioral approach to the analysis of negotiation seeks to develop and test predictive theory about the impact of environmental conditions on negotiator behavior and the impact of these conditions and behaviors on negotiation outcomes. Most branches of the social sciences have contributed to and have influenced the study of negotiation. For example, economists and game theorists have developed important mathematical models of rational behavior in negotiation. The behavioral analysis of negotiation has also been influenced by books and manuals, written by practicing experts, that provide advice to negotiators. The results of many behavioral studies of negotiation have practical implications as well as mathematical underpinnings.

Most behavioral studies of negotiation reflect a general paradigm or model of thought, which is shown schematically in [Figure 1](#). Conditions that prevail at the time of negotiation, for example, characteristics of the social context, are assumed to have an impact on psychological states, such as motives, cognitions, and emotions (path A in [Figure 1](#)); recent research in the neuroscience of negotiation has used fMRI imaging to observe these processes. Psychological states, in turn, have either a direct impact on negotiation outcomes (path B) or an impact that is mediated by negotiator strategies and tactics (paths C and D), which includes the things that negotiators might say to one another (e.g., 'This is my last offer, take it or leave it').

Issues, Offers, and Outcomes of Negotiation

Issues and Offers

The topics that negotiators discuss can usually be divided into one or more issues that require a decision. Each issue entails two or more options or alternatives that are often expressed in offers, which are proposals that negotiators place 'on the table.' Take for example the buying and selling of a car: the main issue is how much to pay for the car. The alternatives being considered include prices between \$9000 and \$11 000. A second issue is whether a package of accessories is installed in the car. The alternatives for this issue are installation versus non-installation. An offer might be 'I'll give you 9k for the car.'

Divergence of interest between two negotiators can be precisely defined in terms of a 'joint utility space,' which is shown in [Figure 2](#). The points in this space define the alternatives available for possible agreements for a set of issues. The solid points define alternatives currently under consideration. The hollow points define alternatives that can be devised if the negotiators show some creative thinking. The axes of [Figure 2](#) define the utility (subjective value) to each negotiator of the alternatives shown.

[Figure 2](#) represents the car buying example mentioned previously. Options 1–5 are prices between \$9000 and \$11 000. These options are arranged so that higher prices have greater utility to the dealer and less utility to the customer. In other words, the parties differ in their utility ordering for at least some of the options under consideration, which is divergence of interest.

Figure 1 Causal sequence in the general negotiation paradigm that dominates behavioral research on negotiation.

Figure 2 Joint utility space in car buying example. The following options are shown: NA = no agreement; 1 = \$9000; 2 = \$9500; 3 = \$10 000; 4 = \$10 500; 5 = \$11 000; 6 = \$10 000 plus options package (o.p.); 7 = \$10 500 plus o.p.; 8 = \$11 000 plus o.p.

Options 6, 7, and 8 are mutually beneficial options. For these alternatives, the dealer will throw in accessories that cost less than they are worth to the customer. They are shown as hollow points because they do not yet exist, that is, that parties have not thought of them at the start of the negotiation. There is a divergence of interest among these three options as well. However, options 6, 7, and 8 have an advantage: they are better for both parties than some of the options that do not include the accessory package. These are mutually beneficial options. Thus, the negotiation illustrated in [Figure 2](#) has *integrative potential*. Integrative potential refers to the existence of possible options that can integrate the interests of the two negotiators and thus provide greater mutual benefit.

Outcomes

There are four basic kinds of outcomes that can end negotiation:

1. Victory for one negotiator (a win-lose agreement), for example, in [Figure 2](#), agreement on option 1 or 5.
2. A compromise, defined as an agreement on some middle ground on an obvious dimension that connects the parties' initial offers. For example, an agreement on options 2, 3, or 4 in [Figure 2](#).
3. A win-win agreement (also called an 'integrative agreement'), where the parties achieve higher joint benefit (collective utility) than they could with a compromise.

For example, in [Figure 2](#), an agreement on one of the mutually beneficial options 6, 7, or 8. Win-win agreements can have a number of advantages over compromises: they are more likely to be complied with and are more beneficial to the relationship between the parties. A win-win agreement is 'efficient' (sometimes called 'Pareto optimal') in the sense that when the parties achieve the maximum joint gain possible, neither party can do better in an alternative agreement unless the other does worse.

4. Failure to reach an agreement, which is shown by the point marked 'NA' (no agreement) in [Figure 2](#). Either party can drop out of negotiation and thus produce a failure to reach an agreement, which is unlike the other options that require joint approval. Often, the value of nonagreement is the utility of what has been labeled the 'best alternative to a negotiated agreement' (BATNA). For example, a car buyer would have a BATNA of \$10 000 if he or she knew that the same car could be bought from another dealer at that price. BATNA is usually identical with the status quo, that is, the situation that would have occurred if negotiation had never taken place. In [Figure 2](#), no agreement is shown as a poor outcome for both parties. But this is not always the case: one negotiator may be advantaged by the status quo, making no agreement the same thing as victory for that negotiator (e.g., NA could be at point 1 or point 5 in [Figure 2](#)).

Most negotiations take place in mixed-motive settings, which evoke both competitive and cooperative motives in the parties involved. The competitive motive arises because the players have opposing preferences (i.e., a divergence of interest) for some pairs of options. Thus, in the car buying example shown in [Figure 2](#), the buyer prefers option 1 over option 2 and option 6 over option 8, while the seller has the opposite preferences. The cooperative motive arises because the players have similar preferences for other pairs of options. Thus, both of them prefer option 7 (one of the win-win options) to option 3 (the equal outcome compromise), and options 2, 3, and 4 to no agreement (NA).

The mixed-motive nature of negotiation can create a dilemma for negotiators. The competitive motive encourages negotiators to be contentious and to try to push the other party into making concessions that could mean a more favorable outcome. But the cooperative motive encourages negotiators to engage in problem-solving, which might lead to better outcomes. The dilemma stems from the possibility that one's cooperative gestures might not be reciprocated but instead may be exploited by a contentious opponent.

Research Tasks

Behavioral research on negotiation has been conducted in both laboratory and field settings. Field research often involves case studies of actual instances and questionnaire surveys where professional negotiators are the respondents. Laboratory studies usually entail undergraduate volunteers who are asked to negotiate with one another, a confederate, or a computer program. In laboratory studies, communication is sometimes face to face, sometimes via voice only as with phone, and sometimes via other devices or services such as smartphone,

e-mail, sms, and sns. The tasks used in laboratory experiments usually involve stripped-down simulations of real-life negotiation. Two kinds of tasks are most common. The first involves negotiation about a single issue, for example, the price of a hypothetically used car. The second involves negotiation about two or more issues, such as the price of a car and the accessories to be mounted on it. The latter type of task provides the opportunity to study the development of the 'logrolling' type of win-win agreement.

Strategies and Tactics

It is possible to distinguish five broad strategies that can be used in negotiation. A strategy is a plan of action for negotiation that specifies broad objectives and the general approach that negotiators should take to achieve them. Some of these strategies must be translated into more specific tactics in order to be used, and there is evidence that the ordering of strategies in negotiation is important. The strategies include:

1. Concession-making (yielding) – reducing one's goals, demands, or offers – in other words, changing one's proposal so that it provides less benefit to oneself.
2. Contending – trying to persuade the other party to concede or trying to resist similar efforts by the other party.
3. Problem-solving – trying to locate and adopt options that satisfy both parties' goals.
4. Inaction – doing nothing or as little as possible, for example, putting off meetings, talking around the issues, etc.
5. Withdrawal – dropping out of the negotiation.

Concession-Making

There are three basic, interrelated findings about the effects of concession-making on the outcome of negotiation. One finding is that if an agreement is reached, a firm negotiator will often achieve a larger outcome. A firm negotiator has high goals, makes large initial demands, and resists concession-making. For example, the car seller in [Figure 1](#) starts with option 5 and only extremely reluctantly makes a concession to option 4.

A second finding is that negotiator firmness lengthens negotiation and makes an agreement less likely. The more negotiators demand at first, and the slower they make concessions, the harder it will be for them to reach an agreement. This unsurprising finding is true in most cases. However, there is a strange reversal when one negotiator is at the low (very soft) end of this dimension. If one negotiator makes a really low initial demand or makes very fast concessions, an agreement is less likely and takes longer to reach than if that negotiator had been a little more ambitious. This is because very fast concessions signal extreme weakness to the other negotiator, leading the other negotiator to expect more and thus stop making concessions. This makes an agreement less likely.

A third finding is derived from the first two. Given that an agreement has value to a negotiator, there will be an inverted U-shaped relationship between negotiator firmness and negotiation outcome. Negotiators who demand too little may reach an agreement but they will achieve very low profits. Negotiators who demand too much will fail to reach an

agreement and thereby do poorly. Thus, the most successful negotiators, the ones who will maximize their outcomes in the long run, will be those who are moderately firm and who make moderate demands and moderate concessions.

Contending

There are many tactics that can be used to implement contending, including threats, positional commitments, and persuasive arguments.

Threats

Threats are effective to the extent that the penalty threatened has credibility. Credibility refers to the perceived likelihood that a threat will be carried out. Threat credibility goes up when threats have been regularly carried out in the past. It goes down when fulfilling the threat is costly to the threatener as well as the target. Credible threats can reduce the attractiveness of the no agreement option for the target of the threat. Credible threats can be successful at eliciting concessions. Sometimes they are the only way to get the other party to negotiate at all. However, threats have their down side: they tend to generate resentment and resistance, and they tend to be reciprocated, which can produce counterthreats and destructive conflict spirals.

Positional commitments

Positional commitments (also called 'irrevocable commitments') are often combined with a threat to break off negotiation if the other party does not accept an offer. They are only effective if failure to reach an agreement is costly to the target. As with threats, positional commitments must be credible to be effective. They are not very credible if it is clear that their user will be badly hurt by no agreement. One way to demonstrate credibility is to show that one has a credible alternative to a negotiated agreement (a favorable BATNA). But positional commitments can be hazardous: they can lock the negotiator into a position that is unworkable because it is completely unacceptable to the other negotiator – it exceeds the other's limit or minimally acceptable level of benefit. Negotiators can get around this hazard by hedging the commitment, indicating that it is not completely firm. Although this can endanger credibility, it allows a graceful retreat from the commitment if it is unworkable. Another approach is to delay making positional commitments until later in negotiation. There is evidence that experienced negotiators, in comparison to novices, will tend to delay positional commitments to the end of negotiation.

Persuasive arguments

Social psychologists have long been interested in the effectiveness of persuasive arguments. In negotiation, persuasive arguments have the objective of convincing the target that one's proposal is in the target's best interests.

What effect do contentious tactics have on negotiation? Unequal use of contentious tactics can lead to an agreement that favors the heavier user. But such victories can be short-sighted when the negotiation situation has integrative potential. This is because contentious tactics often lead to low joint benefit and, when limits are high, to failure to reach an

agreement. Users of contentious tactics tend to focus on particular demands, which makes them unlikely to seek or discover new options. Contending creates a rigidity of thought that is incompatible with creativity. Contentious tactics are especially problematical when they are reciprocated by the other negotiator, when threats elicit counterthreats. Many studies have shown that reciprocated contentiousness is associated with failure to reach an agreement in negotiation and poor long-run relations between negotiators.

However, despite their defects, contentious tactics can be useful as precursors to, or in conjunction with, problem-solving. They can lead a reluctant adversary to the negotiation table and they can reduce a tough negotiator's goals to a realistic level that may then allow the discovery of an agreement. They may persuade an adversary that contentious tactics will not succeed, which might encourage them to shift to problem-solving.

Problem-Solving

There are very many problem-solving tactics, including the provision of information about one's own priorities among the issues. Some problem-solving tactics involve joint problem-solving, in which the two parties work together to try to find a mutually acceptable alternative. Others involve individual problem-solving, which has one or both negotiators acting on their own.

Problem-solving can lead to win-win agreements if there is integrative potential and the parties adopt ambitious but realistic goals. Win-win agreements can be reached in several different ways. Some win-win agreements are constructed by increasing the available resources so that both sides can get what they want, which is called expanding the pie. A second way to construct win-win agreements is for the negotiators, or a third party, to analyze the concerns that underlie the positions in the negotiation and then seek a way to reconcile these concerns. Alternatives that reconcile both negotiators' underlying concerns are called bridging solutions. Often, bridging solutions are novel, as in the case of two people who were fighting over ownership of an orange. The problem was completely solved when it was discovered that one wanted the orange only for its pulp to make juice and the other wanted only the peel for use in making a cake. Sometimes only one negotiator's underlying concerns need to be examined, because that negotiator will accept the other's demands if these concerns are handled. Alternatives that resolve one negotiators' underlying concerns are called cost cutting solutions.

A third way to construct win-win agreements is for negotiators to exchange concessions on different issues, with each negotiator yielding on issues that are of low priority to oneself and high priority to the other party. Such concession exchanges are sometimes called 'trade-offs' or 'logrolling,' after the old American tradition of helping neighbors roll logs into a pile for burning. Many laboratory studies of negotiation use multiple-issue tasks that provide the opportunity for trade-offs among the issues.

Sometimes negotiators are willing to speak directly about goals, priorities, and concerns, which is called information exchange. Information exchange is a crucial element of joint problem-solving – a process in which the negotiators view their

separate interests as a common problem and ponder possible alternatives for solving it. Both laboratory and field studies have confirmed that information exchange and joint problem-solving are useful ways to achieve win-win agreements.

It can be argued that joint problem-solving is the best approach in negotiation, since it can attenuate the rigidities and delays that are inevitable when negotiators develop their proposals before coming to the negotiation table. Unfortunately, information exchange and joint problem-solving require a high level of trust in the other party, which is often lacking in negotiation. Without trust, negotiators tend to fear that the other party will misuse any information provided.

Inaction and Withdrawal

Both inaction and withdrawal are different from the other strategies in that they do not push negotiation toward agreement. Withdrawal means breaking off the negotiation. Inaction can take a number of forms such as not showing up for meetings or talking around the issues during negotiation. Inaction is sometimes a way station in negotiation, prior to adoption of some other strategy. But if inaction goes on and on, it is essentially withdrawal. Negotiators who are advantaged by the status quo tend to opt for inaction.

Stages of Negotiation Strategies

Changes over time in negotiation strategy reflect an explicit design, for example, as seen in the famous 'good-cop/bad-cop' sequence, which is a shift from contending to problem-solving (and often exercised by a two-person team). It is effective, in part, by creating the impression that problem-solving cannot be exploited and therefore should be reciprocated.

Studies in political science suggest that a period of 'hurting stalemate' (contending by all parties) often gives way to problem-solving when the parties realize they are going nowhere. Several studies suggest that such a shift is associated with the parties adopting win-win agreements, and that these 'turning points' are more often positive than negative.

Psychological Antecedents of Negotiation Strategy

The psychological antecedents of negotiation strategy and outcome can be roughly divided into two broad categories of processes: motivational and cognitive. These processes can influence the negotiator's choice of strategy or they can have a direct impact on the outcome of negotiation (see [Figure 1](#)).

Motivational Antecedents

The most comprehensive account of negotiator motives is the dual concern model. It asserts that negotiation strategies result from the conjunction of two independent motives: self-concern and other-concern. Self-concern and other-concern are regarded as independent dimensions. The model is shown in [Figure 3](#).

The dual concern model predicts negotiator preferences among the strategies described earlier from combinations of high and low self- and other-concern. It makes the following

Figure 3 The dual concern model showing strategies of negotiation as a function of two motives: concern for own outcomes and concern for other's outcomes.

four predictions: (1) high self-concern coupled with low other-concern encourages contending, (2) high other-concern and low self-concern encourage concession-making, (3) high self-concern and high other-concern encourage problem-solving, and (4) low self-concern and low other-concern encourage inaction. Of course, the negotiator's choice of strategy has many other antecedents in addition to the two concerns specified by the dual concern model. But the model is one basis for making predictions about the negotiator's strategic preference.

The dual concern model can be viewed as a theory of personality, that is, of individual differences in conflict style. Conflict style is the way a person most commonly handles conflict situations. There is a psychometric tradition of research on the dual concern model that involves scaling of the methods individuals use for dealing with conflict. Taken together, the data suggest that conflict style is a function of the strength of two nearly independent personality variables, concern about own interests and concern about other people's interests, which are the two dimensions of the dual concern model.

The dual concern model is also a theory about the impact of changing conditions on strategic choice in negotiation. Some of these conditions affect concern about one's own interests, while others affect concern about the interests of the party with whom one is negotiating. Combinations of these conditions can predict the strategy that will be chosen in a given circumstance.

Self-concern in negotiation is a general reluctance to making concessions. This reluctance is often determined by the height and rigidity of limits and goals, and the strength of needs and principles that are linked to limits and goals. Higher limits tend to produce larger initial demands and greater resistance to concession-making. Principles in negotiation, that is, convictions about what is proper or fair, are another source of goals and limits. This is because people aspire to, and are unwilling to concede beyond, benefits to which they feel entitled.

Other-concern is often enhanced by positive feelings toward and a perception of common group identity with the other negotiator. However, in negotiation, other-concern more often arises from instrumental considerations. Such considerations

arise when people expect to be dependent on the other party in the future and wish to make a good impression now.

One way of looking at the dual concern model is that high other-concern leads to two different forms of cooperation, depending on the strength of self-concern: problem-solving and concession-making. When self-concern is strong, other-concern encourages problem-solving. This implies that negotiators are likely to do their most creative thinking about the issues under circumstances that force them to try to reconcile both parties' interests. An example of such circumstances is when they are caught between a desire to please powerful constituents and a need to get along with the other negotiator in the future. But when self-concern is weak, high other-concern produces concession-making. With no strong concern about their own outcomes, subjects develop weak goals which they easily abandon in the face of a strong desire to please the other negotiator. Hence, they do not work at satisfying both parties' interests. This suggests that concern about other people's interests – whether due to altruism or instrumental considerations – is usually quite desirable, but that it will lead to suboptimal results unless it is coupled with a healthy respect for one's own interests as well.

The dual concern model predicts a negotiator's preferred strategy. But if this strategy seems infeasible, he or she will shift to another strategy. Thus, high self-concern will lead to a preference for contending. But if contending seems infeasible, negotiators are likely to shift to problem-solving as the next best approach to achieving their goals. Some conditions will influence the perceived feasibility of a given strategy. For example, time pressure encourages both concession-making and increased use of contentious tactics. This is because the basic effect of time pressure is to reduce the feasibility of inaction and thus to heighten the urgency of taking action to move toward agreement. Concession-making is one form such action can take, contending is another; hence, time pressure can produce both reactions. For problem-solving to seem feasible, it is necessary for there to be perceived integrative potential, that is, some basis for believing that one can find a win-win solution.

Cognitive Antecedents

The analysis of cognitive mechanisms in negotiation extends theory and research in social cognition, information processing in cognitive psychology, and decision theory, to negotiation. The root of the problem of suboptimal outcomes in negotiation is that negotiators have limited attention, limited capacity to store and retrieve information from memory, and limited capacity to process information.

As a result of cognitive limitations, negotiators consciously or unconsciously rely on heuristics and schemas. Heuristics are mental shortcuts and simplifying strategies that people use to help to manage information. Schemata are cognitive structures that contain information about aspects of a particular situation or a general class of situations. Schemata are thought to develop from prior observations of the phenomena to which they are relevant, and they lead people to construe situations in specific ways. Schemata tend to guide information processing, directing attention and memory, and thus cause some events to be noticed and remembered while others are ignored or forgotten.

A litany of cognitive effects and processes has been identified in negotiation. They include the fixed-pie assumption, reactive devaluation, overconfidence, availability, representativeness, framing, and anchoring.

The fixed-pie assumption

An example of a schema that is often found in negotiation is the assumption that the two parties' interests are directly opposed, that is 'your win is my loss.' This fixed-pie (also called zero-sum or win-lose) assumption, which is tantamount to low-perceived integrative potential, makes problem-solving seem infeasible and hence encourages contentious behavior. For example, in multiple issue negotiation, the fixed-pie assumption implies that the other has the same priorities on the issues as the self. This is a faulty judgment that can block the discovery of a win-win solution.

Reactive devaluation

Proposals and offers suggested by the opposing negotiator tend to be devalued in negotiation, simply on the basis of the knowledge that the adversary has offered them. In one study, some negotiators rated the value of an opposing negotiator's concession before it was actually made and others rated the concession after it was offered. The results indicated that negotiators denigrated and misconstrued concessions offered by the opposing negotiator. Apparently, negotiators reason that whatever is good for the other must be bad for the self. Other work indicates that reactive devaluation is caused by the fixed-pie assumption.

Overconfidence

Another cognitive source of suboptimal agreement in negotiation stems from the beliefs that negotiators have about their likelihood of success. Negotiators sometimes believe that the opposing negotiator will make greater concessions than they will. Also, sometimes, negotiators believe that the consequences of nonagreement are more favorable than they actually are.

Availability and representativeness

Availability is the negotiator's use of the ease of recall of information as a cue for judgments about frequency or likelihood of occurrence, which in some circumstances can produce biased judgment. Information that is more available in memory, more salient, or more concrete and vivid may play a greater role in judgment than it should. Availability can lead negotiators to rely too much on salient information and therefore produce biased negotiator judgment. For example, negotiator behavior can be unduly affected by the salience of costs associated with failing to reach an agreement.

Representative thinking can also bias judgment. This involves making judgments solely on the basis of the most obvious features of the object being judged and ignoring more subtle features that would permit a more balanced judgment. The object being judged may be the opposing negotiator, or it may include features of the negotiation context or issues.

Availability and representativeness may underlie the tendency for negotiators to rely too much on historical analogies. If an historical incident is highly memorable, or seems representative of a current situation, it may exert greater influence in the current decision than may be warranted. This may lead

negotiators to miss other, possibly better, alternative outcomes, or other approaches to the negotiation. For example, in 1938 in Munich, negotiations between Neville Chamberlain and Adolf Hitler produced an agreement that resulted in British appeasement and unchecked Nazi aggression, with calamitous consequences. More than 50 years later, the statement, "If this aggression goes unchecked it will be another Munich," is sometimes used to justify the choice of struggle over negotiation. In this case, an historical negotiation is seen as representative of a current situation, when the current situation may in fact be quite different.

Framing

Issues and offers in negotiation are often judged in the light of a reference point, for example, the status quo. If construed as a loss, negotiators are less likely to make concessions and reach an agreement than if construed as a gain, an effect that is associated with negotiator aspirations. There is additional evidence that a loss frame is more likely to migrate across the negotiation table and be adopted by the other negotiator than a gain frame.

Anchoring

Anchoring occurs when judgments and behavior assimilate to salient reference points. There is evidence that a negotiator's first offer is likely to become an anchor, leading the other negotiator to adapt to it. But if other parts of the negotiation are salient, such as the BATNA, or the negotiator's aspirations, the anchoring effect of the first offer is eliminated.

Emotion Antecedents

Emotion also has been shown to impact negotiation behavior and outcome, with regard to mood states as well as via the impact of emotion expression, that is, knowing the other parties' emotion.

Mood states

Mood states, such as positive affect – pleasant feelings that are typically induced by commonplace events such as reading a cartoon, hearing a joke, or getting a small gift or piece of candy – can have important effects in negotiation. For example, professional mediators have been known to tell humorous stories prior to and during negotiation in an effort to improve cooperation between negotiators. Positive affect diminishes hostile and contentious behavior and makes problem-solving behaviors more likely. Positive affect also enhances concession-making.

In addition to these effects, positive affect enhances cognitive functioning, including the capacity for creative problem-solving. The result is that positive affect can enhance the likelihood of adopting win-win agreements. In one study, the subjects with positive affect were no more likely than the control subjects to exchange information during negotiation, but they were more likely to discover that the negotiators had complementary priorities among the issues and, hence, to discover win-win agreements. This was a sign of improved cognitive functioning. In contrast, negative mood and emotion can increase contending and interfere with the development of win-win agreements.

Emotion expression

Expressing anger in negotiation can lead the other to expect less, and thus accept less in negotiation; but expressing anger is also associated with lesser problem-solving and the discovery of integrative agreements. And there is evidence that angry negotiators are avoided in future dealings. The former effect appears to be a result of assumptions about the other party's limit, with an angry other being seen as more stubborn on the issues, so greater concessions are needed if an agreement is to be reached. The opposite results when the other is seen as happy in the negotiation. There is evidence that these effects are especially likely when negotiators have time to process information about the negotiation, or are motivated to have a deeper understanding of the negotiation.

Social Antecedents of Negotiation Strategy

Other antecedent conditions that affect negotiation (see Figure 1) are social context variables, which include social norms, the nature of the relationship between the negotiators, group processes, and culture.

Social Norms

Norms are shared beliefs about how people should behave. They are very often important in negotiation. They can affect the positions taken, the arguments and concessions made, and the agreements reached. Fairness principles are also particularly important, with the general finding that negotiators tend to be more concerned about fairness to self than fairness to the other negotiator.

Among the most important norms are principles of fairness (also called 'distributive justice' norms), which govern distribution of resources. There are three broad classes of fairness principles: the equality rule, which specifies that everybody benefits or contributes equally; the equity rule, which specifies that benefit should be proportional to contribution (e.g., that pay should be proportional to the work done); and the needs rule, which specifies that benefit should be proportional to need (e.g., that sick people should be taken care of). Each of these classes embraces a number of more specific rules, for example, the principle that both sides in a negotiation should make equal concessions as they move toward an agreement. This reflects the reciprocity norm which is an adaptation of the broader equality norm.

Norms often curtail social conflict: (1) They sometimes prevent conflict altogether, for example, the principle of equal dues makes it unnecessary to debate the issue of whether some members should pay more than others. (2) Norms often regulate the way conflict is conducted, for example, talking directly first before taking the dispute to a third party. (3) Norms can help resolve a dispute by providing a solution once conflict arises, for example, a dispute in which two friends are both trying to pay the entire restaurant bill may be solved by splitting the bill evenly.

Though norms often curtail conflict, they sometimes exacerbate it instead. This happens when they require one to challenge another person, for example, to fight injustice or defend

one's rights. This also happens when two or more parties disagree about which norms are applicable to their situation or how to interpret a norm that is clearly applicable.

In negotiation, agreement is more likely and is reached more rapidly when a single fairness principle can be applied compared to when no principle can be applied. There are two reasons for this. One is that both sides are likely to view fair outcomes as correct and hence not quibble about them. The other is that both sides are likely to think that such outcomes are inevitable, because the other side cannot be expected to accept less than a fair outcome.

Even when there is a principle that clearly applies to the issues under consideration, agreement is not always reached. One reason for this is that the parties may disagree about how to interpret this principle or the nature of the evidence that pertains to it. For example, the principle of equal concessions is vulnerable to a partisan bias such that each party views the other's concessions as smaller than his or her own.

Relationships Between Negotiators

Preexisting relationships between the negotiating parties, especially aspects of power and trust, can have a great influence on how negotiation progresses.

Power in negotiation is usually viewed as the control of resources which, if used, will affect the other party's future welfare. One can reward the other or punish the other, and thus have a positive or negative effect. When viewed as an element of the relationship between two parties, there are two dimensions of power: relative power and absolute power. Relative power is the extent to which one party is more powerful than the other; for example, most supervisors have more power than their subordinates. Absolute (also called 'total') power is the extent to which the parties have power over each other. Several studies have shown that, in the case of unequal power to punish the other negotiator, the party with greater power made fewer concessions than the one with less power. This accounts, at least in part, for the better outcome usually achieved by the party with greater power.

The opposite of power is dependency. If A has power over B, B is dependent on A. This is often reflected in negotiation in terms of BATNA, with the party that has the better alternative to agreement less dependent and thus more powerful. Powerful negotiators tend to make the first offer and tend to achieve more favorable outcomes. In one study of negotiation in romantic couples, it was found that the party who was more in love achieved lower outcomes. This may have been because that party was the more emotionally dependent of the two. His or her partner had more power because of having less need for the relationship.

A mild discrepancy in power can put the negotiators at cross-purposes, producing what is sometimes called a 'power struggle.' High-power negotiators apparently expect to achieve more than their opponents, but low-power negotiators were unwilling to accept this lower status and fought for equal treatment. The high-power negotiators put up a return fight, creating an escalation that often wrecked the negotiation. Such a struggle did not occur when there was a large discrepancy in power, presumably because the low-power negotiators realized that struggle was hopeless.

Several studies have looked at the impact of absolute power, finding that fewer threats were made and more agreements were reached when the two parties had high punitive power rather than moderate or low power.

Trust is the expectation that the other party will cooperate in the future. It is an aspect of the relationship between parties in that it deals with how the parties perceive each other. Trust has been shown to have many antecedents. Trust can be a personality variable – a general faith in humanity that is measured by a self-report inventory. Or it can be produced by environmental conditions, for example, when the other has cooperated with oneself, especially recently, or if the other is known to have cooperated with other people in the past. Several studies suggest that trust encourages the exchange of information about values and priorities and makes it easier to reach an agreement.

Group Processes

Negotiators often represent other people, who can be called their ‘constituents.’ When negotiators are a representative, they are motivated to make a positive impression on their constituents and avoid making a negative one. In one study, negotiators representing a simulated helping agency were more likely to use an allocation rule they thought would please their constituent than a rule that would provide the most effective help to these constituents. If they believe that their constituent wants them to be contentious, negotiators will tend to make high demands and few concessions. But they will tend to make concessions if they believe their constituent favors cooperation and agreement.

Representatives are especially eager to please their constituents when they are accountable to these constituents. Accountability is the extent to which negotiators can be rewarded or punished by their constituents for their performance. It is produced by giving the constituents power over negotiators’ outcomes or by making it clear that the constituents will receive information about the outcome of the negotiation. Accountability has usually been found to slow concession-making and enhance contending, making it harder to reach an agreement.

Representatives are also especially eager to please their constituents when they feel insecure about their standing in the group. Negotiators are insecure when they have a low status in their organization or when they feel distrusted by their constituents. Representatives who have a higher status in their group are not so tied to their constituent’s views and thus are freer to make concessions than those with a lower status. These findings suggest a paradox: even though distrusted group representatives aspire to improve their relationship with their group, they often undermine their group’s interests by failing to reach an agreement with others outside the group. Constituent surveillance of the negotiation also tends to reinforce perceived constituent preferences.

In some cases, representatives can be more rational than their constituents, having a better understanding of the other party’s priorities and hence being more realistic about success. Also, negotiation through representatives provides an opportunity for the use of tactical stratagems, such as the ‘black-hat/white-hat’ routine. In this routine, the representative adopts a cooperative stance, while one of his or her constituents

shows a tough stance. For example, the representative might say, “I’d like to give you this really good price on the car; but I can only do so if my manager approves it, and she’s pretty tough about these matters.” Such a strategy has been shown to be effective in eliciting concessions.

Sometimes negotiation is conducted by a negotiation committee or by teams, small groups of individuals whose responsibility is to negotiate on behalf of a larger group or organization. Team negotiation does seem to produce better outcomes compared to outcomes achieved by individuals. Negotiation teams are better at problem-solving and discovering win–win agreements than are individual negotiators.

Group boundaries can also have a large influence on negotiation. Negotiators who deal with a member of their own group make more concessions and are more likely to adopt a problem-solving strategy than those who negotiate with a member of another group. Also, negotiations within a group are characterized by greater trust and greater concern that both parties should attain a good outcome.

Moreover, several studies suggest that within-group processes can have important carryover effects on between-group negotiation. In one study, groups whose members engaged in a cooperative or competitive negotiation within their group adopted the same approach to a subsequent negotiation with an out-group. Within-group cooperation made between-group cooperation more likely, and within-group conflict diminished the likelihood of between-group cooperation. This has implications for third parties in an intergroup conflict. If they want to facilitate between-group cooperation, they should foster within-group cooperation prior to between-group negotiation.

There is evidence that group identity can impact negotiation. Indeed, when property is an issue in negotiation, the more that group identity is associated with the property, the greater it is valued. And such property is especially highly valued if at the same time the opposing side also professes a group identity association to that property.

Culture

Most behavioral research on negotiation has been conducted on Western participants, with an assumption that effects generalize broadly across cultures. But there is now considerable evidence that cultures differ in how negotiation is conducted. For example, there is evidence that Japanese people show greater concern for preserving an opponent’s face and maintaining relationships in negotiation, which reflects the cultural variable, collectivism. One study found that Chinese people (collectivists), in contrast to Americans, were more likely to prefer consensual procedures (negotiation and mediation) to resolve a conflict than third-party procedures such as arbitration. Western society reflects individualism, a cultural variable that emphasizes attainment of individual outcomes as opposed to group outcomes. Consistent with this, there is evidence that accountability to constituents encourages individualists to adopt a contentious approach to negotiation, whereas it encourages collectivists to adopt a problem-solving approach. Individualism and collectivism are instances of many cultural variables, and a good deal of recent research effort focuses on identifying and delineating the effects of other culture variables on negotiation.

Expanding the General Negotiation Paradigm

Current research on negotiation is largely devoted to expanding the field of vision beyond the general paradigm. An important advance in the field concerns a broader consideration of the nature and types of outcomes of negotiation, for example, whether the subjective aspects of outcome are as important, perhaps even more important, than the objective aspects. Subjective aspects are about feelings: feelings about instrumental outcomes such as the amount of money achieved in the agreement, feelings about one's self such as perceived competency, feelings about the process such as whether the negotiation was constructive, and feelings about the relationship such as whether the negotiation preserved it. Moreover, there is increasing attention being paid to the possibility that many of the integrative bargaining effects uncovered to date pertain largely to 'logrolling' negotiations, where there are multiple issues and the possibility of trade-offs. But there are other types of win-win agreements and a large question is about the extent to which findings obtained about logrolling generalize to these other types.

The 'agreement circumplex' model, shown in Figure 4, reflects a larger set of negotiation outcome types, of which logrolling is just one. The others are bridging, cost cutting, compensation, compromise, superordinate, modify, and expand, all defined on the basis of whether they deal with achieving the parties' underlying interests, or the parties' positions, and whether they entail changing the negotiator's preferences or

changing an aspect of the environment of issues to fit the negotiator's preferences.

Considerable research attention is now being paid to how to overcome cognitive biases, and this has focused on tactical solutions, as well as the identification of moderating conditions. There is evidence that motives can overcome cognitive biases; for example, a loss frame combined with a cooperative motivation can enhance the likelihood of discovery of win-win agreements. Also, there is evidence that motives to enhance intellectual functioning in negotiation can have the same effect by reducing the use of reliance on cognitive heuristics.

Another approach to overcoming cognitive bias effects is via negotiator training and the use of negotiator support systems. Studies suggest that training programs can enhance the likelihood that negotiators will later uncover win-win agreements, especially if the training involves learning by analogy, where the training cases embody general principles that can be extracted and applied at a later point. Negotiation support systems, entailing computer support, can help negotiators handle large amounts of information, and there are numerous success stories, for example, the negotiations around the United Nations Convention on the Law of the Sea.

There are recent trends that indicate that future research in negotiation will focus on the technological aspects of negotiation, and how different technologies (e.g., e-mail, sms, sns) can transform negotiation in communities and organizations. These are but a few of the areas of inquiry that will advance theory and research in the psychological analysis of negotiation.

Neuroesthetics: The Body in Esthetic Experience

V Gallese and C Di Dio, University of Parma, Parma, Italy

© 2012 Elsevier Inc. All rights reserved.

Glossary

Esthetic appraisal The subjective evaluation of an object based on an introspective identification of the emotional responses to the object. It is not the expression of high-order cognitive considerations and mechanisms, but rather of association processes between the perceptual object and the beholder's emotional memories. It answers the question: 'Do you like it?'

Esthetic attitude The implicit mindset enabling to appreciate the esthetic content of the contemplated object by focusing attention to its esthetic qualities. It leads to esthetic experience.

Esthetic experience The response to perceptual objects consisting of the embodied simulation of the actions, emotions, and sensations that the content of the object evokes in the beholder. Such experience is not necessarily confined to the appreciation of artworks, although this is grounded on it.

Esthetic judgment The explicit esthetic rating of an object according to culturally and socially determined esthetic canons. It represents the most cognitive aspect of the relation established with artworks. It answers to the question: 'Is it beautiful?'

Introduction

In the last few decades, cognitive neuroscience has extended its field of investigation to the domain of art, focusing in particular on music and visual arts. For the sake of concision, in the present contribution we will exclusively deal with the neuroscientific investigation of esthetic experience in visual arts. The term currently employed to define this approach is neuroesthetics.

The term neuroesthetics was coined by Semir Zeki referring to the study of the neural bases of beauty perception in art. Zeki's approach to art is closely related to the definition he provides for the functioning of the visual brain, namely a search for the constancies (unchanging properties) of objects, situations and so forth, with the aim of obtaining true knowledge about the world. In this process, the brain (as the artist) needs to discard inessential information from the visual world in order to represent the real character of an object in an enduring manner. For instance, when defining color constancy, the brain needs to discard information regarding the exact composition of the wavelength reflected by objects' surfaces; with dimension, inessential information is the precise visual distance; whereas, with form, it would be the exact viewing angle. It is in this selection process that the brain is able to retain and categorize never-changing information about a world that, on the other hand, is in continuous transformation.

In brief, according to Zeki "the overall function of art is an extension of the function of the brain: the seeking of knowledge in an ever-changing world." It is for their ability of capturing the essential elements of the world that artists, according to Zeki, can be defined as 'natural scientists' able to elicit an esthetic response in the creative brain of the observer.

Another noteworthy construal of esthetic experience viewed from a neuroscientific perspective is that of the neurologist V.S. Ramachandran. Ramachandran's approach to neuroesthetics is concerned with the unfolding of 'universal rules' that govern beauty perception in art. The description of these 'universals' relates to the way in which visual perceptual rules can account for art processing in an observer and, most importantly,

to their underpinning brain mechanisms. In particular, Ramachandran's theory rests on the interaction between cognition and physical pleasure, which is claimed to be rooted in the human biological makeup. Indian representations of women's body, for example, often reflect attention to primordial elements that recall the idea of procreation, such as pronounced hips and breasts. This concept is accounted for by the 'universal' of *emphasis*.

As with Zeki's approach, Ramachandran's description of artistic experience ultimately results in the pleasure gathered from the unfolding of perceptual elements that capture conceptual cores. For example, *grouping*, a perceptual process that allows the brain to extract a figure from the background, may be an enjoyable process. Pleasure would be the ultimate stage of an evolutionary driven motivational process, whereby individuals' survival depends on the necessity to discover alerting events in the environment, such as predators. In this way, attention is drawn toward important features. According to this perspective, perceptual grouping comes about as reinforcement to early vision at every stage of visual processing. The resolution of visual ambiguity would then result in a pleasant 'aha' experience accompanying the perceptual experience we make of the world. Artists' skill would then hinge upon their ability to evoke these biological perceptual processes in the observer, who is urged upon a creative and pleasurable reconstruction of the observed artistic object.

The study of the brain as it responds to art implies the existence of neural mechanisms entailed in art appreciation that are common to all individuals. The elements that are able to elicit these neural processes, that is, the 'access keys,' though, may be various and variable. In fact, they are under the influence of cultural and experiential constraints that define fluctuating trends over time and across individuals, even within the same cultural frame. When we visit a museum or an art gallery, we do not simply perceive images, but we contemplate objects whose presence in that specific physical space is justified and determined by their status of artworks. Our fruition of art is certainly cognitively mediated because the peculiar quality of our esthetic experience is influenced by our culture,

by the environment in which we were educated, by the esthetic canons informing our time, by our level of expertise and familiarity with the artworks we contemplate.

Both Zeki and Ramachandran's approaches to neuroesthetics resolve this variability problem with the ability of the visual brain to process essential information from the world that remains immutable and that can most naturally find a biological access to the observers' creative mind. Yet, the complexity of the relation that builds between an artwork and the observer compels us to reason beyond the mere, though vital, perceptual – and mostly visual, as accounted for by Zeki and Ramachandran – ability of the brain to capture essential perceptual elements from the environment. In esthetic experience, there are components that, in our view, cannot be disregarded as they constitute the most direct 'access keys' to the observers' comprehension of the artwork; that is, the embodied motor and emotional components of esthetic experience.

Our idea is that through the involvement of sensory-motor processing, the esthetic experience of art allows the beholder to feel the artwork in an embodied manner. More specifically, our hypothesis follows from the proposal by Freedberg and Gallese that the esthetic experience of artworks consists of activating embodied simulation of actions, emotions, and corporeal sensations, and that these mechanisms are universal. Observing the world is a more complex enterprise than the mere activation of the visual brain, as it implies a multimodal notion of vision that encompasses the activation of somatosensory and emotion-related components, within the more general frame of the intrinsic pragmatic nature of every intentional relation with the external world.

Our proposal challenges more standard accounts of esthetic experience privileging the primacy of cognition in our responses to art. In particular, our hypothesis, echoing historical views (see below), stresses the empathic nature of the relationship automatically established between artworks and beholders and capitalizes upon the discovery of the mirror neurons mechanism.

The present article is composed of four sections. In section 'An Historical Perspective: *Einfühlung* and Esthetic Experience,' we will concisely review aspects of the historical contribution of the notion of *Einfühlung* (empathy) to esthetic experience and show why we believe that such tradition of thought in esthetics is still highly relevant, if discussed on the basis of recent neuroscientific evidence. In section 'Neuroesthetics: Explicit Appraisal and Reward,' we will chart the available empirical evidence in neuroesthetics in relation with the cognitive aspects of esthetic experience, particularly focusing on the dimensions of reward and of the explicit appraisal of the esthetic value of artworks. In section 'Neuroesthetics: Embodied Approaches,' we will address the putative role of mirror mechanisms in esthetic experience, dealing first with actions and then with emotions.

An Historical Perspective: *Einfühlung* and Esthetic Experience

Invoking a role for the body in esthetic experience while contemplating visual artworks is an old idea. The notion of empathy (*Einfühlung*) was originally introduced in esthetics by the German philosopher Robert Vischer in 1873, thus well before

its use in psychology. By *Einfühlung*, literally 'feeling-in,' Vischer meant the physical responses generated by the observation of forms within paintings. He described how particular forms aroused particular responsive feelings, depending on the conformity of forms to the design and function of the muscles of the body, from those of the eyes to our limbs and to our bodily posture as a whole. Vischer clearly distinguished a passive notion of vision – seeing – from an active one – looking at. According to Vischer, it is the act of looking that best characterizes our esthetic experience when perceiving images, in general, and artworks, in particular.

This account of art perception implies an empathic involvement, which, in turn, encompasses a series of bodily reactions of the beholder. Particular observed forms would evoke specific emotional reactions on the basis of the conformity of the former with the design and functionality of the body of the beholder. According to Vischer, symbolic forms acquire their meaningful nature first and foremost because of their intrinsic anthropomorphic content. Symbols are something different from the indirect manifestation of concepts. It is through the nonconscious projection of her/his body image that the beholder is able to establish a relation with the artwork.

Developing Vischer's ideas, August Wölfflin (1886) speculated on the ways in which observation of specific architectural forms engage the beholder's bodily responses. Very shortly afterwards, Theodor Lipps wrote at length about the relationship between space and geometry on the one hand, and esthetic enjoyment on the other (1897, 1903).

The work of Vischer also exerted a very powerful influence over two other German scholars whose contributions are highly relevant for our present proposal: Adolf von Hildebrand and Aby Warburg. The German sculptor Hildebrand in 1893 published a book entitled *The Problem of Form in Figurative Art*. In this book, Hildebrand proposed that our perception of the spatial characters of images is the result of a constructive sensory-motor process. According to Hildebrand, space does not constitute an a priori experience, as suggested by Kant, but its product. The reality of artistic images resides in their effectuality, conceived both as the end result of the artist's actions producing them and of the effects artistic images produce on the beholder. According to the same constructivist logic, the esthetic value of artworks would reside in their potentiality to establish a link between the intentional creative acts of the artist and their reconstruction on the side of the beholder. In this way, creation and artistic fruition are directly related. To understand an artistic image, according to Hildebrand, means to implicitly grasp its creative process. A further interesting aspect of Hildebrand's proposal concerns his notion of the fundamental motor nature of experience. It is through movement that the available elements in space can be connected, that objects can be carved out of their background and perceived, that representations and meaning can be formed and articulated. Ultimately, according to Hildebrand, sensible experience is possible and images acquire their meaning just because of the acting body.

Hildebrand exerted a strong influence on another famous German scholar, Aby Warburg. Warburg conceived art history as a tool to shed light on the psychology of human expressive power. His famous notion of 'pathemic form' (*Pathosformel*) of expression implies that a variety of bodily postures, gestures,

and actions can be constantly detected in art history, from Classic art to the Renaissance period, just because they embody in exemplar fashion the esthetic act of empathy as one of the main creative sources of artistic style. According to Warburg, a theory of artistic style must be conceived as a 'pragmatic science of expression' (pragmatische Ausdruckskunde).

Warburg, when describing the classic marble group known as the Laocoon, identified transition as a fundamental element to turn a static image in movement charged with pathos. Several years later, the Russian movie director Ejzenstejn, when commenting on the same Laocoon sculpture, wrote that the lived expression of human sufferance portrayed in this masterwork of classic art is accomplished by means of the illusion of movement. Such movement illusion is obtained by condensing in one image different aspects of expressive bodily movements that could not possibly being visible at the same time.

Phenomenologists such as Maurice Merleau-Ponty further highlighted the relationship between embodiment and esthetic experience. Merleau-Ponty suggested the relevance for art appreciation of felt bodily imitation of what is seen in the artwork. Consistent with the role of *Einfühlung*, Merleau-Ponty also emphasized the importance of the artist's implied actions for the esthetic experience of the beholder, exemplifying it by referring to the paintings of Cézanne. He famously stated that we cannot possibly imagine how a mind could paint.

In conclusion, these scholars and many others believed that the feeling of physical involvement with a painting, sculpture, or architectural form, provokes a sense of imitating the motion or action seen or implied in the work, and also enhances our emotional responses to such work. Thus, it constitutes a fundamental ingredient of our esthetic experience of artworks.

The last sections of this article show how contemporary neuroscientific research can revitalize and shed new light on the role of empathy in art appreciation.

Neuroesthetics: Explicit Appraisal and Reward

The empirical investigation of the basic neural mechanisms underpinning our responses to art and the ensuing esthetic experience are complex issues. There is great heterogeneity across results from investigations trying to clarify the neural correlates associated with esthetic experience of visual art.

The esthetic experience of visual artworks begins with the visual analysis of the stimulus, which then undergoes further processing. This progression may lead to an esthetic experience likely based on biological and embodied mechanisms that can be modulated by factors such as the context, individuals' interest in the artwork, prior knowledge, and familiarity. Thus, one possibility for the heterogeneous results of studies on neuroesthetics is that they may reflect the output of different esthetic processing levels. Even more fundamental is the distinction between the cognitive processes that produce rewarding experiences in the beholder and the emotions directly associated with esthetics. This distinction highlights the concepts of esthetic judgment and esthetic pleasure, which can be related to the cognitive and emotional aspects of esthetics, respectively.

In experimental tasks, the need to explicitly verify participants' subjective judgments leads to self-evaluation and

decision-making processes. These processes imply the involvement of high-order cognitive processes in which the effects of cultural and individual traits may play a crucial role in defining the esthetic experience. These evaluations may interfere with the ultimate goal of neuroesthetics to unfold the basic neural mechanisms involved in esthetic experience shared by all individuals. Thus, the data obtained may only be partially representative of the actual neural underpinnings under investigation or, in some cases, even misleading.

It is important to distinguish between processes underlining esthetic pleasure and those underpinning esthetic judgment. These two processing levels of esthetic experience are tightly bound, yet not interchangeable. Whereas esthetic pleasure is more concerned with an automatic emotional response to artworks, esthetic judgment requires the contribution of explicit cognitive appraisal, holistically grouping the individual's values, knowledge and personal taste, all factors that are influenced by cultural and experiential dynamics. Though separable, these two aspects are strongly related and continuously affect each other during the building up of the esthetic experience.

The study of neuroesthetics has mostly dealt with esthetic judgment, in that participants are typically asked to explicitly judge a visual stimulus either as beautiful or ugly. One of the first attempts to define the neural underpinnings of the esthetic experience of beauty was designed by the founder of neuroesthetics, Semir Zeki. Kawabata and Zeki used fMRI to investigate the neural correlates of beauty perception during the observation of different categories of painting (landscapes, portraits, still life and abstracts) that participants judged beautiful, neutral, or ugly. The brain imaging results revealed different brain activations for judged-beautiful stimuli versus both neutral and ugly images in medial orbitofrontal cortex (OFC). Additionally, comparison between judged-beautiful and judged-neutral images elicited activation in the anterior cingulate gyrus and the left parietal cortex. While showing that functional specialization lies at the basis of esthetic judgments, because during an esthetic experience different categories of stimuli elicit activation of brain areas specifically devoted to their visual analysis (e.g., the fusiform gyrus for portraits), Kawabata and Zeki also discussed OFC differential activation by the observation of beautiful, neutral, and ugly stimuli as an effect of reward.

This latter observation deserves a consideration. Activation of OFC, and particularly of its medial sector, has often been associated to the perception of rewarding stimuli. Reward-related processing may be reasonably expected in esthetic experience as being spontaneously evoked to reinforce behavior that produces positive experiences. This architecture has biological foundations since hedonic sensations associated with rewarding mechanisms are at the basis of the motivation that drives the consolidation of behavior.

These processes have to be distinguished from the basic emotions and sensations that hallmark esthetic experience in the first place, which are of a different nature and that are processed at other neural levels (see below). The activation of limbic structures such as OFC or the cingulate gyrus, found active by Kawabata and Zeki, underpins the involvement of rewarding processes that represent a component of esthetic experiences, though at a more cognitive level of processing.

Further neuroscientific evidence showing that rewarding processes are involved with esthetic experience comes from a

study of Vartanian and Goel. This event-related fMRI study investigated esthetic preference for representational versus abstract paintings in three versions: originals, altered, filtered. Participants explicitly appraised the presented images by entering their response during stimulus presentation and indicating their preference on a rating scale. Behavioral results showed that preference was accorded to representational more than to abstract paintings. In both categories, original paintings elicited higher preference. In terms of brain activations, a decreased activation was observed in the right caudate nucleus extending to putamen in response to decreasing preference for paintings (in depressed patients, low activity in caudate nucleus correlates with decreasing ability to experience pleasure and reward – anhedonia), while activity in left cingulate sulcus, bilateral occipital gyri, bilateral fusiform gyri, and bilateral cerebellum increased in response to increasing preference for paintings. Because the involvement of the striatum in processing emotionally salient and reward-based stimuli is well established, these results suggest, according to the authors, that the decrease in activation in right caudate nucleus in response to decreasing preference may be a specific example of its general pattern of reduced activation in response to less rewarding stimuli. Additionally, increased activation in the primary and extrastriate visual cortices is in line with their role in processing pictures and faces varying in emotional valence.

This evidence suggests that the reward mechanisms are involved in the course of esthetic experience. The pattern of activations observed in OFC (Kawabata and Zeki's) and in the right caudate nucleus (Vartanian and Goel) indicate that both brain structures respond with decreased activation, with respect to baseline, to esthetic stimuli. Decreased activation, in both instances, is more pronounced for stimuli judged of poorer esthetic value.

Neuroesthetics: Embodied Approaches

The Motor Component of Esthetic Experience

The biological mechanism upon which embodied theories of esthetic experience rest is the mirror neurons mechanism. Mirror neurons are motor neurons originally discovered in the ventral premotor cortex of macaque monkeys (area F5) that discharge when the monkey executes goal-related hand motor acts such as grasping objects, and also when observing other individuals (monkeys or humans) executing similar acts. Neurons with similar properties were later discovered in a sector of the posterior parietal cortex reciprocally connected with area F5. Mirror neurons provide the neurophysiological basis for primates to recognize different actions made by other individuals: the same neural motor pattern characterizing a given motor act when actively executed is also evoked in the observer when witnessing the motor behavior of others.

This matching mechanism has also been shown in humans, both indirectly by means of brain imaging techniques and, more recently, at the single neuron level. Furthermore, empirical evidence suggests that the same neural structures that are involved in the subjective experience of emotions and sensations are also active when we see others express the same emotions and sensations. A whole range of different 'mirror

matching mechanisms' is present in the human brain. These mirroring mechanisms have been interpreted as constituting a basic functional mechanism in social cognition, defined by Gallese as embodied simulation.

Since the activation of the mirror mechanism for action is typically induced by the observation of ongoing actions, its relevance for the esthetic experience while contemplating static artworks could be negligible. However, even the observation of static images of actions lead to action simulation in the brain of the observer, through the activation of the same brain regions normally activated by execution of the observed actions.

The significance of mirror neurons in understanding esthetic responses to art has not been fully assessed. Freedberg and Gallese recently proposed that a fundamental element of esthetic response to works of art consists of the activation of embodied mechanisms encompassing the simulation of actions, emotions, and corporeal sensations. As we have shown above, historically, theorists of art have commented on a variety of forms of felt bodily engagement with works of art, but the mechanisms by which this happens have remained unspecified or entirely speculative. Mirroring mechanisms and embodied simulation can empirically ground the fundamental role of empathy in esthetic experience. Freedberg and Gallese's theory of empathic responses to works of art is not purely introspective, intuitive or metaphysical, but has a precise and definable material basis in the brain/body system.

This theory is articulated in two complementary aspects. (1) The relationship between embodied simulation-driven empathic feelings in the observer and the content of artworks, in terms of the actions, intentions, objects, emotions, and sensations portrayed in a given painting or sculpture. This aspect can be viewed as the 'what' of esthetic embodied experience. (2) The relationship between embodied simulation-driven empathic feelings in the observer and the quality of the artwork in terms of the visible traces of the artist's creative gestures, such as brush work, chisel marks, and signs of the movement of the hand more generally. We can refer to this component as the 'how' of esthetic experience (see also next section).

The sensory-motor or 'cold' component of the mirror mechanism includes the activation of parietal and premotor areas, which have been often found active in neuroesthetic studies. The recent work by Di Dio and colleagues provides suggestive evidence compatible with this hypothesis. In this investigation, the observation of Classical and Renaissance sculptures elicited activation of the ventral premotor cortex and of the posterior parietal cortex, suggesting motor resonance congruent with the implied movements portrayed in the sculptures. The observation of sculptural representations of the human body, although depicted in a bidimensional image viewed under an unnatural context like that of an MRI scanner evokes motor resonance congruent with the implied movements portrayed in the sculptures and underpinning an embodied comprehension of the observed object. In other words, we do not only see an artwork with our eyes – and our visual system, but also experience it with our body as the repository of our potentialities for action.

The involvement of parietal and premotor areas in esthetic experience was also observed in the fMRI study of Jacobsen and colleagues. In this study, participants were required to make an esthetic appraisal of abstract geometrical shapes, whose

symmetry and level of complexity had been manipulated. Brain imaging results indicated that, in both the comparisons of symmetry judgment and esthetic judgment tasks versus the control condition (observation of an arrow), activations were enhanced in areas subserving visuomotor processes, including the intraparietal sulcus and the ventral premotor cortex.

Additional evidence in this respect comes from a study by Cela-Conde and colleagues, in which gender-related similarities and differences in the neural correlates of beauty were investigated. The experimental stimuli consisted of a set of images of either artistic paintings or natural objects, divided into five groups: abstract art; classic art; impressionist art; postimpressionist art; photographs of landscapes, artifacts, urban scenes, and true-life depictions. Through magnetoencephalography (MEG), which allows studying the various temporal stages of brain stimulus processing, enhanced activation for 'judged-beautiful versus judged-ugly' stimuli in several parietal foci was shown, bilaterally for women and mainly in the right hemisphere for men, with a latency of 300 ms after stimulus offset.

In humans, as in monkeys, the posterior parietal cortex is involved in the organization and recognition of action. Physiological and anatomical studies on macaque monkeys suggest that the posterior parietal cortex is part of the motor system. It has been shown that posterior parietal areas map different motor acts (such as grasping) on the basis of the goal of the action (such as eating) of which they are a component. This functional organization, shared by posterior parietal and ventral premotor areas, likely underpins high-order cognitive functions, such as understanding others' basic motor intentions through an embodied simulation mechanism. These functions have been observed in the inferior parietal lobule (IPL) where visual information of ventral and dorsal stream is integrated with motor information, to build a pragmatic description of the observed object.

Most studies in neuroesthetics show activation of parietal and, in some cases, premotor areas. This evidence supports the idea that esthetic experience is strongly characterized by visuo-spatial coding as well as, importantly, by motor mapping. The exact role of the motor component, though, can be better understood when considering this aspect of esthetic experience as the automatic access to emotional levels of stimulus processing. This aspect of esthetic experience is the focus of next section.

Emotion in Action

Emotions and sensations represent the esthetic quality that characterizes the success of the relationship established between the observer and the artwork. This concept can be readily understood when thinking of explicit visual representations of human emotional states, with which the observer can automatically relate through the mirror neurons mechanism. In this stance, embodied simulation mechanisms are in place, likely mediating the empathic feeling arising in the observer toward the representational content of the artwork.

A representative example of the idea of bodily empathy experienced by art viewers is given by I Prigioni (the Prisoners), a series of unfinished sculptures by Michelangelo. Through the observation of these sculptures, viewers are led to experience the struggle of the prisoners to free themselves from the

stone. The effect of the struggle is expressed through the effective and forceful representation of the muscles carved from the stone. In this example, one can appreciate the relevance of embodied simulation in art, whereby the mere visual description of the artwork develops into an esthetic experience in which the bodily sensation felt by the viewer is in consonance with the artist's intention to ultimately convey a specific emotional state. The expressed or implied movement within the representational content of a work of art becomes the vehicle through which viewers can find an automatic access to those emotions and sensations that underpin the esthetic experience.

On what grounds, though, can we describe the human tendency of ascribing feelings and emotions to inanimate objects, independently of their abstract or concrete nature? Philosophical accounts of emotion in esthetics suggest that emotion ascription to nonsentient objects is due to imagination processes that either associate or impute states of mind to the object as representative of the emotion state of the artist or of the character depicted in the artwork.

These accounts differ considerably from our conception of an emotional embodied esthetic experience. For example, what is there in the representation of a landscape displaying the violence of the blowing wind if not the marks left behind by the artist's violent brush strokes? The observers' eyes catch not only information about the shape, direction and texture of the strokes, but most importantly – by means of embodied simulation – breach into the actual motor expression of the artist when creating the artwork.

Observers are likely able to appreciate the violent nature of the artwork because those brush strokes feature the movements they resonate with by means of the mirror mechanism. In this example, the artwork becomes the mediator of the motor and emotional resonance that establishes between the artist and the observer. The sensory-motor component of stimulus processing represents the most direct and automatic level of processing, which allows the beholder to feel the artwork in an embodied manner.

The marks on the painting/sculpture are the visible traces of goal-directed movements, hence capable of activating the relevant motor areas in the observers' brain, as suggested by the mirror neuron research. While at present there are no published experiments specifically targeting this issue, there is empirical evidence indirectly suggesting that this could be the case. Studies by Longcamp and colleagues show that motor simulation is induced in the observer's brain also when observing the static graphic consequence produced by the action, such as a letter or a graphic stroke. This shows that our brain can reconstruct actions 'a posteriori' by merely observing the static graphic outcome of the agent's past action. We posit this reconstruction process during observation to be the expression of the embodied simulation mechanism, relying on the activation of the same motor centers required to produce the observed graphic sign. We predict that similar results could be obtained using as stimuli artworks characterized by peculiar gestural signs of the artist, as in the case Fontana's or Pollock's works.

The relationship between esthetic experience and emotion was recently revealed by the abovementioned fMRI study by Di Dio and colleagues. Analyses of the imaging data showed that esthetic experience of artworks is marked by an emotional

component that is processed at different anatomical levels. The areas involved in the emotional portrayal of esthetic stimuli were the insula and the amygdala.

In this experiment, Classical and Renaissance sculptures were presented in two versions: originals and proportion-modified. The distinctive feature of this study was to allow participants to observe the images without expressing any explicit judgment. In the attempt to induce the required implicit 'esthetic attitude,' participants were instructed to examine the images as if they were in a museum (as much as they could in a scanner). Explicit esthetic and proportion evaluations were required only in subsequent conditions. Imaging results showed that the observation of original sculptures, relative to the modified ones, produced activation of lateral and medial cortical areas (lateral occipital gyrus, precuneus, and prefrontal areas) and, importantly, of the right anterior insula. Activation of the insula was particularly strong during simple observation condition, in which observers, hence their brain, responded most spontaneously to the presented images.

The contrast of canonical versus proportion-modified images in the study of Di Dio and colleagues highlighted the brain areas that preferentially code for esthetic stimuli, so defined by their intrinsic physical properties. In particular, insular activation may be involved with a matching mechanism relating the artwork or some of its attributes with some descriptive processing levels in the beholder's brain. We can define this kind of esthetic experience an 'objective' one: it emerges from the processing of sensory-motor input and, crucially, from the feeling of pleasure, mediated by the activation of the insula.

Though, esthetic experiences are only partially built on objective measures. In order to separate the objective esthetic value from subjective esthetic evaluation, a further analysis was carried out, contrasting brain responses to liked versus disliked images as judged by each participant during the explicit esthetic judgment condition in which they were asked how much they liked the displayed stimuli. Here, preferred stimuli selectively activated the right amygdala, a brain structure mapping the emotional salience of stimuli for the observer. These results support the idea that the more 'subjective' aspect of esthetic experience is mediated by association processes with the observer's own emotional experiences.

Overall, these results suggest an overt neural link between esthetics and emotion, showing that core emotion centers like the insula and the amygdala mediate esthetic preference, at least at basic levels of processing.

Of particular interest for the emotional and sensory comprehension of an artwork is insular activation and, more specifically, its anterior portion. Anterior insula is often found active in studies investigating social empathy or emotional mirror resonance. The anterior sector of the insula has an agranular/disgranular structure and is characterized by its extensive connections with prefrontal and premotor areas as well as with limbic structures and with centers involved in autonomic functions. Functionally, the anterior insula is thought to mediate feelings and the behavioral dispositional attitudes associated to specific emotional states. It is plausible to assume that insular activation during esthetic experience mediates the specific esthetic quality defining artworks and the feelings associated

with them by bridging evoked motor resonance with the associated emotional state.

A study by Cupchik and colleagues supports this idea. In this study, participants viewed various categories of representational paintings (portraits, nudes, still-life, and landscapes) that were classified as 'hard-edge' (containing well-defined forms) and as 'soft-edge' (containing ill-defined forms). The underlying rationale for this classification was based on the hypothesis that 'soft-edge' paintings should facilitate esthetic experience by stimulating active image construction. Both 'hard'- and 'soft'-edge paintings were presented in two conditions: one that required the participants to observe the images in an objective and detached manner to gather information about the content of the stimulus (pragmatic condition), and one that required the participants to observe the paintings in a subjective and engaged manner, appreciating the feelings evoked by the stimuli (esthetic attitude condition).

Observation of representational paintings under the esthetic attitude condition versus baseline condition (viewing of non-representational paintings accompanied by no explicit task-related instructions) elicited bilateral activation of the insula, suggesting that this area is crucially implicated in the emotion feeling specifically associated with esthetic experience.

Like in the paper by Di Dio and colleagues, in this study too insula activation was particularly enhanced in conditions in which no explicit judgment of the stimulus was required, but where participants were induced to appreciate the artworks by explicit instruction given prior to scanning. Under these conditions, observers viewed the artworks with an implicit 'esthetic attitude.' In an experimental setting, explicit judgments are usually required to induce specific task-related states of mind that, however, may mask basic neural processes. In fact, self-evaluation and decision-making processes may diminish spontaneous hedonic responses associated with stimulus processing. Intention guides attention, and this is possibly the reason why participants' intention and 'attitude' play a crucial role in the classification of a visual experience as an esthetic one.

Conclusions

More than being a discipline, neuroesthetics is a specific field of neuroscientific investigation that has just begun to identify the functional relationship between the brain/body system and esthetic experience. One crucial problem concerns the specific quality of esthetic experience related to artworks. To which extent the same perceptual content – the beauty of a sunset – evokes the same esthetic experience when observed in nature or in a painting by Turner? Does the a priori definition of an image as an artwork affect the esthetic experience of the perceived object qua artwork? And does it entail the activation of specific brain mechanisms? These are only some among many excruciating questions neuroscience can perhaps help to answer.

The term esthetic experience connotes a multilayered state in which several dimensions can be distinguished. The current available evidence suggests that specific attention must be paid to the distinction between mere observation, esthetic attitude, esthetic appraisal, and esthetic judgment. These different ways

of relating to an object are apparently underpinned by different brain mechanisms. It is possible that what really counts in esthetic experience is not the quality defined a priori of an object as artwork, but the way we decide to relate to it. Such decision can dramatically modulate the quality of an esthetic experience. A variety of contextual and culturally determined factors affect this decision.

The contemporary way of appreciating artworks is historically and culturally determined. However, while believing that esthetic experience is multilayered, we still posit it to be grounded on a core component without which it cannot be fully understood. We posit that this component can be found in the variety of embodied resonance mechanisms we concisely reviewed in the present article.

Art is the ripe fruit of the way in which human beings at a given point of their cultural evolution were able to relate with the external world. The material world was no more exclusively considered as a domain to exploit for the utilitarian satisfaction of biological needs. Material objects lost their unique status of tools to become symbols, public epiphanies able to make visible something absent, something that apparently is only present in the mind of the artist and of the beholder. Human beings, thanks to the expression of their artistic creativity, acquired the possibility to give shape to material objects, conferring them a meaning they intrinsically lack. Such meaning is the outcome of the artist's action of laying colors on a canvas or turning a marble block into a David or a Proserpina's Rape. Today cognitive neuroscience has the tools to shed new light – from its own peculiar and reductionist perspective – on the esthetic quality of human nature and its natural creative inclination. This new research field has the potentiality to help us understand how and why artworks are probably the most fundamental expression of our human nature.

From a certain point of view, art is more powerful than science. With much less expensive tools and with greater power for synthesis, artistic intuitions show us who we are, probably in a much more exhaustive way with respect to the objectifying approach of the natural sciences. Being humans square with the ability to ask ourselves who we are. Since the beginning of mankind, artistic creativity has expressed such ability in its

purest and highest form. It is therefore perhaps understandable why many scholars in the field of the humanities are afraid that a neuroscientific approach to esthetics may hinder, if not even destroy, the magic and wonder normally accompanying our appreciation of art.

We believe that such fears are unjustified. We think that the empirically based approach to art and esthetic experience provided by neuroesthetics can in principle enable a further valorization of the most distinctive feature of human creativity.

Glossary

Brain fingerprinting A technique which may be able to detect whether a person recognizes a picture, word, or phrase. Brain fingerprinting uses EEG readings in an attempt to identify changes in brain activity when a subject is presented with familiar information. These EEG readings are then compared to the subject's verbal report regarding what he knows.

Compatibilism The view that human action can be understood to be free even if it is fully determined by a physical-causal chain of prior events, if the act is linked in a particular way to a person's desires or psychological states.

Dualism The view that humans have two components: the physical self and a nonphysical mind or soul.

Electroencephalography (EEG) The recording of the electrical activity along the scalp produced by the firing of neurons within the brain. These electrical voltages, often called brain waves, vary as a function of time and type of brain activity (e.g., the EEG of a person in a coma will look different from the EEG of a normal, awake adult).

Libertarianism The view that free will exists only where an act is uncaused by prior physical effects, but is not random or uncaused. This position usually entails the idea that an immaterial self or soul is the causal agent in human action.

Magnetic resonance imaging (MRI) An imaging technique used to visualize detailed internal structure and function of the body. MRIs use a powerful magnetic field to align the nuclear magnetization of atoms in the body. Radio frequency (RF) fields are then used to produce a signal that can construct an image of the internal structure of the body. Functional MRIs (fMRIs) measure signal changes in the brain due to changing neural activity by detecting increases and decreases in blood flow.

Neuroethics The body of work exploring the ethical, legal, and social implications of neuroscience.

Neuroimaging Technologies such as computed tomography (CT), anatomical and functional magnetic resonance imaging (aMRI and fMRI), and positron emission tomography (PET), which can display the structural and functional neurobiological bases of our cognitive capacities and psychological states.

Physicalism The view that humans are made of only one component, the physical stuff (and thus there is no immaterial soul or immaterial mental state).

Position emission tomography (PET) An imaging technique that produces an image of the functional structure of the body. The technique uses a tracer that is introduced into the subject's body and its presence is then detected and reconstructed into a three-dimensional image.

The term 'neuroethics' was coined in 2003 by political journalist and New York Times columnist William Safire. At a conference convened by Safire and the Dana Foundation, of which Safire was the Chairman, Safire defined neuroethics as 'the field of philosophy that discusses the rights and wrongs of the treatment of, or enhancement of, the human brain.' He then charged 150 neuroscientists, bioethics scholars, policy-makers, and journalists with the task of exploring the ethical, legal, and social implications of neuroscience.

Safire's definition has since been expanded to include not only the ethical implications of neuroscientific research – the ethics of neuroscience – but also the neuroscience of ethics. According to Adina Roskies, the neuroscience of ethics is concerned with a neuroscientific understanding of the brain processes that underpin moral judgment and behavior. The ethics of neuroscience, on the other hand, includes the potential impact that advances in neuroscience may have on social, moral, and philosophical ideas and institutions, as well as the ethical principles that should guide brain research, treatment of brain disease, and cognitive enhancement.

This article discusses these different aspects of neuroethics, with a special focus on how neuroscience might impact our sense of self and personal responsibility, a concern that cuts across these categories. For example, it discusses whether the advancing knowledge of brain states or processes undermines

common notions of free will and responsibility. It also examines whether certain treatments of brain abnormality are ethical (is it acceptable to irreversibly 'cure' pedophilia or obsessive/compulsive disorder?), a discussion that falls squarely under the category of the ethics of neuroscience. Finally, it discusses whether the neuroscience of ethics can provide insight into who should be deemed criminally responsible via a neuroscientific analysis of intentional action.

Neuroscience: The Self, Free Will, and Responsibility

Neuroscience is a scientific discipline, which aims at understanding how human behavior and capacities are related to brain structure and systems. Neuroscience includes neurophysiology, neuropsychology, and neuroanatomy, and utilizes techniques such as electroencephalography (EEG) as well as brain imaging technologies such as computed tomography (CT), anatomical and functional magnetic resonance imaging (aMRI and fMRI), and positron emission tomography (PET). These technologies can explain the structural and functional neurobiological bases of our cognitive capacities and psychological states and processes, such as decision-making, desires, memories, and emotions.

Other disciplines that treat human beings as objects of scientific inquiry include anatomy, biology, and chemistry.

However, neuroscience focuses upon the operations of the nervous system, which is the locale of capacities closely associated with personality, character, and the self. Thus, neuroscientific findings are thought to have deep philosophical implications with regard to who we are (and possibly, what we are).

So, who are we according to neuroscience? Neuroscience describes the brain as a causal machine. This means the brain goes from state to state as a function of prior, or antecedent, conditions: if the antecedent conditions were different, the result would be different; if the antecedent conditions were the same, the result would be the same. For example, at the beginning of some of these functional state changes is a perceptual (or sensory) input and at the end of some series of changes is a behavioral output (action).

Somewhere in between the input (perception of the environment) and output (action), thoughts, preferences, memories, and decisions seem to reside. Neuroscience provides us with new means to examine how these mental states and processes are instantiated in the brain by allowing scientists to observe the brain undergoing processes in response to stimuli via fMRI machines. Data from an fMRI scanner shows what sites in a subject's brain are active (indicated by an increase of the blood flow signal) during mental activity, such as the experience of particular conscious mental states. Additionally, aMRI and PET scans allow scientists to view the structure of the brain, thereby facilitating the identification of abnormalities in the brain tissue. It may then be postulated that such abnormalities impact brain function in particular ways.

Neuroscience is thus thought by some to comment upon three age-old philosophical problems: First, what is the nature of the human mind? Second, how is the brain related to human action? And third, for which acts may a person be held responsible?

Neuroscience and the Mind

Long before neuroscience informed our ideas of how the brain operates, many philosophers and scientists were already convinced that the position of dualism – that humans are made out of two types of stuff, a physical part and a nonphysical mind or soul – was false. Many feel that there is little evidence in support of an immaterial mind, especially if one thinks this immaterial mind has causal effects. Neuroscience adds to the already substantial body of evidence to the fact that brain states and processes either enable or constitute our psychological states and processes, including thoughts, memories, and even higher mental functions such as consciousness and reasoning.

The tools of neuroscience thus provide further evidence that the brain constitutes the mind, and may even eventually describe which parts of the brain constitute which mental states or processes. However, neuroscience does not necessarily rule out the possibility of a nonphysical aspect of the mind. Some think that conscious states, such as pain or love, are just what it feels like to undergo certain neural processes. Frank Jackson, however, has argued that the conscious feel of a mental state, such as the perception of the color red, could be an immaterial 'add-on' to a physical brain state. Jackson notes, however, that in this case it is most likely that such immaterial states, which he calls 'qualia,' are epiphenomenal: that is, they

have no physical-causal effects. This means that it would be the neural instantiation of the state of pain or thirst that causes behavioral effects, not the immaterial conscious feel.

Although neuroscience may not definitively rule out immaterial qualia, it does seem to indicate that the cognitive capacities we consider most representative of the 'self,' such as decision-making capacities and modulation of emotions, can be functionally identified as discrete states or processes within the brain. fMRI studies have allowed us to isolate and locate important cognitive capacities within the brain by identifying stored representations (memories) as functionally dissociated from the processes that operate upon them (decision-making). Neuroscience indicates that the frontal lobes do not contain many of our mental representations or memories, and that they instead reside in the posterior cortical regions, in the temporal and parietal lobes. (An exception may be motor representations and some representations involved in procedural or working memory.) The prefrontal lobes primarily contain the thought processes, often called executive processes by neuroscientists, which monitor and manipulate representations.

As we shall see, neuroscience's increasing ability to provide a structural and functional description of the brain has far-reaching implications. First, it could allow us to designate a portion of the brain as particularly important – because it functions in a way crucial to decision-making, for example – and in need of protection against manipulation or even enhancement (see below). Second, neuroscience may be able to not only identify brain abnormalities, but also explain why certain disorders of the brain are experienced as particularly harmful. Third, neuroscience could provide us with a better understanding of which decisions and acts persons should be held responsible for, via the analysis of the function of that part of the brain that is most closely associated with the self and decision-making.

Free Will

Philosophers have long questioned whether the everyday concept of free will – the libertarian version of free will where a free act is uncaused by prior physical effects, but is not random – is true. However, because neuroscience advances the idea that the brain is a causal machine, it has provided further evidence that this traditional libertarian theory of free will is false. Neuroscience appears to support what scientifically minded philosophers had long surmised: that there are no explanatory gaps in our brain processes wherein the causal chain is broken and libertarian free will steps in to cause action. Neuroscientific evidence, like a biological understanding of the conditions under which a neuron fires (or fails to fire), indicates that one need not appeal to an immaterial self or 'soul' to explain human behavior.

In particular, the work of Libet caused many people outside the field of philosophy to think that neuroscience meant human free will is an illusion. Libet conducted experiments in which he had subjects make voluntary hand movements while he measured their brain activity using event-related potentials. Subjects were told to report the position of a black dot when they made the conscious decision to move their hands. Then this moment was compared to the time when the subject's brain appeared to change in relation to the desire to move the hand.

Libet discovered that the brain appeared to initiate the sequence resulting in the hand movement before the subject was consciously aware that he or she had made a decision to move: about 300 ms elapsed between the beginning of brain activity and the decision. Thus, it seems our brains know we are going to make a decision, and perhaps maybe even what the decision is, before we do. (The 'we' here is the conscious agent.)

Libet noted, however, that there are about 100 ms left after the initiation of the act for the conscious mind to either endorse or veto the decision. Therefore he argued that free will was not entirely an illusion, claiming that it consists of this veto power that consciousness may have over a decision.

Regardless of how one interprets Libet's results, neuroscience does not force one to abandon the concept of free will. Many philosophers now accept the position of *compatibilism* – that human action can be understood to be free even if it is fully determined by a physical-causal chain of prior events. Walter Stace, for example, argues that free acts are "those whose immediate causes are psychological states in the agent," regardless of whether those states are physically instantiated and part of a larger causal chain. That is, it may be that your desire to get a drink was initiated by some physical state equal to thirst and that your decision to get up and open your refrigerator was causally determined by this physical state. But because these states are 'yours' the action should be considered free. By contrast, unfree acts are acts whose immediate cause is some state of affairs external to the agent, such as one holding a gun to your head.

Who Is Responsible?

Quite a few scholars have raised the alarm in the criminal courts regarding the use of neuroscience precisely because they feel that criminal responsibility requires libertarian free will. But as indicated above, even if neuroscience provides a new sort of explanation of the causes of behavior, this explanation does not necessarily constitute an excuse. The current criminal justice system can hold persons responsible even if human actions have full physical explanations: that is, even if a desire to kill is neuronally instantiated and has a complete causal history, the criminal justice system is designed to attribute responsibility when that desire leads to criminal harm.

Criminal responsibility requires that action be immediately caused in a certain way. If a harmful act is connected to the actor's desires or goals, and if the actor holds certain beliefs about the harm that could result from the act, then he or she is criminally responsible. Thus, to be guilty of murder under the US Model Penal Code, for example, one must have a *mens rea* (or a mental state) that includes: (1) the desire to perform an act that results in the death of another; and (2) performance of the act with the desire to kill, knowledge one will kill, or with such reckless indifference that there is a chance that one may kill.

It is possible (although unlikely, at least given the current state of the science) that neuroscience may provide a complete physical-causal description of the mental states required for criminal responsibility – the desire to kill and the understanding that the act will result in a death. But even if this were to happen, it need not affect the categories of culpability (such as

murder, rape, and theft) themselves. The breadth of category is a policy decision determined by legislatures and judges. Neuroscientific knowledge can thus be understood as a tool to help us better categorize defendants as guilty or not guilty on the basis of the existing categories of culpability and defense.

However, there is some chance that neuroscience will make us alter or abandon the categories we use to attribute criminal guilt. Some have suggested that the vast majority of offenders on death row suffer from severe prefrontal lobe damage. What if it turned out that the vast majority of murderers had severely compromised executive function, such that, using the delicate tools of neuroscience, we determined they could not either control or understand their violent acts in the way that those without compromised brain function can? In other words, what if they did not have normal desires or did not understand the nature or consequences of their acts in a 'normal' way? Would punishment still be justified?

In the United States, criminal punishment tends to be justified on the basis of one or several of the 'principles of punishment' such as deterrence, incapacitation, or retribution. Neither retribution nor deterrence would seem to justify severe punishment of persons with brain function compromised in a way relevant to criminal responsibility (e.g., with regard to intentional or rational action). Such persons would not deserve retribution if they truly did not understand the nature of the act they were performing or were unable to stop themselves from performing it. Similarly, an understanding of the act as criminal and the ability to stop oneself from performing the act is crucial to the effectiveness of deterrence.

However, just as we incapacitate those deemed legally insane or 'guilty but mentally ill' despite the fact that they are ineligible for punishment, we might also decide to incapacitate violent offenders who lack the capacity to understand or abstain from criminal acts. Thus in this case, neuroscience might alter our theoretical handling of offenders with abnormal brain processes, but our actual treatment of the offenders – incapacitating them – may not change.

Brain Research, Treatment, and Enhancement

In addition to its implications for the traditional philosophical concepts of mind, will, and responsibility, there are other ethical concerns raised by advances in neuroscientific research. These ethical concerns include issues of privacy and the way in which the 'self' might be altered or enhanced via neuroscience.

Privacy

Take, for example, the use of neuroscience as a 'lie detector.' The first lie detector consisted of a polygraph test. A polygraph is an instrument that measures and records physiological indices such as blood pressure, respiration, pulse, and skin conductivity while the subject is asked and answers questions. Although many dispute the accuracy of polygraph tests, some argue that lying produces a physiological response that can be differentiated from true answers.

A recently developed lie-detector technique, however, uses neuroscience. 'Brain fingerprinting' devices use EEG readings in an attempt to identify changes in brain activity when a

subject is presented with familiar information. An EEG records the electrical activity along the surface of the scalp produced by the firing of neurons within the brain. These electrical voltages, often called brain waves, vary as a function of time and type of brain activity (e.g., the EEG of a person in a coma will look different to the EEG of a normal, awake adult). In brain fingerprinting, changes in EEG readings are compared to the subject's verbal report regarding what he knows. The device is thus thought to be able to determine whether a criminal suspect is familiar with some aspect of a crime, and hence whether the suspect is telling the truth concerning his/her involvement. Such a device could also be used by potential employers, or even insurance companies, to determine if a job candidate or person seeking insurance is being honest about his/her past work experience, or any preexisting conditions.

Because brain fingerprinting detects brain activity directly, it is thought by some to be a more accurate lie detector than the polygraph. This is because it does not entail detection of emotional responses, which can be consciously manipulated by some subjects. However, there is controversy over whether brain fingerprinting provides consistently accurate results. In addition, brain fingerprinting can only indicate whether a subject is familiar with certain information; the technique cannot indicate how the subject gained this information (e.g., via being present at the crime scene, or reading about the crime in the newspaper).

There are other ways that neuroscience may provide access to previously private mental states. Newly developed quantum dot technology is being used to gather information on the brain at the level of the neuron. Nanosized functional quantum dots can help build data-capture devices that are easy for neuroscientists to use. Many feel that nanotechnology in conjunction with neuroscience will eventually allow for targeted interactions between neurons, the cells responsible for signal transmission in the brain. Ultimately, it seems clear that nanotechnology will allow us to visualize and track functional responses in neurons and this means we will be provided information about a person's thoughts remotely.

Several ethical issues are raised by the possibility of the use of brain fingerprinting devices or functional quantum dots. Normally, an employer or a police officer must rely upon information voluntarily offered: regardless of what one thinks, the information actually spoken is what counts, and most persons have control over the words they choose to speak. Insofar as neuroscience allows others direct access to one's consciousness or mental states, it would appear to entail a serious violation of privacy. And in the cases mentioned above, the consequences of the violation are severe: one might not get a job or qualify for health insurance, or in the case of criminal law, one could lose his or her liberty or life.

Enhancement

The possibility of brain enhancement via neuroscience brings forth other ethical worries. Pharmacological enhancement of brain function is already widely practiced via drugs such as selective serotonin reuptake inhibitors (SSRIs, prescribed for mood enhancement), Ritalin (for improved attention and concentration), and Aricept (for improved memory). Although originally conceived to make up for deficits in cognitive ability

due to disorders such as depression and attention deficit hyperactivity disorder, such drugs are now often used by those with highly functioning, and even 'normal' cognition, like those diagnosed of being vulnerable to depression (but without any current depressive symptoms).

Enhancement may also be achieved by brain implants. Brain implants have been used to lessen the effects of several common disorders, such as Parkinson's and chronic pain. For example, in the case of Parkinson's, a technique called deep brain stimulation (DBS) uses a brain implant to deliver electrical impulses to a region at the center of the brain that controls and coordinates movement. DBS has also been used in an attempt to stimulate various parts of the brain which appear dysfunctional in those who suffer from major depression and Tourette's syndrome. In the future, it is possible that DBS could be used to enhance the cognitive function of those without psychological disorders.

Scientists are currently making progress using both carbon nanotubes and conventional silicone implants in the brain. Ultimately, such implants may be used to manipulate thought, possibly via transmission or implantation of thoughts. One possible use of this technology could be to help soldiers to fight better under combat situations, or to aid athletes in performing their sport.

One ethical concern regarding brain enhancement is the idea that for humans to fully enjoy or appreciate life, they must experience both joy and pain. Overuse of SSRIs or other brain enhancing drugs might thus blunt a person's ability to enjoy the full range of human experience. Another worry is about the way in which enhancement will be distributed. It is likely that the wealthy and privileged will have more access to such enhancements, thus creating an even wider gap between socioeconomic classes. For example, a drug that assists in memory may mean that those who can afford the drug may have an advantage in the job market, and athletes with neuroenhancements will be able to out-compete those without enhancement.

Yet another concern regarding neurological enhancement is that it is done in accordance with a normative idea of the optimal human being or life. However, there is much disagreement about the 'good life' for human beings, and even capacities we might all agree are beneficial with regard to specific tasks could turn out to have negative outcomes overall. For example, there is some evidence that the average human level of forgetfulness actually helps us attend to the things that are important, instead of being distracted by unnecessary details. There is certainly no evidence that having better mental capacities will make human beings happier.

There is also the possibility of the use of neuroenhancement or manipulation in the criminal justice system. For example, a handful of US states have chemical castration laws, which means that at least some subset of their criminal offenders either must or may submit to chemical castration as a part of their sentence. Depro-Provera is the drug most often used for chemical castration. The chemical used is an analogue of the female hormone progesterone, which reduces the normal level of testosterone in a male, thus reducing sex drive, and often diminishing seminal ejaculator fluid to zero.

Depro-Provera has to be continually administered, which requires non-incapacitated offenders to submit themselves to

weekly shots. One might imagine neurological castration as a replacement to this drug regimen. Neurological castration might directly inhibit activity in certain parts of the brain (e.g., within the hypothalamus), by blocking connectivity between areas of the brain (e.g., between representations of children and sexual arousal). One might imagine that a nanotechnological approach to castration may be more successful, and have far fewer side effects, than current methods.

Neurological castration could just be the beginning of neurological sentencing techniques. If it becomes possible to neurologically inhibit strong violent responses to stimuli, the state might offer offenders the option to submit to this operation in exchange for a shortened or commuted sentence. Granted, at the moment this possibility is more fiction than science. However, given the success in drug interventions on aggressive behavior – for example, with tranquilizers and some antidepressants – it is possible that neuroscience could discover a more targeted means of delivering the same result.

Neuroscience could thus potentially allow us to reimagine the principle of rehabilitation by providing a means to directly change behavior. One might even wonder whether we could eventually come up with what some might call an ‘artificial conscience.’ Until recently, persons who violate the law have been allowed to remain the sort of person they have been (even if that person was a pedophile), although the space within which they have been allowed to be that person is limited to a prison. And after offenders served their time, they were released to continue to pursue their individual desires. However, neuroscience instead might allow us to permanently change a person’s character, such that he or she no longer commits criminal acts.

Any neuroscientific manipulation or enhancement that changes a person’s loci of decision-making represents nothing less than changing their identity. Most philosophers believe that one’s psychological states – beliefs, desires, memories, and emotions – are a crucial component of one’s identity. Our psychological states are the ‘source’ of our behavior: we act in a certain way because we desire and believe certain things. If neuroscience changes what we want, what we know, or what we believe, it changes who we are.

With regard to criminal offenders, involuntary manipulation of psychological states via neuroscience would be a severe violation of human agency in that it would infringe upon the ability of a human being to choose, and be responsible for, his own acts. However, use of technology in this way raises serious ethical concerns even if offenders participated in such programs voluntarily. Would we really be giving offenders a choice with regard to neuro- or nanotechnological alteration if they must choose between 30 years in prison and freedom after a ‘simple’ operation? There are real worries that such an option would be no option at all.

A Neuroscientific Understanding of Moral Judgment and Action

Traditionally, philosophers such as Immanuel Kant argued that higher level reasoning was crucial to moral judgment and action. However, it has become increasingly clear that moral judgments are not the sole product of reason or introspection, isolated from emotion. Indeed, it turns out that emotional

input is crucial to moral action and the judgments we make regarding whether others’ actions are right or wrong.

Neuroscientific research attempting to isolate the regions involved in moral reasoning and behavior supports this conclusion. Neuroimaging indicates that there is no particular ‘moral center’ of the brain. Widely distributed brain areas have been found to be activated during moral reasoning tasks, including those regions associated with higher cognitive functions and those involved in emotional responses. There appears to be a complex interplay between reasoning and emotions in the formulation of a moral decision, indicating that there may not be an easy distinction between thinking and feeling when it comes to morality.

It is somewhat difficult to parse apart findings indicating the brain regions associated with moral judgments from those regions associated with behavior that we might judge immoral or ‘bad.’ This is because being able to determine that a situation requires moral judgment, and treating a decision as a moral decision, may be important for moral behavior. If one does not see one’s decision to steal a neighbor’s TV, or not to give money to the Red Cross, as a moral judgment with ethical implications, then it seems one is less likely to make a decision that others will approve.

Moral Judgments

Studies have found significant neurological differences between subjects making judgments on personal moral dilemmas, and those contemplating impersonal moral dilemmas and non-moral dilemmas. Moral dilemmas involving a personal component – where one is asked to consider whether they would personally perform some moral or immoral act – seem to activate the orbital, ventromedial and dorsolateral prefrontal cortex (PFC), the medial frontal gyrus, and possibly the posterior cingulate cortex, amygdala, and inferior parietal lobe. These regions are associated with the integration of emotions, mental imagery, and memories into decision-making, representation of rewards and punishments, and control of risky or inappropriate behavior. In addition, the medial frontal gyrus, anterior and posterior cingulate cortex, and temporal areas (such as the superior temporal sulcus and temporal pole) are associated with the theory of mind, the ability of human beings to attribute mental states to others as a means to understand and predict their behavior.

Antonio Damasio and colleagues have found that patients with a damaged posterior ventromedial cortex have impaired ability to make moral judgments. However, their impairment was primarily emotional; they appeared to have an inability to generate and effectively use what Damasio calls ‘somatic markers’: neural representations of body states that give potential bodily actions (sometimes unconscious) an emotional feel, making them more or less appealing. If you ask subjects without ventromedial damage to imagine running over another person in their car, they tend to have a negative emotional response in association with the mental image. Although subjects with ventromedial damage could imagine performing the act and its consequences, and knew that society would judge such an act as wrong or criminal, they failed to have a normal emotional response to the mental image.

It seems the more personal a moral dilemma, the stronger one’s potential emotional response. Greene and Haidt scanned

subjects using an fMRI while they responded to a series of personal and impersonal moral dilemmas, as well as nonmoral dilemmas. They determined that a moral violation is personal if it is clear that the subject is hurting some particular person, whereas it is impersonal if it did not require the subject directly harm someone else. A classic philosophical thought experiment, for example, asks whether the subject would pull a switch to move a trolley car from one track, where five people are likely to be hit by the trolley and killed, to a second track, where only one person is going to be hit and killed. This is an impersonal moral dilemma because it does not require that the subject's act directly causes harm, but only deflect harm from one party to another. On the other hand, when a subject is asked to push a fat man onto the tracks to derail the trolley to keep the five persons from being killed, the dilemma becomes personal because it requires direct harm to be caused by the subject to a person who would otherwise be safe.

Greene and Haidt found that responding to personal moral dilemmas, as compared with impersonal and nonmoral dilemmas, produced increased activity in the medial frontal gyrus, posterior cingulate gyrus, and the angular gyrus. These areas are associated with social and emotional processing. Impersonal and nonmoral dilemmas, on the other hand, produced increased activity in areas associated with the working memory, such as the dorsolateral prefrontal areas. These findings again indicate the importance of emotional input in moral decision-making: subjects faced with a moral dilemma tended to be quick to moral condemnation but slow to approval of personal violations, apparently due to the salience of negative emotions, whereas approvals and disapprovals took equally long when subjects were faced with impersonal and nonmoral dilemmas.

In sum, neuroscience indicates that many different capacities are important to moral reasoning and judgment, including normal decision-making and theory of mind capacities; however, the importance of emotional input may be particularly important to moral judgments (as opposed to many other types of judgments).

Moral (or Immoral) Behavior

As indicated above, there is significant overlap between the brain regions associated with moral judgment and the regions associated with immoral or antisocial behavior. Regions common to both include the ventral and medial PFC, the amygdala, and the angular gyrus/superior temporal gyrus. One difference, however, is that persons who tend toward antisocial behavior show hippocampal and anterior cingulate impairment, whereas moral judgment studies fail to indicate such activation consistently in moral reasoning tasks. However, psychopaths also show frontotemporal-limbic gray matter reductions (DeOlivera-Souza et al., 2008) and reduction in connections between the amygdala and OFC (Craig et al., 2009).

Adrian Raine and colleagues have argued that some of the neurological impairments found in antisocial individuals disrupt moral-emotional decision-making, which in turn acts as a factor predisposing such individuals to antisocial behavior. Some antisocial personalities, and psychopaths, appear to show normal or excellent moral reasoning ability, but appear to fail to apply the outcome of such reasoning processes because of a lack of emotional input.

As an example, some argue that the ventromedial frontal cortex (VM cortex) mediates between the neural systems for arousal and emotion, and is therefore important to moral behavior. Patients with VM cortex damage tend not to show deficiency in moral reasoning; that is, in their ability to identify potential moral conflicts and potential solutions to such conflicts. However, at least some VM patients *feel* differently about the identified solutions than those without VM damage. Going back to the trolley thought experiment, both VM patients and persons without VM damage realize that killing one fat man will save five others lying in wait on the other trolley track. However, persons without VM damage tend to judge that it is wrong to kill him. Persons with VM damage, however, are more likely to judge that pushing the fat man onto the tracks is the right thing to do.

Not surprisingly, the difference between the two judgments seems to be emotional: as indicated above, many think psychopaths act immorally partially owing to a lack of normal affect. Thus, persons with VM damage may be more likely to engage in antisocial or immoral behavior, precisely because they do not feel badly about such an action. In conclusion, many argue that it is predominately the failure to *feel* what is moral, rather than knowing what is moral, that leads many to antisocial or immoral action.

Neuroscientific Evidence and the Criminal Law

From the perspective of the criminal justice system, it is difficult to understand what the conclusion that many antisocial persons lack emotional insight should mean. To the extent that neuroscience has thus far been used by the criminal law, it has been introduced to help the court determine whether a defendant had either minimal capacity to form the intent to commit a crime, or if the defendant was capable of forming the highest level of intent (e.g., the intent to kill in the first degree or 'purposely,' for which the defendant might qualify for capital punishment). In this way, neuroscience has been understood to be a rough tool for commenting upon the basic decision-making capacities necessary to understand the nature and quality of one's actions in a normal way.

For example, in 2003, Burns and Swerdlow reported the case of a 40-year-old schoolteacher, in an otherwise normal state of health, who developed an increasing interest in pornography, including child pornography. The patient also began soliciting prostitution at 'massage parlors,' which he had not previously done. Magnetic resonance imaging revealed a large tumor in his right orbitofrontal lobe. The patient's symptoms disappeared after the tumor was removed. The tumor in the frontal lobes had impacted several important higher cognitive functions (executive processes), including inhibition (denial of immediate gratification), the moderation of emotional responses, and consideration of the potential future consequences of actions. Burns and Swerdlow hypothesized that the tumor had not given the patient new goals or desires, but had rather impacted the patient's ability to conform his behavior to societal norms and laws.

The patient was arrested for sexual assault of his stepdaughter. If the case had gone to trial, it would seem that identification of the man's tumor would seem to be extremely helpful to an accurate understanding and categorization of his behavior. Indeed, it would appear to be unjust to deny a judge or jury a

chance to consider the neuroscientific evidence of the presence of a tumor in the man's orbitofrontal lobes as evidence of diminished legal capacity.

However, this specific use of neuroscientific evidence in criminal law is quite different from imagining the implications of finding that some high percentage of antisocial behavior is linked to brain abnormalities. In the above case, the tumor in the brain of the patient described by Burns and Swerdlow led him to behavior that was abnormal by his standards (and disappeared after the tumor was removed), indicating that it is only appropriate to attribute lesser responsibility to the patient for an act that is actually linked to the tumor. However, as stated above, if all murderers have certain common brain abnormalities, does that mean we have a better indicator of the sort of person we feel is dangerous and want to punish, or does it mean such persons are less culpable? This question does not appear to have an empirical answer and seems to fall instead within the realm of public policy.

Glossary

Automatic processes Behavioral patterns that are invariant, do not require decision, and typically occur when the consequences of actions are known in advance.

Behavioral assessment of the dysexecutive syndrome (BADS) A battery of clinical neuropsychological tests utilized to diagnose patients' deficits in organizing and planning nonroutine behaviors.

Biased competition Signals from a higher-order brain system to a lower-order brain system that selectively enhance or suppress some among a set of competing stimulus or action representations, based on the current context or task requirements.

Cognitive estimation A neuropsychological test whereby the participant is asked to estimate some quantity whose value is not common knowledge but can be logically derived from other quantities that are common knowledge.

Contention scheduling system The neural system for choosing among a repertoire of automatic behaviors.

Controlled processes Behavioral patterns that require decision, and that typically occur when the consequences of actions are not known in advance.

Dysexecutive syndrome A pattern of mental deficits that tends to include distractibility, inability to deal with nonroutine situations, and difficulty in organizing and planning actions.

Prefrontal inhibition Signals from the prefrontal cortex to subcortical systems that serve to override a prevailing response when the context calls for a different response.

Stroop test A neuropsychological test whereby words for colors are presented in ink of either the same or a different color as the one the word represents. The participant is asked to state the ink color rather than read the word.

Supervisory attentional system The neural system for detecting contexts that require nonroutine behaviors and for deciding on appropriate actions for those contexts.

Tower of London A neuropsychological test of planning and monitoring functions, whereby the participant is asked to move from one configuration of balls on poles to another configuration in at most a prespecified number of moves.

Trail Making Test A neuropsychological test whereby the participant is asked to draw connections between circles in a prespecified sequence without lifting his or her pencil.

What Is Brain Executive Function?

There are many formulations of executive function by different neuroscientists, experimental psychologists, and clinical neuropsychologists, all pointing to similar themes. Broadly speaking, executive function denotes those cognitive processes required to manage or direct behavior in nonroutine situations. A sampling of essentially equivalent definitions follows:

The executive system is a theorized cognitive system in psychology that controls and manages other cognitive processes. It is also referred to as the executive function, executive functions, supervisory attentional system, or cognitive control. (Wikipedia).

In our daily life, we often rely on executive, or cognitive, control processes, which can be defined in general terms as the means by which our brain optimizes the flexible use of limited cognitive resources to currently prioritized tasks. Such control may become necessary when automatic or previously learned behaviours can no longer achieve a goal – for example, when we need to override habitual responses, inhibit distracting stimuli, solve new problems or shift between different tasks. (Mansouri et al., 2009: 141).

Executive functioning is the term used to encompass a range of cognitive skills including problem solving, planning and organization, self-monitoring, initiation, error correction and behavioural regulation. (Evans, 2008: 193).

The cognitive psychologist Alan Baddeley and his colleagues developed a theory of working memory in which the 'central executive' controls two 'slave systems': the phonological loop and visuospatial sketchpad. The Baddeley theory led some scientists to define executive function to include the

cognitive functions discussed in the last three definitions but to exclude the behavioral regulation Evans mentioned. However, that reformulation separates emotional from cognitive aspects of behavioral control, which seems unwarranted because of the strong mutual influences in the brain between emotion and cognition. Therefore, this article defines executive function in the more commonly used manner that includes behavioral regulation as well as cognitive control.

Since the early 1970s, executive function in the brain has been widely associated with the prefrontal cortex, the far forward (association) part of the frontal lobes. There are many reasons the prefrontal cortex has received special attention in analyses of executive function. First, there have long been data from both human patient studies and monkey lesion studies showing that prefrontal damage leads to disorganized behavior, deficiencies in planning, and reduced ability to keep a goal in mind without external cues. This set of observations generated a variety of clinical tests of executive function that are often given to prefrontal patients. Second, the prefrontal cortex is the slowest part of the mammalian brain to develop, both in the evolution of species and in the life of individuals. This developmental consideration supports the notion that the prefrontal cortex is the most 'advanced' part of the brain, the area that allows primates (humans especially) to engage in more complex cognition and social organization than other species.

Recent advances in cognitive neuroscience have deepened our knowledge of the role of the prefrontal cortex in executive functioning. Yet as this knowledge has developed, the notion

of a unitary executive in one brain location has gradually been replaced by the concept of an *executive system*. Our current knowledge of the executive system includes differentiated and interacting roles not only for prefrontal subregions such as dorsolateral, orbital, ventral, and anterior cingulate, but also for nonprefrontal regions that have extensive bidirectional connections with the prefrontal cortex. Executive functions commonly engage the basal ganglia, amygdala, hypothalamus, and parietal cortex, for example.

History of the Executive Concept

The concept of neuroexecutive function developed in the 1960s and 1970s to explain behavior that is not repeatable in fixed patterns but adapted to current contexts, situations, and goals. It is a fusion of concepts from experimental psychology and from neuroscience.

Experimental psychology in the 1960s was starting to emerge from the dominance of behaviorism and to embrace the study of complex cognitions and internal mental states. One of the ideas that emerged was that perceptual responses are not automatic reactions to particular stimuli but heavily influenced by previously developed categorizations. For example, the pioneering psychologist Donald Broadbent modeled selective attention using the idea that two separate processes influence selection: one process coming from the physical inputs themselves and the other from internal codes that activate categories.

Broadbent did not, however, clearly develop the origins and functional organizations of the two selective processes. A further clarification of his idea was the distinction the psychologists Walter Schneider and Richard Shiffrin introduced in the 1970s between *automatic* and *controlled* processes. Controlled processes require the participant's active decision and are utilized when the consequences of specific actions are not known for sure. Automatic processes do not require active decision and are utilized when the consequences of actions are invariant. Often, learning changes a process from controlled to automatic, as when one learns to drive a car or speak a language.

Around the same time, neuroscience was embracing the plasticity of neural connections, which had been discovered in the pioneering work of several investigators starting with Nobel laureate Eric Kandel in the mid-1960s. The growth of interest in plasticity generated a search for the neural correlates of controlled (presumably more plastic) versus automatic (less plastic) processes.

In the mid-1980s, the neuropsychologist Tim Shallice posited two interacting neural systems for generating automatic and controlled cognitive processes. Shallice called the generator of automatic processes the *contention scheduling system* (CSS) and the generator of controlled processes the *supervisory attentional system* (SAS). His joint book chapter with Donald Norman enumerated the following types of situations that require SAS involvement:

1. Those that involve planning or decision making.
2. Those that involve error correction or troubleshooting.
3. Situations where responses are not well learned or contain novel sequences of actions.

4. Dangerous or technically difficult situations.
5. Situations which require the overcoming of a strong habitual response or resisting temptation. (Norman and Shallice, 1986; paraphrased by Wikipedia).

Concurrently, interest was developing during the 1970s and 1980s in the specific functions of brain regions that are several synapses removed from primary sensory or motor pathways and are involved in regulating attention, cognition, and behavior. In particular, there was an emerging interest in functions of the prefrontal cortex, which had previously been treated as 'silent cortex' because it is not required for the most elementary or routine movements. In fact, the prefrontal cortex had been regarded as unimportant enough that prefrontal lobotomies were accepted as a means to control mood and anxiety disorders. Yet the famous century-old case of Phineas Gage, who changed from sober to impulsive after a railroad accident injured that part of his brain, should have clued neuroscientists and clinicians to the importance of the prefrontal cortex for organizing behavior, that is, for what we now call executive function. Indeed, by the 1970s, many clinical neuroscientists had found evidence that prefrontal lesions could lead to many types of executive deficits, including distractibility; disorganization; inappropriate behavioral control, which could manifest as either impulsiveness or overdeliberateness; and paradoxically, both perseveration in formerly rewarding behavior and excessive attraction to novelty.

Hence Shallice's laboratory looked for correspondence between their SAS and prefrontal cortex. They enumerated some evidence that patients with damage to the prefrontal cortex (especially its dorsolateral portion), more than those with damage to other areas of cortex, had trouble engaging the SAS and were therefore under the control of automatic contention scheduling. Shallice's laboratory developed several types of cognitive tasks in which patients with prefrontal lesions were deficient. One of these tasks was the Tower of London (TOL), a simplified version of the much older Tower of Hanoi. The TOL involves moving three colored balls sitting on poles from one configuration to another in a certain pre-specified number of moves. For many TOL problems, the optimal long-term strategy differs from the strategy that produces apparent short-term gains. Prefrontal patients, being deficient in planning, tended to use solutions that appeared advantageous in the short term but did not reach the right configuration in the right number of moves. Another type of task involving the prefrontal cortex was *cognitive estimation*, whereby the participant was asked to estimate some quantity that was not common knowledge but could be deduced from some other quantity that was more widely known. An example of a quantity to be estimated was the average length of an adult male's legs, which could be estimated as approximately half of the widely known average adult male's height. Shallice and his colleagues found that prefrontal patients could retrieve widely known quantities from memory but had trouble making deductions from known to unknown quantities.

The conception of prefrontal executive functions developed from human patient studies was further reinforced by results from monkey single-neuron studies. In particular, the neuroscientist Joaquin Fuster and his colleagues found that in the course of cognitive tasks such as delayed matching to sample

(whereby the monkey was reinforced for approaching an object identical to one it had previously seen), neurons in the monkey prefrontal cortex became selectively responsive to various aspects of the task (e.g., the stimulus, the delay, and the responses). Results such as these led Fuster to develop his theory that the overarching function of prefrontal cortex was linking events across time, which is an important component of controlled cognitive processes.

Further clarification of the executive roles of prefrontal cortex awaited the development of noninvasive human brain imaging. The current explosive growth in functional magnetic resonance imaging (fMRI) studies of executive function began in about the mid-1990s. Results of fMRI studies enabled neuroscientists to incorporate insights of pioneering investigators such as Brenda Milner, Walle Nauta, Karl Pribram, Tim Shallice, and Joaquin Fuster into theories that include specified functions for prefrontal subregions (e.g., orbital, ventral, dorsolateral, and cingulate).

Top-Down Cognitive Control

The neuroscientists Earl Miller and Jonathan Cohen described the overarching function of prefrontal cortex as *top-down cognitive control* of other brain systems. This notion is a concise neural instantiation of the supervisory system's influence on the contention scheduling system. Numerous fMRI studies have found that when tasks require conscious attention they tend to activate prefrontal regions, whereas after the tasks are learned and have become automatic the primary activation shifts to further posterior regions such as posterior parietal cortex or premotor cortex.

Cognitive control is sometimes discussed under the rubric of *prefrontal inhibition*. The idea of prefrontal inhibition captures the insight that control is necessary when the task requires suppressing an automatic or habitual response. A commonly discussed example is the Stroop test: a word for one color is presented in ink of another color and the participant has to consciously name the color of the ink when his or her automatic response is to read the word. Yet top-down control is not exclusively inhibitory: it also involves enhancing selective attention to task-relevant items, and sometimes includes disinhibition of a previously inhibited response. The prefrontal cortex seems to selectively enhance or inhibit subsets of a set of competing action representations at other brain levels including the posterior parietal cortex. That mixture of selective enhancement and inhibition has been observed elsewhere in the brain, such as in the influence of higher-order on lower-order visual cortex, and has been termed *biased competition*.

Within the prefrontal cortex a consensus has emerged on the roles of specific prefrontal subregions. In particular, there are widely accepted conceptions of the dissociable executive functions for the three large regions of orbitofrontal cortex (OFC), anterior cingulate cortex (ACC), and dorsolateral prefrontal cortex (DLPFC).

The executive role of the OFC and nearby prefrontal areas involves monitoring the emotional values of stimuli and utilizing emotional information to guide behavior. OFC damage has been observed to lead to poor decision making and inappropriate social behavior in many patients including the

nineteenth-century patient Phineas Gage. These clinical observations, combined with some animal lesion studies, indicate that the OFC forms and sustains mental linkages between specific sensory events in the environment and positive or negative affective states. This region creates those linkages via interactions both with neural activity patterns in the sensory cortex that reflect past sensory events and with other neural activity patterns in the amygdala and hypothalamus that reflect emotional states. Long-term storage of affective valences is likely to take place at connections between the OFC and amygdala.

For the part of prefrontal cortex devoted to visceral and emotional monitoring, neuroscientists often designate a larger area called the ventromedial prefrontal cortex (VMPFC). VMPFC includes the medial portion of the OFC (Brodmann areas (BAs) 14 and the medial portions of areas 11 and 13) and parts of areas 25, 32, and 10 in the medial prefrontal cortex. Many scientists have identified the VMPFC's basic function as holding in working memory the positive or negative emotional properties of objects or potential actions during the implementation of behaviors.

The executive role of DLPFC involves selectively sustaining task-relevant working memory representations. DLPFC is involved with information processing at a higher level of abstraction than the OFC. For example, in monkeys, while OFC lesions impair learning of changes in reward value within a stimulus dimension (i.e., reversal learning), DLPFC lesions impair learning of changes in which dimension is relevant. Evidence from human fMRI studies indicates that DLPFC is involved in choosing correct actions based on task-appropriate rules, particularly in tasks that require overriding a prevailing response.

Within the DLPFC and adjoining areas, there is a hierarchy whereby anterior regions encode more abstract rules and posterior regions encode more concrete rules. In an fMRI study by Kalina Christoff and Kamyar Keramian, participants were given tasks that required rule-guided behavior at three levels of abstraction. Their targets consisted of circles that were half black and half white. For the concrete rule the target had a black side oriented in a specific direction (right, left, up, down); for the first-order abstraction it was a pair of those circles whose orientation was the same or different; for the second-order abstraction it was two pairs of circles whose orientations were either 'related' (both the same orientation or both different) or 'unrelated' (one the same and one different). The use of concrete rules for attention activated posterior areas of cortex, whereas first-order abstraction activated the DLPFC (BAs 9 and 46) and ventrolateral prefrontal cortex (areas 12 and 47). As the rules moved toward second-order abstraction there was more activation further anterior, in the rostral prefrontal cortex (area 10).

The ACC (parts of BAs 24, 25, and 32) is involved in detection either of potential response error or of conflict between signals promoting competing responses. The ACC tends to be activated when a subject must select or switch among different interpretations or aspects of a stimulus. Also, in fMRI studies of the Stroop color-naming task, the ACC is consistently more active when the two rules conflict (i.e., a word for one color is written in ink of another color) than when the two rules agree. In an fMRI study of judgment by

Wim DeNeys and his colleagues, participants were asked to estimate the probability of a person in a group being in one of two professional categories (engineer or lawyer), based both on the numbers of people in the group (base rates) and a personality description stereotypical of one of the professions. DeNeys et al. found that ACC activation was greatest in the incongruent case, such as the combination of a lawyer stereotype with a group that was more than 99% engineers.

The ACC is closely connected with the limbic system, hypothalamus, and hippocampus, and is sometimes classified as limbic cortex. These connections allow it to play a strong role in the emotional regulation aspects of executive function. Some investigators divide the ACC into a 'cognitive' component (dorsal ACC) and an 'emotional' component (ventral and rostral ACC). Yet more recent investigators emphasize the deep interconnections and mutual influences between emotion and cognition, making it hard to separate different brain regions responsible for each.

Recent Neuroimaging Studies

A 2006 book chapter by Todd Braver and Hannes Ruge reviews much of the recent work in functional neuroimaging of executive function. These authors identify seven different categories of executive functions, all interrelated but each emphasized in different tasks. These seven categories are (1) strategic control of memory; (2) stimulus-response interference; (3) response inhibition; (4) underdetermined responding; (5) performance monitoring; (6) task management; and (7) higher cognition.

These authors summarize recent fMRI findings about areas activated by those categories of tasks as follows:

Task conditions involving the preparatory cuing of attention or the use of attentional control to resolve interference tend to activate posterior and inferior regions of lateral prefrontal cortex (PFC).

Task conditions requiring the temporary suppression of ongoing responses tend to activate right inferior PFC regions.

Task conditions requiring rapid shifting of attention to different dimensions or reconfiguration of task sets reliably engage the superior parietal cortex.

Task conditions involving the free selection of potential response alternatives engage superior medial frontal areas near the supplementary motor area (SMA).

Task conditions involving the processing of internal or external feedback related to the outcome of generated actions reliably engage the ACC and nearby medial frontal areas.

Task conditions that require the tracking of changing stimulus-response contingencies elicit activation in the OFC.

Complex cognitive activities (such as planning, analogy verification, and controlled episodic retrieval) that involve the evaluation or integration of abstract dimensions maintained in working memory tend to engage the anteriormost regions of PFC (BA 10).

(Braver and Ruge, 2006: 330).

Figure 1 shows the locations of some of the key regions for specific executive functions.

Clinical Disorders of Executive Functions

An early clinical investigator described some characteristic effects of prefrontal dysfunction as "disturbed attention, increased distractibility, a difficulty in grasping the whole of a complicated state of affairs ... well able to work along routine lines ... cannot learn to master new types of task in new situations ..." (Rylander, 1939: 20). Alan Baddeley coined the term *dysexecutive syndrome* (DES) for that pattern of

Figure 1 Locations in the brain of regions that typically are activated by selected executive operations. Adapted from Braver TS and Ruge H (2006) Functional neuroimaging of executive function. In: Cabeza R and Kingstone A (eds.) *Handbook of Functional Neuroimaging of Cognition*, 2nd edn., pp. 307–348. Cambridge, MA: MIT Press, with permission from MIT Press.

deficits, noting that it involves malfunctioning of the SAS Shallice and Norman described.

From the mid-1980s through the 1990s, Baddeley, Shallice, and their associates gradually developed a variety of tests for the DES as it applied to daily life situations. This development culminated in a series of tests called the BADS (Behavioural Assessment of the Dysexecutive Syndrome). The BADS includes the following:

Rule Shift Cards Test: In the first part of the test, participants are asked to say 'Yes' to a card of one color and 'No' to a card of another color. In the second part they are given a different rule, namely, to say 'Yes' if the card is the same color as the previous one and 'No' if it is a different color from the previous one.

Action Program Test: Participants are asked to solve the mechanical problem of getting a small piece of cork out of the bottom of a thin tube. There is a beaker of water available, and the solution requires moving water from the beaker into the tube.

Key Search Test: Participants are presented with a piece of paper with a small square in the center and a small black dot below the square. They are asked to imagine that the square is a field in which they have lost their keys. Then they are asked to draw a line from the black dot into the square to show where they would search to be sure they had found their keys.

Temporal Judgement Test: This part is similar to Shallice's cognitive estimation test, but the questions specifically involve time estimation. Examples could have answers that involve either a small amount of time (e.g., How long does it take to blow up a party balloon?) or a large amount of time (e.g., How long is the life of a typical dog?).

Zoo Map Test: Participants are given a map of a zoo and asked to imagine how they would visit a series of designated locations within the zoo. Some rules are attached that limit the variations on the order in which they can visit those locations. In one part of this test, visiting the designated locations in the order in which they are given in the instructions leads to errors, thereby testing the participant's initiative and planning ability.

Modified Six Elements Test: Participants are instructed to do three tasks of different types (dictation, arithmetic, and picture naming), and each task is divided into two parts. They are required to attempt at least something from each of the six task parts within a 10-min interval, but not allowed to do two parts of the same task in order.

The BADS is only one of several measures utilized by clinical neuropsychologists to assess executive functions. It has supplemented but not supplanted other tests that have been in use for longer, such as the Wisconsin Card Sorting Test, TOL, Verbal Fluency Test, and Trail Making Test. The BADS and TOL deal primarily with the planning, task management, and monitoring parts of executive functioning (categories (5) through (7) in the schema of Braver and Ruge). So does the Trail Making Test, which requires the participant to connect a sequence of numbered circles on different parts of a page in ascending numerical order without lifting his or her pencil from the page. Yet some of those tests also engage other categories of executive function. For example, the Rule Shift

Cards Test requires the processing of a change in stimulus-response contingencies (category (2) of Braver and Ruge), albeit at a fairly abstract level. (The neuroscientists Rasika Dias, Trevor Robbins, and Angela Roberts note a distinction between DLPFC and OFC function, in that orbitally lesioned monkeys have difficulties in learning changes in the reward value of specific stimuli, whereas dorsolaterally lesioned monkeys have difficulties in learning changes in the relevant stimulus dimension. Dias et al. call this distinction "dissociation ... between affective and attentional shifts." However, learning is affectively motivated in both cases, so I believe it is more useful to call the distinction between those two regions dissociation between less and more abstract shifts.) So does the much older Wisconsin Card Sorting Test (Milner, 1964), whereby participants first learn to classify a particular type of card using one criterion (e.g., color of the designs on the card) and then are required to shift, without warning, to using a different criterion (e.g., shape or number of the designs on the card). Underdetermined responding (category (4)) is often tested by means of the Verbal Fluency Test, whereby the participant is required to generate as many words as possible beginning with a certain letter or as many words as possible that fit a particular category such as animals or household objects. Response inhibition (category (3)) is often tested using the Stroop Test or the Iowa Gambling Task (IGT), whereby participants must choose between four virtual decks of cards that yield probabilistic gains or losses, and the two decks that yield the highest initial payoffs are not the decks that are most advantageous in the long run.

Emotionally derived impulsiveness can easily interfere with performance on 'cognitive' tasks such as TOL, and improper memory monitoring can easily interfere with performance on 'emotional' tasks such as the IGT. All these executive subfunctions reinforce one another, which makes it hard to parcel executive tasks neatly by what subfunctions they engage.

Just as there is no one test that always captures deficits in executive function, there is no one treatment that works for all patients presenting with executive deficits, most of whom sustained damage to one or more prefrontal regions as adults from an accident, stroke, or removal of a tumor. A variety of treatments for executive disorders are reviewed in the 2009 book edited by Oddy and Worthington. Some treatments involve cognitive aids, such as repeatable organizing techniques that the patients can learn to have a better handle on the steps they need to take in nonroutine situations. Other treatments are pharmacological, particularly involving drugs that increase available dopamine in the prefrontal cortex and thereby facilitate attention and learning. However, there is appreciable danger that dopamine agonists can lead to undesirable side effects such as inappropriate, aggressive, and even psychotic behaviors.

Summary

Executive functions include a large number of skills that are somewhat dissociable from other forms of intelligence. That is, high scores on traditional IQ tests do not necessarily translate into an ability to plan and organize behavioral sequences, monitor one's behavior, and react appropriately to changing reinforcement contingencies.

The various executive functions engage different parts of the prefrontal cortex and related regions and are difficult to disentangle from one another. Further technical advances in the near future, both theoretical and experimental, can advance our understanding of behaviorally and cognitively relevant interactions between all these brain regions.

On the theoretical level, there has been rapid progress in the last decade in biologically realistic neural network modeling. For example, Stephen Grossberg and Lance Pearson developed the LIST PARSE model which “joins together a cognitive working memory, a motor working memory, a motor trajectory generator, and a volitional controller that coordinates variable-rate recall of both novel and previously learned sequences as they are read-out into sequential action from a cognitive plan” (Grossberg and Pearson, 2008: 686). Executive function might be simulated by combining LIST PARSE or a similar model with some other model that replicates decision processes and reinforcement learning.

On the experimental level, fMRI techniques have begun to move beyond simple measures of brain region activations to mapping of neural patterns and functional interactions. Future advances in this type of recording are needed to make the implications of imaging measurements less ambiguous and more reflective of actual brain processes in the behaving individual. Another technique increasingly likely to be used to map functional interactions in humans is transcranial magnetic stimulation, which temporarily inactivates a small selected area of the brain.

The systemic understanding generated by these technical advances should in turn suggest hypotheses for what forms of intervention will help with what types of patients with executive disorders. Also, our understanding should suggest hypotheses for what sorts of human activities and interactions optimize executive functioning in nonbrain-damaged individuals, with implications for many fields including education, psychotherapy, and organizational management.

Neuroimaging of Dementia

J C Masdeu, New York Medical College, Valhalla, New York, NY, USA

Published by Elsevier Inc.

Glossary

Alzheimer's disease A disease that causes memory loss and as it progresses affects also other cognitive aspects, such as language and the ability to navigate unfamiliar surroundings. There is excess deposition of amyloid in the brain and damage of the structure of brain cells, leading to their progressive loss.

Amyloid A protein that is derived from the amyloid precursor protein and is the primary component of plaques characteristic of Alzheimer's disease.

Dementia A condition of deteriorated mentality that is characterized by marked decline from the individual's former intellectual level, enough to interfere with professional or social activities.

Diffuse Lewy-body disease A progressive disorder characterized by impairment of cognitive abilities, similar to Alzheimer's disease, but in addition the person has slowing of movements, and stiffness in the muscles, similar to people with Parkinson's disease.

Frontotemporal dementias A group of diseases causing dementia through the loss of brain cells. The location of cell loss in the brain typically differs from Alzheimer's disease and for this reason, rather than starting with memory loss,

they tend to start with bizarre behavior, apathy, language disorders or hand clumsiness.

Magnetic resonance imaging A noninvasive diagnostic technique that produces computerized images of internal body tissues and is based on nuclear magnetic resonance of atoms within the body induced by the application of radio waves. It is also called MRI.

Positron emission tomography A technique that yields an in vivo, cross sectional image of the distribution of a compound in the tissue object of study, the brain in the case of this article. The image is obtained by determining by means of a computerized process the distribution of gamma radiation given off in the collision of electrons in cells with positrons emitted by radionuclides incorporated into the substance object of study. It is abbreviated as PET.

Single-photon emission computed tomography A medical imaging technique that is used especially for mapping brain function and that is similar to positron emission tomography in using the photons emitted by the agency of a radioactive tracer to create an image but that differs in being able to detect only a single photon for each nuclear disintegration. Often known as SPECT.

Introduction

At the time of writing of this article, three panels of the US National Institute of Aging are completing a set of new guidelines for the diagnosis of diseases leading to dementia. Novelties include the use of neuroimaging tools as biomarkers of disease and the attempt to diagnose these disorders before cognitive impairment occurs, at what could be called the pre-symptomatic stage. A practice guideline on the management of dementia states: "Neuroimaging is now the most important ancillary investigation in the work-up of dementia to aid in differential diagnosis and management decisions." Few areas in medicine are evolving as quickly as the ability to image the human brain. Indeed, the rapid development of neuroimaging tools in the past few years has provided the physician with a panoply of imaging modalities, each with a somewhat complex technology and with specific applications. A learning need exists to update the knowledge of neurologists and other physicians on the current role of imaging in the management of dementia, which is one of the most prevalent neurological disorders. Currently, around 24 million people in the world have dementia, with the number being projected to double every 20 years. Moreover, therapeutic intervention is likely to be most effective in the preclinical stages of the dementing process, or at least in the early stages of cognitive impairment, when the halting of progressive neuronal loss seems most feasible. At these early stages of the process, neuroimaging

provides key information to determine whether the patient has a degenerative dementing disease and which type it is, particularly when neuroimaging is combined with genetics.

When facing a patient with a dementing process, a major concern is to rule out the unusual situation of a nondegenerative disorder, such as a brain tumor, presenting with the clinical picture of dementia. However, as the prognosis and management of the various neurodegenerative dementias begins to differ, there is an interest in diagnosing the type of degenerative dementia as well. As most disorders causing dementia do not have a curative treatment at present, physicians are most eager to know about ongoing research that may lead to more effective treatments of these devastating disorders. Therefore, this article is divided into three main sections:

1. Neuroimaging to diagnose nondegenerative dementia.
2. Neuroimaging to distinguish the various degenerative dementing processes.
3. Use of neuroimaging in dementia research and in the evaluation of new therapies.

Neuroimaging to Diagnose Dementia Caused by Nondegenerative Disorders

Potentially reversible neurological or psychiatric conditions leading to cognitive impairment may be diagnosed with the help of neuroimaging (Figure 1). For this reason, the 1994

American Academy of Neurology (AAN) guideline on the management of dementia, which did not require the use of imaging to diagnose a degenerative dementia in a patient with progressive memory loss and no motor or sensory findings or epilepsy, was changed to require structural imaging (computed tomography (CT) or magnetic resonance imaging (MRI)) in the 2001 guideline. The report of patients with a clinical picture of progressive memory loss caused by tumors or subdural hematomas (Figure 2) contributed to this change. Unless a tumor infiltrates the cortex, for instance in the case of very rare lymphomas or metastases from malignant melanoma, a CT without contrast is enough to rule out potentially reversible structural brain lesions. The European guidelines for the work-up of dementia suggest that, if possible, an MRI be performed to increase specificity, given that MRI provides additional information on the vascular causes of dementia, and to distinguish the various degenerative dementias.

Symptomatic hydrocephalus in an older person presents with gait impairment and urinary incontinence, which generally are more prominent than cognitive impairment. When present, cognitive impairment is characterized by psychomotor slowing and impaired executive function and memory, but with preserved naming. Cortical sulci may be large and ballooned in symptomatic hydrocephalus (Figure 3). This finding should not be confused with the sulcal dilatation observed in hydrocephalus 'ex vacuo,' caused by atrophy of the brain.

The role of vascular disease as a cause of dementia continues to need further definition. Small vessel infarction, of the subcortical type, seems more likely to contribute to dementia than large cortical infarctions. The effect of vascular and degenerative changes is cumulative. When vascular disease is the primary cause of dementia, multiple infarctions are generally present on CT or MRI (Figure 4), particularly involving the thalamic nuclei bilaterally. By contrast, the extent of white matter involvement on T2-weighted images does not correlate with cognitive impairment in many studies, but it does in some. Medial temporal atrophy, a feature of Alzheimer's disease (AD), also correlates with cognitive impairment in

Figure 1 Potentially reversible primary etiologies for cognitive impairment in 1000 patients referred to a memory disorders clinic. A potentially reversible primary etiology for cognitive symptoms was identified in 19% and a potentially reversible concomitant condition in 23% of all patients. As this was a referral sample, it may not represent the proportion of these disorders among the population with dementia at large. Note that vascular dementia is not included here. Red arrows indicate the main etiologies ruled out by structural brain imaging. Depression or mania can be suspected in a patient with a normal metabolic brain study.

vascular dementia. Cognitive impairment is a prominent feature of cerebral amyloid angiopathy (CAA), which presents with white matter hyperintensity on T2 MRI and cortical microhemorrhages, best seen on gradient-echo MRI sequences (Figure 5). Amyloid deposition in CAA can now be imaged with ^{11}C PiB PET (Pittsburgh Compound B positron emission tomography) (Figure 6). In rare cases, CAA can be worsened by regional inflammation, susceptible to immunosuppressive treatment (Figure 7). Involvement of the white matter of the frontal and temporal poles on MRI may help differentiate cerebral autosomal-dominant arteriopathy with subcortical infarcts and leukoencephalopathy (CADASIL) from sporadic subcortical arteriosclerotic encephalopathy (Figure 8).

Prion diseases may present as a rather rapidly progressive dementing process, often accompanied by clinical manifestations of basal ganglia or cerebellar involvement. Imaging is very helpful and tends to be abnormal before the onset of any characteristic electroencephalography (EEG) pattern. Bilateral caudate or thalamic areas of high signal intensity on diffusion-weighted or fluid-attenuated inversion recovery (FLAIR) MRI are characteristic (Figure 9). The cortical ribbon is often affected, particularly in the parietal regions of the frontal lobes. The same regions have reduced metabolism on 2-deoxy-2-fluoro-D-glucose (FDG) PET.

Most cognitive impairment from depression or mania can be readily diagnosed from the clinical findings and response to therapy. However, in some older patients, making these diagnoses may not be straightforward. In a patient with impairment in various areas of cognition, likely to be attributable to an attentional deficit with a normal structural imaging study, a negative PET or single-photon emission computed tomography (SPECT) study may help decrease the probability of a neurodegenerative disorder. A normal ^{18}F FDG-PET study lowers the probability of the patient presenting a neurodegenerative disorder in the following few years to about 10%. The 67% probability of a pathologically confirmed diagnosis of AD with a clinical diagnosis of possible AD was lowered to 52% with a negative SPECT. The findings characteristic of neurodegenerative dementia on PET and SPECT will be reviewed below. A negative ^{11}C PiB PET will decrease the probability of AD and dementia with Lewy bodies (DLB), but not of a frontotemporal dementia (FTD).

Figure 2 Dementia with meningioma. (a) T1-weighted and (b) gadolinium-enhanced T1-weighted MRI of the brain of a 65-year-old woman, showing a large, contrast-enhancing mass lesion in the left lobe that compresses the left hippocampus and displaces the midbrain.

Figure 3 Hydrocephalus. (a–d) Axial sections of the MRI from a 71-year-old woman with progressive gait and cognitive impairment, as well as urinary incontinence (Case 1). Notice the low signal in the Sylvian aqueduct, due to a flow void from a vigorous CSF flow in this structure (A, arrow). Although the basal cisterns (a) and the interhemispheric and sylvian fissures (b–c) are dilated, the sulci in the high convexity (d) are compressed. Transependymal reabsorption of CSF, suggested by the homogeneous high signal in the periventricular white matter (c), need not occur in all cases of symptomatic hydrocephalus.

Figure 4 Vascular dementia. Shown are axial T2-weighted and coronal T1-weighted images from an 80-year-old woman with impairment of cognition and gait. Note the thalamic infarctions and the large areas of altered signal (increased on T2 and decreased on T1) in the centrum semiovale.

Figure 5 Cerebral amyloid angiopathy (CAA). Shown are MR images from a 72-year-old woman with dementia and CAA. The white matter contains many abnormal areas, which appear hyperintense on the transverse FLAIR image and hypointense on the sagittal T1-weighted image. Multiple lacunar infarcts are present in the lenticular nuclei and few in the thalami. Microbleeds, best seen on the gradient echo images, dot the lenticular nuclei, thalami, and the cerebellum. Scattered microbleeds can also be seen in the cortex or subcortical white matter.

Neuroimaging to Distinguish the Various Degenerative Dementing Processes

In this section, I review the most characteristic imaging findings in the most frequent types of neurodegenerative dementia. Many of the disorders that we now consider diseases, such as Alzheimer's, may turn out to be caused by a variety of genetic and environmental conditions. As an example, the genetic heterogeneity of the FTDs has become apparent in the past

few years. Thus, the classification I follow is mostly syndromic, based on the clinical presentation and some associated imaging or neuropathological changes.

From an imaging/neuropathology perspective, the advent of compounds such as PiB to image amyloid deposition in the brain (**Figure 10**) allows us to separate dementias with amyloid deposition (AD, DLB) from dementias without amyloid deposition (frontotemporal and other dementias) (**Table 1**).

Alzheimer's Disease

Structural Imaging (MRI and CT)

Most cases of AD start with mesial temporal atrophy, which can be appreciated by a dilation of the temporal horn of the lateral ventricle on CT or by atrophy of the entorhinal and hippocampal cortex on MRI (Figure 11). The same is true of mild cognitive impairment (MCI) leading to AD. Scheltens has developed a visual rating scale to gauge medial temporal atrophy (Table 2). The sensitivity and specificity of this scale for the detection of mild to moderate AD compared with controls has been estimated as 85% and 88%, respectively. In practical terms, if the probability of AD were 60% before taking temporal atrophy into account (in line with the sensitivity values for

the National Institute of Neurological and Communication Disorders and Stroke-Alzheimer Disease and Related Disorders Association (MINCDS-ADRDA) criteria), the presence of temporal atrophy raises the probability to 91% and its absence lowers the probability to 20%. Automated methods are more precise and facilitate longitudinal follow-up. The accuracy of the software that classifies clinically appropriate cases has been compared favorably with that of trained readers. Cortical atrophy predicts worsening from MCI to AD.

As the disease progresses, atrophy extends from the limbic cortex to the neocortex, particularly in regions posterior to the rolandic sulcus. Medial temporal atrophy is not specific to AD, and happens in FTD and vascular dementia as well. Greater bilateral symmetry and predominantly posterior atrophy tend to suggest AD over FTD. In some patients, early atrophy of areas in the parietal, occipital, or posterior temporal lobe can be prominent, giving rise to presentations such as Balint's syndrome (Figure 12). In such cases, regional atrophy may be determined by automated methods, such as voxel-based morphometry now available in some clinical units. By facilitating the comparison of two or more studies, automated methods greatly simplify the determination of the annual rate of volume change in temporal cortex, which distinguishes AD from controls with greater sensitivity and specificity than one-time measurements. Whereas the volume loss in normal aging is less than 1%, rates as high as 4% occur in early AD.

Figure 6 Amyloid deposition in CAA. Shown are transverse supraventricular Pittsburgh Compound B (PiB)-PET and coregistered gradient-echo MRI images from a patient with cerebral amyloid angiopathy. Microbleeds, seen as dark dots on MRI, at times appear close to foci of amyloid deposition on PiB-PET (arrows).

Regional Cerebral Metabolism Studied with PET

Regional cerebral metabolism studies with PET have used ^{18}F -FDG as a metabolic marker. The most typical pattern found in early AD is decreased metabolism bilaterally in the parietotemporal association cortex and posterior cingulate gyrus (Figures 13 and 14), as well as the medial temporal

Figure 7 Amyloid-angiopathy-related inflammation. Magnetic resonance imaging (MRI) appearance in patients with cerebral amyloid angiopathy (CAA)-related inflammation, managed with immunosuppressive treatment. The gradient echo images from patients 1 and 2 show multiple small hypointense lesions characteristic of CAA-related microhemorrhages. The fluid-attenuated inversion recovery (FLAIR) images performed at presentation and after follow-up intervals of 2 months (Patient 1) or 22 months (Patient 2) demonstrate confluent regions of white matter hyperintensity that largely resolve at follow-up.

Figure 8 CADASIL. Images obtained in representative patients with biopsy-proved cerebral autosomal-dominant arteriopathy with subcortical infarcts and leukoencephalopathy (CADASIL, top row) and sporadic subcortical arteriosclerotic encephalopathy (sSAE, bottom row) display the differentially involved temporopolar and superior frontal white matter. Note the marked symmetry of lesions and the extension of lesions into the superficial white matter in CADASIL (arrows).

Figure 9 Creutzfeldt-Jakob disease. Images shown (FLAIR MRI) are from a 39-year-old woman who developed chorea, followed by anxiety and progressive cognitive and motor impairment, leading to inability to walk and marked dysarthria and dementia by the time this imaging study was obtained, that is, 5 months after symptom onset. Note the high intensity of the caudate and of the anterior portion of the lenticular nuclei (arrows). For comparison purposes, the lower image row was obtained with a similar technique, but from a control individual.

region. As the disease progresses, the frontal association cortex becomes involved, while the paracentral cortex (primary motor-sensory areas) remains preserved. The specificity and sensitivity of these findings continue to be debated. In studies with neuropathological confirmation, the sensitivity (84–95%) has been higher than the specificity (71–74%), which in a normal study is seldom associated with AD. FDG-PET improves diagnostic accuracy over the clinical evaluation in separating histologically

proven AD from FTD. This clinical application of FDG-PET has been approved by the Centers for Medicare & Medicaid Services (CMS, USA) since 2004. Among persons with MCI, the most likely to progress to AD have metabolic findings similar to AD. FDG-PET may predict better than structural MRI or SPECT the worsening from MCI to AD.

Regional cerebral perfusion studied with SPECT

The most commonly used tracers for studying cerebral perfusion with SPECT are ^{99m}Tc HMPAO (hexamethyl propylamine oxime, CeretecTM), a lipid-soluble macrocyclic amine, and ^{99m}Tc ECD (ethyl cysteinate dimer, NeuroliteTM). The pattern of decreased regional perfusion in parietotemporal cortex, hippocampus, anterior and posterior cingulum, and dorsomedial and anterior nucleus of the thalamus had a sensitivity of 86% and a specificity of 80% for AD compared to normal controls. In a group of 70 patients with dementia and 14 controls, all with autopsy, SPECT was most useful when the clinical diagnosis was of possible AD, with a probability of a diagnosis of AD of 67% without SPECT, of 84% with a positive SPECT, and of 52% with a negative SPECT. Although perfusion SPECT is less expensive and more readily available than FDG-PET, the consensus is that PET is slightly more sensitive and specific than SPECT for the diagnosis of mild AD, but it is clearly better for the differential diagnosis of vascular dementia.

Amyloid Imaging

Until very recently, brain amyloid could be imaged only with ^{11}C PiB, helping to separate the dementias with marked amyloid deposition from the rest. Now, at least two similar compounds are labeled with ^{18}F , a much more versatile isotope, which will greatly facilitate the clinical application of this technique. In some initial studies, PiB positivity is a strong predictor of worsening to AD in individuals with MCI. It has also been found to predict dementia in cognitively normal individuals and to correlate with a higher genetic risk for AD.

Figure 10 In vivo imaging of β -amyloid ($A\beta$) burden in aging and dementia. Representative distribution volume ratio (DVR) PET transaxial images (top) and sagittal images (bottom) of a 73-year-old healthy control (HC) subject (Mini-Mental State Examination (MMSE) = 30), a 78-year-old patient with dementia with Lewy bodies (DLB) (MMSE = 19), an 82-year-old patient with Alzheimer's disease (AD; MMSE = 22), and an 80-year-old patient with frontotemporal dementia (FTD; MMSE = 25). DVR PET images show clear differences when comparing HC or FTD subjects with DLB or AD patients, with nonspecific Pittsburgh Compound B (PiB) binding in white matter in the HC and FTD subjects compared to PiB binding in the frontal, temporal, and posterior cingulate/precuneus cortex of the AD and DLB patients.

Table 1 Amyloid deposition in the dementias

<i>Dementias with amyloid deposition</i>	<i>Dementias without amyloid deposition</i>
AD	Frontotemporal dementias
Lewy-body dementia	Corticobasal degeneration
Some prion disorders	Progressive supranuclear palsy
Amyloid angiopathy	Vascular dementia without amyloid angiopathy

Figure 11 Temporal atrophy with AD. Coronal MRI at the level of the mammillary bodies. The entorhinal cortex has been outlined in a normal control (a) and a person with mild cognitive impairment of the amnesic type (b).

Table 2 Scheltens' scale for the visual assessment of medial-temporal-lobe atrophy

<i>Score</i>	<i>Width of choroid fissure</i>	<i>Width of temporal horn</i>	<i>Height of hippocampus</i>
0	Normal	Normal	Normal
1	↑	Normal	Normal
2	↑↑	↑	↓↓
3	↑↑↑	↑↑	↓↓
4	↑↑↑	↑↑↑	↓↓↓

↑, increased; ↓, decreased.

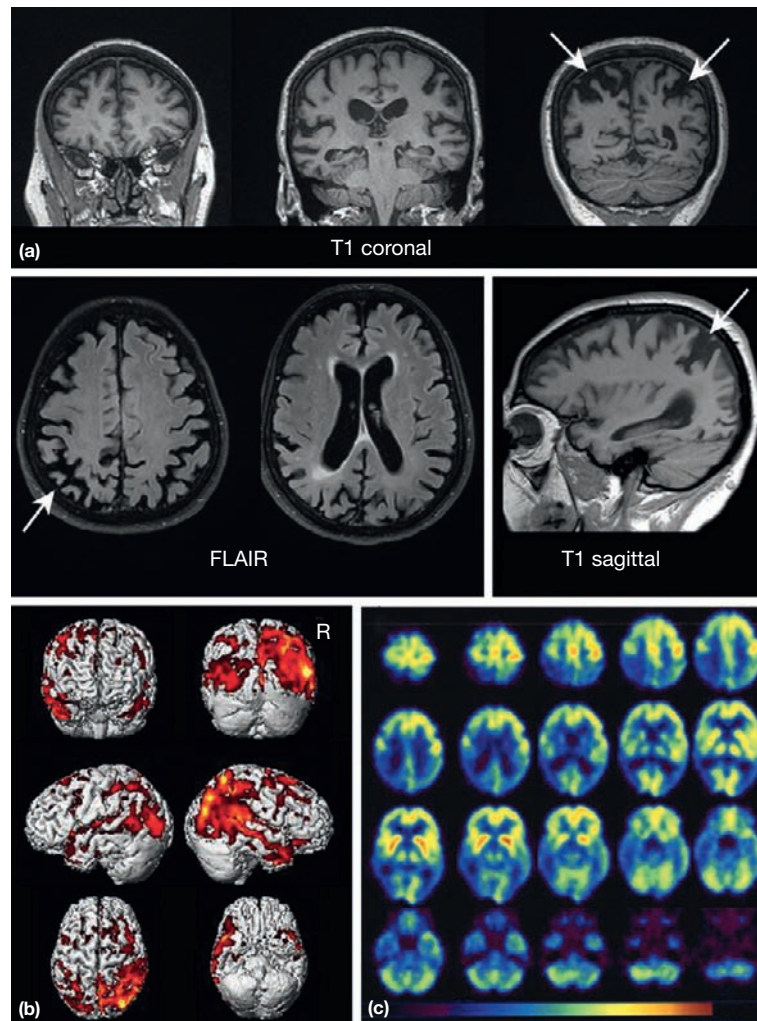

Figure 12 Balint's syndrome with AD. Shown are the (a) conventional MRI, (b) volumetric MRI on a rendered image, and (c) PET studies from a 61-year-old woman with a 3-year history of progressive reading difficulties, aphasia, and dressing apraxia. On examination, she had Balint's syndrome, with simultanagnosia, apraxia of eye movements, optic ataxia, and 'tunnel vision.' Note in (a) the marked atrophy in the lateral parietal lobe, with dilation of the intraparietal sulcus (arrows). There is also hippocampal atrophy, albeit less prominent. In (b) voxels with significant atrophy (compared with SPM to 48 controls, $p < 0.05$ uncorrected; $k > 20$) are displayed in red. Note that in (b) the right side of the brain is displayed on the right side of the image, opposite to the radiological convention on the conventional MRI (a) and PET (c). Areas of decreased metabolism on PET (c) most closely match the clinical picture.

Lewy-body dementia

There are very few neuropathologically confirmed imaging studies of Lewy-body dementia (LBD). More occipital atrophy in LBD than in AD has been reported by a group with a good diagnostic record. In agreement is the finding of decreased metabolism in occipital association cortex. As PiB binds with much greater affinity to β -amyloid than to α -synuclein, positive PiB studies in LBD probably reflect amyloid binding.

Frontotemporal dementias, corticobasal degeneration

Clinically, neuropathologically, and genetically, FTD comprises a heterogeneous group of disorders. It can present with a frontal-lobe syndrome, characterized by impulsivity and

disinhibition, or as a progressive aphasia, either semantic (Figure 15) or nonfluent (Figure 16). Atrophy on MRI or decreased metabolism on FDG-PET tends to be regional and corresponds well to the area preferentially affected by the pathology. Except for rare cases with motor neuron involvement, these disorders tend to affect the association cortex rather than the primary motor or sensory cortices (Figures 17 and 18). The clinical, imaging, and neuropathological findings are summarized in Table 3. The most common clinical variety, FTD, is also the most neuropathologically and genetically heterogeneous, as is the more recently characterized hippocampal sclerosis dementia. Frontotemporal abnormalities on FDG-PET/SPECT may antedate the atrophy that eventually becomes obvious on MRI (Figure 16). For this reason, PET has been approved for FTD diagnosis by the CMS. Amyloid imaging is negative in the FTDs.

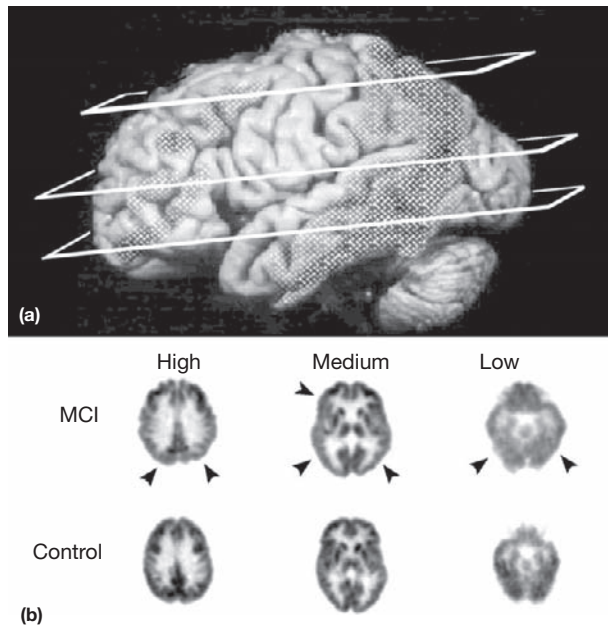

Figure 13 PET in AD. (a) Regional density of amyloid plaques and neurofibrillary tangles in a sample of patients with Alzheimer's disease. The density is represented on the lateral aspect of the left cerebral hemisphere and is greatest in the temporoparietal association cortex. (b) PET with fluorodeoxyglucose of a 71-year-old individual with mild cognitive impairment (MCI) and a healthy control. The person with MCI had isolated memory impairment. Selection of axial sections (3 of the 15 comprising the full study) at the levels indicated in (a). Sections identified high, medium, and low. Note the hypometabolism (see arrows) in the region with the greatest density of amyloid plaques and neurofibrillary tangles. The medial temporal region of both hemispheres, visible in the lowest section, has the lowest metabolism in the MCI case. This region has not been marked in the corresponding section, in order not to obscure the surrounding structures.

Figure 14 PET in AD: group findings. Projected on a rendered MRI and shown in red are areas with low metabolism in a group of 28 patients with mild AD, compared to 28 normal controls.

Figure 15 Semantic dementia. Shown is a coronal FLAIR image from a 72-year-old man with progressive anomia. Although the patient's spontaneous language was almost normal, he could not name by confrontation objects as common as a table. Note the marked atrophy in the anterior portion of the temporal lobes, more pronounced on the left.

In corticobasal degeneration (CBD), FDG-PET shows decreased metabolism in the affected hemisphere, ipsilateral lenticular nucleus, and ipsilateral thalamus (Figure 19).

Use of Neuroimaging for Dementia Research and in the Evaluation of New Therapies

An important application of longitudinal yearly or bi-yearly MRI studies is to determine atrophy rate as a surrogate marker of disease progression in patients with MCI or AD, thus facilitating the evaluation of new therapies. For instance, in a study of a new muscarinic agonist with a sample size of 192 patients and a follow-up of 1 year, disease progression was better gauged in 99% of the patients with measurements of hippocampal atrophy than with cognitive or behavioral testing ($p < 0.001$). Using neuroimaging markers would allow a marked reduction of the sample size. In this study, the estimated number of subjects required per arm to detect a 50% reduction in the rate of decline over 1 year were as follows: AD Assessment Scale–cognitive subscale, 320; Mini-Mental Status Examination, 241; hippocampal volume, 21; and temporal horn volume, 54. Longitudinal studies of the yearly decline in glucose metabolism could also be used to monitor the rate of decline in therapeutic trials. Using maximal glucose metabolism reductions in the left frontal cortex, Alexander et al. estimated that as few as 36 patients per group would be needed to detect a 33% treatment response with one-tailed significance of $p \leq 0.005$ and 80% power in a 1-year, double-blind, placebo-controlled treatment study. The practicality of using MRI or PET in collaborative controlled trials is being evaluated since 2005 in the Alzheimer's Disease Neuroimaging Initiative (ADNI), a project cofinanced by the National Institutes of Health (NIH) and pharmaceutical companies.

Neuroimaging is being used for the presymptomatic diagnosis of the onset of the dementing process in families with familial dementia. Diffusion tensor imaging is not the only modality that can be used for this purpose; even more striking results are available from longitudinal measurements of the medial temporal lobe or from studies of brain

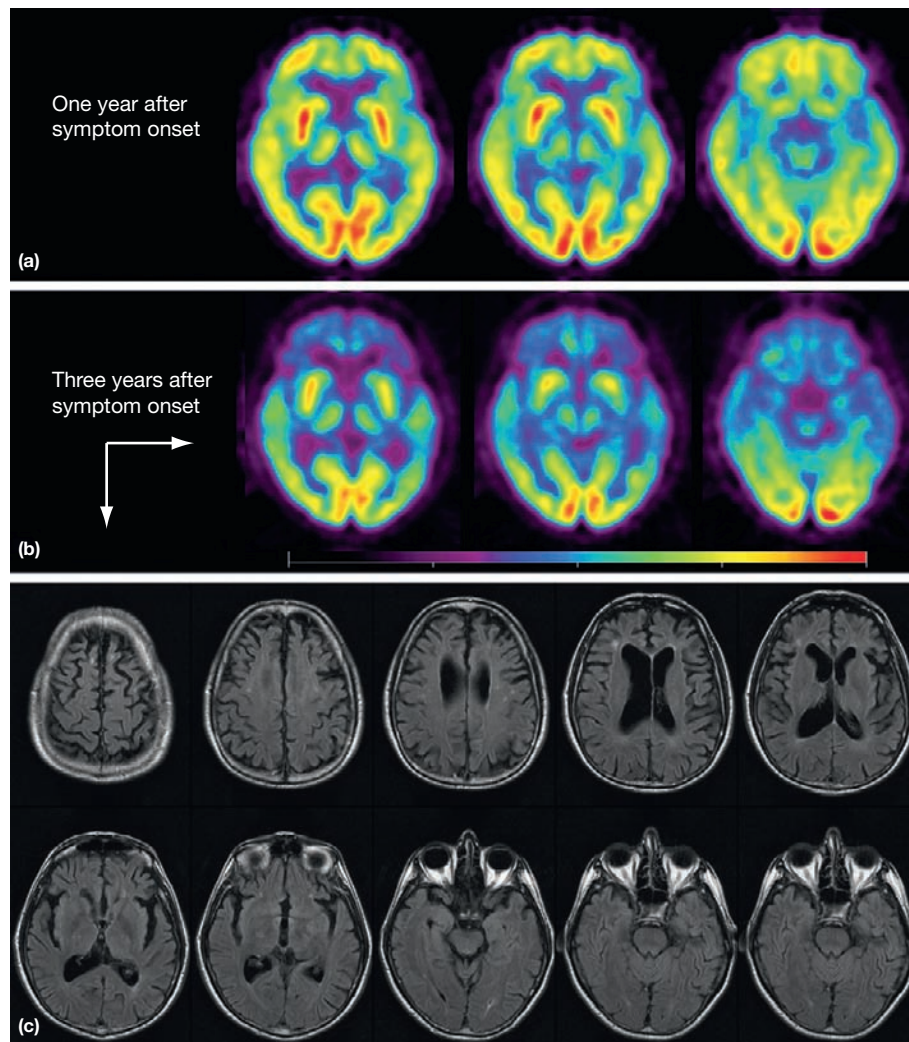

Figure 16 Frontotemporal dementia. Shown are FDG-PET (a, b) and FLAIR MRI (c) studies from a 51-year-old man with progressive speech apraxia and impaired planning, to the point of mutism and complete dependency for activities of daily living when studies (b) and (c) were obtained, taken on the same day. Metabolism was already decreased on the initial PET study, particularly on the frontal opercula and temporal tips, but it is much more obvious on the follow-up study, showing extensive frontotemporal hypometabolism. Note that the frontotemporal abnormality is much more obvious on the PET study (a, b) than on the MRI study (c), which shows frontal atrophy.

Figure 17 Coronal FLAIR (top row) and axial T2-weighted (bottom row) MRI images showing mild to moderate leukoaraiosis of the frontal periventricular white matter and lacunar infarctions in the left putamen, globus pallidus, pulvinar, and internal and extreme capsules. They are from an 80-year-old right-handed man with a stuttering course leading to progressive nonfluent aphasia.

metabolism. These findings suggest that the combination of genetic and neuroimaging information can be of great value to study disease-modifying or preventing therapies at very early stages of the process, when neuronal loss is still limited.

Similar to patients with AD, some cognitively normal individuals have brain amyloid deposits detected with PiB, while their cerebrospinal fluid (CSF) amyloid- β 42 is decreased. This finding suggests that AD may be related to impaired clearance of β -amyloid from the brain. Inflammation that is present in AD could be simply reactive to tissue damage or play a role, either positive or negative, in the disease process. The brain inflammatory cells, activated microglia, can be imaged with the PET agent (R)-PK11195. PET can also be used to image the regional density of a host of molecules that may be relevant to understand better the mechanisms of the dementias, such as acetylcholine esterase in AD.

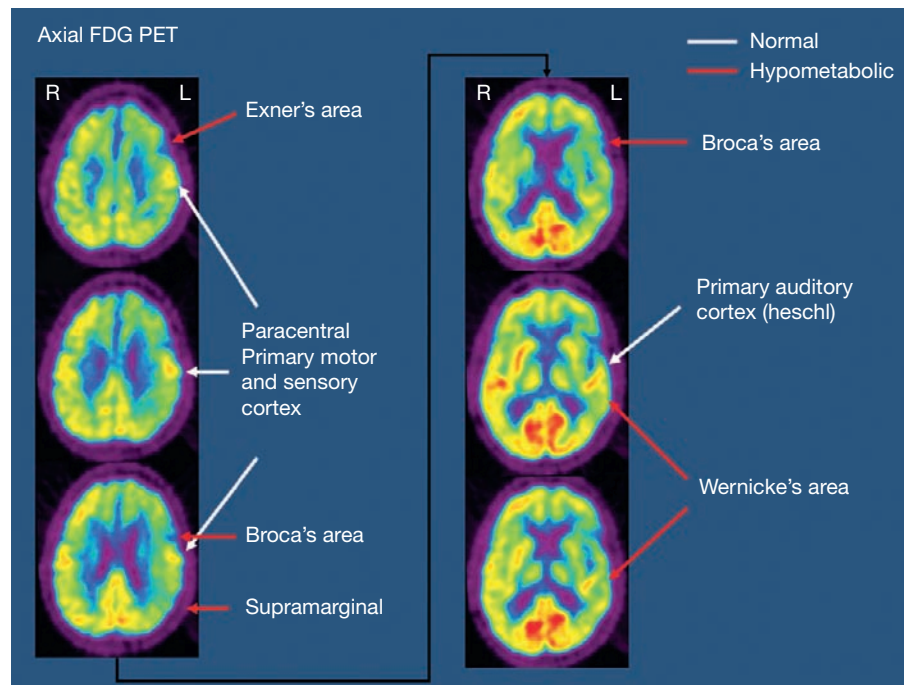

Figure 18 Functional study with PET of the same patient whose MRI is shown in [Figure 17](#). Axial FDG-PET showing hypometabolism in the perisylvian association cortex of the frontal, parietal, and temporal lobes of the left hemisphere. The primary auditory and motor-sensory cortices are spared. Selective sparing of the primary cortices is indicative of a neurodegenerative disorder, rather than ischemic disease, as possibly suggested by the MRI findings in [Figure 17](#).

Table 3 Nonamyloid dementias

<i>Dementia type</i>	<i>Clinical findings</i>	<i>Atrophy (MRI)</i> ↓ <i>Metabolism (PET)</i> ↓ <i>Perfusion (SPECT)</i>	<i>Motor neuron disease (%)</i>	<i>Ubiquitinated bodies (TDP-43) (%)</i>	<i>Tau (%)</i>	<i>Known genetics</i>
Behavioral variant frontotemporal dementia (bvFTD)	Behavioral and personality changes and executive dysfunction	Bilateral frontotemporal atrophy, hypometabolism, and hypoperfusion	20	50	50	Progranulin (PGRN) and microtubule associated protein tau (MAPT)
Frontotemporal dementia with motor neuron disease (FTD-MND)	Similar to bvFTD	Frontal > temporal lobe atrophy, hypometabolism, and hypoperfusion	100	100	0	Possible Chromosome 9
Semantic dementia (SD)	Anomic aphasia, loss of comprehension, surface dyslexia	Bilateral (L>R) anterior temporal, atrophy hypometabolism and hypoperfusion	<5	80	20	None determined
Progressive nonfluent aphasia (PNFA)	Nonfluent speech with agrammatism	Left perisylvian association cortex atrophy, hypometabolism, and hypoperfusion	<5	20	80	PGRN and MAPT
Corticobasal syndrome (CBS)	Apraxia, rigidity	Asymmetric frontoparietal, lenticular, and thalamic atrophy, hypometabolism, and hypoperfusion	<5	5	95	MAPT H1 haplotype and PGRN (four families)
Progressive supranuclear palsy syndrome (PSPS)	Vertical supranuclear palsy, apathy, symmetric parkinsonism	Midbrain atrophy, mild frontal lobe atrophy, hypometabolism, and hypoperfusion	<1	1	99	MAPT H1 haplotype

Courtesy of Dr. Keith Josephs.

Figure 19 Corticobasal degeneration. Shown are axial sections of an FDG-PET study from a 47-year-old man with progressive agraphia and apraxia, as well as right-sided parkinsonism. Metabolism in the association cortex of the frontal and parietal lobe is decreased (white arrows), as well as in the ipsilateral thalamus (arrowhead) and lenticular nucleus (red arrow).

Glossary

Functional magnetic resonance imaging (fMRI) A neuroimaging technique employing magnetic fields in which, most commonly, the difference in the magnetization state of hydrogen atoms in oxygenated and deoxygenated hemoglobin is used to image the changes in local blood flow accompanying changes in neural activity.

Hemodynamic response function (HRF) A quantitative description of the compensatory blood flow generated by neural activity in the brain, and an indirect measure of neural activity employed by fMRI and frequently by PET.

Magnetoencephalography (MEG) A neuroimaging technique that reconstructs an image of brain activity with excellent temporal resolution based on the detection of magnetic fields generated by electrical activity in the brain.

Positron emission tomography (PET) A radionuclide-based neuroimaging technique in which positrons emitted by intravenously administered radiolabeled tracers give rise to coincident γ -rays used to reconstruct an image.

Single-photon emission computed tomography (SPECT) A radionuclide-based neuroimaging technique in which γ -rays emitted by intravenously administered radiolabeled tracers are used to reconstruct an image.

Introduction

Cognitive neuroscience is a discipline that attempts to determine the neural mechanisms underlying cognitive processes. Specifically, cognitive neuroscientists test hypotheses about brain–behavior relationships that can be organized along two conceptual domains: *functional specialization* – the idea that functional modules exist within the brain, that is, areas of the cerebral cortex that are specialized for a specific cognitive process – and *functional integration* – the idea that a cognitive process can be an emergent property of interactions among a network of brain regions, and thus that a brain region can play a different role across many functions.

Early investigations of brain–behavior relationships consisted of careful observation of individuals with neurological injury resulting in focal brain damage. The idea of functional specialization evolved from hypotheses that damage to a particular brain region was responsible for a given behavioral syndrome characterized by a precise neurological examination. For instance, the association of nonfluent aphasia with right-sided limb weakness implicated the left hemisphere as the site of language abilities. Moreover, upon the death of a patient with a neurological disorder, clinicopathological correlations provided information confirming the site of damage that caused a specific neurobehavioral syndrome. For example, in 1861, Paul Broca's observations of nonfluent aphasia in the setting of a damaged left inferior frontal gyrus cemented the belief that this brain region was critical for speech output. The introduction of structural brain imaging more than 100 years after Broca's observations, first with computerized tomography and later with magnetic resonance imaging (MRI), paved the way for more precise anatomical localization in the living patient of the cognitive deficits that develop after brain injury. The superb spatial resolution of structural neuroimaging has reduced the reliance on the infrequently obtained autopsy for making brain–behavior correlations.

Functional neuroimaging methodologies, broadly defined as techniques that measure brain activity, have expanded our ability to study the neural bases of cognitive processes. As technology has advanced, a number of these techniques have arisen, including single-photon emission computed tomography (SPECT), positron emission tomography (PET), functional MRI (fMRI), and magnetoencephalography (MEG). Using these techniques, researchers can measure regional brain activity in healthy subjects while they perform cognitive tasks, and thereby link localized brain activity with specific behaviors. For example, functional neuroimaging studies have demonstrated that the left inferior frontal gyrus is consistently activated during the performance of speech-production tasks in healthy individuals. Such findings from functional neuroimaging complement findings derived from observations of patients with focal brain damage. To provide the reader with the necessary background for understanding functional neuroimaging data, this chapter focuses on the principles underlying each of these techniques, and their relative strengths and weaknesses. Particular attention will be paid to fMRI, as it is perhaps the most widely employed neuroimaging method. The chapter concludes with some of the novel ways in which these techniques are being combined to harness their complementary strengths to answer questions in cognitive neuroscience.

Single-Photon Emission Computed Tomography

One of the earliest methods used for functional imaging, SPECT relies on the use of radionuclide-labeled agents. The radionuclide emits photons, primarily in the γ range, that are detected by a collimator and then used to generate a three-dimensional reconstruction of the distribution of the radionuclide within the brain. In a typical study, a subject receives an intravenous injection of the radiolabeled tracer. Depending on the nature of the tracer, a number of minutes are allowed to

pass prior to imaging, allowing the agent to distribute throughout the body. Images are then obtained and analyzed.

The first important choice when using SPECT, and one of the primary advantages of this technique, involves the nature of the radioligand. The two commonly used radioisotopes – ^{99m}Tc and ^{123}I – can be incorporated into larger molecules that are relevant to the neuroscientific process of interest (in a fashion similar to PET, and unlike fMRI and MEG). Tracers in clinical use, for example, include ^{99m}Tc -hexamethylpropylene amine oxine (HMPAO) and ^{123}I -Ioflupane. The former agent provides a measure of cerebral perfusion. When infused, this lipophilic agent rapidly crosses the blood–brain barrier in proportion to cerebral blood flow. Once inside cells, it undergoes a reaction that renders it hydrophilic, preventing it from leaving the cell and generating a marker for cerebral areas with greater blood flow. In contrast, the latter agent – a cocaine analog – binds to dopamine reuptake transporters. As such, it provides a marker for the dopamine system, and has been used clinically to investigate, for example, whether subjects with parkinsonism have reduced uptake of the tracer in the basal ganglia. An important note concerns the nature of these markers: they allow the researcher/clinician to obtain a single snapshot of activity, rather than ongoing assessments of activity. At times, this snapshot can be an advantage – clinically, one may be able to capture blood flow during a seizure, then image hours later – or a disadvantage, when a measure of ongoing activity at different points during a process is desired.

Once the radionuclide is absorbed and distributed, the γ -ray signals it generates must be detected. The resolution of the γ -rays is limited by at least two factors: physical factors, such as absorption or scatter of the emitted photons by other structures/tissues within the body; and instrumentation factors, including the detection efficiency and spatial resolution of the collimator. These factors limit the overall spatial resolution of the sample. In SPECT scanners in everyday use, this limit is on the order of 1 cm, though specialized collimators in use with small animal studies can reduce the spatial resolution to ~ 5 mm. Because the measure of incident photons is not spatially independent, the SPECT signal cannot be quantified in absolute terms.

In total, SPECT imaging has a number of advantages over PET, with which it is most often compared. The cost of SPECT equipment is considerably cheaper, the radionuclides have longer half-lives and do not require a nearby cyclotron for synthesis, and the radiation levels are lower. Its disadvantages with respect to PET, however, have led SPECT to serve primarily as a clinical imaging technique. These disadvantages are discussed in the next section.

Positron Emission Tomography

Like SPECT, PET is a technique that relies upon the detection of signals generated by radionuclides. In this case, the radioactive substance emits positrons that collide with, and are annihilated by, nearby electrons. The resulting collision generates two high-energy photons that travel in exactly opposite directions. PET imaging relies on the idea of coincidence

detections: that is, that the coincident identification of two γ -rays traveling in opposite directions permits the localization of the source in space.

Commonly used radionuclides include ^{18}F , ^{15}O , ^{11}C , and ^{13}N . Due to its longer half-life (~ 110 min), ^{18}F may be most commonly used. As with SPECT, these radionuclides can be incorporated into molecules that are associated with the neuroscientific process of interest – for example, ^{18}F -fluorodeoxyglucose to study energy metabolism, ^{15}O - H_2O to monitor cerebral blood flow, and ^{18}F -DOPA to study dopamine receptor occupancy. The tracer of choice is injected into the subject intravenously, and images are obtained, often as subjects perform a task of interest but possibly also as subjects lie quietly in the scanner (depending on the nature of the tracer).

Relative to SPECT, PET has a number of advantages. A primary advantage is the increase in spatial resolution. Unlike SPECT, which relies upon detection of γ -rays, PET's use of coincidence detection significantly increases the specificity of the signal. Typical spatial resolution is on the order of 5 mm. Moreover, the ubiquity of the radionuclides allows almost any molecule to serve as a tracer, unlike SPECT tracers that are based primarily on the use of ^{99m}Tc , which can be difficult to incorporate into small molecules. Finally, the variety of half-lives allows for studies that provide images at different time points during an experiment. The half-life of ^{15}O , for example, is ~ 2 min, permitting frequent imaging (although requiring multiple tracer injections).

An important implication of the ability to image subjects repeatedly has to do with task design. Because multiple images can be acquired, PET permitted the development of so-called 'block designs,' in which variations of a task, or contrasting cognitive processes, can be repeated within the same subject in the same session. For example, Roskies and colleagues compared a 'synonym' task, in which subjects judged the meaning of two words, with a 'rhyming' task, in which subjects implicitly evaluated the sounds of two words, to identify brain regions that were differentially activated by semantic and phonological language tasks. This capability represented a significant advance over SPECT, which was subsequently trumped by the development of event-related designs in fMRI (see section on fMRI). In current usage, PET has now largely been supplanted by fMRI, for reasons discussed later. However, its capacity to obtain information about specific neurotransmitter systems continues to make it a unique and valuable methodology.

The Physiological Basis for Neuroimaging Signals

As has been evident in the discussion of both SPECT and PET (and will become important for fMRI), these methods are based on indirect measurements of neural activity, either hemodynamic or metabolic. (Studies of receptor occupancy can be considered somewhat separately in this case, as they do not purport to measure neural activity. On the other hand, MEG, which measures magnetic fields generated by neuronal activity, is in this sense a more direct measure.) Hemodynamic and metabolic measurements rely on the tight coupling between neural activity and other physiological changes. In the case of metabolic changes – as measured, for example, by

the uptake of labeled fluorodeoxyglucose – this coupling is quite direct: as the neural activity in a brain region increases, the metabolic activity in neurons and astrocytes increases, leading to greater glucose demands and greater tracer uptake.

In the case of hemodynamic signals, the local increase in metabolic demands leads to an increase in blood flow and a corresponding rise in the oxygenated:deoxygenated hemoglobin ratio. These increases peak at ~6 s after onset, then decline to levels that frequently dip below the previous baseline before returning to prestimulus levels ~10–15 s after onset. This response is typically described concisely by a hemodynamic response function (HRF), the precise shape of which can vary by brain region. Although neuronal spiking is a prominent feature of neuronal activity, it is thought that the basis for the HRF lies in the postsynaptic activity of large collections of neurons and associated astrocytes. Importantly (as discussed in the relevant sections of this article), the nature of the hemodynamic response places constraints on the ultimate spatial and temporal resolution of the detected signal.

Functional Magnetic Resonance Imaging

fMRI has now become the predominant functional neuroimaging method for studying the neural basis of cognitive processes in humans. At its foundation, MRI of any kind (functional or structural) relies upon the magnet of the scanner to generate a large magnetic field (commonly 1.5 or 3.0 T) that differentially aligns the spins of hydrogen atoms. When this large magnetic field is briefly perturbed and then returned to baseline, different hydrogen atoms will dephase and return to alignment with the large magnetic field at different rates, determined by their local chemical environments. For example, a hydrogen atom that is part of a water molecule will ‘relax’ at a different rate than one that is part of a long carbon chain in the lipid of a fat cell. This differential signal is exploited by structural MRI to distinguish different tissues in the brain (and body).

In fMRI, the difference between the local environments of the hydrogen atoms in oxygenated and deoxygenated hemoglobin serves as the basis of the functional signal. Because of the aforementioned tight coupling between neural activity and blood flow, brain regions that show greater activity also show greater blood flow with a larger concentration of oxygenated hemoglobin. This indirect neural signal – the so-called BOLD (blood-oxygen-level-dependent) signal – can be detected in fMRI and exploited to determine which brain regions are active.

fMRI as a Cognitive Neuroscience Tool

Compared to its predecessor, PET scanning, fMRI offers many advantages. For example, MRI scanners are much more widely available, and imaging costs are less since MRI does not require a cyclotron to produce radioisotopes. MRI is also a noninvasive procedure since there is no requirement for injection of a radioisotope into the bloodstream. Moreover, given the half-life of available radioisotopes, PET scanning is unable to provide comparable temporal resolution to that of fMRI, which can provide images of behavioral events occurring on the order of seconds rather than the summation of many behavioral events over tens of seconds. PET scanning is also

unacceptable for studies of children, for example, due to the radiation exposure.

In selected circumstances, PET can provide an advantage over fMRI for studying certain questions concerning the neural basis of cognition. PET scanning may remain desirable or necessary when studying certain populations of individuals. For example, amnesic patients suffering from cerebral anoxia often have implanted cardiac pacemakers, precluding them from having MRI scans because of the adverse effect of the magnetic field on the pacemaker. A particular advantage of PET scanning in the study of cognition that can nicely complement fMRI studies is its ability to assess neurochemical (neurotransmitter and neuromodulator) systems. Radioactively labeled ligands may be used to directly measure density and distribution of particular receptors and even receptor subtypes, as well as the distribution of presynaptic terminals or enzymes involved in the production or breakdown of particular neurochemicals.

The MRI scanner, compared to a behavioral testing room, is less than ideal for performing most cognitive neuroscience experiments. Subjects perform experiments in an acoustically noisy environment in the somewhat awkward supine position, often requiring them to visualize the presentation of stimuli through a mirror. Moreover, many individuals develop some degree of claustrophobia due to the small bore of the MRI scanner and find it difficult to remain completely motionless for the long duration of time that is required for most experiments (typically 60–90 min). These constraints of the MRI scanner make it especially difficult to scan children or certain patient populations (e.g., Parkinson’s disease patients), resulting in fewer fMRI studies involving children than those involving adults, and involving neurological patients in general. However, mock scanners with motion devices have been built in many imaging centers to acclimate children (and patients) to the scanner environment before they participate in fMRI studies. This approach has increased the number of fMRI studies of children, which are providing tremendous insight into the mechanisms underlying the developing brain.

All sensory systems have been investigated with fMRI including the visual, auditory, somatosensory, olfactory, and gustatory systems. Each system requires different technologies for successful presentation of relevant stimuli within an MRI environment. The most common means of presenting visual stimuli is via a liquid crystal display (LCD) projector system, with the sophistication of the system depending on the quality of image resolution required for the experiment. For auditory stimuli, several options exist, including piezoelectric or electrostatic headphones. However, the biggest challenge remains the acoustic noise produced by the pulsing of the fMRI gradient coils. For example, during echoplanar imaging within a 4 T magnet using a high-performance head gradient set, sound levels can reach 130 dB. As a reference point, Food and Drug Administration (FDA) safety regulations require no greater than an average of 105 dB for 1 h. One of the biggest technical challenges within an MRI scanner has been the ability to present olfactory stimuli. However, sophisticated MR-compatible olfactometers have been designed and utilized successfully. Such methods use a nasal mask in which the change from odorant to no-odorant conditions occurs within a few milliseconds.

Acquiring ancillary electrophysiological data such as electromyographic recordings to measure muscle contraction or electrodermal responses to measure autonomic activity enhances many cognitive neuroscience experiments. Devices that are MR compatible for these types of measurements, as well as for other physiological measures such as heart rate, electrocardiography, oxygen saturation, and respiratory rate have been developed. The recording of eye movements is becoming commonplace in MRI scanners, predominantly via the use of infrared video camera equipped with long-range optics. Video images of the pupil–corneal reflection can be sampled at 60/120/240 Hz allowing for the accurate ($<1^\circ$) localization of gaze within 50 horizontal and 40 vertical degrees of visual angle. Although most behavioral tasks used in cognitive neuroscience experiments rely on collecting manual responses, the ability to reliably collect verbal responses without introducing significant motion artifacts has been demonstrated by several laboratories.

Electroencephalography (EEG) recordings have also been successfully performed during MRI scanning (see later sections as well). However, the recording of event-related potentials (ERP), a signal that is much smaller in amplitude than the signal in EEG, can be more difficult in a magnetic field due to artifacts induced by gradient pulsing and head movement from cardiac pulsation. New monitoring devices and algorithms to remove artifacts have been developed, allowing for reliable measurements of ERPs during MRI scanning. In summary, most initial challenges facing cognitive experiments within the MRI environment have been overcome, creating an environment that is comparable to standard psychophysical testing labs outside of a scanner. Although individual laboratories have achieved most of these advancements, MRI scanners originally designed for clinical use by manufacturers are now being designed with consideration of many of these research-related issues.

Temporal resolution

Two types of temporal resolution need to be considered for cognitive neuroscience experiments. First, what is the briefest neural event that can be detected as an fMRI signal? Second, how close together can two neural events occur and be resolved as separable fMRI signals?

The time scale on which neural changes occur is quite rapid. For example, neural activity in the lateral intraparietal area of monkeys increases within 100 ms of the visual presentation of a saccade target. In contrast, as noted above, the BOLD signal gradually reaches its peak magnitude within 4–6 s after an experimentally induced brief (<1 s) change in neural activity, and then decays back to baseline after several more seconds. Thus, neural dynamics and neurally evoked hemodynamics, as measured with fMRI, are on quite different time scales.

The sluggishness of the hemodynamic response limits the temporal resolution of the BOLD signal to hundreds of milliseconds to seconds, in contrast with the millisecond temporal resolution of EEG or MEG recordings of neural activity. However, brief changes in neural activity can be detected with reasonable statistical power using fMRI. For example, appreciable BOLD signal can be observed in sensorimotor cortex in association with single finger movements and in visual cortex during very briefly presented (34 ms) visual stimuli. In contrast, the temporal resolution of fMRI limits the detection of

sequential changes in neural activity that occur rapidly with respect to the hemodynamic response – that is, the ability to resolve the changes in the BOLD signal associated with two neural events often requires the separation of those events by a relatively long period of time compared with the width of the hemodynamic response. This limitation results from the fact that two neural events closely spaced in time will produce a hemodynamic response that reflects signal accumulation from both neural events, rendering estimates of the contribution of each individual neural event difficult. In general, evoked BOLD responses to discrete neural events separated by at least 4 s appear to be within the range of resolution. However, provided that the stimuli are presented randomly, studies have shown significant differential functional responses between two events (e.g., flashing visual stimuli) spaced as closely as 500 ms apart. In some tasks, the order of individual trial events cannot be randomized. For example, in certain types of working memory tasks, the presentation of the information to be remembered during the delay period, and the period when the subject must recall the information are individual trial events whose order cannot be randomized. In these types of tasks, short time scales (<4 s) cannot be temporally resolved. These temporal resolution issues in fMRI have been extensively considered regarding their impact on experimental design.

Spatial resolution

It is yet to be determined how precisely the measured BOLD signal, which arises from the vasculature, reflects adjacent neural activity. Thus, the ultimate spatial resolution of BOLD fMRI is unknown. fMRI studies in both monkey and man at high field (4–4.7 T) have demonstrated that BOLD signal can be obtained with high spatial resolution – $\sim 0.75 \times 0.75 \text{ mm}^2$ in-plane resolution. In monkeys, with novel approaches involving a small, tissue-compatible, intraosteally implanted radiofrequency coil, ultra high spatial resolution of $125 \times 125 \text{ mm}^2$ has been obtained. Using this method, Logothetis and colleagues demonstrated cortical lamina-specific activation in a task that compared responses to moving stimuli with those elicited by flickering stimuli. This contrast elicited BOLD signal mostly in the granular layers of the striate cortex of the monkey, which are known to have a high concentration of directionally selective cells. Advances in such methods would allow for imaging of hundreds of neurons per voxel as opposed to hundreds of thousands of neurons per voxel, which is more typical for a human cognitive neuroscience fMRI experiment.

Virtually all fMRI studies model the large BOLD signal increase resulting from the local low-deoxyhemoglobin state to detect brain changes correlating with a behavioral task. However, optical imaging studies have demonstrated that preceding this large positive response is an initial negative response reflecting a localized increase in oxygen consumption that causes a high-deoxyhemoglobin state. This early hemodynamic response is called the ‘initial dip’ and is more tightly coupled to the actual site of neural activity evoking the BOLD signal as compared to the later positive portion of the BOLD response. For example, Kim and colleagues, scanning cats in a high-field scanner, demonstrated that the early negative BOLD response (e.g., initial dip) produced activation maps that were consistent with orientation columns within visual cortex. This finding is quite remarkable, given that the average spacing between

two adjacent orientation columns in cortex is ~ 1 mm. In contrast, the activation maps produced by the delayed positive BOLD response appeared more diffuse and cortical columnar organization could not be identified. Thus, empirical evidence suggests that deriving activation maps by correlating behavioral responses with the initial dip may markedly improve spatial resolution. Several groups have detected the columnar architecture (in this case ocular dominance columns) by modeling the positive BOLD response in humans scanning at 4 T.

Another unique method for improving spatial resolution, called functional magnetic resonance-adaptation (fMR-A), could provide a means for identifying and assessing the functional attributes of sharply defined neuronal populations within a given region of the brain. Even if the spatial resolution of fMRI evolves to the point of being able to resolve a population of a few hundred neurons within a voxel, it is still likely that this small population will contain neurons with very different functional properties that will be averaged together. The adaptation method is based on several basic principles. First, repeated presentation of the same type of stimuli (i.e., a picture of one object) causes neurons to adapt to those stimuli (i.e., neuronal firing is reduced). Second, if these neurons are then exposed to a different type of stimulus (i.e., a picture of another object) or a change in some property of the stimulus (i.e., the same object in a different orientation), recovery from adaptation can be assessed (i.e., whether or not the BOLD signal returns to its original state). If the signal remains adapted, it implies that the neurons are invariant to the attribute that was changed, while if the signal recovers from the adapted state, it would imply that the neurons are sensitive to that attribute. For example, Grill-Spector and colleagues demonstrated that an area of lateral occipital cortex thought to be important for object recognition was less sensitive to changes in object size and position as compared to changes in illumination and viewpoint. Thus, with this method it is possible to investigate the functional properties of neuronal populations with a level of spatial resolution that is beyond that obtained from conventional fMRI data analysis methods.

Considering all the neuroscientific methods available today for studying human brain-behavior relationships, fMRI provides an excellent balance of temporal and spatial resolution. Improvements on both fronts will clearly add to the increasing popularity of this method.

Magnetoencephalography

Unlike the previous three methods, MEG relies on a much more direct measure of neuronal activity. In response to a stimulus, neural activity – specifically, electrical activity – changes within the brain as ion channels open and close. These electrical currents generate an associated magnetic field, oriented according to a right-hand rule in which the magnetic field is perpendicular to the direction of current. In the brain, the source of this magnetic field is thought to be the postsynaptic currents that arise in the dendrites and flow to the cell body. Unlike electrical currents, magnetic fields are not distorted by intervening tissues; thus, unlike EEG, in which the signal recorded by scalp electrodes is compromised by the

intervening brain, skull, and scalp, magnetic fields arrive outside the brain relatively unaltered.

This lack of distortion is a significant boon to analyses. On the other hand, magnetic fields are compromised by intrinsic and technical issues that render them more difficult to record. One factor is their exceedingly small size. Relative to the earth's magnetic field, other magnetic field generators within the body (e.g., the heart), and other magnetic fields produced by ubiquitous electrical currents operating lab equipment, for example, those generated by the brain are many orders of magnitude smaller. Therefore, the MEG recordings must be done in magnetically shielded rooms. Additionally, they require special sensors for detection: so-called SQUIDS, or superconducting quantum interference devices. Current MEG set-ups commonly include SQUIDS numbering over 100. Because these devices require liquid helium to operate, they are of necessity a distance of 2 cm or more from the scalp, a factor that further decreases signal because these magnetic fields decrease in magnitude with the square of the distance. Despite these hurdles, MEG can obtain very good spatial resolution (on the order of 1 cm or less) and excellent temporal resolution (on the order of 1 ms).

To overcome measurement noise, one approach is to repeat tasks studied using MEG numerous times to obtain an event-related magnetic field, or ERF. As with EEG signals, a range of frequencies is obtained, and bands ranging from α (~ 10 Hz) to γ (> 30 Hz) can be used to search for links to cognitive tasks. These ERFs are then used to estimate the sources of the electrical field (the electrical dipoles) that generated them. Rather than attempting to predict magnetic fields based on the underlying electrical currents (a so-called 'forward problem'), the experimenter attempts to reconstruct the underlying currents from their outputs. This 'inverse problem' has an infinite number of solutions that can be consistent with the observed magnetic field, so the location of the cortical surface, as determined by MRI, and other nontrivial constraints – such as the number of dipoles – are often employed to define a solution. A larger number of dipoles or an incorrectly estimated number of dipoles can potentially change the solution. The use of the ERF also favors the identification of dipoles that are both time- and phase-locked to the stimulus.

Newer reconstruction techniques include 'beamformer' approaches. In this case, the previously defined brain space is spatially filtered to reflect the relative contributions of different areas to the signal. Based on the covariance in the data, the relative contribution of each of the SQUID sensors is defined for each voxel in brain space. The activity in different areas in the brain can then be determined by applying the weights to the ongoing MEG signal. In this way, regions that are time-locked, but not necessarily phase-locked, to the stimulus can be identified, and whole-brain maps produced. These statistical parametric maps can be analyzed in much the same way as previously discussed for fMRI data. Further improving and standardizing these methods remains an active area of research. In particular, techniques that take advantage of statistical knowledge about the likely number of magnetic sources and temporal relationships between them may further improve resolution.

Practically, the excellent spatial and temporal resolution of MEG is also tempered by a factor having to do with the

arrangement of cortical neurons and the cortical surface. Signals from structures that consist of parallel current generators – such as pyramidal neurons in layer five of the neocortex – are detected with significantly greater fidelity than those generated by other arrangements of neurons, such as those in subcortical structures (in addition to the distance-related reduction in signal strength from these structures). Even within cortex, because of the right-hand rule, regions that are parallel to the surface of the skull (e.g., cortex that can be found in the walls of sulci) are much better detected, because their magnetic fields emerge from the head oriented radially. Improving the detection of magnetic field signals from these other regions also remains an ongoing area of research.

With respect to the other neuroimaging methods, MEG has a number of advantages. First and foremost is a temporal resolution on the order of milliseconds, which is at least two orders of magnitude greater than that for fMRI. Its spatial resolution of ~ 1 cm approximates that of PET, approaches that of fMRI, and may continue to improve as MEG analysis techniques are refined. Disadvantages specific to this technique include some difficulty imaging subcortical structures and limitations in identifying dipoles that are present in the crowns of gyri.

Combination Methods

With the availability of all of these methods, attempts are being made to combine them with other imaging modalities in the same subjects, often simultaneously, to improve spatial resolution, data reconstruction, and other technical factors. Initial work, for example, has combined these functional methods with structural imaging in order to better constrain and localize acquired signals. SPECT-CT and PET-CT take advantage of the anatomical information in the CT scan to co-register functional data across multiple scan sessions. Similarly, as mentioned previously, fMRI analyses rely on anatomical MRI images obtained in the same scanning session to localize fMRI data in the brain; and MEG takes advantage of anatomical MRI images to constrain source localization.

More recently, a particularly exciting area of methods development has focused on the integration of multiple forms of functional neuroimaging. As mentioned, fMRI, for example, has been combined with EEG to obtain timing information at a resolution not possible in whole-brain fMRI images. Additionally, recent papers have described the development of combined high-field fMRI – PET scanners for animal studies. Because the photomultiplier devices used in PET scanners are very sensitive to magnetic fields, the new systems have either developed optical means for moving the signal outside the magnetic field, or photomultipliers based on MRI-compatible equipment. Such systems open the possibility of visualizing, for example, the location of neurotransmitter systems along with functional activity based on blood flow. Finally, not only

structural MRI, but also fMRI, images are being used to constrain MEG sources, in a way that strengthens both localization and timing of functional signals.

Conclusions

The neuroimaging techniques discussed in this chapter for studying brain–behavior relationships represent extremely valuable tools that have emerged over a relatively recent period of time. Readily available, minimally invasive, and with generally excellent temporal and spatial resolution, they provide complementary mechanisms for investigating brain function. New approaches to experimental design and data analysis, especially for fMRI and MEG, are appearing in the literature at a rapid rate, leading to numerous options for testing hypotheses on brain–behavior relationships. Combined with information from other methods (such as studies of patients with focal lesions, healthy individuals with transcranial magnetic stimulation, pharmacological interventions, and ERP), data from studies based on these techniques can provide new insights regarding the organization of the cerebral cortex and other brain structures, as well as the neural mechanisms underlying cognition. Moreover, the clinical applications of these techniques are sure to increase as their neuroscientific applications and technological improvements continue.

Glossary

Cognitive neuroscience The field of study that links cognitive processes to brain function.

Frontal lobes Most forward part of the brain involved in attention focusing and emotional processing.

Functional brain imaging Refers to techniques such as functional magnetic resonance imaging, positron emission tomography, and single photon emission computed tomography that measure change in brain function.

Hypothalamus A small central brain structure with many important functions such as regulating basic body functions, hormones, and the immune system.

Limbic system A group of structures such as the hippocampus and amygdala in the inner part of the temporal lobes and involved in emotional responses.

Neurotheology The field of study that links religion and theology to neuroscience and psychology.

Neurotransmitters Molecules that the brain uses to support mental functioning.

Parietal lobe Located along the back-top part of the brain and involved in spatial and body orientation.

Thalamus A central brain structure that subserves many functions, particularly as a main sensory relay.

Introduction

Neurotheology is an emerging field of study that seeks to integrate in some manner cognitive neuroscience with religion and theology. Its development as a field is attested to by significant interest in both the academic and lay population. Neurotheology is multidisciplinary in nature and includes the fields of theology, religious studies, religious experience, philosophy, cognitive science, neuroscience, psychology, and anthropology. Each of these fields may contribute to neurotheology, and conversely, neurotheology may ultimately contribute in return to each of these fields. Ultimately, neurotheology must be considered a multidisciplinary study that requires substantial integration of divergent fields.

'Neurotheology' has garnered substantial attention in the academic and lay communities in recent years. As would be expected, there have been many positive and negative responses to purported neurotheological studies. Early Buddhist and Hindu texts frequently make reference to the functioning of the mind and spiritual pursuits. Many philosophers from Plato to Kant also attempted to address how human thought might relate to the spiritual or divine nature within us. In the 1800s Phrenologists attempted to better delineate the areas of the brain associated with a variety of psychological and spiritual processes, but did not have available the current abilities of today's cognitive neuroscientist to measure changes in brain function associated with different neurocognitive processes. The field of neurotheology may have found its origins in the line of research and scholarship that began in 1975 when Eugene d'Aquili and Charles Laughlin published 'The Biopsychological Determinants of Religious Ritual Behavior.' Their thesis was that all religious phenomenology arose from neuropsychology, but in a way much more complex than simple materialistic reductionism. The first 10 years of this scholarly movement were very difficult indeed. The attempt to integrate neuropsychology and theology was extremely controversial in the mid-1970s and often dismissed as an attempt to integrate incommensurables. The early scholars painted neurotheology

with broad strokes in part due to the limitations in brain research at the time. More recent scholars have contributed in different ways with some providing empirical data via state-of-the-art functional brain imaging studies, and others providing the theoretical or theological foundation.

Individuals engaged in neurotheology can help develop theoretical models of the neurophysiological mechanisms of brain activity during religious and spiritual practices such as meditation, prayer, or ritual. This analysis also includes the spiritual or religious experiences associated with such practices as well as those that arise spontaneously such as near-death experiences. The overall purpose of this area of neurotheology is to generate a substantial theoretical base from which to explore the other aspects of religious and spiritual phenomena. Models will typically build upon both the known neuropsychological and neuroscientific literature in order to determine exactly how various brain structures function both individually and as an integrated whole. Models will typically include not only general brain function, but changes in a variety of neurotransmitter and hormonal systems. An analysis of various types of neuropsychiatric disorders such as schizophrenia or temporal lobe epilepsy as they relate to religious and spiritual phenomena must also be considered as a way of helping to understand various aspects of religious experience. It is also important to consider whether religious or spiritual phenomena associated with known pathological conditions are in fact the same as religious or spiritual phenomena that are not associated with any pathology.

The brain structures that have already been shown to be involved in religious practices such as meditation or prayer include the frontal lobes (involved in attention focusing and emotional processing), the limbic system (part of the temporal lobes and involved in emotional responses), the parietal lobe (involved in spatial and body orientation), the thalamus (a main sensory relay), and the hypothalamus (regulating basic body functions, hormones, and the immune system). However, most analyses involved more specific details as to the brain processes associated with various religious and spiritual phenomena.

Defining Neurotheology

Clearly, one of the initial problems with neurotheology as a field is the use of 'neurotheology' as a term. Too often, the term 'neurotheology' has been used inaccurately or inappropriately. Many times, it appears to refer to a study or idea that incorporates neither neuroscience nor theology. Strictly speaking, neurotheology refers to the field of scholarship linking the neurosciences and theology. Neuroscience would thus refer to the empirical study of the central nervous system or brain and theology would refer to the critical and rational analysis of a particular religious belief system, specifically one pertaining to God. Of course, both the terms 'neuroscience' and 'theology' have evolved over time. Neuroscience used to imply the study of nerve cells and their function without a clear regard for behavioral and cognitive correlates. Neuroscience today tends to extend over many different fields including cognitive neuroscience, neurology, psychiatry and psychology, and sociology. The tools have also become much more advanced, including a variety of brain imaging capabilities, for exploring the relationship between the brain and various cognitive, emotional, and behavioral processes.

Theology has also changed over time. In a very strict sense, theology is the study of a *theos* or God. Thus, the word 'theology' should be reserved for theistic religions only, and even more specifically, from those arising out of the Judeo-Christian tradition. However, with the development of comparative theology in the early part of the last century, it became apparent that the nonpersonal Eastern religions possessed many of the formal characteristics of the classic Western religions. It became academically fashionable to use the term 'theology' for the formal study of any belief system centered on an Ultimate or Absolute, whether personal or nonpersonal, whether understood as God or as an ultimate state. It is now acceptable to speak of a theology of Buddhism, of Hinduism, and even of Shamanism.

Within each religious tradition, the word 'theology' can be used in two senses – natural theology and theology proper. Natural theology is not really theology at all, but rather a branch of philosophy. It attempts to prove, or at least prove probable, the existence in reality of the 'hypothesis – God, or of the hypothesis – Absolute' by reason alone, without any appeal to Divine Revelation (in the West) or to fairly rare esoteric experiences (in the East). Theology proper represents intellectual deductions from a foundational story or myth (i.e., the primary myth upon which the religion is based) as well as 'reasonable' extrapolations upon such a myth. Such extrapolations may also involve the employment of analogical reasoning and symbolic logic that does not necessarily neatly fit within a logical reasoning pattern. Eventually, theology becomes a process of reflecting upon the way individuals of a particular religion should live out their faith. The beginning point of theology proper, at least in the West and in primitive societies, is a belief in the transcendent truth of the foundational doctrine either at the literal surface level or at a deeper symbolic level. Depending on how it is applied, neurotheology may be of use in both natural theology and theology proper. Neurotheology may also inform scholars regarding the process of theology proper to help better elucidate how and why human beings come to specific beliefs and understandings about religion and God.

For neurotheology to be a viable field, it most likely should not be limited to only neuroscience and theology. In reconsidering the term 'neurotheology' then, it seems appropriate to allow for expanded uses of the 'neuro' component and the 'theology' component. It would seem appropriate for neurotheology to refer to the totality of religion and religious experience as well as theology. This ability to consider, in a broad scope, all of the components of religion from a neuroscientific perspective would provide neurotheology with an abundant diversity of issues and topics that can ultimately be linked under one heading. On the other hand, if the target of study encompasses so many aspects of religion and spirituality, the field might become so broad that it loses its ability to say something unique about religious and spiritual phenomena. If neurotheology becomes too broad, then, it might become very difficult to distinguish brain correlates of religious and spiritual phenomena from a variety of cognitive, affective, and experiential processes. The neurosciences also may be considered broadly to include not only what goes on within the human brain per se, but within the human body as a whole. Furthermore, since mental processes are intimately linked to the brain, the 'neuro' component of neurotheology should be considered to include psychiatry, psychology, endocrinology as well as other macro- and microperspectives of the neurosciences. One might even consider variations on the theme of neurotheology to include other hybrid terms such as 'neuro-spirituality,' 'psychotheology,' or 'biotheology.' For now, however, the word, 'neurotheology' appears to be the term that has received the most use and acknowledgment in both the academic and popular domains.

An important point about neurotheology as a field and term is that neurotheology should be considered a 'two-way street' with information flowing both from the neurosciences to the theological perspective as well as from the theological perspective to the neurosciences. In other words, neurotheology should not be considered the 'neuroscientific study of religious or theological concepts,' since this would greatly limit what neurotheology might be able to offer. Theology and religion must also be able to freely inform scholars about neuroscience and how to interpret human activities from a psychological, social, and spiritual perspective. By enabling a free exchange of ideas, data, and information, neurotheology can achieve a very high level of sophistication.

Brain Functions and Theological Argument

We now turn briefly to an analysis of theology and theological constructs from a neurotheological perspective. Since we have already described theology as a complex rational deduction from a foundational doctrine, we must consider how this rational deduction arises. Rather than selecting specific theological concepts and describing them from a neurotheological perspective, we examine a variety of overarching brain functions to determine how theological concepts, in general, might be derived. It should be stressed that the brain functions described below relate to broad categories of functions which may have many subfunctions. Future neurotheological scholarship will need to better evaluate the specifics of different brain processes to determine if and how they relate to religious and theological concepts.

The Holistic Function

The brain has the ability to perceive holistic concepts such that we perceive and understand wholeness in things rather than particular details. Thus, we understand the family as a wholeness of related individuals, and from a religious or spiritual perspective, we might understand a concept of absolute oneness as pertaining to the universe or God. This function would seem to be of fundamental importance for theology since it enables an account of God's otherwise noncommunicable attributes such as omnipresence, omniscience, and ability to bind and maintain the entire universe. Thus, any serious consideration of the implications of the functioning of the holistic processes in the brain necessitates, at least, considering the expansion of any foundational myth to apply to all of reality, including other people, other cultures, other animals, and even other planets and galaxies. In fact, as human knowledge of the extent of the universe has evolved, the notion of God has evolved to incorporate the expanding sense of the totality of the universe. The holistic functions of the brain pushes us to contemplate that whatever new reaches of the universe astronomers can find, God must be there. No matter how small and unpredictable a subatomic particle might be, God must be there, too.

That the holistic functions must be taken into account when evaluating foundational doctrines is never more apparent than in the Christian concept of the Trinity consisting of the Father, Son, and Holy Spirit. Christian thought has generated great effort to maintain the notion of the trinity in the face of the holistic need of God's being an absolute unity. Thus, the three components of the trinity are traditionally understood to be discrete as regard to *persons* (rational subjectivities), but all are said to possess the same, single, and absolutely undifferentiated divine nature. Attempts at explaining this seeming contradiction have included each person eternally and perfectly proceeding from the others as well as each person being eternally and perfectly immanent in the others. But there is always that perfectly undifferentiated divine nature which prevents the trinity from deflating into tritheism. The holistic function has, in some sense, forced the issue and made the situation far more complex (in terms of human understanding) than perhaps it would have been without this function.

The Reductionist Function

The antithesis of the holistic function is the reductionist function which enables us to break things down into their component parts. We observe the brain processes that underlie this global function prominently in fields of science such as when an attempt is made to break all matter down to its subatomic constituents. This function also occurs in philosophical traditions dependent on extreme logical rationalism. Of course, this sense of underlying reality quickly develops into the theological/philosophical concept that the whole comprises, and only comprises, the sum of the parts. When applied to the foundational myths of the monotheistic religions, the result is the notion that God actually comprises the totality of all of the parts of the universe. This is akin to the concept of pantheism in which God is considered to be the universe. Clearly, it seems that the reductionist function would not lead to the notion of a transcendent God. However, reductionism is important in

theology as a way of establishing specific elements of a religion and how they relate to individual behaviors and practices. From the neurotheological perspective, reductionism is also important in helping to determine whether religious and spiritual phenomena can eventually be reduced only to biological processes.

The Quantitative Function

In the most general sense, the quantitative processes of the brain helps to produce mathematics and a variety of comparisons of objects in the world. Similar to the reductionist function, the quantitative function clearly both underlies and supports much of science and the scientific method. Science essentially is based upon a mathematical description of the universe. In terms of philosophical and theological implications, the quantitative function appears to have heavily influenced the ideas of philosophers such as Pythagoras and Baruch Spinoza who often used mathematical concepts such as geometry to help explain the nature of God and the universe. Further, religions throughout history have placed strong emphasis on a certain magic inherent in numbers and mathematics. Numbers abound in the bible and lend their significance in terms of time, people, and places. Various numerologies in the folk practices of Christianity and Islam as well as the gematriot in Judaism all bear witness to the powerful force of the quantitative function to impress the mind with the 'mysticism' of numbers.

The Binary Function

The binary processes of the brain enable us to set apart two opposing concepts. This ability is critical for theology since the opposites that can be set apart include those of good and evil, justice and injustice, and man and God among many more. Many of these polarities are encountered throughout religious texts of all religions. Much of the purpose of religions and their myths is to solve the psychological and existential problems created by these opposites. Theology, then, must evaluate the myth structures and determine where the opposites are and how well the problems presented by these opposites are solved by the myth structure. In particular, this concept, similar to the Hegelian triadic concept of thesis, antithesis, and synthesis, is crucial to the development of theology, because it is ultimately the foundational and soteriological myth, and specifically the power of God, that brings together the problematic opposites.

The Causal Function

The ability of the brain to perceive causality is also crucial to theology. When the causal processes of the brain are applied to all of reality, it forces the question of what is the ultimate cause of all things. This eventually leads to the classic notion of St. Thomas Aquinas's Uncaused First Cause as an argument for God's existence. For monotheistic religions, the foundational doctrines posit that God is the cause of all things. However, this very question of how something can be uncaused is a most perplexing problem for human thought. In fact, theologians, philosophers, and scientists have tangled with causality as integral to understanding the universe and God. Aristotelian philosophy postulated four aspects of causality – efficient

causality, material causality, formal causality, and final causality. These notions of causality led to the understanding of a metaphysic that would later be integrated into traditional Christian theology. The question of causality thus became applied to God to determine how, in fact, God could cause the universe.

However, the problem of causality in the world leads to many other related theological issues. Foremost is the notion of free will. The notion of free will relies heavily on causality, but is also a substantial problem arising in current cognitive neurosciences. Free will is of particular interest to Christian theology, but clearly is important in other religions. Free will is a necessary part of Christianity's foundational myth particularly with regard to the notion of sin, and in particular, original sin. Free will must be maintained in order for someone to be responsible for committing a sin. If everything is predetermined, then a sinful act cannot be ascribed to the person committing that act since they had no choice. If the person freely chooses to commit a sin, then they can be held accountable for that sin. Free will is also the *sine qua non* of ethics. In order for ethics to be viable, free will has to exist. Thus, the notion of causality in relationship to free will becomes an important issue within theology.

Eastern traditions have a slightly different perspective in terms of causality. The Buddhist and Hindu ideologies suggest that causality manifests within the Karma of living beings and that it is critical to escape causality in order to eliminate suffering. The individual ego and material reality are seen more or less as an illusion, with ultimate reality being the true reality in which causality is removed. These traditions suggest that once the experience of ultimate reality is attained and the usual causal relationships are removed, there is a natural flow of right behavior which derives from it and that this type of behavior is what comprises ethics.

Abstract Thought

Abstract thought is tied into the brain structures that underlie language and the conceptualization of categories of things. In some senses, this process derives the essential characteristics of whatever types of objects the brain is working on and presents us with a sense of 'thingness' or 'being' since it generates the basic components of any object and reifies that object as a particular thing. The 'conceptual thingness' of the totality of reality is akin to the Greek concept of Being either in the Platonic or Aristotelian sense. It is the formal and organizing element indwelling matter and giving matter meaning. Thus, the brain's abstract thought processes can yield a profound sense that reality is fundamentally Pure Being. From this profound sense soon arises philosophical/theological concepts such as Plato's *The Good*, Aristotle's *Hylomorphism*, or Aquinas' *Being*, or Paul Tillich's *Ground of Being*, as a description of God. This 'ground substance of being' could be attributed to God. Theology must then be forced to explain how God can be the ground substance of all being while performing other roles stipulated in the foundational doctrines. Certainly issues as to whether God constantly supports existence or simply wound up the clock and lets things work out on their own lies at the heart of important theological controversies. However, it seems that the notion of God as the ultimate being

and supporting all of existence would be a natural consequence as well as constrained by the abstract thinking supported by the brain.

Emotional Values

One of the most important functions of the brain is not cognitive, but emotional. The ability to impart emotional values upon whatever is presented within our experience has a profound influence on our ability to perceive and understand the world. If there is a positive emotional interpretation of all things, then the result is that the entire universe appears to be an overwhelmingly beautiful, blissful, and loving place. When applied to mystical states, the experience may be perceived in a personal manner such that the individual has become one with God or some form of a divine being. When applied to the concepts of theology, God is the primary driver for this overwhelmingly positive affect that pervades the universe. However, this immediately presents important theological problems since the pain and suffering that exists in the world must somehow be explained in light of the overwhelming love of God.

If the universe or God is perceived as emotionally neutral, then all is considered to be impersonal and distant. In terms of mystical experiences, this neutral emotion is likely to be associated with Void Consciousness or Nirvana in which there is an empty, impersonal consciousness that lies at the foundation of the universe. When the neutral emotion is applied to theological or philosophical concepts, it may underlie the notions elaborated upon in existentialism. Existentialism is based on the fact that all we can do is exist and 'feel' our way through. Other than our emotional sense, we can get at no other understanding of that reality. From a theological perspective, the conclusions drawn from the neutral interpretation suggest that God is impersonal or perhaps that there is no God at all and everything simply is without purpose or even meaning. This existential approach is antithetical to most theistic religions; however, theology must contend with the possibility of an existential universe.

It is also conceivable that the universe is perceived with negative emotions. The result is that the entire universe would be viewed as intrinsically evil and horrible. There are very few examples of absolute negative emotions in the mystical literature. The negative emotions applied to theology may help us understand the notion of Hell in which all of existence becomes horrible and terrifying. In Judeo-Christian theology, though, it becomes difficult to explain how such a negative existence can be maintained alongside the generally positive image of God.

Willfulness and Orienting Functions

There remain two other parts of the brain, the functioning of which may relate to theological concepts. These are related to the areas of the brain that support willful or purposeful behavior and the areas that support our ability to orient our self within the world. The willful processes that appear to arise in large part from the frontal lobes might enable us to comprehend a sense that everything is derived from intention or will. The notion that the entire universe is derived from will also leads to several theological implications. Certainly, the will of

God has a prominent place in Western traditions. God used His will to create the universe and to carry out all divine actions. Thus, it could be argued that will is the driving force of the universe; however in religion, it is God's will. That human beings have a part of the universal will also leads to an analysis of free will.

The orienting function of the brain as related to the external universe and God leads to several more theological concepts. The brain continuously attempts to orient our selves with respect to space and time in the world around us. In terms of time, we might experience the sense of eternity or timelessness, which is often considered to be a characteristic of God. Similarly, God can be thought of as being spaceless or infinite even though God can be manifested also in the space that exists within material reality. Thus, the orienting processes of the brain can be useful in understanding certain theological concepts related to time and space.

Reflections on Major Topics of Neuroscience

There are a number of neuroscience topics that directly influence and are influenced by neurotheological research. One of the major issues that neurotheology faces is the problem with the ability to determine the subjective state of the subject. This is also a more universal issue in the context of cognitive neuroscience. After all, one can never know precisely what a research subject is thinking at the precise moment of imaging. If you have a subject solving a mathematical task, one does not know if the person's mind wandered during the task. You might be able to determine if they did the test correctly or incorrectly, but that in and of itself cannot determine why they were right or wrong. The issue of the subjective state of the individual is particularly problematic in neurotheology. When considering spiritual states, the ability to measure such states empirically while not disturbing such states is almost impossible. Hence, it is important to ascertain as much as possible what the person thinks they are experiencing. Neurotheology research can help better refine subjective measurements. Spiritual and religious states are perhaps the best described of all states, and thus, can be an important proving ground for advancing research in the measurement of subjective states.

The problem of consciousness and its ability to arise in the brain is of primary concern in the neurosciences. Consciousness of anything, and particularly self-reflexive consciousness in human beings, is something that has not been adequately elucidated on the basis of current empirical research. Spiritual and religious states often involve altered states of consciousness. And in many circumstances, these states are purposefully manipulated. Those individuals who are most capable of altering their consciousness and enabling that consciousness to affect other parts of their body, might be particularly useful in furthering our understanding of human consciousness.

Another area in which neurotheology could provide important information is in understanding the link between spirituality and health. A growing number of studies have shown positive, and sometimes negative, effects on various components of mental and physical health. Such effects include an improvement in depression and anxiety, enhanced immune system, and reduced overall mortality associated with

individuals who are more religious. On the other hand, research has also shown that those individuals engaged in religious struggle or who have a negative view of God or religion, can experience increased stress, anxiety, and health problems. Research into the brain's responses to positive and negative influences of religion might be of great value in furthering our understanding of the relationship between spirituality and health.

Finally, one of the most important goals of cognitive neuroscience is to better understand how human beings think about and interact with our environment. In particular, this relates to our perception and response to the external reality that the brain continuously presents to our consciousness. Neurotheology is in the unique position to be able to explore epistemological questions that arise from neuroscience. Integrating religious and scientific perspectives might provide the foundation upon which scholars in a variety of disciplines can address some of the greatest questions human beings face.

Reflections on Major Topics of Theology

Of course, neurotheology can also provide new perspectives on theological questions. Theological questions regarding the nature of God, God's existence and relationship to the universe, the nature of spiritual revelation, the soul's existence, and how human beings can be saved through religion all may be approached from a neurotheological perspective. Neurotheology can encourage research to explore the neuropsychological aspects of these issues and help to determine which functions of the brain directly relate to these questions.

Theology attempts to make logical arguments that address these and other issues related to God and God's relationship to the world. A number of 'arguments' have been offered throughout history which include the Cosmological Argument – that since the world exists and since the world cannot come from nowhere, there must be an original or first cause which is God; the Teleological Argument – which suggests that there is a purpose and intelligent design in the universe which must arise from God; the Moral Argument which states that God is what must have provided human beings with their sense of morality; and the Ontological Argument – which states that that if we could conceive of a Perfect God who does not exist, then we could conceive of something greater than God. Since this is impossible, God must exist. What is interesting about each of these arguments, and the many other arguments put forth to prove, or at least support, God's existence, is that they each depend on various functions of the human brain. Thus, the rationale that these arguments provide are highly dependent upon the brain functions that conceive of them.

Is it possible that neurotheology could play a role in the discussion regarding the existence of God? If it can be shown that the human brain definitely creates the concept of God and its elaboration through religion, then neurotheology could provide critical information as to how this might happen. If on the other hand, such a determination can never be made, this will have important implications for assessing the overall intersection between religion and science. A neurotheological perspective would also have to take into consideration the possibility of religion being a cultural construct and must

include other factors such as philosophy, nationalism, racism, myth, and ritual. However, neurotheology must also constantly remind scholars of the limitations imposed on human beings in discerning reality. For example, a brain scan that demonstrates changes in certain structures when a nun experiences being in God's presence could suggest that the brain changes created the experience or that the brain was responding to the actual experience. The scan itself should not be construed as proving the existence or nonexistence of God in this context. Neurotheology should continue to encourage research of brain function during religious experience and seek to determine if a study design might be possible that could more specifically address the proof of God question. The methodological challenges of such a study are clearly very substantial, but it is important to stress the need for careful planning and interpretation of results.

If God does exist, then neurotheology continues to provide information about how human beings relate to God, but there is also the possibility that such studies might determine which ways of relating are 'better' than others. This is a potentially dangerous proposition since the implication is that various religious groups could utilize such information to proselytize, criticize, oppress, or attack other groups. It would seem unlikely that any neurophysiological study could provide the kind of evidence that would support which beliefs are more accurate, but results from such studies might help individuals determine what works best for them. There is probably too much variability in normal human function to clearly differentiate the effectiveness and accuracy of certain beliefs or practices. Nonetheless, neurotheology has the potential to be thrust into the middle of many different kinds of conflicts and anyone seeking to be a scholar in this field should maintain a very cautious position regarding results and interpretations of such studies.

Another interesting aspect of theological concepts is the determination of the attributes of God. God's attributes are sometimes divided into those that cannot be shared with human beings (incommunicable), and those that can be shared (communicable attributes). There is a clear distinction between what the human brain can and cannot perceive. Incommunicable attributes are those related to God being considered: omnipotent, eternal, infinite, omniscient, and omnipresent. Communicable attributes are related to those things that human beings can potentially perceive such as: mercy, justice, wrath, and love. Neurotheological methods could be utilized to better evaluate the human perception of different attributes of God to help assess which are able, or more easily able, to be processed by the brain. One might design a study to help better understand how the brain deals with concepts such as infinity or eternity. God's immanence in the world may also be an appropriate question for neurotheology in the context of how God might be immanent within the human brain. By tracing the effects of religion and spirituality and the brain, one might question whether this informs the discussion regarding how God might affect the brain, such as an interaction actually exists. After all, the ability of God to be immanent within the human brain would seem to be crucial for understanding the relationship between God and human beings.

The nature of good and evil, particularly in relation to God, has great importance for theology since it helps to establish a

sense of morals and also relates to sin and free will. A number of recent brain imaging studies have explored the nature of moral processing in the brain. Questions related to the cognitive and emotional elements of morality can be studied. Of course, one of the pressing concerns most individuals have is why apparently bad things happen to apparently good people. One might question their faith if they feel that in spite of doing everything they are supposed to do, bad things continue to happen to them. The individual might feel that their religious beliefs are not helping and ultimately reject them. In the Bible, the story of Job plays a pivotal place in considering this issue. Theology itself strives to address such questions, but the eventual answer is that these issues are not always understood by the mind of human beings. Human beings can have a basic moral understanding of how to act in the world, but are limited in their ability to determine what is ultimately right and wrong. Research into the brain has also provided an interesting framework from which to consider the topics of sin and free will. Research suggests that almost any person can be driven to immoral behavior when placed within a certain environment. In other words, the human brain is easily manipulated into doing very bad things. Brain research has also explored interesting aspects related to free will as studies have attempted to determine exactly when decisions are made regarding choices and behaviors. Such research may eventually point to the mechanism by which we do have free will – or it might prove that we do not.

Spiritual revelation in the context of neurotheology is akin to the ability of the human brain to receive God. The concept of Revelation thus raises the issue of how do human beings come to have any understanding that God exists and that God wants us to do certain things? Revelation is more religiously, rather than neurologically, oriented. However, there is much that can be considered from a neuropsychological perspective. For example, how are human beings limited in what can be revealed and how is revelation actually experienced? If human beings can only have access to communicable aspects of God, then there are specific limitations that are placed on the ability to perceive and understand God.

Along similar lines, the ability of a human being to be saved is another important theological issue upon which neurotheology might provide an interesting perspective. One such perspective might be the following: salvation should pertain to both the spiritual and material nature of who we are. It might be argued that salvation requires the brain, at least to some degree, in order to help the individual understand what salvation requires and what thoughts, beliefs, and behaviors are associated with salvation. While salvation refers specifically to the soul, a neurotheological interpretation could be commensurate with psychiatry and neurology which continually seek out ways of improving mental life. However, a deeper understanding of the brain's ability to change and to seek religious and spiritual goals might provide highly useful understanding of the concept of salvation.

It should also be clearly stated that whatever limitations the human brain places on our ability to conceive or receive God, this has no impact on whatever is the true nature of reality. Regardless of whether we can perceive causality, abstract concepts, time, or space, has no bearing on the actual nature of the universe and whether or not God exists. Furthermore, one has

to be very careful interpreting neurotheology as being able to comment on whether or not God does exist and whether the brain creates God or God creates the brain. This is an extremely complex question that is often approached with substantial biases from both believers and nonbelievers. The perspective that is most appropriate from a neurotheological perspective is to carefully evaluate all ways of understanding God, including an absence of God, in order to best determine what the brain can know about reality.

However, the very notion that theology pertains more to the human understanding of God is commensurate with the goals of neurotheology. Neurotheology necessarily must explore how the brain can think, feel, and perceive the concept, (or the actual reality) of God. More specific theological analysis can be developed depending on the focus of a particular course. What is important in terms of neurotheology is to observe how the various developments in theology pertain to human perceptions, feelings, cognitions, and behaviors. Any time the focus turns to one of these aspects of theology, a neuropsychological perspective can be added that deepens the understanding of these concepts.

Conclusions

As an emerging field of study, neurotheology has the potential to offer a great deal to our understanding of the human mind, consciousness, scientific discovery, spiritual experience, and theological discourse. However, neurotheological scholarship must tread carefully upon these topics and try to develop clear, yet novel methods of inquiry. All results of neurotheological scholarship must be viewed and interpreted

cautiously. However, if neurotheology is ultimately successful in its goals and principles, it has the potential to revolutionize our understanding of the universe and our place within it.

Nonverbal Communication

Glossary

Nonverbal communication It refers to the sending and/or receiving of information and influence through

the physical environment, appearance, and nonverbal behavior.

Nonverbal communication is a pervasive influence in our interactions and relationships with others. It is important to appreciate that nonverbal communication is not limited to face-to-face encounters. Any communications medium that carries visual and vocal information is a vehicle for nonverbal communication. Thus, the images on television, films, the Internet, and even in photographs are examples of nonverbal communication. In addition, the audio channels of mediated communication provide vocal cues, including pitch, volume, intonation, and pauses that are elements of the nonverbal system of communication. Although linguistic, or verbal, communication is a powerful means of transmitting a wide range of information, nonverbal communication usually has a greater impact on our social contacts with others.

Introduction

As social animals, our survival and general welfare are dependent on communicating with others. Nonverbal communication is a powerful and efficient means of managing these necessary interactions. The popular referent for nonverbal communication is 'body language,' but this is an unfortunate and misleading term. There are two simple reasons for this. Nonverbal communication involves more than the body and it is not a language. The first point will be covered in more detail later in the section on the components of nonverbal communication. Let us look briefly at the second point. Body language is commonly used in describing the mood and motivation of individuals. When a team is losing badly and its prospects look bleak, sportscasters proclaim that 'you can see it in their body language.' The body language of politicians and other public figures is often scrutinized closely. Although appearance and nonverbal behavior can reflect feelings and attitudes, this is not 'body language.'

To clarify, let us take a brief look at language. There is a consistent vocabulary with language. In contrast, what does a particular smile mean? It might indicate that someone is pleased to see you. The same smile could simply mean that someone wants to be friendly or, perhaps it is a sign of appeasement. The meaning of a particular nonverbal behavior, unlike language, is conditional. That is, it is dependent on the social and behavioral context in which it is issued.

There is, however, more to language than just semantics. With language, there is also a syntax determining how words and phrases are combined in usage. There is no syntax for nonverbal communication. American Sign Language (ASL) is an example

of a language that is not spoken. ASL does have a vocabulary, with signs carrying specific meaning, as well as a syntax. Even though ASL engages signing, it functions like a verbal language, and shares the identical neural basis in the brain. ASL and verbal language are primarily controlled by areas in the left hemisphere of the brain. In contrast, most of the sending and receiving of nonverbal signals is controlled by areas in the right hemisphere of the brain. Speech and sign language are similar in function, but different from nonverbal signals such as gaze, facial expression, interpersonal distance, and touch. Thus, nonverbal communication is not body language.

Characteristics of Nonverbal Communication

The distinctiveness of nonverbal communication is particularly clear when compared to verbal communication. A first and basic characteristic of nonverbal communication is that the nonverbal channel is always 'on' in social settings. That is, as long as there is some visual, auditory, tactile, or olfactory information, the nonverbal channel is open. Even when there is no movement, the physical appearance of the interactants still registers and affects the judgments of others. In contrast, verbal communication is intermittent and typically involves partners taking turns. Even amidst animated conversation, the verbal channel is sometimes closed as people pause or reflect about others' comments. Of course, just because the nonverbal channel is always open does not mean that we process everything from our social environments. Attention is selective, and we preferentially notice events that affect us and our welfare.

A second characteristic of nonverbal communication is that the sending and receiving of nonverbal signals may occur simultaneously. In fact, this is critical in coordinating our behavior with those around us. This happens both in conversational exchanges and in situations where individuals are simply sharing a common presence, with no intention of mutual interaction. For example, in choosing a seat in a waiting room or standing in line at the grocery store, we make subtle adjustments to others in the setting.

A third characteristic of nonverbal communication is that most nonverbal messages are sent and received automatically and outside of awareness. In contrast, verbal communication usually requires some attention in both speaking and listening. Of course, we can apply effort in thinking about how to manage our own behavior (sending side) and how to make sense of a partner's behavior (receiving side), but this is usually unnecessary. That this kind of concentration is optional reveals a

fourth characteristic of nonverbal communication – it is cognitively efficient. As a result, the routine give-and-take of nonverbal communication drains little from our cognitive batteries, even when the verbal stream has become tiresome.

Components and Patterns

The nonverbal system of communication includes components that are both static and dynamic. That is, some elements are relatively unchanging over the course of an interaction, although others are highly variable. To speak of the ‘elements’ of nonverbal communication may be misleading, however, because how each element functions is tied fundamentally to the other elements in play. In other words, nonverbal communication typically occurs as a coordinated pattern of elements, not simply an additive package. A smile may mean one thing if the smiler is holding a gift, and another if he is wielding a knife. Thus, this section focuses first on the primary component elements of nonverbal communication, and then turns to the patterns that bear the intent and the impact.

Static Features

Every face-to-face interaction occurs in a particular context. The *design and arrangement* of settings are basic factors affecting our communication with others. Something as simple as placing chairs farther from, rather than closer to, one another means that people will probably make eye contact more and speak up when they interact. In the Western business world, powerful individuals in an organizational hierarchy typically have large, well-furnished offices with scenic views. In contrast, lower level employees may simply share a large bullpen area or be pigeon-holed in partitioned cubicles. The particular furnishings and arrangement of executive offices also reinforce the power and status of the people in the top echelon of an organization. Large desks with visitor chairs directly opposite the executive’s chair keep the subordinates at a greater distance than is common in casual interactions outside of the business setting.

The design and arrangement of furniture are also important in our homes. For example, important visitors might be directed to a well-furnished living room rather than to the den or the kitchen. The latter choices may be more common for good friends or family members. In addition, the physical contents of personal territories generate expectancies that facilitate interactions between occupants and visitors. The allocation of time may also be important in setting the context of interaction. In some countries, showing up on time for a meeting implies interest and reliability; in other countries, it implies desperation. Time as a resource is also manipulated by the physical setting. Furniture in fast-food restaurants is engineered to be uncomfortable enough that patrons will finish their meals promptly and interact minimally; cushier furniture in fancier restaurants sets the stage for slower meals and extended interactions. The availability of alcoholic beverages both widens the domain of possible interactions, and signals that the wider domain is tolerated. As a result, even before an interaction begins, the setting imposes physical constraints and social norms on communication.

Next, *appearance characteristics* provide important information affecting impressions and communication. Although

we often hear ‘don’t judge a book by its cover,’ automatic judgments of others are inevitable and often useful. For example, physical appearance provides information about sex, race, and age. Clothing style can also tell us something about a person’s social class, ethnicity, religion, and even occupation. We are also sensitive to appearance because it indicates whether others are similar to or different from us. Although appearance characteristics are imperfect indicators of what others are really like, the automatic judgments they precipitate are useful and relatively accurate. Nevertheless, appearance can also be strategically modified to create desired impressions. Some modifications may be as simple as changing clothing or grooming to increase attractiveness or perceived dominance. Politicians and actors often pay considerable sums of money for ‘makeovers’ that change their covers but not what they hold inside. Other interventions, such as exercise, weight loss regimens, and plastic surgery require a greater investment of time and/or money, but they also indicate how important appearance can be.

Dynamic Behaviors

Although the fixed features of the setting and interactants establish the context for interaction, the dynamic behaviors are the fluid components in the give-and-take of nonverbal communication. Perhaps the most basic elements are *distance and orientation*. Even though the fixed features of design and arrangement of settings affect how individuals space themselves, distance and orientation are still flexible, especially in standing interactions. Distance and orientation are important because they contribute to the overall involvement level in interactions and affect the other dynamic behaviors. For example, as partners are farther apart in interactions, they tend to take a more directly facing orientation, increase gaze, and speak more loudly. In contrast, at closer distances, for example at 0.5 m, partners are typically less directly oriented toward one another, gaze and speech loudness decrease, and touch is possible. Thus, various component behaviors operate as a system, with some behaviors compensating for changes in other behaviors.

Next, *gaze* is fundamentally important, because most of our information about others comes through the visual channel. Gaze also facilitates turn-taking in conversations and provides feedback in face-to-face interactions. In addition, gaze changes can modify the meaning and impact of a message. In general, holding gaze increases arousal in the recipient and increases the impact of a verbal message. The meaning of a particular look, however, depends on more than just the amount of gaze. That is, the impact of gaze is also a product of the facial expressions that frame the gaze and the accompanying posture. This is another example of how separate behaviors combine in shaping the meaning of nonverbal messages.

Facial expressions are particularly rich sources of information. In interactions, most of our visual attention is directed at others’ faces. We also manage our own facial expressions more than we do our other behavior. The research of Paul Ekman and his colleagues suggests that universal patterns in the sending and receiving of facial expression are the hardwired product of natural selection. Much of this research contends that facial expressions are primarily signals of emotions, including happiness, sadness, anger, fear, disgust, and surprise. A different approach, Fridlund’s behavioral ecology theory, proposes

that facial expressions are signs of intentions, not emotions. Thus, facial expressions signal what people are likely to do, not how they feel. For example, an 'angry' face is not actually a reflection of underlying anger, but a threat. A smile is not a sign of happiness, but an indication of wanting to cooperate and be friendly. Facial expressions also complement and qualify verbal comments. When there is inconsistency between the words and the expression, listeners might second-guess the intent or candor of the speaker.

Next, *posture and movement* also provide information about a person's feelings and intentions. An individual's posture can signal interest, respect, and openness toward a partner, or the opposite. For example, a closed and rigid posture is less inviting than a more open and relaxed one. Posture differences can also reflect contrasts in power and status. Usually, more powerful individuals are more relaxed and less vigilant about their social environment than are less powerful individuals. People also differ in how quickly they move and whether they are graceful or awkward, coordinated or clumsy.

Gestures are specific movements of the hands, arms, and even the head that merit distinction from the broader movements just described. Although gestures are usually closely linked to speech, they can also be initiated independent of speech. Nevertheless, the close relationship between gestures and speech suggests that many gestures are really part of the verbal system of communication. Different types of gestures may be distinguished on the basis of their functions. First, *emblems* are gestures that have a specific verbal translation and, like language, their meanings can vary across culture. For example, the 'OK' sign in the United States is an obscene gesture in some countries. Next, *illustrators* depict their linguistic referents. For example, a person might make a downward movement with her hand in referring to a book on the lowest shelf of a bookcase. Finally, *regulators* are pacing gestures that are timed to identify particular referents in a verbal list. Thus, a speaker may quickly raise and then lower a hand as he says 'the first point . . .' A similar gesture may be repeated as he continues talking about subsequent points. Regulators help speakers in presenting their messages fluently, and they benefit listeners' ability to store and recall the verbal messages later.

Next, *touch* is a basic component in nonverbal communication, in all kinds of relationships. Contrary to the teaching of early behaviorists like John B. Watson, tactile stimulation is critical to the physical and psychological health and welfare of infants and young children. The routine touch involved in feeding, changing, bathing, comforting, and playing with infants is an important source of stimulation, and it facilitates bonding between parents and children. Touch is important in other relationships in signaling affection, support, and comfort, but touch is also a component in intense hostile and aggressive encounters. The type and frequency of touch between individuals are also signals of the closeness of relationships. The norms regarding touch vary across culture, and sometimes inappropriate touch leads to very negative impressions. For example, butt-slapping in some cultures is harmless flirtation, while in others it is sexual harassment. Even in one culture, a punch to the shoulder can be a sign of solidarity, yet in another context it can be considered an assault.

Vocal behaviors are characteristics of speech that are distinct from its content or meaning. Changes in tone of voice and

emphasis can modify the meaning of comments, as in the case of sarcasm. More generally, pitch, loudness, emphasis, tempo, and pausing are all vocal (not verbal) characteristics that can indicate something about speakers and their feelings and motivations. The voice also affects first impressions, including judgments of attractiveness and dominance.

Finally, the importance of *olfactory cues* is evident in varying cultural rules about cleansing and grooming, and in the marketing of soaps, shampoos, deodorants, colognes, perfumes, and air fresheners. People spend billions of dollars every year on products to remove unpleasant odors and replace them with more desirable ones. Some natural scents, called pheromones, may not even register consciously, but still affect sexual attraction and even fear. This is another instance where nonverbal communication operates automatically and outside of awareness in affecting judgments and behavior.

Patterns of Behavior

Identifying the component cues and behaviors is only the first step in appreciating the complexity of the nonverbal system of communication. Because nonverbal communication operates in a holistic fashion, it is important to move beyond elemental components to overall patterns. We cannot possibly consider the countless permutations of subtle changes in the various components, and there is no formula for the weighted combinations of elements that determine particular meanings. Nevertheless, we can find some common themes across the various components that shape the meaning of integrated patterns of nonverbal communication. Two-pattern dimensions are particularly important.

The first dimension is *involvement* or immediacy. In general, increased involvement is indicated by a closer distance, touch, gaze, greater facial expressiveness, a more direct-facing orientation, forward lean, gesturing, and vocal expressiveness. Higher levels of involvement reflect greater interest in our partners. For example, friends are usually more comfortable with high levels of nonverbal involvement than are strangers. Nevertheless, high involvement may also occur in negative situations, such as escalating physical conflict between individuals who may be yelling at each other while only inches apart. In both situations, involvement is high, but there is no difficulty in distinguishing the positive from the negative encounters.

Involvement also provides a kind of metric for identifying the intimacy of relationships. Two people walking hand-in-hand and sharing a high level of gaze are more likely to be seen as a couple than are two others who happen to be walking next to one another. Maintaining a comfortable level of involvement is usually achieved automatically and outside of awareness. Nevertheless, a stranger's stare or looming approach can be very uncomfortable, and might result in compensation in the form of increasing distance, decreasing gaze, or even leaving the setting. At the other extreme, avoidance by a good friend who keeps a distance and makes minimal eye contact is also noticeable and uncomfortable. In such a case, one might try to restore involvement by moving closer and even initiating touch as a way to determine the reason for the avoidance.

Of course, involvement can be deliberately managed in order to influence a partner or even to create a particular

impression for others in the setting. We understand that the salesperson's solicitous behavior does not indicate how much he likes us, but rather how much he wants the sale. In contrast, two people who are trying to hide a romantic relationship might minimize their mutual involvement around others.

A second pattern dimension is *disposition*. Because we are social animals and interact with a wide variety of people, we have to make sense of their behavior quickly and they have to make sense of ours. In social settings, we have to signal our intentions and motivations to others and, at the same time, forecast what those around us are likely to do. Particularly important in these processes are the expressive reactions of our faces and bodies. Although facial expressions provide the most detailed information, they are complemented by other behaviors, including distance, gaze, posture, muscle tension, and speed of movement. For example, a friendly greeting is easily distinguished from a hostile threat. We are the products of those hominid ancestors who made such judgments quickly and accurately.

Determinants

Although specific instances of nonverbal communication may vary widely, great consistencies abound as well, as a function of biology, culture, gender, and personality. Much of social interaction is ritualized. For example, greetings, departures, flirtations, solicitations, and a variety of ceremonies transpire with little or no conscious control. In fact, they typically proceed more smoothly if people do not think about them or vary from the prescriptions. This section examines how the basic determinants constrain stable patterns of nonverbal communication.

Biology

From the time of our hominid ancestors, a few million years ago, our species has been shaped by natural selection. Our biological evolution has modified not only on our physical characteristics and physiologies, but also our nonverbal communications. Even the development of language could not replace the efficiency of nonverbal communication in managing the immediacy of our face-to-face interactions. To suggest that biology plays a role in nonverbal communication does not mean that we all react in an invariant, programmed fashion. To the contrary, natural selection breeds diversity as well as communality, and part of the human evolutionary heritage is our plasticity – including our ability to adapt quickly via cultural transmission.

First, because we are social beings, close attention to others is highly adaptive. The nonverbal reactions of others alert us not only to their intentions, but also to changes in the immediate environment. For example, we are wired to target those appearance cues and behavior that can signal threat on one hand or cooperation on the other. This information, in turn, facilitates an appropriate response to changing circumstances.

Next, appearance characteristics and nonverbal behavior are also critical in mate selection. Because both males and females have no direct information about a potential mate's reproductive value, they have to rely on appearance and behavioral cues that signal information about a partner's

characteristics. For example, males' typical preferences for younger, shapely females with symmetrical features, clear skin, and lively behavior correlate with both better health and greater fecundity. In turn, females' typical preference for somewhat taller, older, dominant-looking males with resources reflects her interest in securing a mate who can provide for the welfare and security of both her and her offspring.

Survival of our species also requires long-term, special care of young children. Beyond food and shelter, children need love, stimulation, and security for successful development. One critical signal prompting the appropriate, nurturing care is the baby-face appearance of infants and young children. That is, the large forehead, small rounded chin, and big eyes of infants are powerful stimuli that promote adult concern and care. This effect even generalizes to baby-faced adults who are judged as more innocent, helpless, and less responsible than are more mature-looking adults.

Culture

Our shared biology provides the foundation for basic communalities in nonverbal communication, but different physical and social environments increase variability in nonverbal communication across culture. Many of these differences in nonverbal communication reflect basic cultural dimensions. For example, the *individualism–collectivism* dimension is relevant for cultural differences in expressive behavior. Individualistic cultures, including the United States and most of Western Europe, tend to emphasize the distinctiveness of an individual and promote a focus on the self, personal achievement, and fulfillment. In contrast, collectivistic cultures, including many East Asian countries, tend to emphasize one's identity within a larger social group, and interdependence with that group. Thus, in a situation in which one person is walking ahead of a group, the individual is likely to be seen as a trailblazer by the Westerner, and a glory-hound by the East Asian. Because most people from individualistic cultures are predisposed to value assertiveness and independence, they are more likely to show negative expressions in social situations and are better at identifying them in others than are people from collectivistic cultures. A second dimension, *power distance*, reflects the degree to which power, prestige, and wealth are unequally distributed within a culture. Thus, high power-distance cultures, including Mexico, Colombia, Venezuela, and India, have a clearer hierarchy of power and influence, whereas low power-distance cultures, including Great Britain and Germany, are more egalitarian. In general, a lower power person is likely to show greater respect and control in interacting with a higher power partner in a high power-distance culture than in a low power-distance one. In terms of nonverbal communication, this might be evident in efforts to keep greater distances from high-power others and to minimize negative facial expressions.

The anthropologist Edward Hall proposed that cultures also differ in the degree to which communication is relatively explicit or implicit. Specifically, in *low-context* cultures, most information is transmitted in a relatively direct and explicit fashion through language. As a result, ambiguity in the meaning of messages is minimized. People mean what they say. In contrast, in *high-context* cultures, there is greater ambiguity in messages because there is an increased emphasis on both the

situational cues and the nonverbal behavior of individuals. Thus, in high-context cultures, nonverbal communication plays a larger role in understanding the meaning of interactions. In general, East Asian countries are typically on the high-context end of the continuum, whereas the United States and northern European countries are on the low-context end.

Although the broad contrasts on these dimensions provide some insight into cultural differences, some caution is warranted. Most cultures are not at the extremes of these dimensions, and within a particular society, people vary considerably. Not everyone possesses the cultural characteristic; members of any culture differ in the degree to which they identify with the culture. Differences can and do occur between younger and older generations, and between urban and rural dwellers. Finally, cultural norms are not immutable, especially in this age of global communication and the increased ease of international travel.

Gender

In general, women are more sensitive on the receiving side of nonverbal communication than are men. This may be the result of women simply noticing more or being better at actually forming judgments, or some combination of both. This female advantage in reading others may be the product of both natural selection, and social norms found in most cultures that emphasize women's sensitivity to and caring for others. On the sending side, women's nonverbal behavior is usually more easily read than that of men. Nevertheless, in many cultures it is less appropriate for women than for men to threaten or show anger explicitly.

Next, compared to men, women are usually more comfortable with higher levels of nonverbal involvement in interactions, especially in same-sex interactions. This might be seen in women's closer distances, greater gaze, and occasional touch with same-sex partners. Women also smile more frequently and receive more smiles than men, a sex difference that is probably facilitated by females' higher level of gaze. Smiles are primary signals for getting along with others, and women are generally more invested in their social contacts than men are. In addition, because these sex differences in smiling align with the expectation that women are more sociable than men, smiling may also reflect impression management. Of course, these patterns may be reversed if women are interacting with male strangers and greater reserve is appropriate.

Personality

This section discusses a few of the personality traits that predict distinctive patterns of nonverbal communication. One set of related traits – introversion, social anxiety, and affiliation – all reflect a broader *social approach–avoidance* dimension. That is, introverted, socially anxious, and low-affiliation individuals constitute the 'social avoidance' end of the continuum, whereas extroverted, nonanxious, high affiliation individuals constitute the 'social approach' end. On the sending side of nonverbal communication, social-avoidant individuals typically keep greater distances from others, make less eye contact in interactions, are less expressive, and talk less than social-approach individuals. On the receiving side of nonverbal communication, social-avoidant individuals are less sensitive to

others' nonverbal signals, and less accurate in social judgments than are social-approach individuals. The decreased judgment accuracy of social-avoidant individuals may follow directly from their decreased gaze, which restricts the amount of information they have available.

A second dimension, *field dependence–independence*, identifies contrasting perceptual, cognitive, and interpersonal styles. Field-dependent individuals are more influenced by broader visual and social contexts than are field-independent individuals. For example, on a perceptual task such as identifying an embedded hidden figure, field-dependent types do not perform well in identifying the figure. That is, they are more dependent on and affected by the surrounding visual context than are field-independent individuals. The same holds for social behavior, with field-dependent individuals being more dependent on, or connected to, other people. Thus, field-dependent individuals prefer closer distances and greater gaze in interactions than do those who are field-independent. The social connectedness of field-dependent individuals is also reflected in higher levels of behavioral mimicry in interactions.

The next dimension, *self-monitoring*, is characterized by the tendency for motivated self-presentation, sensitivity to changing situational norms, and the ability to modify one's behavior for different kinds of goals. That is, high self-monitors are more skillful at reading social situations and more flexible in managing their own behavior than are low self-monitors. High self-monitors are social chameleons who can adapt their behavior to fit the situation and influence others. In contrast, low self-monitors are less sensitive to the changing situational demands and less flexible in their behavioral styles. In general, successful politicians, actors, and salespeople are likely to be high self-monitors.

Sometimes, the extremes of personality veer toward frank psychopathology, with consequences for nonverbal communication. In the syndrome of paranoia (seen in disorders such as schizophrenia, mania, stimulant abuse, posttraumatic stress disorder, and in paranoid personality disorder), sufferers may be overly attuned to the nonverbal behavior of others. They may interpret any nonverbal behavior as signifying malicious intent. They may further interpret the behavior as intended toward them even when it is not, such as interpreting the smirk of a TV news commentator as a personal comment (this is known as a *delusion of reference*). At the other extreme lie the autistic spectrum disorders (ASD). Those with these disorders are often insufficiently attuned to the nonverbal behavior of others. In one variant of ASD known as Asperger's syndrome, individuals can be verbally quite articulate but nonverbally clueless. Such ASD examples point to some degree of 'encapsulation' of nonverbal perceptual skills from general verbal fluency.

Overview of Determinants

Biology, culture, gender, and personality are the primary determinants of stable patterns of nonverbal communication. The combination of these factors constitute the 'baggage' that we all bring to social settings, constraining variability in the sending and receiving sides of nonverbal communication. Nevertheless, we are affected also by the specific situation, our individual goals, and our interaction partners. Although these determinants predispose a person toward relatively predictable and even

stereotyped patterns of nonverbal communication, changing circumstances modify the patterns. Thus, the sending and receiving sides of nonverbal communication change across settings and circumstances, as nonverbal communication operates in the service of different functions.

Functions

Providing Information

In social settings, we continuously send and receive information. Appearance characteristics signal basic information regarding gender, race, age, and fitness. Clothing, hair style, grooming, tattoos, and jewelry are frequently indicators of socioeconomic status, group membership, and even personal interests. Behavior provides additional information about personality, attitudes, feelings, and even motives in the situation. It is useful to signal this information to others and to receive it from them. We are the products of those distant ancestors who were effective in their expressive behavior and in gauging the reactions of others.

Automatic judgments are inevitable and relatively accurate. We are not wired to assimilate information and simply suspend judgments until a careful, reasoned assessment occurs. Of course, sometimes rapid judgments are inaccurate and the appropriate corrections require additional reflection. If we are not sufficiently motivated to apply the effort to make the correction, or we are distracted and do not have the necessary cognitive resources, corrections are less likely.

The earlier biology discussion highlighted the importance of appearance characteristics in mate selection and care of offspring. More generally, appearance also informs us whether others are relatively similar to or different from us. Typically, we are more comfortable with others who are more similar to us, and we like them better than those who are different. Although appearance cues are imperfect indicators of what people are really like, they facilitate expectations and adaptive reactions to others.

Even the briefest encounters provide behavioral information about others. Thin slices of behavior, lasting only a few seconds, are sufficient for relatively accurate judgments. In as little as 5–10 s, perceivers make accurate judgments of relationships, status, and competition. In everyday settings, facial expressions, body tension, and speed of movement are critical behaviors that signal how others are likely to act. Finally, behavior can even be self-informing. That is, sometimes we ‘discover’ how we think or feel only after behaving. For example, when we meet someone new, we might realize that we are more engaged and expressive with this person than with others and conclude that we like her. Thus, in some situations, behavior happens first, and it affects how we think and feel later.

Regulating Interaction

Nonverbal communication plays a central role in the routine give-and-take between people in social settings. But interactions involve more than simply having conversations. Sociologist Erving Goffman used the term ‘focused interactions’ to identify instances where people were having conversations, but recognized that interaction often occurs without conversation. People can be interacting when they simply share a close presence with others and accommodate their behavior to them. For Goffman, these were ‘unfocused interactions’; they occurred without

words. Examples of unfocused interactions include standing in line at the grocery store, picking a seat in a half-filled waiting room, or passing by strangers in the mall.

In unfocused interactions, we negotiate our position and relationship with others entirely through our nonverbal behavior. For example, we might quickly glance at a stranger as we enter an elevator, but then avoid gaze for the rest of the ride. In this way, we recognize his presence but then grant him privacy. There are, of course, cultural differences in how unfocused interactions are managed. For example, in Japan, pedestrians approaching one another on the sidewalk are likely to show complete avoidance. In contrast, in the United States, pedestrians frequently glance at the approaching stranger and, occasionally, smile and nod.

In focused interactions, nonverbal communication facilitates the efficient give-and-take of verbal exchanges. Because the momentary goals of speakers and listeners are different, their patterns of nonverbal communication are also different. One of the basic contrasts is that speakers gesture but listeners do not. Speakers usually gaze less at listeners than do listeners at speakers. This is probably due to the greater cognitive demand involved in speaking than in listening. Thus, gaze avoidance may facilitate speakers’ retrieval of verbal content. In fact, speakers occasionally break gazing at the partner as they are searching for the appropriate word. Protracted gaze toward the listener by the speaker is used for emphasis, and prolonged gaze aversion by speakers can signal anxiety, subordination, or indifference. Nevertheless, speaker gaze is important in reading the reactions of the listener and is more likely at the end of a speaker’s turn. Listeners gaze relatively more at speakers because part of the verbal meaning lies in speakers’ expressive behavior. Listeners often respond to speakers’ comments with head nods that signal understanding or agreement. Sometimes, listener vocalizations, such as ‘yeh,’ ‘uh-huh,’ or ‘OK’ substitute for a head nod. These brief listener vocalizations are not attempts to initiate a speaking turn, but simply reinforce speakers’ comments. The absence of listener feedback can be unsettling to a speaker and result in hesitations or rephrasings by the speaker in order to produce the listener’s feedback.

Finally, nonverbal communication is critical in the process of taking turns in conversations. As speakers end a turn, the verbal cue of finishing a grammatical clause is complemented by several nonverbal and vocal behaviors. Among these changes are the following: (1) the cessation of gestures; (2) a change in vocal intonation, particularly a pitch drop on the last few words; (3) decreased loudness on the last few syllables; (4) a longer pause, that is, longer than the brief pauses in the middle of a turn; and (5) an increased probability of listener-directed gaze. Listeners who are about to take a turn typically show the following changes: (1) an audible inhalation; (2) a postural readjustment and start of a gesture; and (3) a louder vocalization, that is, compared to the reinforcing listener vocalizations, such as ‘yeh’ or ‘OK.’ Thus, our face-to-face contacts, in both unfocused and focused interactions, are primarily regulated by nonverbal communication.

Expressing Intimacy

Intimacy is an important element in most relationships. In general, as relationship intimacy increases, so does the typical

level of nonverbal involvement between partners. For example, good friends are more comfortable with high levels of nonverbal involvement than are mere acquaintances. This might take the form of a close approach, touch, gaze, and expressiveness, but not always. Situational constraints and norms may well limit the appropriate levels of involvement. Lovers behave differently in a business meeting than at a party. In addition, intimate relationships are sometimes characterized by the opposite of high involvement, specifically, ignoring one's partner. Thus, long-term partners may be quite comfortable, on occasion, to ignore one another; entire dinners can occur without a word between them.

It is common to assume that one person's feelings for, or commitment to, a partner determines behavior. This might be described as an inside-out link; greater underlying attachment (feelings and attitudes) precipitates increased nonverbal involvement (external behavior) with a partner. The rapport that is characteristic of people in intimate relationships is also reflected in increased behavioral coordination. This is evident in behavioral mimicry and synchrony in the timing of partners' movements, and, for example, in the ability to finish each other's sentences. Typically this happens automatically and outside of awareness.

The intimacy-behavior link is, however, a reciprocal one; either one can determine the other. In the case of first meetings, appearance affects impressions and initial liking, but the give-and-take of behavior can modify the first impressions. For example, a person might notice that she's gazing at her acquaintance and smiling more than usual. She might also lean forward and gesture expressively as she is talking. In turn, her acquaintance might respond in turn, with increased behavioral mimicry as a result. Thus, this pattern of reciprocated high nonverbal involvement and mimicry evolves over the course of an interaction, and the interactants 'discover' that they like each other.

Exercising Influence

Influence is present in all kinds of situations, including face-to-face interactions and various types of mediated communication. In general, exercising influence might be described as goal-oriented behavior initiated to change the behavior, attitudes, and feelings of others. Like many of our everyday activities, influence can operate automatically. Sometimes the goal-oriented behavior, and even the goals themselves, operate outside of awareness. There are several different categories of nonverbal influence. First, nonverbal communication is present in instances of *power and dominance*. In the business world, powerful people typically control larger territories, have greater privacy, and more expensive furnishings. These setting features are not only perquisites of powerful people, but also status cues that help regulate contact with others. In addition, powerful people usually have the prerogative of initiating either high involvement in the form of close approaches, high levels of gaze, and touch – or the opposite, in ignoring those with less power. In contrast, when low-status individuals interact with high-status partners, they have to be more careful in attending to the high-status partner and minimizing negative expressions. Finally, high-status individuals are typically more relaxed in interacting with low-status partners than are low-status individuals with high-status partners.

Second, nonverbal communication is important in providing *feedback and reinforcement*. A smile, pat-on-the-back, or a simple head nod can signal approval to a partner, even without a verbal comment. These may act as reinforcers that strengthen the preceding behavior and increase its frequency in the future. This may be particularly important in influencing the behavior of young children, because for them nonverbal signals may have greater impact than mere words. Third, nonverbal communication is important in *compliance and persuasion*. Extensive research shows that high involvement in the form of a close approach, increased gaze, and touch increases compliance on simple, low-level requests. This might happen with securing small donations or getting people to sign a petition. In such cases, the high involvement may increase stress on the target, and compliance is the easiest way to end an uncomfortable interaction. Changing attitudes, the essence of persuasion, is more complicated and requires an opportunity to reflect on the message and evaluate its merits. Because high involvement is stressful and distracting, it interferes with cognitive processing and is less effective than moderate involvement. Thus, different tactics are effective in gaining simple behavioral compliance versus longer term persuasion. Finally, nonverbal communication is critical in *deception*. Effective deception requires that liars manage their nonverbal behavior to be consistent with the verbal lie. Sometimes successful detection of deception is the result of targets noticing the inconsistency between the verbal statement and the accompanying nonverbal behavior. In some cases, these discrepancies are present in the facial expressions and gestures of liars, especially when the liars are themselves conflicted about lying and betray signs of conflict. Even when these discrepancies are evident, most people are only slightly better than chance at detecting lies. Furthermore, our perceived confidence in detecting lies is unrelated to actual accuracy in detection. This is another example of our having relatively little insight into our own judgments.

Managing Impressions

Nonverbal communication is also critical in impression management. People can change their appearance, clothing, and grooming, and most importantly, their behavior, in order to create particular images or identities. In some cases, people invest considerable time, energy, and resources to modify their appearance. This might include plastic surgery, weight loss programs, exercise, hair replacement, and other interventions, all designed to fashion a more desirable appearance. Behavioral changes are more common as people routinely enter settings with conscious or unconscious goals of creating particular impressions in others. For example, in a job interview, applicants are likely to be more expressive, attentive, and responsive to the interviewer on the sending side of nonverbal communication, than they would be in casual conversation. In addition, on the receiving side of nonverbal communication, applicants will attend closely to any nonverbal signs of approval or disapproval from the interviewer, and they will adjust their behavior accordingly. Similar self-presentation efforts might be initiated on first dates, interacting with one's supervisor, and meeting important people.

Managing impressions is particularly important in politics, and election outcomes are often affected by the appearance

and behavioral style of candidates. Actors and politicians are well known for hiring expensive media consultants to help them tailor and refashion their images. Defense attorneys in high-profile cases hire such consultants to 'make over' their clients to increase the odds of acquittal. Sometimes impression management requires an accomplice in creating a pair or couple identity. For example, at a family gathering, a feuding couple might try to sustain the image of a happy marriage by being attentive and affectionate, even though they can barely stand one another for the moment.

Summary

Nonverbal communication is pervasive in both face-to-face and mediated communication. Because much of nonverbal communication operates automatically and often outside of awareness, it provides an efficient means of regulating our social contacts with others. The determinants of biology, culture, gender, and personality shape stable patterns of nonverbal communication. Nevertheless, the flexibility and utility of nonverbal communication are evident in several distinct functions, including providing information, regulating interaction, expressing intimacy, exercising influence, and managing impressions. Thus, the complementary behavioral and social judgment tracks of nonverbal communication constitute an indispensable system for navigating our social worlds.

Glossary

Classical conditioning Also known as Pavlovian or respondent conditioning; a type of learning in which a neutral stimulus is repeatedly paired with a stimulus that naturally elicits certain responses until the neutral stimulus acquires the ability to elicit the same responses.

Compulsion A ritualistic, stereotypic, or repetitive action generally performed to reduce anxiety associated with an obsession; a compulsion (or ritual) is generally perceived as excessive or irrational, although individuals find the behaviors difficult to resist.

Ego-dystonic Refers to thoughts or behaviors that are inconsistent or in conflict with how one views oneself; ego-dystonic thoughts are experienced as intrusive and unwanted.

Ego-syntonic Refers to thoughts or behaviors that are consistent with how one views oneself.

Negative reinforcement A form of operant conditioning; a process in which a behavioral response increases in frequency because of the avoidance, escape, or removal of an aversive stimulus from the environment.

Obsession A thought, image, or urge that is intrusive, unwanted, persistent, and uncontrollable; an obsession is generally perceived as irrational, excessive, and distressful.

Obsessive–compulsive disorder A syndrome in which obsessions and compulsions occur with significant frequency, duration (at least 1 h day^{−1}), or intensity to impair social, occupational, or family functioning or cause significant psychological distress.

Operant conditioning A type of learning that uses consequences to modify the occurrence and form of behavior.

Nature of Symptoms

Obsessive–Compulsive Disorder

Obsessive–compulsive disorder (OCD) is characterized by the presence of obsessions and/or compulsions. Obsessions are recurrent ideas, images, or impulses that are unwanted, intrusive, difficult to control, and experienced as ego-dystonic. Obsessions can present in a variety of forms, including images, urges, and fears. Obsessional images are vivid scenes that are often violent or sexual in nature (e.g., images of rape or molestation). Obsessional urges are strong impulses to carry out certain inappropriate behaviors (e.g., shouting obscenities at church). Obsessional fears are excessive worries about potential danger (e.g., fears of contamination or harm). Because of the intrusive and unwanted nature of obsessions, individuals often feel compelled to control them through a variety of strategies, including dismissing, suppressing, or neutralizing the obsessions through the use of compulsions.

Compulsions, or rituals as they are commonly called, are repetitive, stereotypic, and intentional behaviors and cognitions (i.e., thoughts, images) performed in response to an obsession to prevent or reduce emotional distress. Compulsions that involve cognitions are referred to as mental rituals. Both forms of compulsions are distinguished from other forms of repetitive behavior, such as addictions or impulse-control disorder, in that they are not performed to increase pleasure or gratification. Examples of compulsions include excessive washing or cleaning and repeated checking. Many individuals also perform mental rituals, such as counting or praying, to undo or neutralize intrusive thoughts.

The Diagnostic and Statistical Manual, Fourth Edition, Text Revised (DSM-IV-TR) emphasizes the functional link between obsessions and compulsions, whereby obsessions cause anxiety or distress, and compulsions are overt (i.e., outward behaviors) or covert (i.e., mental) actions that are performed to reduce the anxiety or distress. Although a limited number of people with OCD may have only obsessions or compulsions, over 90% of individuals with OCD experience both. In fact, when mental rituals are included, only 2% of individuals report experiencing ‘pure’ obsessions (i.e., obsessions without corresponding compulsions).

To meet diagnostic criteria, individuals must experience either obsessions or compulsions. These obsessions and/or compulsions must cause marked distress and interfere substantially with daily functioning. In addition, individuals must recognize that the obsessions or compulsions are excessive and unreasonable, although the level of insight experienced varies. Although not formally part of the diagnostic criteria, avoidance behaviors are also quite common. Individuals with OCD often avoid various situations or events so as not to trigger the obsessions and/or compulsions.

There is considerable variability in the expression of OCD symptoms. However, studies have found that certain obsessional themes and types of compulsions are more common than others. In terms of obsessions, fear of contamination is the most common. Doubting obsessions and sexual/aggressive obsessions are also common, followed by somatic concerns, need for symmetry, and religious/blasphemous obsessions. In addition, compulsions tend to correspond to certain obsessions. Some of the most common compulsions include

washing/cleaning and checking compulsions. Individuals also often report urges to ask or confess, urges to arrange things in a symmetrical or precise manner, and hoarding of objects. That certain obsessions and compulsions tend to be quite common in individuals with OCD suggests that certain subtypes or dimensions of OCD exist.

Many individuals with OCD experience fluctuations in level of insight, depending on the situation and level of anxiety, with higher anxiety leading to poorer insight in the moment. However, a small subset of individuals with OCD also exhibit low levels of insight that is not bound by the situation or anxiety level. In the DSM-IV, a subtype of OCD 'with poor insight' was included to describe these individuals who fail to recognize the senselessness of the OCD symptoms. Approximately 5% of individuals with OCD demonstrate poor insight, which is defined as holding fixed beliefs that obsessions and compulsions are reasonable. An additional 20–25% report strong but not fixed convictions.

OC-Related Disorders

A number of disorders, referred to as OC-related disorders, have similarities with OCD and are conceptualized as existing on a spectrum with OCD. These OC-related disorders include several neurological disorders characterized by repetitive behaviors, such as Tourette's syndrome and tic disorders; impulse-control disorders, such as trichotillomania and skin picking; and disorders associated with bodily preoccupation, such as body dysmorphic disorder and hypochondriasis. These disorders are similar to OCD in that they involve repetitive behaviors that generally function to reduce anxiety or tension.

In tic disorders, individuals perform vocal and motor tics in response to uncomfortable sensory phenomena, such as an itch, tickle, tingle, or pressure on their skin or within their body. These sensory phenomena, referred to as premonitory urges, may be localized to specific areas of the body, experienced as more generalized sensations, or experienced as a psychological feeling that something is not 'just right.' Performance of a tic temporarily relieves whatever tension the individual is experiencing as a result of the urge. Tics can be simple or complex in nature. More complex tics can resemble ritualistic behavior associated with OCD.

Trichotillomania and skin picking also involve maladaptive repetitive behaviors that are similar to compulsive behavior in OCD. In trichotillomania, individuals repeatedly pull hair from various regions of the body. Individuals experience internal tension, and this tension builds until the individual engages in hair pulling. After the behavior is performed, relief and gratification are experienced, similar to the anxiety reduction experienced by individuals with OCD when they perform a ritual. Most individuals engage in two types of pulling: automatic, which occurs outside one's awareness; and focused, which is intentional and purposeful. Similarly, individuals who engage in pathological skin picking do so to relieve internal discomfort. Skin picking often results in noticeable tissue damage and can lead to permanent disfigurement.

Body dysmorphic disorder (BDD) and hypochondriasis are associated with excessive bodily preoccupation. In BDD, individuals are preoccupied with imaginary defects in their appearance or an excessive concern with small physical imperfections.

Individuals with BDD often spend an inordinate amount of time obsessing about their appearance. In addition, they perform repetitive and time-consuming behaviors that are intended to decrease the anxiety they experience because of their imagined defect. These rituals include excessive grooming, camouflaging their perceived defect, checking their reflection, repetitive touching or measuring of parts of the body, and asking for reassurance. In hypochondriasis, individuals are preoccupied with the fear of having a serious physical illness, and they often engage in repetitive internal and bodily checking, as well as reassurance seeking. These rituals are intended to reduce the anxiety associated with their bodily preoccupation; however, they usually have the effect of increasing long-term anxiety.

Epidemiology

OCD is one of the most severe and chronic anxiety disorders. It has been ranked by the World Health Organization as one of the most debilitating psychological disorders. Although early epidemiological studies estimated the prevalence of OCD to be as low as 0.05%, more recent studies have reported higher prevalence rates. The Epidemiologic Catchment Area Study reported the 1-year prevalence rate as 1.6% and the lifetime prevalence rate as 2.5% (based on DSM-III criteria). Other epidemiological studies have reported the 1-year prevalence rate as ~1%, and the lifetime prevalence rate as between 1% and 3%.

Onset of OCD symptoms typically occurs in early adulthood, with 50–70% of individuals reporting onset of symptoms between ages 18–24, and a substantial number of individuals reporting subthreshold symptoms in childhood or adolescence. Approximately 15% of individuals report onset after 35 years. Often, development of OCD symptoms is gradual, although acute onset has been reported in some cases. OCD symptoms often wax and wane in response to stress, and a clear precipitant can be identified in ~60–70% of cases (e.g., pregnancy, childbirth, divorce, death of a loved one). However, about 10% of individuals report episodic and deteriorating courses.

OCD is diagnosed twice as often in boys as girls. However, adult men and women are affected equally. Although men and women do not differ in the rate of diagnosis, other differences have been found in terms of onset and expression of symptoms. Men tend to have an earlier age of onset (13–15 years) than women (20–24 years). In addition, men are more likely to report sexual or aggressive obsessions, and women are more likely to report contamination obsessions. Checking rituals are reported equally in men and women.

OCD has similar prevalence rates and age of onset across cultures. However, obsessional content varies, based on culture. For example, dirt and contamination obsessions are more prevalent in Indian culture than in American culture, and religious and sexual obsessions are more prevalent in cultures with strict religious moral codes.

Comorbidity

There is a high rate of comorbidity between OCD and other Axis I disorders. In fact, 50–65% of individuals with OCD have at least one current additional Axis I diagnosis, and 85% have

another Axis I diagnosis at some point in their lifetime. Depression is one of the most common comorbid diagnoses; 30–50% of individuals with OCD have an additional diagnosis of current major depressive episode or dysthymia, and 65–80% are diagnosed with depression in their lifetime. Onset of depressive symptoms tends to occur following onset of OCD symptoms, suggesting that the effects of OCD often lead to development of a secondary depressive disorder. Although in some cases depression precedes the onset of OCD symptoms, the progression of OCD to depression occurs three times more often than progression of depression to OCD. Comorbid depressive symptoms can exacerbate OCD symptoms.

OCD often occurs with other anxiety disorders as well. Approximately 50% of individuals with OCD have a comorbid anxiety disorder. When OCD co-occurs with other anxiety disorders, OCD tends to be the primary or most debilitating diagnosis. Individuals with OCD often have additional diagnoses of social phobia (35–41%) or specific phobia (17–21%). The relationship between OCD and other anxiety disorders, such as panic disorder and generalized anxiety disorder (GAD), is not as clear. Some studies have found that panic disorder has a moderately high comorbidity rate (29%) with OCD, but other studies report a lower comorbidity rate (12%). Similarly, studies have found comorbidity rates between OCD and GAD that range from 7% to 22%.

Individuals with OCD are also frequently diagnosed with OC-related disorders. Approximately 17% of individuals with primary OCD have comorbid Tourette's syndrome. It is much more common for individuals with primary Tourette's syndrome to have comorbid OCD; studies have reported comorbidity rates ranging from 28% to 63%. In addition, individuals with OCD and comorbid tics are more likely to have aggressive and sexual obsessions and intrusive images than individuals without comorbid tics. Less is known about comorbidity with impulse-control disorders, although studies have found higher rates of lifetime OCD in individuals with trichotillomania. In addition, 15–37% of individuals with primary OCD have comorbid BDD.

OCD also co-occurs with many personality disorders. In fact, 50–65% of individuals with primary OCD also meet the criteria for an Axis II disorder, and at least half of those individuals are diagnosed with more than one personality disorder. Between 5% and 30% of individuals with OCD are also diagnosed with either dependent personality disorder (PD), avoidant PD, histrionic PD, schizotypal PD, or obsessive–compulsive personality disorder (OCPD). Avoidant PD is often cited as the most common comorbid personality disorder (30%), followed by dependent PD (10–20%), histrionic PD (5–25%), schizotypal PD (15%), and OCPD (ranges vary widely from 2% to 55%, with the median being 6%).

Differential Diagnosis

OCD has many similarities with other disorders. Therefore, differential diagnosis is extremely important and can sometimes be challenging. Depressive ruminations can appear similar to obsessional thinking. Ruminative thinking and obsessional thinking are both very repetitive. However, depressive rumination involves pessimistic ideas about the self or others; whereas

obsessions are anxiety-provoking thoughts that are often related to danger. Ruminations are ego-syntonic, meaning that they are consistent with how the individual views himself or herself; whereas obsessions are ego-dystonic, meaning that they are inconsistent with how the individual views himself or herself. Finally, ruminations and obsessions differ in the level of effort expended to control the thoughts. Typically, individuals try to suppress obsessions but expend much less effort trying to control ruminations.

Worry thoughts, which are present in GAD and other anxiety disorders, are also sometimes confused with obsessions. Often, the obsessional style of thinking in GAD is similar to thought patterns in OCD. The difficulty in distinguishing worry from obsessions is even more apparent when outward behavioral compulsions (e.g., handwashing, checking locks) are not present, as when individuals have only mental compulsions or 'pure' obsessional OCD. Some differences between worry and obsessional thinking are related to the content of the thoughts and how the individual responds to the thoughts. Like depressive ruminations, worries are experienced as ego-syntonic, and obsessions are experienced as ego-dystonic. As a result, individuals typically try to strongly resist or suppress obsessions, but resist worry thoughts to a much lesser extent. In addition, worry thoughts are typically focused on more common and everyday concerns; whereas obsessions are more related to less likely situations and sometimes even have a magical quality to them. Worries are often focused on long-term consequences of actual situations, and obsessions are often focused on consequences of the thought itself.

Obsessive–compulsive personality disorder (OCPD), which is characterized by a rigid preoccupation with perfectionism, orderliness, rules, and mental and interpersonal control, shares some similar features with OCD. Certain features of OCPD are more often associated with OCD than with others. Perfectionism, for example, is significantly elevated in individuals with OCD. In addition, OCPD traits may be associated more with particular subtypes of OCD symptoms, such as doubting/checking. Although OCD and OCPD share some similar features, most individuals with OCD do not have comorbid OCPD. One important difference between OCD and OCPD is that obsessions in OCD are generally ego-dystonic, whereas obsessions in OCPD are generally ego-syntonic.

It is also important to differentiate between strongly held beliefs, or overvalued ideas, and delusions. Many individuals with OCD have overvalued ideas, which are less fixed than delusions. An example of an overvalued idea within the context of OCD may be an individual who strongly believes (s)he will become ill if (s)he comes into contact with a contaminated object. Overvalued ideas often cannot be differentiated from delusions based on the level of bizarreness, as OCD obsessions can be quite bizarre in nature. Rather, overvalued ideas are distinguished from delusions based on the level of fixity and the presence or absence of compulsions. A belief may be deemed a delusion if it is held with firm conviction and is not responsive to clear contradictory evidence. Overvalued ideas, on the other hand, are less fixed. Other features that suggest a delusion as opposed to an overvalued idea are failure to elicit distress or anxiety and the absence of compulsions. It is important to assess the level of insight, as poor insight can negatively affect treatment outcome.

Models of Development and Maintenance of OCD Symptoms

Several models have been used to describe the etiology, development, and maintenance of OCD symptoms, including biological, neuropsychological, behavioral, and cognitive models.

Biological and Neuropsychological

The role of genetic variables in the etiology of OCD has been examined using twin studies and family history. Twin studies have found that monozygotic twins of individuals with OCD show higher rates of OCD symptoms than do dizygotic twins. Further, first-degree relatives of individuals with OCD have OCD themselves at a rate 3–12 times higher than the general population. Although this suggests that genetics may play a role in the etiology of OCD, it is important to note that environmental factors likely play an important role as well.

Studies have found neuroanatomical abnormalities in the brain of individuals with OCD, including dysfunctional circuitry involving the orbitofrontal cortex, anterior cingulate, basal ganglia, and medial thalamus. These abnormalities lead to the proposal that the direct and indirect striatopallidal pathways of the basal ganglia may be involved in OCD. The direct pathway projects from the cortex to the striatum, then to the globus pallidus and the thalamus, and then back to the cortex. The function of the direct pathway is to facilitate routines. The indirect pathway projects from the cortex to the striatum, then through the globus pallidus to the subthalamic nucleus, before returning to the globus pallidus, thalamus, and the cortex. The role of the indirect pathway, which is a negative feedback loop, is to break up the routines driven by the direct pathway. OCD may be a result of an imbalance between these two pathways. In individuals with OCD, the direct pathway is thought to overfunction and contribute to obsessive thoughts; and the indirect pathway inadequately regulates the repetition of routines and accounts for compulsions.

Various neuropsychological differences have been identified in individuals with OCD. Individuals with OCD are more likely to be unable to inhibit and direct attention from distressing thoughts and images toward more pleasant or less-distressing mental experiences. In addition, there are deficits in executive functioning, specifically set shifting. There is also some evidence that individuals with OCD have deficits in nonverbal memory, as well as lower confidence in memory judgments.

Behavioral

The development and maintenance of OCD symptoms is influenced by environmental variables and learning principles. In terms of environmental variables, the onset of OCD often occurs following significant life events, such as marriage, childbirth, and death of a loved one. In addition, the course of the disorder typically waxes and wanes in response to various life stressors, such as career or job changes, relationship difficulties, and school-related problems.

The behavioral theory of OCD was based on Mowrer's two-stage theory of fear and avoidance. Mowrer's theory has been used to explain how symptoms are acquired and maintained

through classical and operant conditioning. Although empirical support for the acquisition phase is lacking, there is evidence that Mowrer's theory can explain the maintenance and growth of fear and avoidance behavior. Additionally, Mowrer's theory aids in the conceptualization of OCD symptoms and led to development of the primary evidence-based behavioral treatment for OCD, which is exposure and response prevention (ERP).

Mowrer's theory purports that learning occurs via two stages. In the first stage, obsessions develop through classical conditioning: a neutral stimulus is paired with a stimulus that naturally elicits discomfort or anxiety, and then the previously neutral stimulus takes on the function of eliciting discomfort or anxiety itself. Through this process, objects, thoughts, and images can take on the ability to elicit anxiety. In the second stage, performance of behaviors that reduce anxiety (i.e., compulsions or rituals) are developed and maintained through a process of negative reinforcement. Each time a compulsion is performed and successfully reduces the fear experienced by the individual, the likelihood that (s)he will perform that compulsion in the future in response to the obsession increases.

Cognitive

Several cognitive models have also been proposed. Salkovsk'i's Inflated Responsibility Model states that intrusive thoughts are experienced by everyone and only turn into obsessions because of distorted appraisals about personal responsibility for preventing harm. This model suggests that distorted appraisals provoke anxiety, and neutralizing rituals and subsequent thought suppression occurs as a means of reducing the anxiety. Rachman proposed a Misinterpretation of Significance Model, in which obsessions are the result of interpreting intrusive thoughts as personally significant and as signifying a threat. Clark's Cognitive Control Theory of Obsessions emphasizes the role of faulty beliefs about the importance of mental control: individuals misinterpret their obsessions and engage in faulty evaluation of their mental control efforts and perceived consequences of failure to control the obsession.

Finally, the Obsessive–Compulsive Cognitions Work-Group Model has identified six belief domains that may have etiologic importance and may be specific to OCD. These domains incorporate many of the earlier models: (1) inflated responsibility – the belief that one has the power to bring about or prevent negative events; (2) overimportance of thoughts – the idea that having a thought indicates that it is important; (3) overestimation of threat – believing that harm is more probable than is realistic; (4) importance of controlling thought – thinking that it is possible and desirable to exert complete control over one's thoughts; (5) intolerance of uncertainty – the belief that one must be certain and one cannot cope with uncertainty or unpredictable change; and (6) perfectionism – believing that there is a perfect solution to problems, that it is possible and necessary to complete tasks perfectly, and that minor mistakes are unacceptable and catastrophic.

Diathesis–Stress

Although many models have been proposed, no single model is able to fully explain why OCD develops. Therefore, the etiology of OCD may best be explained by complex

interactions between the various models (e.g., biological, behavioral, and cognitive). A diathesis-stress model of OCD suggests that certain individuals have a biological predisposition to develop OCD, and that onset of the disorder occurs only when specific environmental variables or learning patterns interact with these biological factors. This model is supported by evidence that individuals without OCD often experience obsessive-compulsive symptoms that differ only in frequency, intensity, and experienced distress. That many individuals experience obsessive-compulsive symptoms without developing OCD suggests that individuals with OCD may have a biological and/or psychological vulnerability to developing the disorder.

Treatment

Several treatment modalities are effective in treating OCD. Behavior therapy, specifically ERP and pharmacotherapy, have the largest evidence base. Cognitive therapy also has been shown in some studies to be effective; however, other studies have found cognitive therapy to be inferior to ERP and pharmacotherapy. Other treatment approaches that include a mindfulness component are also being explored, but their efficacy is not yet well established.

Exposure and Response Prevention

Early behavioral interventions for OCD included systematic desensitization, modeling, operant reinforcement, aversion relief, and relaxation therapy. These interventions produced mixed results. In 1966, Victor Meyer described a new behavioral intervention, ERP, which was based on Mowrer's two-factor theory of fear and avoidance. The basic approach of ERP is that individuals expose themselves to situations that trigger their feared obsessions, and they then tolerate any anxiety that is provoked by the exposure while refraining from the associated compulsion or ritual. At the beginning of treatment, individuals generate a fear hierarchy, which is a list of situations or objects that elicit obsessions, provoke anxiety, and which the person typically avoids. The individual then ranks the exposures based on level of distress. After the hierarchy is developed, the individual begins exposing himself or herself to these situations, starting with items that provoke a moderate anxiety level and then gradually moving to items that provoke higher anxiety levels. It is important that the individual remains in a situation without ritualizing until habituation is achieved (i.e., until the anxiety decreases significantly). Therapists often provide encouragement and support (not reassurance) and will sometimes model the exposure prior to asking the patient to complete the exposure.

ERP is the most effective intervention for OCD, with 60–85% of individuals who complete ERP showing significant symptom improvement. Of those who respond to the treatment, about 75% maintain their gains long term. Actually, a deliberate focus on relapse prevention has a significant effect on maintenance of treatment gains. Compared with pharmacotherapy, ERP is generally superior, particularly when maintenance of gains is considered. Those who receive ERP also demonstrate lower dropout and refusal rates compared with individuals who receive pharmacotherapy.

Despite these encouraging results, ERP is not an effective or desirable treatment for everyone. Approximately 25% of people refuse ERP, and another 3–12% will begin but not complete it. This leaves a large number of individuals who are not able to benefit from ERP. In addition, most outcome studies have included mostly individuals with cleaning and checking rituals as primary compulsions. Less is known about efficacy of ERP for individuals with other types of OCD symptoms, such as obsessional slowness, hoarding, symmetry/ordering rituals, or mental compulsions.

Several factors may have a negative effect on response to ERP. Individuals with mild-to-moderate comorbid depression, for example, may not experience gains as significant as those without comorbid depression, and severe depressive symptoms are associated with poor response to ERP and higher risk of relapse. Any comorbid personality disorder diagnosis also is predictive of poorer treatment outcome for both ERP and pharmacotherapy, especially diagnoses of schizotypal and borderline personality disorders. Overvalued ideation has also been shown to be a predictor of poor treatment outcome.

Pharmacotherapy

Antidepressants are also an effective treatment for OCD. Several double-blind, randomized, placebo-controlled studies have demonstrated the efficacy of these drugs in reducing OCD symptoms, including clomipramine (Anafranil), sertraline (Zoloft), fluoxetine (Prozac), fluvoxamine (Luvox), citalopram (Celexa), escitalopram (Lexapro), and paroxetine (Paxil). Of these, clomipramine is the only drug from the tricyclic family, whereas the others are selective serotonin reuptake inhibitors (SSRIs). Tricyclics were the first generation of antidepressants, and they work by increasing the amount of norepinephrine and serotonin in the brain. Although the tricyclic antidepressants are quite effective for many people, because they interfere with other neurotransmitter systems, they also have a number of side effects.

SSRIs work by slowing the reuptake of serotonin by the secreting neuron and allowing the dendrites of the receiving neuron to make contact with and use more of the secreted serotonin. Because SSRIs do not interfere with other neurotransmitter systems, they generally have fewer side effects and are better tolerated than tricyclics. Forty to sixty percent of individuals with OCD show significant improvement following treatment with SSRIs. However, serotonergic drugs are not more effective than ERP, and when medications are discontinued, relapse is common. Although serotonergic drugs do not increase the benefits of ERP, these treatments are commonly combined in clinical settings.

Cognitive Therapy

Cognitive therapy (CT) is often combined with, and is sometimes used instead of, ERP for OCD. CT focuses on changing maladaptive beliefs or interpretations of one's obsessions. For OCD, some common maladaptive beliefs include overestimating the probability of danger, viewing thoughts as overly important, and believing that having a thought is the same as performing an action (i.e., thought-action fusion). Therapists use Socratic questioning and other cognitive techniques to challenge these maladaptive beliefs.

Generally, CT combined with ERP (i.e., CBT) is an effective treatment for OCD. However, only a few studies have directly compared CT with ERP. These studies have produced mixed results, with one study suggesting that CT is superior to ERP, two studies suggesting that ERP is superior to CT, and at least one study finding no difference between the treatments. In addition, these studies are difficult to interpret because CT often includes behavioral experiments and ERP often includes cognitive techniques, thereby confounding the independent variables. Mode of treatment delivery may also confound results. Some studies employ group rather than individual therapy, which may affect treatment outcome, depending on the severity of symptoms; more severe OCD may respond better to individual as opposed to group therapy.

CT and ERP have different strengths, and individuals may respond differentially based on various factors. For example, severity of symptoms may affect response to CT versus ERP. One study showed a trend for mild-to-moderate patients to respond better to CT and more severe patients to respond better to ERP. Type of symptoms may also affect response to CT versus ERP. Symptoms such as hoarding and mental rituals may respond more to the addition of cognitive techniques. CT may result in lower refusal and dropout rates for certain individuals than ERP, although this pattern is not strongly supported in the literature.

Future Directions

Despite the effectiveness of ERP and pharmacotherapy, many individuals do not adequately benefit from these treatments. Therefore, other treatments continue to be explored. Several treatments are emerging that use a mindfulness-based approach to OCD. Mindfulness-based interventions may be particularly well suited to the treatment of OCD because of the fact that individuals with OCD tend to ascribe special meaning and significance to their obsessions, and mindfulness training fosters a nonjudgmental stance toward one's thoughts and feelings. Some treatment approaches that have been applied to OCD are acceptance and commitment therapy (ACT) and metacognitive therapy (MCT).

ACT posits that experiential avoidance, which is the tendency to avoid or control thoughts and emotions, is a key process of any psychological disorder. Rather than targeting the form, frequency, or situational sensitivity of thoughts and emotions, ACT therapists instruct individuals in various exercises, including mindfulness exercises. These exercises are designed to assist individuals in experiencing their obsessions as just thoughts and their anxiety as just an emotion, thereby reducing the need to ritualize. Like CT, ACT can be conducted with or without in-session exposure therapy. When exposures are conducted, the purpose is to help individuals develop willingness to experience thoughts and emotions in the service of moving toward their values, not to achieve habituation.

MCT is another approach that incorporates mindfulness. MCT is based on a theory of psychological dysfunction that suggests that all disorders are a result of a dysfunctional pattern of cognition – specifically, inflexible self-focused attention, perseverative thinking (i.e., worry and rumination), attentional strategies of threat monitoring, and coping strategies that fail to challenge and modify maladaptive beliefs. To

combat this dysfunctional thinking pattern, MCT therapists incorporate detached-mindfulness techniques. Detached mindfulness, which is considered to be incompatible with the dysfunctional thinking style that is characteristic in psychological disorders, consists of being conscious of one's thoughts, comprehending that thoughts are not facts, being able to refocus one's attention flexibly, having low conceptual processing of one's thoughts, and not having the goal of removing or avoiding threat.

The efficacy of these approaches is not yet well established, as no randomized controlled trials for ACT or MCT for OCD have been conducted. However, one multiple baseline study suggests that ACT may produce clinically significant reductions in compulsions. ACT may also be beneficial for other OC-related disorders, such as trichotillomania and skin picking. Evidence from experimental and case studies is also emerging that MCT may be an effective treatment for OCD. In many ways, these mindfulness-based approaches may not differ radically from more standard approaches. For example, the meta-cognitive approach to obsessions is also used in standard CBT for OCD; the detached-mindfulness techniques of MCT are similar to imaginal exposures used in ERP; and, even though habituation is emphasized, ERP promotes willingness to tolerate anxiety to pursue one's values. To sort out whether there are meaningful differences between these mindfulness-based approaches and standard CBT approaches, head-to-head comparisons of these treatments will need to be conducted.

Conclusions

Over the past 30–40 years, our knowledge of OCD and its treatment has advanced significantly. Comorbidity with other anxiety disorders, OC-related disorders, depression, and personality disorders has been investigated. In addition, factors that may affect treatment outcome have been examined, including negative factors such as the presence of overvalued ideation, severe depression, and personality disorders, and positive factors such as deliberate focus on relapse prevention. However, numerous questions remain, particularly regarding improving treatment outcomes. Future research will need to continue refining our ability to identify individuals most likely to benefit from available treatments, address how best to treat various forms or subtypes of OCD, and determine whether the addition of various cognitive and mindfulness-based techniques may improve treatment outcomes, and for whom.

Glossary

Comorbid Two distinct disorders that exist within a person at the same time.

Obsessive–compulsive disorder An anxiety-based disorder that consists of obsessions (repetitive, unwanted intrusive thoughts) and compulsions (acts that need to be completed in a certain rigid fashion).

Psychoanalysis Developed by Sigmund Freud, psychoanalysis describes various theories relating to conscious and unconscious psychological processes.

Semistructured interview Administered by a clinician, the interview has a certain set of questions that are posed to the patient. Based on the response, the clinician uses clinical judgment to continue or discontinue the line of questioning.

Unstructured interview Administered by a clinician, this is an interview style in which questions can be changed or adapted. Unlike in structured interviews, there is no preset manner in which questions must be asked. The increased flexibility provided by this interview style brings some potential drawbacks such as a decreased ability for generalization and limited diagnostic capabilities.

The origins of obsessive–compulsive personality disorder (OCPD) can be traced back to Sigmund Freud in the early 1900s, who characterized individuals with this disorder as having “a neurosis connected with difficulties at the anal phase in psychosexual development.” Freud referred to this neurosis as the ‘anal character.’ According to classical analytic theory, the anal character arises out of conflicts over toilet training in the second to third year of a child’s life. Improper toilet training techniques coupled with high levels of tension between the child and the child’s caretakers can result in an anal fixation. This anal fixation or anal character is what we know today as OCPD. Although the field has moved away from this psychoanalytic explanation, the traits that characterize these individuals remain largely unchanged.

Diagnosis

According to the DSM-IV-TR, OCPD is described as a “pervasive pattern of preoccupation with orderliness, perfectionism, and mental and interpersonal control, at the expense of flexibility, openness, and efficiency.” These behaviors typically begin in early adulthood and present in a variety of contexts. In an effort to maintain control, individuals with OCPD become obsessed with rules, details, lists, order, organization, and schedules. Such individuals hold themselves and others to high, unrealistic standards, resulting in problems with relationships, friendships, and with their own personal sense of well-being. These individuals are oblivious to the fact that in their quest for perfection, they are sacrificing efficiency and, as a result, they are often unable to accomplish everyday responsibilities and meet deadlines. For example, an individual with OCPD might spend more time searching for a lost shopping list than spend a few moments to rewrite it.

People with OCPD are often excessively dedicated to work and the need to be productive, for reasons beyond obvious economic necessity. For this reason, they rarely participate in leisure activities and feel they do not have time to take vacations. When they do take a vacation, they are unable to relax.

They equate not working with wasting time and become so uncomfortable with this idea that they bring work to do while they are on vacation. Individuals with OCPD prefer activities that are structured, with clear rules to follow, such as sports. They are not, however, able to play sports ‘for fun.’ Sports and activities are approached very seriously and they strive for perfection. For example, a game of basketball is considered an opportunity to develop the perfect free throw rather than an enjoyable way to spend time with friends.

According to DSM-IV criteria, individuals with OCPD tend to be overconscientious, scrupulous, and inflexible about matters of morality, ethics, or values. They tend to be self-deprecating about personal mistakes. Rules and laws are followed rigidly and interpreted literally. They believe rules are not meant to be bent or broken under any circumstances. These behaviors should not be accounted for by cultural or religious identification.

Many people have collections of objects that are meaningful to them. People with OCPD, however, tend to be ‘pack rats’ and have trouble discarding worn-out or useless objects, even those without sentimental value. They will often engage in hoarding behavior and collect many different materials, such as old appliances and magazines, out of a fear of needing them, not because they enjoy the objects of their collection. They can also be very stingy or miserly with money and see it as something to be hoarded and conserved for potential emergencies.

Individuals with OCPD have great difficulty in delegating tasks to others. They believe that there is only one right way to do a task and that everyone should conform to their high expectations. They are typically controlling, bossy, and give detailed instructions on how to complete menial tasks (e.g., how to load the dishwasher, how to wash the car). They become upset and irritated if their directions are not followed exactly. It is unusual for OCPD to be the patient’s primary reason for seeking treatment as people with this disorder are generally oblivious to the impact of their behaviors on other people. Often, they will begin therapy to receive treatment for problems with anxiety, stress, or relationship issues. Diagnosis depends on careful observation and behavioral assessment,

especially since some features of OCPD may overlap with other personality disorders. It is necessary to assess the impact of these behaviors on daily functioning as these traits, in moderation, can be desirable and adaptive. It is also important to distinguish between obsessive-compulsive disorder (OCD) and OCPD. Although these disorders share certain behavioral features, there are notable differences, affirming that OCPD is not a prerequisite to the development of OCD. People with OCD have obsessions and compulsions; however, they are not typically relevant to real-life problems and cause significant distress to the individuals. Symptoms experienced as part of OCD are ego-dystonic, that is, they are inconsistent with the person's self-conception and personality and have variable intensity, duration, and morbidity. Individuals with OCPD are comfortable with their rules, procedures, and beliefs. Unlike in OCD, these behaviors are considered ego-syntonic or congruent with the person's self-concept and are therefore not subject to resistance. Additionally, the behaviors tend to be fixed, long-standing, and enduring. In reality, a person may be suffering from both OCD and OCPD, but the two disorders are not always comorbid. OCPD has been associated with conditions other than OCD, including ulcerative colitis, hypochondria, depressive disorders, anorexia nervosa, self-mutilation, and somatoform disorder, in addition to anxiety disorders.

Assessment

A diagnosis of OCPD is most typically made following the administration of either a semistructured or an unstructured diagnostic interview. There are five semistructured interviews used to diagnose the DSM-IV personality disorders, including OCPD: Diagnostic Interview for Personality Disorders (DIPD), International Personality Disorder Examination (IPDE), Personality Disorder Interview-IV (PDI-IV), Structured Clinical Interview for DSM-IV Axis I Personality Disorders (SCID-I), and Structured Interview for DSM-IV Personality Disorders. The questions asked in semistructured interviews are systematic and tend to provide a more comprehensive and reliable assessment than unstructured interviews. Semistructured interviews provide specific questions for the diagnostic criteria of OCPD and increase the ability to replicate the results across interviewers. Currently, results of structured assessments are not part of the diagnostic criteria for OCPD in the DSM-IV, though it has been proposed by the APA and National Institute of Mental Health DSM-V Nomenclature Work Group to be included in the DSM-V. Proponents of unstructured interviews prefer to use assessments such as Shedler-Western Assessment Procedure-200 (SWAP-200). The increased flexibility of this type of interview allows the therapist to obtain additional information about the individual's life history in order to put their symptoms in context. This measure has been shown to have excellent construct validity when used to assess personality disorders.

Etiology

Multiple researchers have tested the validity of Freud's theory regarding toilet training and the development of anal character traits. One study reported a significant positive relationship between anal eroticism and obsessional-compulsive traits,

but overall, there appears to only be meager, if any, support for this psychoanalytically based explanation. Currently, psychologists favor an explanation based on a combination of biological, psychological, and environmental factors. Although there is no evidence to currently support a solely biological basis for OCPD, there is empirical support for the following environmental factors: parental overcontrol, learned compulsive behavior, and emphasis on perfectionism. Children who reported higher levels of perfectionism and rigidity have higher rates of OCPD than children not reporting those traits. Individuals with OCPD tend to have been raised by authoritarian parents. These parents are characterized as being extremely strict and having high expectations for their children but show only minimal levels of emotional nurturance. As a result, children become used to striving for perfection in order to please their parents but do not form strong emotional bonds. To avoid the feelings of shame and guilt that result when these standards are not met, these individuals mimic their caregivers, develop an obsession with perfection, and become acutely focused on minute details to ensure their flawlessness. There are no data that upbringing alone is responsible for the development of OCPD. These environmental factors most likely interact with biological factors such as a shared genetic predisposition. In turn, these psychological and behavioral dispositions appear to be reinforced by family factors such as authoritarian parenting styles.

Epidemiology

Although estimates of prevalence rates vary, it is generally accepted that the prevalence of OCPD in community samples is about 1% and about 3–10% in clinical samples. According to a National Epidemiologic Survey published in 2004, 14.8% of adult Americans (or 30.8 million) had at least one personality disorder. Of these disorders, OCPD had the highest prevalence, with approximately 7.88% (or 16.4 million) having this diagnosis. Odds of developing OCPD were found to be the highest for young Caucasians with at least some college education ($OR = 1.18$) though the effect size for education was small. Caucasians have a higher prevalence rate of OCPD than both Hispanics ($OR = 0.71$) and Asians ($OR = 0.60$). Odds of having OCPD were lowest for respondents in the oldest age groups ($OR = 0.62$) and for those with less than a high school education ($OR = 0.77$). There were no differences in prevalence for gender, income, marital status, or region. It is necessary to be cautious when interpreting results of epidemiological studies as the prevalence rates provided have been shown to vary based on methodological issues such as when the assessment occurred, presence of axis I disorders, the source of information, and the instrument used. For example, personality disorders tend to be made less frequently with unstructured interviews than with semistructured interviews. In addition, incidence of OCPD is higher in epidemiological studies utilizing DSM-III criteria as the DSM-IV-TR has a higher amount of criteria required for diagnosis.

Treatment

Of all the personality disorders, OCPD is considered to be the most responsive to treatment. There are three primary approaches to the treatment of this disorder. Though the

approaches are different, the goal is to help the individuals develop more realistic expectations for themselves and others and to help them understand that decreasing rigidity can increase productivity. The first of these approaches, cognitive-behavioral therapy (CBT), tends to be the most accepted by people with OCPD as it is the most structured. CBT focuses on changing maladaptive beliefs that performance is either perfect or the person is a failure. Because people with OCPD have difficulty relating to and recognizing the feelings of others, empathy training and interpersonal skills are commonly included in CBT. A second approach is group therapy, although care must be taken to ensure a proper balance of personalities within the group. Due to the controlling nature and lack of empathy often found among people with OCPD, these individuals try and dominate the group and are often rejected by the other group members. The third most commonly used form of therapy is psychodynamic psychotherapy, which helps the individuals recognize and reconcile their insecurities resulting from problems with toilet training. Traditionally, psychodynamic psychotherapy is unstructured with the therapist assuming a more passive role than other forms of therapy. This can be problematic when dealing with people with OCPD since techniques such as free association can result in the individual ruminating about minute details. There has been very limited empirical research surrounding the efficacy of these different treatments for OCPD. Even less data exist regarding cross-cultural and gender issues in treatment. Therefore, most treatment efficacy data and recommendations come from generalizations drawn from clinical experiences or by looking at OCPD as part of a broader category of personality disorders. Research has, however, shown a significant decrease in OCPD symptoms when using long-term supportive–expressive psychodynamic therapy, although it may be more realistic and practical to utilize a more short-term and goal-directed form of therapy.

Glossary

Aversive control Changing the probability of behavior through the use of punishment or negative reinforcement.

Conditioned reinforcer A stimulus that maintains behavior because it predicts the occurrence of a reinforcer.

Delay-reduction theory (DRT) A model for predicting choice, according to which the value of a conditioned reinforcer is greater the more improvement it signals in time to reinforcement.

Discriminative stimulus (S^D) An event or stimulus that precedes, and sets the occasion for, an operant behavior.

Extinction In operant conditioning: (1) when responding no longer produces reinforcement; (2) the decline in responding that occurs when responding no longer produces reinforcement.

Matching law Responding on two or more concurrent schedules of reinforcement is distributed in proportion to the amount of reinforcement available on each schedule.

Negative reinforcement A response is strengthened (becomes more likely) when it is followed by the removal, through avoidance or escape, of an aversive stimulus or situation.

Operant conditioning The increase or decrease of an operant (instrumental) behavior as a function of the consequences that follow it.

Punishment The likelihood of a behavior decreases when it is followed by an aversive stimulus or event or by the withdrawal of a positive stimulus or event.

Reinforcement An increase in the likelihood of a behavior when it is followed by a (usually positive) stimulus or event.

Reinforcement principle A higher frequency (more preferred) behavior can serve as a reinforcer for a lower frequency (less preferred) behavior; conversely, a lower frequency behavior can serve as a punisher for a higher frequency behavior.

Stimulus control The degree to which behaviors reinforced in the presence of particular stimuli are emitted in the presence of other stimuli.

Three-term contingency (S^D -R- S^R) A response (R) that is emitted and reinforced (S^R) in the presence of a discriminative stimulus (S^D) becomes more probable in the future in the presence of that, or a very similar, stimulus.

The American psychologist B.F. Skinner (1904–1990) suggested that much of an organism's observable behavior could be categorized into classes of actions that he termed operants, since these actions operated on (and changed) the environment in some specifiable way. Thus, the process by which an organism's interactions with its environment modified its future actions came to be known as operant conditioning or instrumental conditioning. The consequences responsible for this modification are known simply as reinforcement and punishment. Responses followed by reinforcement are more likely to recur; those followed by punishment are less likely to recur. The response–reinforcer relationship is central to operant conditioning and helps distinguish it from Pavlovian conditioning, as we discuss briefly below.

More is needed, however. Rarely does a professor lecture unless there is at least one student in the classroom. Rarely does a motorist drive through a red traffic signal. Another term is needed then in addition to response and reinforcement. This useful third term is the discriminative stimulus, a stimulus preceding or accompanying the operant response. In the examples given, the discriminative stimulus for lecturing is a classroom with students present and the discriminative stimulus for the motorist to drive is a green traffic signal. These stimuli are called discriminative stimuli because they signal which responses may lead to positive reinforcement and which may lead to the avoidance or reduction of punishment. In other words, they set the occasions on which responses may be reinforced.

Basic Concepts

The Three-Term Contingency

The three-term contingency refers to the relationship between these three central events: the discriminative stimulus, the response, and the reinforcer: a response that is emitted and reinforced in the presence of a discriminative stimulus becomes more probable in the future in the presence of the same or very similar discriminative stimulus. A different relationship between stimuli, responses, and reinforcers occurs in Pavlovian conditioning. Thus, we should briefly distinguish between these two fundamental conditioning processes.

Operant Versus Pavlovian Conditioning

Both operant and Pavlovian conditionings are powerful ways of modifying behavior. There is an important difference, however, in the kind of behavior they affect. Pavlovian conditioning (also called respondent conditioning or classical conditioning) deals with responses that follow, or are elicited by, a specific stimulus (the unconditioned stimulus or US). Examples include salivating to the taste of food and recoiling at the touch of fire. Operant behavior has the appearance of being voluntary, whereas there is no question of interpreting most respondent behaviors (e.g., an eye blink to a bright light or to an air puff directed at the eye) as voluntary. In Pavlovian conditioning, an originally neutral stimulus, such as the ringing of a bell, is paired with a US such as meat powder, for a hungry dog (which salivates

to the taste of meat powder, the UR or unconditioned response). After repeated pairings, the neutral stimulus (CS or conditioned stimulus) comes to elicit salivation, that is, the CS elicits what is now the CR, or conditioned response. In operant conditioning, by contrast, the critical relation is between the response and reinforcer: the latter makes the former subsequently more probable. The experimenter cannot arrange response–reinforcer pairings unless the organism makes the response.

Stimulus Control

If a response that has been conditioned in the presence of one stimulus is then emitted when new stimuli are presented, we say that stimulus generalization has occurred (the response has generalized to the new stimuli). If the response is not emitted when new stimuli are presented, discrimination has occurred (the new stimuli do not signal the same response–reinforcer relation as in the presence of the original stimulus). Thus, generalization and discrimination reflect differing degrees of stimulus control, or covariation of stimuli and responses. Generalization reflects relatively imprecise (or broad) stimulus control and discrimination reflects relatively precise (or narrow) stimulus control. Generalization and discrimination are matters of degree and may be represented by generalization gradients. Two examples of generalization gradients are shown in **Figure 1**. These gradients indicate the extent to which responses conditioned in the presence of one stimulus are emitted in the presence of (generalize to) other stimuli along the same sensory continuum. The gradient shown at the top of **Figure 1** depicts a scenario in which reinforcement has been delivered to an organism, such as a pigeon, for responding to a stimulus with a wavelength at 589 nm (yellow light). Following this training, the organism is exposed to an assortment of wavelengths across the visible spectrum with reinforcement typically no longer provided. The experimenter measures the

rate of responding (here responses per minute) as a function of wavelength. The figure describes the typical generalization gradient with a peak at the previously reinforced wavelength and with diminishing response rates as the wavelength becomes more distant from 589 nm. The fact that responding occurs at relatively high rates to wavelengths different from 589 nm is an example of generalization; the fact that the responding is less for wavelengths other than 589 nm is an example of discrimination. By contrast, the lower gradient in the figure represents the outcome if reinforcement training had not occurred: low rates of responding, undifferentiated with respect to wavelength.

Discrimination can be trained if responses to one stimulus (say a yellow light) are reinforced and responses to a second stimulus (say an orange light) are not. Discrimination training results in more precise stimulus control and is reflected in a steeper generalization gradient. A history of such experiences (differential training) accounts for the marvelous discriminatory power sometimes demonstrated by connoisseurs (e.g., wine tasting experts).

Acquisition and performance

We must take care to acknowledge that performance may not always reflect what has been learned (or acquired). The lower gradient in **Figure 1** might also be obtained if the organism being tested were colorblind. And such low, undifferentiated rates of responding might also be evident should the organism not be properly motivated, that is, deprived of the reinforcer (e.g., food may not motivate key pecking reinforced with food when the organism is already sated with respect to that food). This is the basis of the classic learning–performance distinction: The availability of an adequate reward for a deprived organism may be required to translate learning into performance.

The Nature of Reinforcement

Classical learning theory posited a fixed set of what were known as primary reinforcers, such as food, water, and sex. However, it was obvious that other reinforcers motivated most behavior. Thus, there occurred a proliferation of putative reinforcers such as exploration, affection, avoidance of discomfort, etc. A better way to treat reinforcement conceptually was provided by David Premack who called it the reinforcement principle; today, it is often called the Premack principle.

The Reinforcement Principle

Premack made the point that almost any activity may be reinforcing depending on its availability. He stressed that it was more useful to discuss reinforcers in terms of activities (e.g., eating) rather than the stimulus (e.g., an ear of corn). He showed that the same activity that serves as a reinforcer for some responses may be the reinforced response in other situations. For example, he showed experimentally that a thirsty rat will run more than usual when doing so produces access to water while a long-idle rat will drink more water than usual when doing so obtains access to a running wheel. An implication of this, confirmed in studies with humans and nonhumans, is that deprivation affects an activity's position in an

Figure 1 Generalization gradients before (bottom) and after differential reinforcement training. Adapted from Fantino E and Reynolds GS (1975) *Introduction to Contemporary Psychology*. San Francisco: W.H. Freeman & Co. Shadings indicate different colors. See text for details.

organism's reinforcement hierarchy. Every organism has a reinforcement hierarchy consisting of most preferred to least preferred activities. The hierarchy may be determined by observation and/or by preference tests. Given comparable deprivation conditions, the higher ranked activity is the one performed and chosen more often. The crux of Premack's theory and experimentation is that any activity on the hierarchy may reinforce any activity below it (i.e., the higher ranked activity made contingent upon the performance of the lower ranked activity will make the lower ranked activity more probable than it would be otherwise). Similarly, that same higher ranked activity will be reinforced (i.e., made more probable) when its performance leads to a still higher-ranked activity.

The Correlational View of Reinforcement

The second relativistic breakthrough involved the realization that correlation, not simple temporal contiguity, was the cornerstone of conditioning. This was shown to be true for both Pavlovian conditioning and operant conditioning. Events that bring the organism into the presence of higher rates of primary reinforcement, or closer in time to primary reinforcement, themselves serve as reinforcers. In order for the reinforcement effect (response strengthening) to occur reliably in the presence of a particular stimulus, responding during the occurrence of the stimulus should be correlated with a higher rate of reinforcement than that occurring in its absence. It is not enough to consider only the absolute temporal relation between the stimulus and the reinforcer. This correlational view will be elaborated when discussing the topics of choice and conditioned reinforcement.

Learning Phenomena

The acquisition of new behavior is sometimes acquired by deliberate shaping, a simple process in which successive approximations to the target behavior are reinforced. New behavior may also be learned by modeling or by imitation, and for organisms with language, with instructions. Once behavior is acquired, how is it maintained?

Schedules of Reinforcement

Just as reinforcement is instrumental in the acquisition of behavior, so it is in the maintenance of that behavior. Although in some situations appropriate reinforcers are provided each time the relevant response occurs (as when we receive today's *New York Times* and we give the newsboy \$2.00), most reinforcers do not occur on continuous schedules of reinforcement (CRF). Instead, they are obtained on schedules of partial or intermittent reinforcement. For example, only some of our phone calls are answered and we may drive past our destination several times seeking out a parking space. There are many intermittent schedules of reinforcement. We shall consider seven of the most common. Interval schedules are those in which reinforcement occurs for the first response after a certain amount of time has elapsed. In a fixed-interval (FI) schedule, that period of time is constant. Thus, in a FI 1-min schedule, the first response after 1 min has elapsed is

reinforced. In a variable-interval (VI) schedule, that period of time is variable so that in a VI 1-min schedule, reinforcement becomes available after intervals that average 1 min in duration. Ratio schedules are those in which the *n*th response is reinforced. Thus, a CRF schedule is effectively a fixed-ratio (FR) 1 schedule. While the ratio is always the same (or 'fixed') in any FR schedule, in variable-ratio (VR) schedules, the ratio varies from trial to trial (as the intervals do in a VI schedule) with an arithmetic mean equal to the value of the VR schedule. Fixed-time (FT) and variable-time (VT) schedules are analogous to FI and VI schedules except that no response is required for reinforcement – hence, these are response-independent schedules of reinforcement. Finally, extinction (EXT) is a schedule in which reinforcement does not occur. We consider the important role of EXT in the next section.

The basic schedules of reinforcement generate reliable and characteristic patterns of responding: very high constant rates on VR schedules, which make them popular with operators of slot machines and unpopular with labor leaders; a pause after a reinforced response on FR and FI schedules, with accelerated response rates on FI schedules as the interval elapses; and steady response rates on VI schedules which make them ideal for use as baselines in studies of independent variables, for example pharmacological agents. Although no responding is required on either FT or VT schedules, substantial amounts of responding typically occur – perhaps due to adventitious reinforcement – also known as superstitious responding.

While we can identify everyday examples of all of these schedules, behavior maintained on schedules of reinforcement is not always easy to recognize. Much of behavior is under the control of more complicated schedules that only recently have been studied intensively in the laboratory. The laboratory study of simple schedules nonetheless helps us to understand much human behavior and also helps us to understand behavior on more complex schedules. Reinforcement schedules have predictable, orderly, and sometimes profound effects on the organism's pattern and rate of responding.

Extinction

EXT would appear to be the simplest of schedules (along with CRF), but it has several important functions. First of all, of course, a behavior placed on EXT will soon cease to be emitted. This is true of behavior that had been reinforced on simple schedules of reinforcement in the laboratory as well as of problem behaviors such as temper tantrums that have occurred in the home or school. How quickly EXT is effective depends on the schedule that had previously maintained the behavior. Behavior after CRF extinguishes rapidly since the discrimination between the former reinforcement period and the new EXT period is easily formed. Thus, you are unlikely to place money in a previously reliable vending machine after it fails to produce a soft drink when you have inserted the requisite \$2.00. Most likely, one trial of EXT will be enough to send you in search of another machine. Similarly, if a parent has always reinforced tantrum behavior in his child (by giving in to the child's demands), it should be relatively easy to extinguish the tantrum behavior by placing it on EXT (by ignoring it). On the other hand, if the parent had only occasionally reinforced the tantrums (say on a lean VI schedule), the tantrums may take a very long time to extinguish: from the child's point

of view, it would be difficult to discriminate the former period of reinforcement (on the lean VI) and the present period of EXT. In general, EXT proceeds most rapidly after CRF, next most rapidly after the more predictable fixed schedules (FR and FI), and most slowly after more variable schedules (such as VI and VR).

EXT does not wipe the behavioral slate clean. First of all, after EXT appears to be complete (the behavior placed on EXT is no longer emitted), spontaneous recovery typically occurs. Thus, the next time a pigeon is placed in the apparatus in which it has undergone EXT, the previously reinforced behavior will emerge again, though for a relatively short time. Similarly, if you come across the vending machine a week after it had malfunctioned, you may well risk another \$2.00. Spontaneous recovery can also be understood in terms of discrimination: the situation when the pigeon is placed in the experimental chamber again resembles the times when responding has been reinforced as well as the one time when EXT was in effect. Second, when reinforcement is reestablished for a response that has been extinguished, it is reacquired almost instantaneously, revealing that EXT had not eradicated the original acquisition of the response. This fact is reminiscent of the learning-performance distinction we made earlier. The first reinforced response after EXT reactivates response strength.

EXT plays a critical role in discrimination training, as we discussed in our section on stimulus control. We elaborate on EXT's role in discrimination learning next when we turn our focus to attention.

Attention

Organisms attend more to stimuli differentially correlated with reinforcement. Thus, hungry pigeons orient toward a light that precedes food, and people attend to others who dispense reinforcers and punishers (e.g., parents, police officers, and professors). Just as differential reinforcement facilitates discrimination learning, so does it predispose organisms to attend to stimuli that are differentially correlated with reinforcement. For any given organism and situation, certain stimuli will be more readily attended to than others. Thus, cats attend much more readily to movement than to color, and humans to what is presented on a television screen than to the box of tissues sitting on top of it.

Attention has been studied with compound stimuli that consist of two or more component stimuli – for example, a vertical line on a green key or a horizontal line on a red key. Would pigeons presented with these two stimuli attend to the color or form? In one experiment, all four pigeons showed control by the color in the compound but not by the form. Thus, it appears that they attended to color and ignored form. But subsequently, the pigeons were given discrimination training in which the vertical line was uniquely correlated with reinforcement and the horizontal line was uniquely correlated with EXT. Unsurprisingly, the pigeons readily acquired this discrimination based on form. They were then reexposed to training and testing with the compound stimuli. While their choices had been predominantly controlled by color before the discrimination training with form, after this training they attended predominantly to form. These results demonstrate that reinforcement history affects attention.

The control of responding by a stimulus depends on its salience and on the history of reinforced (or extinguished) responses in its presence as well as on the sensory capacities and genetic predisposition of the attending organism. However, it also depends critically on the salience and reinforcement history of other stimuli simultaneously present. This generalization is supported not only by results from the compound stimulus experiment discussed above but also from experiments on overshadowing and blocking. Overshadowing is a phenomenon known since Pavlov's time: a more intense CS will overshadow a less intense CS, meaning that the CS will not be likely to elicit a CR. The same phenomenon occurs in operant conditioning. Overshadowing has been shown to be an attentional phenomenon that can be best understood in terms of stimulus (or sensory) properties. A more complex phenomenon of stimulus selection can be demonstrated with compound stimuli. In blocking, the prior correlation of a stimulus with reinforcement prevents (or blocks) the development of effective control by a second stimulus when the two stimuli are presented concurrently in compound. The phenomena of overshadowing and blocking have helped shape the contemporary view of attention and of stimulus control.

In summary, organisms are predisposed to attend to particular stimuli in their environment. Certain classes of stimuli may be more attention getting than others, either owing to the organism's sensory capacities or its prior experience with members of this stimulus class. The particular situation, or stimulus context, may help direct which stimuli are attended to. For example, if a student tries a new food (scallops) for lunch in his college cafeteria and then begins to feel ill, he is more likely to associate the illness with the scallops than with his luncheon companions or with the table at which he is sitting. The importance and ubiquity of such stimulus–consequence interactions have been widely demonstrated.

Conditioned Reinforcement

In Pavlovian conditioning, an originally neutral stimulus, becomes an effective CS by virtue of pairings with a US. A similar process occurs in operant conditioning in the sense that stimuli that reliably predict the occurrence of reinforcement themselves become conditioned reinforcers. Conditioned reinforcers are familiar to anyone who has seen animal acts at a zoo or marine park. The clickers that are used to train and maintain spectacular chains of behavior at these shows are conditioned reinforcers that reinforce behavior by virtue of their learned association with reinforcement. Conditioned reinforcers are also commonly used in dealing with children and adults with behavior problems. But in addition to their widespread applications, conditioned reinforcers have played a prominent role in clarifying what is the nature of reinforcement.

Theories of Conditioned Reinforcement

Establishing the necessary and sufficient conditions for establishing a stimulus as a conditioned reinforcer has been the lively source of theoretical and empirical disputes. The traditional view of conditioned reinforcement held that stimuli that were

contiguous with reinforcement became conditioned reinforcers. Thus, the pairing hypothesis of conditioned reinforcement stipulated that stimuli frequently paired with reinforcers themselves became (conditioned) reinforcers. However, research showed that pairing a stimulus with a reinforcer is neither a necessary nor a sufficient condition for establishing that stimulus as a conditioned reinforcer. It is not necessary because stimuli that are not in close temporal contiguity with reinforcement may nonetheless act as conditioned reinforcers. It is not sufficient because stimuli in close temporal contiguity with reinforcement do not necessarily function as conditioned reinforcers.

Two more contemporary theories of conditioned reinforcement are uncertainty-reduction theory (also known as the information hypothesis of conditioned reinforcement) and delay-reduction theory (DRT). We consider each in turn as well as an elegant body of experiments that distinguish between them.

Uncertainty-reduction theory states that the conditioned reinforcing strength of a stimulus is a function of how informative it is about the availability (or nonavailability) of reinforcement. In other words, the more the occurrence of a stimulus reduces uncertainty about the availability of reinforcement, the stronger a conditioned reinforcer that stimulus will be.

DRT states that the conditioned reinforcing value of a stimulus is in part a function of how temporally distant reinforcement had been prior to the onset of that stimulus. The greater the percentage improvement, in terms of contiguity to reinforcement, correlated with the onset of the stimulus, the stronger a conditioned reinforcer that stimulus will be. Thus, a stimulus associated with a FI 30-s schedule should be a stronger reinforcer if it is preceded by a 120-s period of nonreinforcement than if it is preceded by a 15-s period of nonreinforcement. In the first case, the onset of the FI 30-s stimulus is correlated with an 80% reduction in time to reward (120/150); in the second case, the onset of the FI 30-s stimulus is correlated with only a 33% reduction in time to reward (15/45). Another theory of conditioned reinforcement that is similar in spirit to DRT is the hyperbolic value-added model. It would make the same prediction in the case above since the FI schedule that follows the longer period of nonreinforcement represents greater value added than the same FI schedule following the shorter period of nonreinforcement.

Observing

The major experiments that have been conducted to distinguish between the efficacy of uncertainty-reduction theory and DRT have used the observing-response procedure. Observing responses are those that produce stimuli correlated with schedules of reinforcement but have no effect on the occurrence of reinforcement. For example, two equally probable schedules of reinforcement differing only in frequency of reinforcement – say, VT and EXT – may alternate unpredictably. Effective observing responses would produce stimuli, identifying the schedule in effect.

The study of observing responses has been deemed central to an understanding of the basis for conditioned reinforcement. Does a stimulus function as a conditioned reinforcer (and therefore maintain observing responses) because it is correlated with the occurrence of primary reinforcement (as required by DRT and other conditioned-reinforcement hypothesis views) or does

a stimulus function as a conditioned reinforcer (and therefore maintain observing responses) because it predicts or informs about the availability of reinforcement (the information or uncertainty-reduction hypothesis)? As Bloomfield argued, the critical test for distinguishing between these views is whether or not a stimulus associated with an undesirable outcome, or bad news (in this case, the news that the current schedule is EXT), is reinforcing. The overwhelming preponderance of evidence shows that it is not, a result consistent with the conditioned-reinforcement hypotheses such as DRT. These results have been obtained with humans as well as with nonhumans (including several experiments with pigeons).

Given that stimuli associated with negative outcomes do not serve as reinforcers, we can ask whether the less positive of two stimuli in a situation will serve as a reinforcer. This is a fundamental question since the less positive stimulus is still associated with primary reinforcement. In other words, if a stimulus is paired with an FI 5-min schedule and its availability alternates with an FI 1-min schedule, will the FI 5-min stimulus serve as a reinforcer (e.g., will it maintain observing)? The answer is that it will not. Yet, the very same stimulus (associated with the same FI 5-min schedule) will serve as an effective reinforcer (and maintain observing) if it instead alternates with a FI 10-min schedule (instead of the FI 1-min schedule of the prior example). In the case of the alternating FI 1 and FI 5 schedules, the average time to reinforcement is 3 min. While occurrence of the stimulus associated with the FI 1 represents a reduction in time to reinforcement (from 3 to 1 min), and therefore serves as a conditioned reinforcer, occurrence of the stimulus associated with the FI 5 schedule actually represents an increase in expected time to reinforcement (from 3 to 5 min) and therefore does not serve as a reinforcer. When that same FI 5 alternates with FI 10, however, its occurrence is correlated with a reduction in time to reinforcement (from seven and one-half minutes to five) and therefore functions as a conditioned reinforcer. This is a critical discovery and one that clearly undermines the viability of views based strictly on temporal contiguity (such as the pairing hypothesis discussed earlier). It is the correlation of a stimulus with a reduction in time to reinforcement – not its contiguity with reinforcement – that largely determines its reinforcing strength. A similar conclusion applies to Pavlovian conditioning.

In summary, the research on observing points to this conclusion: only the more positively valued of two stimuli should maintain observing, since the less positive stimulus is correlated with an *increase* not a decrease in time to reinforcement (or a reduction, not an increase, in time to a punishing event). Conditioned reinforcers are those stimuli correlated with a reduction in time to reinforcement (or with an increase in time to an aversive event).

Choice

Most of our behaviors involve making choices about whether to engage in an activity or not (go-no go choice) or choosing among two or more simultaneously available options. The established method for studying choice is to present at least two schedules of reinforcement simultaneously. Technically, these are concurrent schedules of reinforcement. If two VI

schedules are presented concurrently, for example, the organism's responses on each of two response keys are reinforced according to the VI schedule associated with that key. The consequences of responding on each of the two keys may be varied systematically, and the effects upon the organism's choice responses may be measured.

As might be expected, choice in this procedure is remarkably sensitive to the manipulation of independent variables. Thus, organisms distribute more of their choice responses to outcomes with greater magnitudes (or durations) of reinforcement (say 6 s *versus* 2 s of food reward for a pigeon), to more preferred reinforcers (say bananas over lettuce for a monkey), or to the response that requires least effort (say if the force to activate the key is varied across keys). The variable that has been assessed most intensively, however, is the rate of reinforcement (e.g., as in VI 1 min *versus* VI 3 min schedules). The assessment of choice as a function of rate of reinforcement has given rise to elegant quantitative models of choice behavior.

The Matching Law

With concurrent interval schedules, the organism obtains a higher rate of reinforcement for responding on both schedules. This results from the fact that on interval schedules, reinforcements become available with the passage of time. If the organism responded exclusively to the preferred key (all other variables being equal, the one associated with the higher rate of reinforcement, i.e., is the richer VI schedule), it would obtain all the reinforcements available from that VI schedule but none from the other (less rich) VI alternative. But by responding at least occasionally on both alternatives, rate of reinforcement may be maximized. For example, if the organism were presented with a concurrent VI 1 VI 3 schedule, it would receive one reinforcement per minute if it responded exclusively on the VI 1, but 1-1/3 reinforcements per minute if it responded occasionally on the VI 3 schedule as well.

Richard J. Herrnstein took advantage of this characteristic of concurrent VI schedules to study how an organism's choice responses varied as a function of the relative rates of reinforcement on each of two concurrently presented VI schedules. He exposed pigeons to a series of conditions, each with a different pair of concurrent VI schedules, and plotted the percentage of choices made to one alternative as a function of the percentage of reinforcements received for responding on that alternative. For example, with a concurrent VI 1 VI 3 schedule, the percentage of reinforcements obtained on the VI 1 alternative is approximately 75%. What is the corresponding percentage of choices made to the VI 1? Herrnstein found that the answer approximated 75%. The results fell on a straight line with a slope approximating 1.0. In other words, the pigeons tended to 'match' their choice proportions to the reinforcer proportions arranged by the experimenter. In symbolic form:

$$R_1/(R_1 + R_2) = r_1/(r_1 + r_2)$$

where R denotes response rate, r denotes reinforcement rate, and the subscripts identify the two alternatives. A comparable matching relation has been shown to describe the amount of time an organism spends responding on one of two alternatives or engaged in one of two reinforced activities. This matching relation has provided a viable approximation to

choice in many different experiments with concurrent schedules, including experiments with pigeons pecking keys, pressing treadles, or responding in a shuttle box procedure; with rats pressing levers; and with humans performing a vigilance task.

The matching equation has been expanded to apply to a wider range of independent variables and situations by Herrnstein and by several of his students, including variations that help to account for absolute rates of responding on single (simple) schedules. The matching law has also been applied with success to address problem behaviors. References are included in the endnotes.

Alternatives to the Matching Law

There are alternative explanations for matching. Perhaps the most venerable is that associated with Alan Silberberg and Charles Shimp and their students. Their maximizing accounts stress the central role played by the interresponse time (IRT) or the duration of time between responses. Shimp has maintained that matching on concurrent schedules is a by-product of the organism's tendency to maximize reinforcement, that is, to select the option with the highest momentary probability of reinforcement at the time that the choice is made. According to this account, matching is a result of emitting IRTs that maximize momentary reinforcement probabilities. We conclude by noting that while organisms are indeed sensitive to momentary reinforcement probabilities, and that this sensitivity may well account for many instances of matching, it is nonetheless the case that matching has been shown to occur in the absence of measurable momentary maximizing.

Choice for conditioned reinforcers

We have already discussed the central role conditioned reinforcement plays in behavior. One attempt to assess the generality of the matching relation involved seeing whether it applied to choice for schedules of reinforcement that are themselves conditioned reinforcers. For example, consider again a choice between VI 1 and VI 3 schedules of reinforcement. This time, however, the schedules are not available concurrently but are the outcomes being chosen in a concurrent-chains procedure, depicted in Figure 2. This procedure measures choice by the rate of responding emitted in the choice phase, consisting of two equal, concurrently available, VI schedules, each leading to a different outcome (the outcome phase). Since the concurrent VI schedules in the choice phase are equal, differences in response rates between them may be assumed to reflect differences in the reinforcing effectiveness of the outcomes being chosen (in our example the VI 1 and the VI 3). Does the organism match its rate of choice responding to the reinforcement proportions available in the outcome phase, as the matching law would require? The answer is negative. Many experiments have demonstrated that the degree of preference for the richer outcome (here the VI 1) is a function of the length of the choice phase. The longer the choice phase, the more rewarding is the acquisition of either outcome: thus, choice for the preferred outcome tends toward indifference (choice proportion close to 0.50). With a very short choice phase, only the richer outcome brings the organism substantially closer to reward. Hence, choice for the preferred outcome tends toward exclusive preference. In summary, as the choice

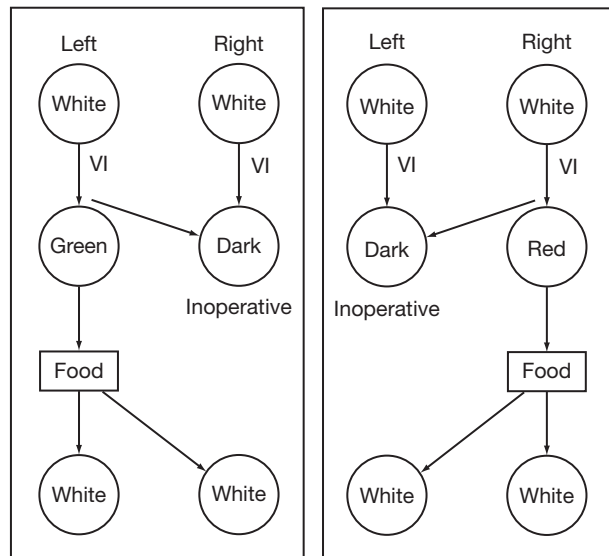

Figure 2 The concurrent-chains procedure, widely used in the study of choice. See text for details. Reproduced with permission from Fantino E (1969) Choice and rate of reinforcement. *Journal of the Experimental Analysis of Behavior* 12: 723–730.

phase increases in duration, the obtained choice proportions vary systematically from exclusive preference (1.0) to indifference (0.50).

Several contemporary models of choice have captured this finding, including two discussed earlier (hyperbolic value-added theory and DRT). The matching law fails here because it has no term for temporal context: it requires a 3:1 preference for the VI 1 over the VI 3 whatever the length of the choice phase. When discussing observing, we noted that a given schedule might be a conditioned reinforcer in some situations but not in others, depending upon the temporal context in which it was embedded. An extensive literature on choice for schedules of conditioned reinforcement also underscores the central role played by temporal context: outcomes may not be judged independently of the context in which they occur.

Self-Control

One of the most important by-products of the study of choice is that of the particular choice we refer to as involving self-control. Self-control involves a choice between an immediate smaller reward (the impulsive choice) and a larger more delayed reward (the self-control choice). Self-control, once thought to be an exclusively human ability, has been demonstrated in nonprimates as well. For example, hungry pigeons were given the opportunity to peck a red key (the impulsive option) and obtain food immediately, followed by a penalty period in which the pigeon waited in darkness for the next trial to commence. However, if the pigeon waited until the red key light turned green, it could peck the green key (the self-control option) and obtain food (in one condition, three times) without a subsequent penalty period (the next trial commenced as soon as the food was consumed). The results (averaged across the data for three pigeons) are shown in Figure 3. Note that while the pigeons demonstrated minimal self-control, their

Figure 3 Rudimentary self-control in the pigeon. The more advantageous the delay, the more likely pigeons were to demonstrate self-control. The higher and flatter gradients indicate greater self-control. See text for details. Reproduced with permission from Fantino E (1966) Immediate reward followed by extinction vs. later reward without extinction. *Psychonomic Science* 6: 233–234.

tendency to do so increased in proportion to the advantage of delaying. In a subsequent experiment, pigeons were given the opportunity to avoid the impulsive option (pecking the red key) by making a ‘commitment’ response that prevented appearance of the red key. Some pigeons consistently made the commitment response, thereby demonstrating much higher rates of self-control than observed in the prior study.

A characteristic feature of self-control is preference reversal. Far enough in advance, humans invariably choose the larger, delayed reward (e.g., waking on time to do exercises before work, thus improving long-term health). However, as the actual choice approaches, preference may shift toward the smaller more immediate reward (an extra hour of sleep). Self-control in the larger sense involves rearranging our environment so that we are more likely to choose the larger delayed reward. Thus, in the example above, we may set an alarm clock and place it out of immediate reach, thus increasing the likelihood that we will arise in time for the exercises. The phenomenon of preference reversal is not restricted to humans. In a classic experiment, Howard Rachlin and Leonard Green showed that pigeons’ preference shifted from self-control to impulsivity as the actual choice approached.

In summary, self-control, as all choice behavior, is a product of environmental contingencies, and acquiring self-control involves understanding these contingencies and rearranging our environments to achieve our desired goals.

Other Issues

A complete account of behavior is obviously more complex than that presented in this brief overview. Here, we have

summarized some central conclusions about other important behavioral phenomena.

Aversive Control

We have concentrated on behavior maintained by positive reinforcement. The same principles apply to behavior maintained by negative reinforcement, that is, to behavior that is strengthened by the avoidance of or escape from aversive stimuli. Both positive and negative reinforcements strengthen the behavior they follow. On the other hand, punishment is the opposite of reinforcement in that it weakens the behavior it follows. Although there are subtle differences (punishment may create anxieties and may result in escape from a therapeutic situation), punishment and reinforcement are symmetrical in their effects (though, of course, opposite in sign) and no special behavioral principles are required to understand punishment.

Other Phenomena

Phenomena such as autoshaping, taste aversion learning, and the biological context of conditioning have been the subject of scores of landmark conditioning experiments.

Applications

The principles and methods of operant conditioning have been put to important use in several applied settings, notably clinical (especially in the treatment of autism and phobias) and educational settings. The application to the enhancement of self-control has already been noted, though the range of techniques has not. The methodology of operant conditioning has been exploited with great success in research on psychopharmacology and on brain mechanisms. In addition, cognitive phenomena have been better understood with the application of operant theory and methodology. References and suggested

readings appear in the endnotes. While the applications of operant conditioning may constitute the field's most celebrated contributions (and there are far more applied than basic practitioners), these contributions rest firmly on the theoretical and empirical underpinnings provided by the at least 60 years of research inspired initially by the canonical writings of B.F. Skinner.

Glossary

Context effects The influences of organizational contexts on individuals and groups in them. The influences of individuals and groups on their organizational contexts. The reciprocal influences of individuals, groups, and organizational contexts.

Macroorganizational behavior Approaches to gaining knowledge about organizations that examine organizations as entities, and account for their structures and reciprocal influences with their environments.

Microorganizational behavior Approaches to gaining knowledge about organizations which focus on internal characteristics and processes, particularly on the behavior of individuals and groups in organizations.

Organizational behavior The systematic study of the antecedents and outcomes of the behaviors of individuals and groups in organizations and of the behaviors of organizations and populations of organizations.

The study of organizations and behavior in them has its roots in industrial, social, and cognitive psychology, organizational sociology, industrial/organizational economics, and public administration theory. Organizational behavior (OB) is the systematic study of antecedents and outcomes of individual and group behavior in organizations and the behavior of organizations and populations of organizations. The objects of study are everything from individuals and groups in organizations, to the organization as a whole, populations of organizations, and the relationship of organizations to larger social structures, such as the state and society. The field's primary goal is to understand behavior in organizational contexts.

The analytical tools of OB are those of social science generally. Data may be drawn from existing databases or collected specifically for a given study; common sources include individual or organizational surveys, laboratory studies, structured interviews, observation and ethnography, or corporate filings, reports, and press releases. Current quantitative analytical methods are similar to psychological, econometric, and epidemiological methods, such as ANOVA, multiple regression, computer simulations and survival analysis. Qualitative methods include grounded theory analyses, comparative case studies, and historical or archival research.

OB research is both interdisciplinary and relatively young. As such, it remains in a state of theoretical development. New theories and concepts are introduced on a regular basis, but there is little agreement on appropriate substantive issues for and styles of inquiry. OB typically divides itself into concern with 'micro' issues, or those issues that focus on individuals and groups in organizations, and 'macro' issues, or concerns for organizations and groups of organizations. Attention is beginning to be given to linking individuals and organizations to one another and to their contexts. This article describes the major research preoccupations in each of these areas.

Microorganizational Behavior

Early contributions to microissues in organizational behavior have their roots in industrial and social psychology. Systematic research on small group phenomena began with Kurt Lewin's

studies of leadership and the examination of small group processes at the Hawthorne works of Western Electric. Both of these activities occurred during the late 1920s and the 1930s.

For a number of years, the major topics of interest to researchers in organizational behavior were motivation, work attitudes, and leadership. Other specialties were more recently added to this body of research. Studies of these issues often ignore context effects.

Motivation

Motivation research in organizational behavior attempts to explain how individuals direct their energy over time toward accomplishing a shared, organizational goal. Motivation is a function of an individual's intensity, direction, and persistence of effort, and, coupled with his or her ability to perform, it accounts for employee performance on a given task.

The history of research in motivation can be roughly divided into earlier theories that espouse a needs-based approach, and contemporary theories that focus on cognitive antecedents to performance. Despite the fact that early theories have little empirical support, they retain importance in the work setting since managers frequently cite them, presumably because they are both intuitively appealing and because they persist in MBA curricula. Key early theories include Maslow's Hierarchy of Needs Theory, which postulates inherent, ordered human needs; MacGregor's Theory X and Y, in which employees are viewed as either inherently disliking and resisting work or as amenable and willing to participate in work; Herzberg's Two-Factor (Motivation-Hygiene) Theory, in which intrinsic factors are related to job satisfaction and extrinsic factors are related to job dissatisfaction; and McClelland's Three Needs Theory, which divides employees by their need for achievement, power, and affiliation. One of the earliest attempts at examining motivation is Skinner's Reinforcement Theory, in which behaviors are environmentally caused (e.g., if you do X, you will get Y). It is important to note that reinforcement is often excluded from theories of motivation because it does not account for the initiators of behavior.

Contemporary theories of motivation include Locke and Latham's Goal-Setting Theory, Cognitive Evaluation Theory,

Bandura's Self-Efficacy Theory, Adams' Equity Theory, and Vroom's Expectancy Theory. The key finding of Goal-Setting Theory is that high specificity in management goals is positively related to high performance on a task, and particularly that goals with high difficulty, when accepted by employees, produce high performance. Cognitive Evaluation Theory demonstrates that extrinsic rewards (such as pay) for a behavior that was previously intrinsically motivated decreases overall motivation, suggesting that pay should not be contingent on performance. Bandura's Self-Efficacy Theory, also known as Social Learning or Social Cognitive Theory, focuses on an individual's belief that he or she is capable of performing a task, and develops tools to stimulate this belief. Equity Theory argues that employees compare the ratios of their effort on the job and pay relative to a judgment of a comparison employee's effort and pay; the individual then adjusts one or more components, such as his or her effort, to achieve equity. Current research in Equity Theory attempts to address not just the rewards allocation and comparison group, but also the distributive, procedural, and interactive justice of certain decisions. Expectancy Theory is the most current of the contemporary theories of motivation; its key result is to emphasize the cognitive links between effort and performance (expectancy), performance and rewards (instrumentality), and rewards and personal goals (valence). Expectancy Theory admonishes the manager to focus on clearly linking and aligning organizational goals, individual rewards, and employee goals.

Work Attitudes

A second frequently researched topic in organizational behavior is work attitudes, or positive or negative evaluations about various aspects of one's work. Much of the work is concerned with developing attitudinal measures and searching for antecedents and consequences of work attitudes. Newer lines of research explore the basic nature of affect (emotion), the relationship of moods and work, and the expression of emotion at work. Despite substantial evidence that job satisfaction is not consistently linked with performance, it still remains the most frequently studied topic, followed by job involvement and commitment.

Considerable debate has swirled around whether work attitudes are inherent within individuals or whether they are a product of the environment. A weak but significant correlation has been found between twin work attitudes, suggesting there may be a genetic link. This position is questioned by researchers who provide evidence that situational factors influence emotion. For example, individuals' attitudes are often shaped by the attitudes of others around them, the amount of pay they are given to do a job, their position as a demographic minority or majority among their coworkers, or the financial performance of their employers. Some theorists propose that job attitudes are the result of an interaction between individuals and their environments. For instance, narcissists are more likely to enjoy tasks where there is ample recognition for their achievements, whereas the attitudes of individuals who are less narcissistic are likely to be unaffected by this characteristic of the task. In the interactionist approach, what matters for job attitudes is the match between an individual's personal values and the values of an organization. Yet, some research

cautions that this middle-ground is still an oversimplification of the relationship between individuals and their roles and does not adequately account for how both personalities and situations respond to each other and change through time.

Leadership

Leadership is probably the largest, yet most nebulous area of management research. In general, the field is concerned with an individual's capacity to influence a group toward a shared set of goals, particularly through the development of vision, strategy, organizational alignment, and individual inspiration. Researchers predominantly agree that there is a difference between *management* and what a manager does versus *leadership* and what a leader does, even if the those roles are occupied by the same person; both are concerned with satisfaction and performance, though a manager focuses on the 'engineering' tasks of planning and implementing, while a leader focuses on the 'visionary' tasks of clarity and change. In both the research and managerial spheres, this difference is often described as a distinction between transactional and transformational forms of leadership. Transactional leadership centers on social exchange principles, and emphasizes role and task clarification and rewards schemes to motivate followers. Transformational leadership, often partnered with charismatic leadership, focuses on leader-follower identification, and emphasizes consideration and intellectual stimulation to inspire followers to transcend personal self-interest for the organizational good.

The field has gone through three basic stages of development, and, despite recent theoretical advancements, it remains relatively weak empirically. The first set of theories focused on the personal traits that make leaders different from others – first on physical traits, such as height and appearance, then later on charisma and across the Big Five personality characteristics. The main difficulty with this early work is a lack of convincing causal relationships. For instance, while extraversion strongly predicts leadership emergence, it has no relationship with effectiveness as a leader. Another problem is that charisma, a key construct in leadership, is itself still poorly understood.

While the first set of theories argued that leaders are born, the second set argues that leaders can be made, promoting the situational and behavioral aspects of leadership. Two famous studies (by Ohio State and University of Michigan researchers) came to similar conclusions about critical behaviors that are associated with high-performance leadership. First, individuals can be trained to display an employee-oriented focus, emphasizing interpersonal relations characterized by trust, respect, and consideration. Second, individuals can be trained to display production-oriented (or initiating structure) focus, in which they develop task structure according to job design precepts and clearly assign roles to improve goal attainment.

The third set of theories used results from trait and behavioral theories to develop contingency models of leadership, meaning that the appropriate leadership style depends on other things. Fiedler's Contingency Model deals with relationship- or task-oriented leadership styles, which are assumed to be fixed within a person, with three main situation types: leader-member relations, task structure, and position power. A key finding from this research is that

task-oriented leaders perform best in situations of high and low control, while relationship-oriented leaders perform best in moderate control situations. Cognitive Resource Theory describes stress as 'situational unfavorableness,' and identifies leaders as those who can use their intelligence and experience to mitigate stress. Although it has poor research support, Situational Leadership Theory added critically to the debate on leadership by drawing attention to the role that followers at different levels of readiness, ability, and desire play in the leadership dynamic. Leader Member Exchange (LMX) Theory is a social exchange perspective which argues that, due to time pressures and other constraints, leaders establish special relationships with a small group of their followers who are trusted, get a disproportional amount of their attention, and play a special role in influencing decisions. In turn, other followers get less attention and are relegated to the social out-group. Finally, Path-Goal Theory argues that the leader's task is to provide resources to achieve the common goal, and that this is evidenced through four main types of leader behavior: directive, supportive, participative, and achievement oriented.

The most current stream of research in leadership examines the construct in a network context. The 'New Science of Leadership' describes leadership as the effective leveraging of skills and resources by maintaining a strong network position, coupled with the capacity to systematize behavior in others. As such, one core finding is that leadership effectiveness is greater when an individual maintains diverse connections to groups that don't mutually know each other, thus avoiding 'echo chambers' caused by clique membership.

Ethics and Responsibility

Driven in part by regulatory pressures and whistleblower provisions, as well as the fear of bearing costs from negative press and litigation, corporations are turning to the formal adoption of ethical principles in their management. Organizational research in ethics and corporate responsibility builds on principles from philosophy to develop ground rules of ethical conduct for managers and employees. For example, Galinsky's Principles of Value-Based Reasoning build on traditional philosophical tensions, such as duty versus utility and intentions versus outcomes, and modern psychological research to provide a route to generate value-ordered preferences applicable in business situations. Especially in a global context, where cultures and contexts differ, it is important for organizations to develop clear beliefs about relativism, the unintended consequences of incentives, and standardized versus contingent norms of conduct.

Research in organizational ethics includes insights from clinical and social psychology, as well as economics and political science. Chen and Santos' research on how monkeys fairly 'pay' each other with food demonstrates a seemingly fundamental sense of fairness that trumps even self-interest. Functional magnetic resonance imaging studies conducted at Princeton University show differential brain activity across choices to act in two scenarios involving people at risk of being killed by a trolley. Of course, nearly all social psychology plays some role in ethical conduct. Two particularly important research streams include Milgram's studies on psychological distance in which subjects are ordered to administer

punishment to a confederate, and Staw's studies on escalation of commitment, which emphasizes the incremental process by which people can unintentionally yield to unethical behavior. Work by Thaler and Sunstein, an economist and a political scientist, on opt-in versus opt-out organ donation programs describes how management can set default values framing choices in terms of gains or losses from which individuals are unlikely to change; this observation has become known as 'paternalistic libertarianism.'

Judgment and Decision Making

Organizational research on judgment and decision making (JDM) exists at three levels of analysis. At the individual level, JDM research focuses on cognitive pathways and heuristics that tend to bias decision making. At the group level, it focuses on how groups amplify or suppress decision quality and task performance. At the organizational level, JDM describes how organizations agree on courses of action, develop rules, and maintain collective memory. This summary addresses the first two levels of analysis; a summary of the organization level appears in the macroorganizational section of this entry.

A decision is defined as a choice among alternative courses of action. At the individual level of analysis, organizational behavior research in JDM complements work done in clinical and social psychology and in behavioral economics. As in these fields, early models of rational decision making (where decision-makers know all the choices and their outcomes in advance, have a utility function that rates outcomes in rank order of preference, and generates an expected utility function) have been supplanted by more realistic behavioral models. Research conducted by the administrative theorist Herbert Simon and his Carnegie School colleagues (including James March, Richard Cyert, and others), and based on the earlier work of Chester Barnard, promoted a conception of the 'bounded rationality' of actors in a firm. Bounded rationality describes how people attempt to act according to a rational calculus, but are prevented by limited time, resources, awareness of alternatives and preferences, and information processing capacity. Unable to properly optimize decisions, individuals instead 'satisfice,' or choose the first decision option that meets a sufficient base set of criteria. Moreover, they often cut short the decision-making calculus altogether by relying on heuristics, or cognitive 'rules-of-thumb' that simplify based on set routines or patterns of stimuli.

Much of JDM research is concerned with the conscious and nonconscious heuristics that can bias decision making. There are dozens of decision-making biases, but many sort into those resulting from the availability heuristic, in which readily available instances are more salient, the representativeness heuristic, in which a phenomenon's chance of occurring is likened to that of similar occurrences, and anchoring-and-adjustment, where initial given values are uncritically relied on in making assessments. Two often-cited biases in organizational research are fundamental attribution error and escalation of commitment. The former describes an individual's tendency to attribute one's own action to a situation, but the actions of others to a person – thereby assuming or divesting responsibility for consequences. The latter describes an individual's tendency to invest additional time, money, or effort into a failing course

of action; this bias is driven by an aversion to admitting mistakes, the effects of sunk costs, and by the consequences of risk aversion described in Kahneman and Tversky's Prospect Theory.

Groups and Teams

Modern research in group dynamics traces its roots to the Hawthorne Studies at Western Electric Company. The original hypothesis was that the level of work place illumination influenced productivity; the findings were that regardless of level of illumination worker productivity increased (even when light level was reduced to about the level of moonlight). On further examination, researchers found that a number of group properties strongly influenced individual behavior – among them that formal and informal groups served different functions.

Since that time research on groups has come and gone in a cyclical fashion. Common research themes include the performance of work groups under various conditions, the identity and perception of group roles, conflict of roles between members, the development and maintenance of norms of conduct, status differentials between members, and cohesiveness of groups over time. Conformity to group norms and the capacity of minority members to influence majority thinking have also been explored in various settings, especially among juries. Studies on negotiation within and between groups have examined ways groups gain the necessary resources for their goals and how status, credit, and rewards are divvied out to group members.

Several emergent decision-making phenomena are evident at the group level of analysis. The first is the simple observation that people must not only attempt, in some form, to align their decision processes, but also that they must agree on outcomes in order to commit to a course of action. In general, group decision making is typically more effective than individual decision making, but is almost always less efficient, as it takes more time to reach consensus. One observation about group decision making is that groups produce outcomes that are more accurate than the outcome of its average member, but less accurate than its most accurate individual member. Groups also enable transactional memory, in which groups are able to remember more collectively than any individual member. Research by Jehn, Kilduff, and others on task-oriented conflict in groups shows that cognitive diversity among group members tends to lead to more optimal and more creative solutions. Other research shows that mere participation in a decision-making process leads to better individual buy-in to the group decision, even if the individual's personal views were not incorporated in the final decision. Group-level decision making also introduces biases produced by norms, conformity pressures, group image, and minority/majority effects. For example, groupthink is a means for a group to protect its positive image by reinforcing assumptions and the majority position, pressuring doubters, and creating illusions of unanimity. Group polarization, groupshift, or 'risky shift' is the tendency of groups to exaggerate an initial position to a more extreme decision than any individual member would be willing to proffer.

In recent years, attention has shifted from the group to the team. Groups are appropriate for tasks requiring pooled

interdependence – these tasks require members to share information and resources in support of each others' areas of responsibility, but do not require frequent adjustment of goals between group members. Teams are appropriate for tasks requiring reciprocal interdependence – simply pooling information is not sufficient for these tasks, frequent exchange of resources and realigning individual goals is necessary. A group of reporters can independently produce a newspaper, but an integrated team of health care professionals is usually needed to produce health in a given patient.

As work becomes more complex and multidimensional, there has been a growing emphasis on the dynamics of teams, and on the maintenance of coordinated relationships between members. However, teams are not unambiguously better than groups. Developing and maintaining teams generally require resources and incentive arrangements that groups do not. For instance, because work group performance is the summation of individual performance, accountability and rewards are often centered on individuals. A similar accountability and reward scheme in a team setting may not only fail, but may be pathological to overall performance.

McGrath and his colleagues identify three levels of dynamic interaction among teams – local, global, and contextual. Both Kozlowski et al. and Marks et al. have developed theories that describe inputs, processes, and outcomes that develop over time as teams interact. While these models differ slightly, each recognizes the underlying notion that teams are complex, dynamic systems existing in larger contexts of people, tasks, technologies, and settings.

Organizational Culture

In organizational behavior, the adage 'The more things change, the more they stay the same' has been empirically investigated in attempts to understand how organizational cultures develop over time. Schein has described organizational culture as 'shared basic assumptions' that are retained and taught to new members. Stated rules, norms, and artifacts of culture provide anthropological insight into the organization's critical assumptions. In studies of IBM employees, Hofstede used dimensions of culture, such as power distance and individualism versus collectivism, to describe the similarities and differences expressed across countries. Schneider proposed that organizational culture is shaped by three processes: attraction, selection, and attrition (A-S-A). First, individuals with values similar to those of an organization are attracted to apply for positions in it (attraction). Next, the organization selects and retains those individuals who best fit its culture (selection). Finally, any remaining individuals who do not fit with the organizational norms eventually leave the organization (attrition). This three-step process leads organizations to become more homogenous over time. The A-S-A model is widely considered fundamental to the development of organizational culture and is generally accepted within the field. In a recent revision, two additional processes were added to the A-S-A model to account for the abilities of organizations to shape individuals and for individuals to shape organizations. Transformation refers to the fact that even if people do not initially fit the organizational culture, their attitudes and behaviors may be molded through socialization and training to improve their

fit. Manipulation, on the other hand, describes the process by which, consciously or unconsciously, individuals may shape the organizations they are in to better fit their individual values and habits.

Emotion

Much attention has been given recently to the role of emotions in how individuals perceive and react to situations within organizations. Research in the perception area focuses on how individuals feel emotions, and the consequences to decision making, creativity, and organizational good citizenship behavior. Research in the reaction area focuses on how individuals display emotions, and the links to group performance. The tight, reciprocal relationship between emotions and cognition is still being explored.

One of the main objectives of research on emotions within organizational behavior is to understand how emotional reactions are socially constructed and how the perception of emotional responses is likewise shaped by organizational contexts. Some roles within organizations require individuals to express particular kinds of emotions; for example, Rafaeli and Sutton's work with bill collectors shows how anger is expressed as a means of social influence. Hochschild's work with flight attendants demonstrates how expressing emotion becomes uncompensated 'emotional labor,' creating stress for individuals who must conceal their true emotions. Research has also investigated how individuals' sensitivity to the emotions of those around them may improve or hinder their work performance, and how emotions from home might spillover into work and vice versa.

Creativity and Innovation

Creativity and innovation are essential means by which an organization competes in a market – yet a comprehensive theory for these concepts is still lacking. Organizational creativity refers to the production of a novel product or process, and organizational innovation to the application of ideas, both novel and adapted from another source or for another purpose, in an organizational context. Identification and measurement remain challenges for creativity research in particular, with expert assessment generally present at some stage.

As with leadership, the earliest conceptions of creativity focused on individual trait-based, or 'genius,' explanations. While these eventually gave way to a focus on creative process, the systematic study of creativity really began in earnest with Guilford's 1950 address to the American Psychological Association. The critical observation driving most research in the twentieth century was the importance of divergent thinking in producing creative ideas. Individuals are, in general, not very creative (cf. Ward's alien drawing task). Groups bringing together diverse perspectives tend to trade off efficiency, but gain the constructive benefits of task conflicts over interpretive ambiguity. In this way, groups are almost always more creative than individuals. Extensive case studies of the creative process of design firms are testimony to the divergent thinking theory. In the organizational context, researchers have sought to understand how organizational structures and roles can be designed to enable greater intellectual flexibility and encourage

divergent ways of thinking. Kanter's 'let a thousand flowers bloom' notion stresses the structural, collective, and social conditions that encourage or discourage the adoption of innovation.

Contemporary research in creativity and innovation continues group divergent thinking, but also focuses on elucidating cognitive and affective processes. A series of new methods and perspectives on creativity, including Csikszentmihalyi's systems model, neuroscience studies of brain and behavior, and cognitive computer modeling, are being used to make progress. Nonetheless, several open debates still remain, such as the association between negative affect and creativity and whether intelligence and creativity are part of the same mental process.

Macroorganizational Behavior

The macroperspective is traditionally associated with the disciplines of sociology and political science, and focuses on the emergent social effects apparent at the organizational, field, or population level of analysis. Foundational sociological pieces by Max Weber analyzing bureaucracy and authority in Europe, as well as early studies by Michel, Crozier, and Gouldner, direct attention to the importance of roles and situations. Similar foundational pieces by Wilson, Barnard, and others in the administrative theory tradition of political science focus on governance, authority, and how organizations persist over time.

As seen by macroorganizational theorists, the elements of organizations are social structure, participants or actors, goals, technology, and environments. Social structure refers to the patterned or regularized aspects of relationships among participants in organizations. Organizational participants are those people who make contributions to organizations for a variety of inducements. Goals are considered to be conceptions of desired ends, and are among the most controversial of organizational components. Technologies consist of not only machines and mechanical equipment, but also the technical knowledge and skills of participants. Environment consists of specific physical, technological, cultural, and social aspects of the larger social system in which an organization resides.

There are several ways to present the macroorganizational perspective. A common approach is to use Scott's rational, natural, and open typology, which defines an organization in terms of mechanistic versus organic construction and its relationship with the environment. We have chosen to present this perspective of four topic areas commonly found in the literature.

Organizations as Meaning-Making Systems

Early research on macroorganizational behavior portrayed organizations as tools for efficiently coordinating the actions of individuals. Recognizing the disparities between an organization's actions and its stated goals, theorists began to critically question this rational perspective. The first institutional theories stressed the importance of unofficial procedures within organizations, and the ways organizational routines are shaped as compromises between competing interests (e.g., unions and managers). More recent institutional ('neo-institutional')

theories stress that organizations are constrained by societal institutions, such as governments and professional associations, and that organizational survival is ensured by being considered legitimate to other organizations. Environmental pressures drive organizations within a given field to abide by the 'myths and ceremonies' by which that field operates. Powell and DiMaggio describe three pressures that shape organizations: coercive, normative, and mimetic. Coercive alludes to regulatory and other pressures from the state; normative, to pressures from professional organizations or other certifying bodies; and mimetic, to pressures to copy successful organizations in order to attain success. A core element of neo-institutional theory is that these pressures are not just norms and values of a given institution, but are diffuse and 'taken-for-granted.' In this way, neo-institutional theory describes the constraint that culture and cognition place on organizational actions. More recent theorizations attend to the ways individuals and organizations agentically construct meaning.

Organizations as Networks

Since the 1970s, organizational behavior research has increasingly portrayed organizational actors, both individuals and groups of individuals, as nodes within complex networks. The relationships between organizations or persons are compared to 'pipes' through which resources and information can flow and 'prisms' that yield systemic effects. Network theory spans several disciplines including information science, where the diffusion of innovations is a central focus, and epidemiology, which examines the spread of disease across individuals. Contemporary research uses the distance and strength of ties between nodes, the central or peripheral location of nodes, the number of nodes between two actors, the structural holes between two focal groups or cliques, and other measures to describe social effects, such as how resources and information move from actor to actor.

Research in the organizational realm includes Granovetter's differentiation between strong and weak ties between individuals, where weak ties yield information benefits, such as job opportunities; and Burt's description of the creativity and social capital benefits that accrue to individuals holding a brokerage position between unconnected groups. More recent work includes more mathematical approaches to simulating simple and complex diffusion, and deeper examinations of the content of individual nodes and the effect of network position on individual choice.

Organizations as Decision Making and Learning Systems

Research in decision making at the organizational level is concerned with the issues of decision making that emerge from, but are not merely reducible to, the limits of individual rationality and interpersonal relations. The members of Herbert Simon's Carnegie School of theorists are generally considered the founders and standard-bearers for theory development in this area. Having jettisoned the idea of the hyper-rational 'Homo economicus' in favor of a more realistic behavioral model of 'bounded rationality,' organizational theorists attempt to reconcile how political and institutional issues affect decisions in organizations.

In *The Behavioral Theory of the Firm*, Cyert and March rectify the classic economic view of the firm with the reality of firms as organizations with multiple goals, decision making by satisficing, and subject to imperfect markets. They describe how organizations are adaptively rational systems, composed of coalitions of individuals with common goals who constantly bargain to receive side-payments of slack resources. They also posit that organizations have memories stored in standard operating procedures which are used to pursue a 'negotiated' environment free of uncertainty. In another core research piece, Cohen, March, and Olsen describe the process-oriented Garbage Can Model of organizational decision making. The model argues that organizations are subject to ill-defined preferences, unclear technology, and fluid participation, and that these pressures lead them to become 'organized anarchies' of solutions seeking out problems, rather than vice versa. This conception of decision making focuses on viable matches of problems and solutions, and diminishes traditional calculations of efficiency.

Building on the decision-making literature related to routines and stability, research in organizational learning (and forgetting) finds that routines in organizations develop incrementally through feedback from the organization's history and environment. The consequences of organizational learning processes can be negative as well as positive. For instance, Levitt and March describe a 'competency trap,' in which organizations depend on historically successful procedures without experimenting with or modifying them over time. Levinthal and March expand on this arguing that the decomposability of problems in an organizational context of specialization leads to an overall 'myopia of learning.' In other words, overlooking temporal and spatial disjunctions and discounting errors for the positive feedback of success leads an organization to over-privilege conservatism, or 'exploitation,' at the expense of experimentation and discovery, or 'exploration.' Therefore, organizations have a propensity to fall into 'failure traps,' where their avoidance of risk by relying heavily on exploitation leads them to avoid the beneficial learning of more costly exploration activities.

Organizations as Populations

Population ecology is a theory that describes the organization as one among many organizations competing for resources in the greater environment. Once structured, the organization enters the environment and grows or dies as a consequence of circumstances largely beyond its control. Density dependence is a key feature of population ecology, which describes how populations of similar organizations occupy a resource space, or 'niche.' In the early period of an organization's life, legitimacy, or the extent to which it is deemed to meet appropriate standards befitting an organization of its type, plays the largest role in determining whether the organization survives. Once many organizations have occupied the niche, competition for resources takes over as a force to determine survival. The graph described is an inverted-U shape, where the carrying capacity is the maximum number of organizations that can survive in the niche. Thus, the theory is considered a selection-based theory, because the manager has very little control of the organization's fate once it is put in motion.

Newer incarnations of population ecology ease the strong anti-managerial and anti-adaptationist propositions in the foundation pieces. In particular, Hannan and Carroll's Resource Partitioning Theory describes how managers can choose particular niche spaces where they can compete more effectively; the concept of Mutualism describes how organizations have alternatives to direct competition, through, for example, symbiotic relationships; and, at the very least, Barnett and Hansen's Red Queen Theory demonstrates how organizations can make gains individually, yet fall behind relative to other organizations in the competitive space. Ecological approaches have also taken a recent turn toward considering how organizations choose and construct which categories of organizations they belong to and the effects of categorization on organizational performance.

Context Effects

Presumably, the uniqueness of behavior in organizations is that the organizational context somehow shapes it. Yet, until recently these context effects were largely ignored. Where it does exist, the traditional approach to studying organizational context correlates perceptual measures of context with self-reported attitudes and intentions. It is difficult to know whether such relationships tell us more about the context or the respondent. Today some studies measure context more directly. Some research examines how contexts affect individuals and groups, some looks at how individuals and groups influence contexts, and some looks at the reciprocal relationships among contexts and people.

How Contexts Influence Individuals and Groups

Sociologists portray contexts in terms of opportunities or constraints they provide for individuals or groups. Most organizational behavior researchers are unaccustomed to thinking of their work in this way despite the fact that the distinction between opportunities and constraints is often implicit in their view of organizations. For example, job enrichment techniques might be viewed as mechanisms for enhancing opportunities, while goal-setting can be seen as a control device that constrains behavior.

A study of the role eunuchs played in administering the Ming Dynasty demonstrates how the interpretation of behavior can change when one's view of context changes. Castration was thought about as a technique used by those in power to ensure civil servant loyalty and commitment. It was viewed as a control mechanism or constraint to eliminate competition with the interests of the emperor. The fact that castration was often voluntary suggests an alternative interpretation. Becoming a eunuch provided an otherwise unavailable avenue for upward mobility. The traditional path into the Confucian civil service included an expensive education. Poor men could attain powerful positions and wealth by becoming eunuch administrators, who were almost as powerful as Confucian scholars. Thus, a phenomenon commonly viewed as a constraint might alternatively be viewed as an opportunity and a situation in which context influences individual behavior.

A study of how technological change influenced radiology illustrates different ways contextual proximity influences

organizations. Computer tomography scanning changed individual skill levels, dyadic interactions, department structure, and organizational status. The technology was invented in the 1970s and slowly diffused into hospitals in the 1980s, with a series of reverberations. It initially modified tasks, skills, and other nonrelational variables, which in turn shaped role relations. These altered role relations either changed or buttressed social networks that comprise occupational and organizational structures.

The Influence of People and Groups on Contexts

Three means by which individuals or groups influence organizations are discussed in the literature. The first means is when autonomous people or groups pose as organizations by taking actions that reflect their preferences but claiming such actions reflect organizational policies. The second means is when powerful people (or groups) take actions that influence organizational structures, process, or performance. And the third means is through the aggregation of individual (or group) attributes that influence the organization as a whole.

For example, powerful leaders can influence organizations both by enacting personal decisions that influence the organization, as well as by shaping the thoughts, feelings, and actions of organizational members. Leaders provide explanations, rationalizations, and interpretations of their organizations' activities, and these in turn provide an important contextual lens for followers to make sense of their individual and organizational performance.

Reciprocal Relationships among Contexts, Individuals, and Groups

Because of the effort required in data collection and analysis (e.g., longitudinal studies), little research has been conducted on the complex interplay among contexts, individuals, and groups. One example of successful research of this sort is an examination of the decision to build and operate the Shoreham Nuclear Power Plant by top management of the Long Island Lighting Co. The study shows how the interplay between top management actions and the organizational and political context created by these actions led the company to spend over \$5 billion on a plant initially estimated to cost \$75 million, and which never became fully operational.

When Context Does Not Matter

Sometimes contextual aspects of organizations have little influence on individuals or groups because they are buffered from or simply ignore them. An example is a study examining the relationship of work demands and stress symptoms among newcomers to organizations. The study found that stress symptoms found 9 months after entry were more strongly predicted by stress symptoms reported before organizational entry than by work demands 6 months after entry. Most stress research is cross-sectional, assessing relationships among measures taken closer together in time. If this research had failed to measure stress prior to organizational entry it may well have concluded what most stress research concludes – that stress is predicted by organizational demands.

Conclusions

The field of organizational behavior provides insight into the dynamics of groups and organizations, and of the individuals which compose them. Individuals form into collectives in order to perform work that is otherwise costly, ineffective, or impossible when performed alone. In the past several decades, we have seen the role and diffusion of technology increase, the costs of travel and communication decrease, work integration across a wider range of socioeconomic strata and the growing influence of network design and thinking. These changes have allowed people to work together in new, exciting, and value-creating ways. However, they have also created increasingly complex work tasks, organizational dynamics, performance expectations, and consequences of error. Thus, we argue that research in organizational behavior, and particularly the integration of micro- and macrofindings, will only grow in importance in the coming years. We draw particular attention to topics such as the coordination of relationships, organizational learning, and systems thinking and the reliability, resilience, and sustainability of organizations over time.

Glossary

Cognition A general term associated with thought processes, including information processing, storage of knowledge, and reasoning.

Cognitive map Mental representation of the world around us resulting from experience, direct and indirect learning, and knowledge integration and processing. The body of knowledge we use to make decisions that require spatial and geographic information/knowledge.

Encoding The process of perceiving the world around us and storing what is perceived in memory; information perceived by any of the senses can be encoded. Encoding is highly dependent on motivation and type of behavior.

Landmark knowledge Knowledge for discrete entities and their place in the world. Landmarks knowledge is the basic building block of our cognitive map and is often the first type of knowledge we acquire about a new place. Landmark knowledge can be stored about places that have been visited and perceived directly or through indirect learning such as from maps, books, movies, or stories. Landmark knowledge is closely associated with declarative knowledge.

Map Accurate representation, usually in two dimensions, of a three dimensional space. Maps are most commonly used

to present Earth and parts of Earth that cannot be seen from one vantage point.

Procedural/route knowledge Knowledge for associations between and among declaratively known places and things, such as landmarks. Procedural knowledge is limited to the direct association or connectivity of places and is essential for route knowledge.

Scale Geographic term associated with both maps (the ratio relationship between the map and the size of the space in reality being represented) and geography. In geography, scale is sometimes used as synonymous with size such that large scale spaces are spaces that are large and small scale spaces are small.

Spatial behavior Acts exhibited as part of goal directed spatial decision making and generally the outcome of processing spatial knowledge held in the cognitive map in response to an internal or external directive.

Survey knowledge Knowledge for configurational relationships between and among places in a cognitive map that supports judgements, decisions, and behaviors that rely on metric knowledge of the world. Survey knowledge allows for accurate judgements about relationships that have not been directly experienced, such as traveling on a shortcut between two known places along a path that has not previously been followed.

When we are lost, we often turn to paper maps to find our way and learn about our surroundings. Similarly, when we are finding our way through the world or facing spatial, geographic, or environmental decisions, we consult another type of map, our cognitive map. Our cognitive map is the internal mental representation of the world as we know it and the accompanying affective responses associated with this knowledge. It functions as the repository of all that we know about the spaces and places we have visited or learned about directly and indirectly. While we rely on this mental representation when making decisions requiring geographic and/or spatial understanding of the world, it is also distorted, incomplete, and a patchwork of what exists in reality that contains metric and nonmetric knowledge. The term 'cognitive map' refers to a cognitive representation of space and geography. The differences between our cognitive understanding of reality and reality itself make it very unlikely that this representation is at all 'map-like.' The term map is a useful reminder of the centrality of space and geography to what is in our cognitive map and how we use that information. Researchers at the intersection of spatial cognition, geography, computer science, philosophy, neuroscience, and education contribute to our evolving understanding of how we come to know the world around us, how we use that knowledge, and the range of individual and group differences associated with our cognitive map.

Cognitive maps are highly dependent on, and play an important role in, human spatial behavior. As we experience the world we acquire spatial knowledge and accumulate that knowledge in our existing cognitive map. The nature of the behavior we are exhibiting or activity we are participating in plays an important role in what we direct our attention to and what spatial information is added to our cognitive map. For example, if we are a passenger in a vehicle driving through a city we will pay attention to quite different things than if we are the driver. If, as the passenger, one is told that they will be required to drive the vehicle on the return trip, attention will again be paid to different features in the environment. At the other end of the cognitive mapping spectrum is the nature of the behavior that requires the use of our cognitive map. We are likely to call upon different information if we are asked to give directions from one place to another as opposed to being asked to walk or travel there on our own, even though the resulting action or activity undertaken for both parties would be very similar. It is also important to differentiate among our cognitive map, the map of geographic information that we hold in our head, and the various ways we use that representation. Depending on why or how we are using our cognitive map different components of it or different depths of its complexity will be called upon. If a task is straightforward or simple, there will be no need to use all that is known about an environment;

such behavior might indicate to an observer that we do not know as much as we do. If someone is asked to travel from one place to another and does so successfully this does not tell us much about what they know of the world beyond that single path. Understanding the ways we use our cognitive map include studying how people find their way in new settings or how we choose a neighborhood in which to live. It is also important to understand the structure, development, and processes that are all part of our cognitive map independent of context specific applications (like navigation, environmental reasoning, opinions and judgements about places, etc.). A variety of theories and conceptual frameworks have emerged to understand how spatial and geographic knowledge is coded, stored, accessed, and processed in our cognitive map. A defining feature of our cognitive map is the importance of individual differences in all aspects of cognitive mapping. Individual differences in how we interact with the world, acquire spatial and geographic knowledge, how knowledge is stored and associated, processing that knowledge for discrete tasks, and externalizing what we know about the world is an essential element of our cognitive maps and makes studying these structures so interesting.

Our cognitive map exists because so much of what we interact with in the world has important spatial character. Verbal and textual descriptions of places and spaces are converted in our cognitive map to a representation that includes spatial properties represented in those descriptions. Viewing maps of spaces that are much larger than what in reality could be experienced in one interaction (maps of the world, continents, countries, cities, etc.) will produce a cognitive map that can be used to find one's way in that space, and subsets of that space, even if we have never visited it or experienced it directly. The richness of our cognitive map, the way we acquire and process the knowledge stored there, and the ways we integrate that knowledge in our day to day lives, makes understanding our cognitive map significant and challenging. As such, there are many approaches to understanding the nature and use of our cognitive map. These include brain focused neurological studies involving advanced scanning techniques (PET and MRI based scans), scientific experiments involving real world and psychometric settings, educational interventions, and qualitative approaches such as interviews, observation, and surveys. The benefit of such a breadth of approaches in how our cognitive map is studied lies in the triangulation of how we develop our knowledge of the world around us, how we transform and manipulate that knowledge, and how it affects the decisions we make and behaviors we exhibit.

Structure and Form of Our Cognitive Map

The knowledge held in our cognitive map is stored in a variety of different ways. The most primitive form of knowledge is declarative; in our cognitive map this is knowledge for places and things, as well as discrete nonspatial information about those places and things. The latter might include size, colour, category, etc., and provides important contextual understanding between and among individual things. In most cases declarative knowledge is associated with discrete objects, like landmarks, locations, places, etc.; however, linear features and areas can also be stored and understood in this manner, such

as rivers, roads, and towns. As will be discussed later, declarative knowledge is generally the building block from which more complicated spatial knowledge is developed. However, there are many instances when such knowledge is useful without being associated spatially with other knowledge. When learning about places and environments indirectly our understanding is anchored by declarative knowledge that might exist as a picture or discrete description. For example, having never been to Paris I do not know the location or relative positions of many of its famous places (Louvre, Eiffel Tower, Champs Elysees, etc.), but I hold in my cognitive map declarative knowledge of these places and their existence within a space called Paris (about which I know very little). The association of these discrete places with another place is an example of how we store spatial and geographic knowledge in a hierarchical fashion when such an encoding scheme is relevant. When multiple places are known and can be related to one another spatially more complicated forms of knowledge can be achieved. These more complicated forms of spatial knowledge include procedural and configurational knowledge.

Before considering procedural and configurational knowledge it is important to understand how the location or position of elements of our cognitive map can be encoded. Encoding and relating knowledge of different elements of our cognitive map relies on frames of reference. Frames of reference can be exocentric (based on things or frames external to the space or object in question), relative (based on the positions of other things in the space), or egocentric (based on one's own position in the space or related to the space). Exocentric frames of reference are structures for storing spatial knowledge that utilize information external to the space in question for knowing or establishing a location. Such frames can be global (cover all of Earth), regional, and local reference systems that relate an object's location to an abstract external frame such as a Cartesian or Polar coordinate system (like the latitude and longitude or Universal Transverse Mercator coordinate systems). Exocentric frames can also be less abstract and related to information that is locally associated with the space in question but still external to the environment in question, such as a street layout and building numbering system. Reference frames of this type are useful for defining locations in large spaces, at a global or national level or even relatively consistent spaces like cities. However, these systems are infeasible in small spaces, like buildings or rooms. Not only do they not lend themselves to these smaller types of spaces, they are unrealistic for cognitive mapping due to their abstract nature and primary utility in defining specific locations or extracting information regarding multiple locations based on the coordinates of each discrete feature. Frames of reference that can establish accurate locations do not necessarily lend themselves to efficient encoding or using spatial knowledge about arrangements of things. For these situations, which are often more intimate spaces, we employ relative frames of reference. Locations in these less formal frames are known with respect to other occurrences in the space or other local spatial information. Examples of these more local reference frames can include street intersections, well known buildings, and the general arrangement of items in a space. When using a truly relative frame of reference one might indicate position with respect to another object in space or with respect to one's body. The latter is called an egocentric

frame of reference, which is commonly used in small spaces through which limited movement is required or possible (such as rooms or tabletops).

As suggested above exocentric relative frames of reference are not limited to global absolute systems; they can include systems in which the referent object is a dominant feature outside the space in question. The referent object of larger spaces might be the surrounding environment itself, or some part of the environment that is not a single object but a linear or areal feature or configuration of features; this could include boundaries (the fence, the wall, the grass, etc.), or a nonsingular object in the environment (a desk, her/him, basketball hoop). The preceding examples provide some location information, but likely not enough information to be sure of an object's location. Such relative reference systems can be used to provide topological, imprecise, ambiguous, or qualitative position such as 'in the geography office' or 'on the right side of the cash register' or can utilize more accurate and even metric distance as in 'the car is 200 ft from the corner.' In the example of the car's location it becomes clear that the accuracy of the location of the referent object relies on the accuracy of the information held by the individual, and that relative distance is critical to the estimation of location in a variety of spaces. The frame of reference used and its inherent ability to provide an accurate location have important implications for the overall accuracy of the corresponding cognitive map.

In addition to storing and processing declarative knowledge as we experience the world around us, we inevitably integrate what we learn with what we already know or what we have recently experienced. Drawing associations between and among what is known is called procedural knowledge, particularly when the associations are between pairs or series of places or location. The existence of procedural knowledge supports our ability to use the spatial knowledge of our cognitive map to solve spatial and nonspatial problems. Being able to string together multiple locations allows us to create or follow routes from one place to another and associate specific knowledge regarding decisions along the way. Procedural knowledge is distinguished by the nature of the connections between and among declarative pieces of knowledge; the interconnections are ordered and as such represent a more holistic (and personal) knowledge of the environment.

Configurational knowledge is developed as our knowledge of an environment becomes more complex and complete. Independent of the theory of knowledge acquisition, configurational knowledge is composed of both declarative and procedural knowledge but provides the user additional knowledge associated with the interconnections among discrete or linked knowledge and information. Most importantly, configurational knowledge allows for judgments and decisions that require knowledge of the angular or directional relationship between and among places in space. Because we are able to make such complicated judgments regarding the relationships among places based on configurational knowledge it is generally accepted that configurational knowledge is both metric and quantitative. The frames of reference necessary are more complete and complex, and likely more closely associated with abstract frames of reference; however these frames of reference are unlikely to resemble latitude and longitude or Cartesian coordinate systems. Furthermore, the connection between

pairs or groups of places does not have to have been experienced or learned directly but can be the result of incrementally increasing the metric knowledge of where things are located on Earth and their relationships to one another. Configurational knowledge might only exist as portions of our cognitive map. This level of knowledge will exist for those places that we know well or with which we have a great deal of experience. The ability to successfully traverse a space along paths that have not previously been traveled is one outcome of having configurational knowledge, as is being able to give directions for travel along such paths or accurately estimate directions among places in known spaces. The declarative, procedural, and configurational categories of spatial knowledge are commonly referred to as landmark, route, and survey knowledge, respectively, in models in of cognitive map development.

Building Our Cognitive Map

Cognitive maps develop over our lifespan and during discrete episodes of experience. The former is called ontogenesis, while the latter is called microgenesis. The dominant microgenetic model of our cognitive map was established in the 1970s and borrows liberally from child development work on spatial reasoning and thinking. This dominant model has its origin in human development and therefore suffers from relying on a developmentally inspired transition from landmark to route and finally survey knowledge of environmental space. The developmental inspiration results in a model for acquisition that explicitly limits the acquisition of more complicated knowledge until declarative and more basic knowledge is acquired to some necessary level. While this is consistent with how ontogenetic cognitive map development occurs as children develop new cognitive abilities and certain skills and processes emerge in their growing brains, it places unfair limitations on how our cognitive map develops in adulthood when experiencing an environment for the first time. In the dominant (ontogenetically inspired) framework, landmarks are discrete occurrences (objects) in the environment while route knowledge is developed by stringing landmarks together and is characterized by the ability to recall and follow that string of landmarks in order to traverse the route. Survey knowledge is characterized by the ability to integrate multiple discrete routes and landmarks in the same cognitive map. Transitions between these phases of spatial knowledge acquisition are qualitative and are not necessarily marked by the acquisition of quantitative metric knowledge of the environment. The dominant framework suggests that humans do not acquire metric information from the environment during early stages of experience with a new environment, and that only the topological relationships between features are encoded during these early stages of microgenetic spatial knowledge acquisition. This limitation is a direct result of the developmental nature of this model for spatial knowledge acquisition and the fact that children do not exhibit the capacity for metric knowledge or spatial judgements in the early developmental periods. Route knowledge is typically described as a sequence of landmarks connected by experienced paths of movement. This model implies that route knowledge connects those anchor points, while the information between landmarks is

irrelevant and incidental to maintaining a course. In the dominant model of cognitive map development, judgments of inter-landmark distance are difficult and uncertain because of the qualitative nature of how they are known and associated with one another. At the most complex level, survey knowledge is a mental representation of metric spatial relationships (e.g., distance and angle) between and among different sets of environmental information. Survey knowledge can include landmarks and/or routes, as well as configurations of locations and features in the environment. It is not until this final stage of development that the adult cognitive map begins to support quantitative and metric judgments (distance and direction) about spatial arrangements.

Taking this fundamental oversight as inspiration, Montello has proposed an alternative framework of microgenetic spatial knowledge acquisition for adults, suggesting that metric information is encoded during the earliest phases of interaction with a new environment and throughout interaction. Furthermore, his framework outlines quantitative changes in the accuracy and completeness of knowledge for a new environment over time. This framework for the microgenetic acquisition of spatial knowledge of adults allows for the stage-like structure of the dominant framework but accounts for an adult's complete cognitive development and the use of all available tools of perception and cognition while acquiring knowledge about the environment. Qualitative changes from nonmetric to metric understanding of space characterize human development, while refinement of metric knowledge characterizes increased experience by a fully developed adult. In summary, the purely microgenetic framework has substituted experience for development as the temporal scale over which knowledge is acquired while preserving the set of abilities afforded by adult cognition.

Rather than basing a model of microgenetic spatial knowledge acquisition solely on developmental conceptualization, a model of spatial knowledge acquisition integrating spatial hierarchies, spatial anchors (regional anchors), and stage development has also been developed. The initial phases of spatial knowledge acquisition are based on a small set of primary anchors around which a subset of the individual's spatial activity takes place. These anchors are fundamental to learning about the spaces that surround and occur between anchor points. Although accurate knowledge of the locations of features surrounding anchors is not necessarily present, features are organized hierarchically and associatively around anchors. Some examples of anchors might include home, work and your regular grocery store. By combining hierarchical concepts and regionalization (around individual anchors) the anchor point hypothesis incorporates additional geographic models of spatial knowledge structures and acquisition. By blending the Siegel and White framework with regionalization and hierarchical organization the anchor point hypothesis provides a single model in which all three can be integrated. One of the advantages of incorporating a hierarchical component is that such tools (hierarchies) are an inherent part of how we store and process many types of knowledge. Hierarchical storage allows for associations to take the place of individual connections between declarative knowledge. For instance, whether Saskatchewan and Nova Scotia are north of Mississippi does not require a person to know

anything about the relationship of Saskatchewan and Mississippi or of Nova Scotia and Mississippi; by knowing that Saskatchewan and Nova Scotia are in Canada, Mississippi is in the United States, and that Canada is north of the United States, allows that individual to answer the specific question about the relationship between each subordinate geographic entity. Evidence for such hierarchical structures has been shown through cases where such mechanisms do not produce correct responses (Is Reno, Nevada east or west of San Diego, California?). The power of hierarchies and segmenting or grouping spatial knowledge is still an active area of research in the realm of cognitive mapping. The importance of hierarchical structures has been uncovered for global and local scale spatial and geographic knowledge and its relevance for the process of spatial knowledge is an ongoing area of research.

The Future of Our Cognitive Map

We use our cognitive map everyday and rely on it to find our way, make important geographic and spatial decisions, and use it to store knowledge and solve problems about a wide variety of spaces and places. Despite our cognitive map not being a direct or complete replication of the world around us or having many map-like qualities it is a wonder of human cognition in that it supports almost all our spatial decision making and behavioral needs. From time to time we might find ourselves lost and unable to find our way, however, it is rare for anyone to stay lost. When lost we tend to find a way to restore spatial and geographic order to our lives. It is the product of the efficiencies and idiosyncrasies of our cognitive map that this is possible; furthermore, it is these idiosyncrasies that make our cognitive map unique. In essence the only cognitive map we need is the one we have in our own head, as it has developed according to our personal experiences and needs, and performs in situations unique to us. Understanding the complexity of how we deal with such a preponderance of different information and situations represents a rich opportunity for research and learning.

Production: Justin Taylor

ABOUT THE EDITOR-IN-CHIEF

V.S. Ramachandran, MD, PhD., is Director of the Center for Brain and Cognition and professor with the Psychology Department and the Neurosciences Program at the University of California, San Diego, and Adjunct Professor of Biology at the Salk Institute. Ramachandran trained as a physician and obtained an MD from Stanley Medical College and subsequently a PhD from Trinity College at the University of Cambridge, where he was elected a Senior Rouse Ball Scholar. Ramachandran's early research was on visual perception, but he is best known for his work in neurology.

He has received many honors and awards, including a fellowship from All Souls College, Oxford, an honorary doctorate from Connecticut College, a gold medal from the Australian National University, the Ariens Kappers Medal from the Royal Netherlands Academy of Sciences for landmark contributions in neuroscience, and the presidential lecture award from the American Academy of Neurology. He is also a fellow of the Neurosciences Institute in La Jolla and a fellow of the Institute for Advanced Studies in Behavioral Sciences at Stanford. He was invited by the BBC to give the Reith Lectures on 'The Emerging Mind' in 2003 and is the first physician/experimental psychologist to be given this honor since the series was begun by Bertrand Russell in 1949 – these lectures were subsequently published as *A Brief Tour of Human Consciousness: From Impostor Poodles to Purple Numbers*.

In 1995, he gave the Decade of the Brain Lecture at the 25th annual (silver jubilee) meeting of the Society for Neuroscience and more recently, the inaugural keynote lecture at the Decade of the Brain conference held by NIMH at the Library of Congress and a public lecture at the Getty Museum in Los Angeles. He also gave the first Hans Lucas Teuber lecture at MIT, the D.O. Hebb lecture at McGill, the Rudel–Moses lecture at Columbia, the Dorcas Cumming (inaugural keynote) lecture at Cold Spring Harbor, the Raymond Adams neurology grand rounds at Massachusetts General Hospital, Harvard, and the Jonas Salk memorial lecture, Salk Institute.

Ramachandran is a trustee for the San Diego Museum of Art and has lectured widely on art, visual perception, and the brain. Ramachandran has published over 120 papers in scientific journals (including three invited review articles in *Scientific American*), coauthor (with Sandra Blakeslee) of *Phantoms in the Brain* that has been translated into eight languages and formed the basis for a two-part series on Channel Four TV in the UK and a one-hour PBS special in the United States. His work is featured frequently in the major news media including BBC and PBS. *Newsweek* magazine recently named him a member of 'The Century Club,' one of the "hundred most prominent people to watch in the next century."

ABOUT THE EDITORIAL ADVISORY BOARD

David M. Buss received his BA from the University of Texas at Austin and his PhD from the University of California at Berkeley. He served in professorial positions at Harvard University, the University of Michigan, and the University of Texas, where he is currently professor of psychology. David Buss received the American Psychological Association (APA) Distinguished Scientific Award for Early Career Contribution to Psychology, the APA G. Stanley Hall Award, and the APA Distinguished Scientist Lecturer Award. The University of Texas awarded Buss the President's Associates Teaching Excellence Award. He served as President of the Human Behavior and Evolution Society (HBES). He is currently Head of the Individual Differences and Evolutionary Psychology Area of the Psychology Department at the University of Texas at Austin.

Buss's books include *The Evolution of Desire: Strategies of Human Mating* (Basic Books; translated into 11 languages); *Evolutionary Psychology: The New Science of the Mind* (Allyn & Bacon); *The Dangerous Passion: Why Jealousy is as Necessary as Love and Sex* (Free Press; translated into 13 languages); *The Murderer Next Door: Why the Mind is Designed to Kill* (Penguin; translated into 12 languages); *The Handbook of Evolutionary Psychology* (Wiley), for which he served as editor; *Why Women Have Sex* (Holt; co-authored with Cindy Meston; translated into 16 languages); and *The Evolution of Personality and Individual Differences* (Oxford University Press). Buss has more than 250 scientific publications to his credit.

Buss has extensive cross-cultural research collaborations and lectures widely within the United States and abroad. His primary research interests include the psychology of sex differences, human sexuality, mating strategies, conflict between the sexes, why people kill, warfare, terrorism, stalking, and the psychology of prestige, status, and reputation.

Richard B. Buxton received his BS (1976) and PhD (1981) degrees in physics from the Massachusetts Institute of Technology, followed by a postdoc in biomedical imaging (PET and MRI) at the Massachusetts General Hospital. He has been on the faculty of the Department of Radiology at the University of California, San Diego, since 1990. Buxton's primary research is in functional magnetic resonance imaging (fMRI), focused on understanding the connections between neural activity, blood flow, and energy metabolism in the human brain. His experimental work combines arterial spin labeling (ASL) methods with blood oxygenation–level dependent (BOLD) methods to estimate changes in brain oxygen metabolism in response to a stimulus or a drug. His more theoretical work involves mathematical modeling of the imaging methods, the BOLD effect, and oxygen transport from blood to tissue. Buxton is based at the Center for fMRI and served as the center's founding Director (2000–2007). He has written a textbook on fMRI, now in its second edition, published by Cambridge University Press (2009).

Nicholas Christenfeld received a bachelor's degree in psychology and social relations from Harvard, and a doctorate in social psychology from Columbia, and joined the faculty at the University of California – San Diego and has remained there for two decades. His research program comprises multiple, changing, only partly overlapping areas. He has addressed such topics as why some people say 'um' so often, whether babies look like their mothers or their fathers, how we choose which box of cereal to buy, why a baseball season is ten times as long as a football season, which parts of the month carry the greatest risk of untimely death, whether the support of a woman is better for one's blood pressure than that of a man, what sort of music might be useful in stress reduction, whether some initials extend and some shorten the lives of their bearers, if people who live in, or even just visit, New York City are at risk of heart attacks, and whether story spoilers do spoil stories. Currently, Christenfeld is also exploring the role of forgiveness in poststress cardiovascular recovery, the impact of crying on hormones, and the nature of a sense of humor. An overarching theme, if one exists, might be the empirical exploration of the everyday phenomena of the world.

Orrin Devinsky is professor of neurology, neurosurgery, and psychiatry at New York University (NYU). He directs the NYU Epilepsy Center and St. Barnabas Institute of Neurology. His research on epilepsy includes phenomic-genomic relations, sudden unexpected death in epilepsy, surgical therapies, new medicines and devices, quality of life, cognition and behavior, and neuroinflammation. His research on behavioral neurology includes hyperfamiliarity, delusions, autonomic nervous function, and anterior cingulate cortex functions. He founded the organization Finding A Cure for Epilepsy and Seizures and cofounded epilepsy.com and the Epilepsy Therapy Project. He serves on the boards of these organizations and has served on the board of the American Epilepsy Society and Epilepsy Foundation. His other interests include the history of neuropsychiatry, evolution, anthropology, and animal intelligence.

Albert M. Galaburda is a cognitive neurologist and neuroscientist, specializing in developmental cognitive disorders in adults and children. He received his medical degree from Boston University in 1971, trained in neurology at Harvard Medical School from 1973 to 1976, and began his research on dyslexia in 1979, when with neuropathologist Thomas Kemper, he reported for the first time minor cortical malformations in the brain of an adult dyslexic who had died in an accident. Following that original report, he published several other cases with similar malformations and launched a research program modeling these malformations in rodent models, which continues to this date.

He uses RNAi and transgenic technologies in his present research to induce cortical malformations in rat and mouse brains, which in turn are tested anatomically, molecularly, and behaviorally in collaboration with Glenn Rosen, Joseph LoTurco, and Holly Fitch, respectively. This latest research has shown that manipulation of dyslexia candidate gene homolog's 1 rodent embryos results in molecular interference with neuronal migration, cell autonomous and noncell autonomous effects on cortical development that mimic the changes seen in dyslexic brains, and behavioral changes affecting auditory perception. *Ex vivo* imaging of the brains of genetically manipulated animals discloses changes in cortical circuits affecting corticocortical and corticothalamic relationships.

Galaburda is presently the Emily Fisher Landau Professor of Neurology at Harvard Medical School, and Head of the Cognitive Neurology Unit at Beth Israel Deaconess Medical Center in Boston. He has published more than 150 scholarly articles on various topics of cognitive anatomy, cognitive

neurology, and dyslexia, as well as several books on related topics. Galaburda has received the Pattison Prize in Neuroscience, the Neuronal Plasticity Prize from the IPSEN Foundation of France, Scientist of the Year from the Association for Children with Learning Disabilities (now, Learning Disorders Association), and has been elected to membership in the American Neurological Association. He has delivered the Rita Rudel Memorial Lecture, the Norman Geschwind Memorial Lecture, the Sylvio Conte Decade of the Brain Symposium Lecture, and the Curt von Euler Memorial Lecture, among others. His research is funded by the Eunice Kennedy Shriver National Institute of Child Health & Human Development. His teaching is funded by the National Institute of Neurological Disorders and Stroke.

William Hirstein is Professor and Chair of the Philosophy Department at Elmhurst College, Elmhurst, IL, USA. He received his PhD from the University of California, Davis, in 1994. He is the author of several books, including *On the Churchlands* (Wadsworth Publishing, 2004), *Brain Fiction: Self-Deception and the Riddle of Confabulation* (MIT Press, 2005), and *Mindmelding: Consciousness, Neuroscience, and the Mind's Privacy* (Oxford University Press, 2012). His other interests include autism, sociopathy, brain laterality, sense of self, and the misidentification syndromes.

William G. Iacono is Regents Professor of Psychology, Psychiatry, Law, and Neuroscience; Distinguished McKnight University Professor; Adjunct Professor of Child Development; and Codirector of the Minnesota Center for Twin & Family Research at the University of Minnesota.

He studies the development of common mental disorders, focusing on the genetic liability for substance abuse and antisocial behavior. He is past president of the Society for Psychophysiological Research (SPR). He has also received the Distinguished Contributions to Psychophysiology Award from SPR for his lifetime contributions to this field. In addition, he has been awarded the Distinguished Scientist Award from the Society for a Science of Clinical Psychology. His research is funded by grants from the National Institute of Mental Health, National Institute on Drug Abuse, and National Institute on Alcoholism and Alcohol Abuse. He currently holds a National Institute of Health MERIT (Method to Extend Research in Time) Award for his research achievement. He has published over 350 scientific articles.

John T. Jost is Professor of Psychology at New York University. His research, which addresses stereotyping, prejudice, political ideology, and system justification theory, has appeared in top scientific journals and received national and international media attention. He has published over 90 articles and chapters and coedited four books: *The Psychology of Legitimacy* (2001), *Perspectivism in Social Psychology* (2004), *Political Psychology: Key Readings* (2004), and *Social and Psychological Bases of Ideology and System Justification* (2011). Jost has received numerous honors, including the Gordon Allport Intergroup Relations Prize (three times), Erik Erikson Award for Early Career Research Achievement in Political Psychology, International Society for Self and Identity Early Career Award, Society for Personality and Social Psychology Theoretical Innovation Prize, Society of Experimental Social Psychology Career Trajectory Award, and the Morton Deutsch Award for Distinguished Scholarly and Practical Contributions to Social Justice.

Jerome Kagan is Emeritus Professor of Psychology at Harvard University. His research over the past 57 years has centered on the cognitive and emotional development of infants and children. During the last 30 years, he and his colleagues have concentrated on the temperamental biases called high and low reactivity in infants. He is a fellow of the American Academy of Arts and Sciences and a member of the Institute of Medicine in the National Academy of Sciences. He has received distinguished scientist awards from the American Psychological Association, the Society for Research in Child Development, and the Child-Mind Institute. Kagan received his PhD from Yale University in 1954 and taught at the Ohio State University and Antioch College before joining the Harvard faculty in 1964.

Leif Edward Ottesen Kennair, PhD, is Head of Department at the Department of Psychology, Norwegian University of Science and Technology, Trondheim, Norway. He graduated as a clinical psychologist from the University of Bergen, 1999, and is a specialist of clinical adult psychology (Norwegian Psychology Association), and a qualified cognitive therapist and supervisor of cognitive-behavioral therapy (Norwegian Cognitive Therapy Association). He has worked as a clinical psychologist/chief psychologist at the Nordfjord Psychiatric Centre and as a researcher at St. Olav's Hospital, Trondheim. His research interests span from mainstream clinical psychology efficacy research (generalized anxiety disorder, OCD) to evolutionary psychology (evolutionary psychopathology, the evolutionary psychology of war, mate choice and sexual behavior). Kennair's PhD thesis was on the topic of evolutionary clinical psychology. He has written an introduction to evolutionary psychology, which has been published in Norwegian and Danish. He lectures on evolutionary psychology, behavioral genetics, and personality psychology and is a much-used lecturer for training psychologists and psychiatrists on topics such as cognitive-behavior therapy and treatment of anxiety and OCD.

David E. Presti is a neurobiologist and cognitive scientist at the University of California in Berkeley, where he has taught in the Department of Molecular and Cell Biology for more than 20 years. For more than a decade (1990–2000) he also worked in the treatment of addiction and of posttraumatic stress disorder (PTSD) at the Department of Veterans Affairs Medical Center in San Francisco. His areas of expertise include the chemistry of the human nervous system, the effects of drugs on the brain and the mind, the treatment of addiction, and the scientific study of the mind and the consciousness. He has doctorates in molecular biology and biophysics from the California Institute of Technology and in clinical psychology from the University of Oregon. Since 2004, he has also been teaching neuroscience to Tibetan monks in India in a program initiated by the Dalai Lama. His primary research interest is the relation between mentality, consciousness, and brain physiology, the so-called mind-body problem.

REVIEWERS

We would like to thank the following for their valuable assistance in peer-reviewing the articles within the Encyclopedia of Human Behavior:

HOW TO USE THE ENCYCLOPEDIA

The *Encyclopedia of Human Behavior* is intended for use by students, research professionals, and interested others. Articles have been chosen to reflect major disciplines in the study of human behavior, common topics of research by professionals in this domain, and areas of public interest and concern. Each article serves as a comprehensive overview of a given area, providing both breadth of coverage for students and depth of coverage for research professionals. We have designed the encyclopedia with the following features for maximum accessibility for all readers.

Articles in the encyclopedia are arranged alphabetically by subject. Complete tables of contents appear in all volumes. The index is located in Volume 3. Because the reader's topic of interest may be listed under a broader article title, we encourage use of the index for access to a subject area, rather than use of the table of contents alone.

Each article contains a glossary, cross-references, and a further reading list. The outline allows a quick scan of the major ideas discussed within each article. The glossary contains terms that may be unfamiliar to the reader, with each term defined *in the context of its*

use in that article. Thus, a term may appear in the glossary of another article defined in a slightly different manner, or with a subtle nuance specific to that article. For clarity, we have allowed these differences to remain so that terms are defined relative to the context of each article.

Each article has been cross-referenced to other related articles in the encyclopedia. Cross-references will always appear at the end of an article. Where multiple cross-references apply to an article, the cross-references will be listed alphabetically. We encourage readers to use the cross-references to locate other articles in the encyclopedia that will provide more detailed information about a particular subject.

The further reading section lists recent secondary sources to aid the reader in locating more detailed or technical information. Review and research articles that are considered to be of primary importance to the understanding of a given subject area are also listed. The further reading lists are not intended to provide a full reference listing of all the material covered in the context of a given article, but are provided as guides.

This page intentionally left blank

PREFACE

The social scientists have a long way to go to catch up, but they may be up to the most important scientific business of all, if and when they finally get to the right questions. Our behavior toward each other is the strangest, most unpredictable, and almost entirely unaccountable of all the phenomena with which we are obliged to live.

Lewis Thomas

Psychology, the study of the human mind, has made many rapid strides during the past four decades. There is now, more than ever before, a real need for a standard reference work covering all aspects of human behavior. The *Encyclopedia of Human Behavior* is the most up-to-date and comprehensive collection of reviews currently available. The essays will be of interest not only to clinical and experimental psychologists but also to students in fields such as psychiatry, neuroscience, philosophy, cognitive science, and medicine. Indeed, given the enormous range of topics covered, no one interested in human nature can fail to find something of interest in each volume. The format of the volumes lends itself just as readily to casual perusal as it does to serious inquiry.

My colleagues and I are often asked questions such as: What is the superego? What is repression? How reliable is eyewitness testimony? How much sleep do we need? What do we know of the psychology of laughter, language, cruelty, or politics? Or of love, cunning, and deceit? We have all experienced the frustration of not being able to answer such questions or find the answers quickly without recourse to extensive library research. This encyclopedia should prove to be an invaluable resource in such situations. Also, students of psychology and related health professions will find this collection of articles useful as a starting point when they embark on new research projects dealing with specific aspects of human behavior.

The study of human behavior is an enterprise that covers an enormous variety of subjects, ranging from the minutiae of neurophysiology to such familiar but poorly understood topics as Freudian psychology. Psychology is a science that is still very much in its infancy even though it has had a very long history, almost as long as that of physics and biology. Anyone interested in the history of ideas should be puzzled by the differences between advances in biology and advances in psychology. The progress in biology has been characterized by a number of landmark discoveries, each of which resulted in a breakthrough in understanding, for example, the discoveries of cells, Mendel's laws of heredity, chromosomes, mutations, and most recently DNA and the genetic code. Psychology, however, has until recently been characterized by an embarrassingly long sequence of 'theories,' each of which was really nothing more than a passing fad that rarely outlived the person who proposed it. I have always found this contrast to be quite remarkable and can think of no simple explanation for it other than the fact that human behavior is inherently more complex, quixotic, and difficult to fathom. Fortunately, the picture has changed radically over the past four decades, particularly in psychiatry and cognitive neuroscience. There are two reasons for this change: First, there has been a growing dissatisfaction with metaphorical explanations (Peter Medawar calls explanations of this kind "analgesics," for "they dull the ache of incomprehension without removing the cause") and a healthy trend toward replacing them with more mechanistic explanations. Second, progress has been aided by the advent of several new technological innovations for studying the structure and function of the human brain. This encyclopedia covers as many of these recent advances as possible within a three-volume set.

My own experience is mainly in neuropsychology, medicine, and visual science, and I am therefore indebted to the editorial advisory board, as they selected the authors in other areas and saw each essay through the long process of peer review, revisions, and copy-editing. Most of the entries are by acknowledged experts in the field.

Given the nature and scope of this enterprise, some degree of overlap among the essays was not only inevitable but also desirable since our goal was to ensure that each article was a self-contained summary of one specific aspect of human behavior. Given the space limitations, each author was encouraged to provide an overview and convey the general flavor of an area of research rather than attempt an exhaustive review. The result is a very stimulating and informative collection of essays.

I have no doubt that this work will prove useful to specialists. If it also succeeds in kindling a spark of interest in some aspect of human behavior among undergraduate and graduate students, then our efforts will have been amply rewarded, for no enterprise is more important to the future of our species than an understanding of human nature in all its diverse manifestations.

V S Ramachandran

Pain

Y Lampl, Wolfson Medical Center, Holon, Israel; Tel Aviv University, Holon, Israel

© 2012 Elsevier Inc. All rights reserved.

Glossary

Allodynia A hypersensitive pain form of low-intensity stimulation which normally would elicit only nonpain sensation.

Central pain Pain caused by a lesion in the central nervous system.

Central sensitization Changes in the central nervous system of pain due to chronic peripheral pain.

Dyesthesia Unpleasant abnormal sensation.

Hyperalgesia Increased sensitivity to pain stimulus with lowering of the pain threshold.

Neuralgia Peripheral nerve pain.

Nociceptor Harmful body tissue endangering stimulus.

Pain threshold Lowest level of sensitivity to pain.

Pain is the most common symptom of human diseases. It is defined as an unpleasant experience which may or may not be primarily associated with tissue damage. Pain experience has two different components – the specific sensory discriminative components and the nonspecific emotional-cognitive components. Melzack and Casey divided the pain system into three dimensions: the cognitive or central control, motivation-emotional, and sensory discriminative dimensions.

In various cultures, pain has a different social meaning. In the Judeo-Christian cultures, for example, the passion of the soul (as Aristotelians defined pain) has a close relationship to guilt and punishment. The word pain is derived from the Greek word *poine* and the Latin word, *poene*, meaning punishment. In the Old Testament, the Hebrew word, *tsaar*, which means sorrow, was used to determine pain.

Although pain is usually combined with sorrow, fear, depression, or agitation, an intensive manifestation of the emotional modality can appear separately and independently from the discriminative modality. Our knowledge of psychiatric diseases has taught us that a pain reaction which is compatible with all pain criteria may not necessarily be accompanied by tissue damage. The different characteristics of acute, chronic, cutaneous, or visceral pain justify the assumption that pain is a result of a complex, multimodal mechanism. Knowledge of the different components of the system is essential for the understanding of this most important phenomenon of human disease.

Anatomy and Neurochemistry of Pain

The Peripheral System

In the past, the question of pain origin was explained by two major theories – the summation theory of intensity theory and the specific theory. At the end of the nineteenth century, Goldscheider postulated that there were no specific pain receptors and that each sensory stimulus, with sufficient intense stimuli, produces pain sensation.

The specific theory suggested that pain, similar to thermal and mechanical stimuli, has a specific ascending tract with a specific pain center located in the brain. This theory which is postulated today, teaches that there is an intermediate position

between both theories. The peripheral system is conducted through the skin, muscles, joints, and somatovisceral stimuli from the periphery to the spinal through axons of the neural cells. The cell bodies are located in the dorsal root ganglia behind the spinal cord. At present, it is well established that two types of axons respond to transduce the pain sensation from the peripheral to the centers – the A_α and C fibers. The primary efferent fibers are coated with sheaths of lipoid substances of different diameters known as myelin.

Generally, the peripheral axons are divided into three major groups (classified by Elanjen and Gasser): A, B, and C, according to the thickness of myelin. Fiber group A is subdivided into another four subgroups: A_α , A_β , A_γ , and A_δ . The thickness of the myelin is directly proportional to the conduction velocity. The primary afferent fibers of the C group are covered by a very thin myelin layer measuring 0.1–1.0 μm usually defined as unmyelinated C fibers characterized by a slow conduction velocity of 0.5–2.0 m s^{-1} . The thin myelinated A_δ fibers (1–4 μm) have a moderated conduction velocity of 12–20 m s^{-1} .

Pain has no specific receptor. Axon fibers detach themselves from the myelin sheaths and terminate as nerve endings in the skin. There are five recognized types of afferent nociceptives which conduct the impulse of pain stimulation. (1) High-threshold A_δ mechanoreceptors respond to moderated intense or noxious mechanical stimuli. (2) Myelinated A_δ mechanothermal nociceptives respond to noxious heat stimuli over 45 °C and intense mechanical stimuli. (3) Pure heat-sensitive A_δ nociceptive. (4) A_δ and C low-threshold cold receptors. (5) C-polymodal nociceptive afferents (CPN). This extremely important group of CPN consists of about 95–98% of the sensory C-units in the skin. They have a high threshold to intense mechanical stimulation (more than 1 g), a graded threshold to heat stimulus (between 38 and 49 °C), and a sensitivity to mechanical stimulus. On repeated mechanical stimulation, the response of the CPN becomes fatigued and on repeated thermal stimulation, its response becomes sensitized.

The visceral nociceptive axons transduce pain stimuli characterized by an aching type of pain in the chest, abdomen, and pelvis. The visceral fibers contain a very high amount of C fibers compared to A_δ fibers (a ratio of 10:1 in the visceral nerve and only a ratio of 1:2 in the dorsal root). Only 10% of the dorsal root consists of visceral fibers which are connected

to the sympathetic fibers. These fibers can also be divided into three main groups: peptidergic nerve growth factor (NGF) (responsive unmyelinated C fibers), glial cell line-derived neurotrophic factor (GDNF) (responsive unmyelinated C fibers), and nerve growth factor (NGF) (myelinated C fibers).

Specification channels – transient receptor potential cation (TRP) – which react to temperature and pH changes in the presence of vanilloid ligands, are involved in the transduction of special thermal modalities. The transduction of the membrane depolarization along the axon is induced by the activation of the voltage-gated sodium channel, especially Na_v 1.7 and Na_v 1.8 (in addition, the following subtypes may be present – Na_v 1.1, Na_v 1.2, Na_v 1.6, and Na_v 1.9). There are two voltage β subunits expressed by the primary sensory neurons. The effect is based on the sodium influx in reaction to membrane depolarization. Each of the various types of the voltage-gated sodium channels has a different role in the sensory pathway.

Neurochemistry of the Peripheral System

Peripheral pain stimulation is caused by the releasing of endogenous chemicals when local tissue is damaged. The pain produces a substance that also has, besides direct receptor stimulation, an influence on the vessel diameter and the permeability of the capillaries. These vascular changes influence the area of the nociceptive receptor and increase their sensibility.

Three groups of chemical substances influence the peripheral nociceptive receptors: (1) A chemical with a direct influence on the afferent nociceptive fibers of which bradykinin and potassium belong. The kinins, by-products of the clotting system found in the plasma, are released into the tissue and accept the direct pain which induces a reaction and have a vasodilatory effect. The most well-known member of the cytokine group is activin, and the chemokines, which include CCL_3 , protectin, trypsin, and the tumor necrosis factor (TNF) β , also play a key role in this mechanism. (2) The second group consists of substances that enhance the reaction of the bradykinin. Prostaglandin, a product of polyunsaturated fatty acids (arachidonic type), also belongs to this group. Although high doses of prostaglandins can produce mild pain, the main physiological effect is the potentiation of the kinin's reaction (especially PGE_{1+} , PGE_2). (3) The third group, substance P (SP), was first described by Euler and Gaddum in 1931. It is synthesized in the spinal ganglions and has an antidromic peripheral effect (transmission in the cutaneous direction and not to the spinal cord). Substance P affects the veins by the extravasation of plasma and changing of the permeability of the capillaries and vasodilatation of the small vessels.

The Dorsal Horn

The primary afference of pain fibers reaches the spinal cord after transversing the tract known as the Lissauer tract. In the cord, the impulses are potentiated or attenuated within the different layers of the gray substance. The root contains the separation – myelin-poor fibers on the outside portion and myelin-rich fibers on the inside portion. Lissauer proved that partial separation resulted in the disappearance of pain in a selective interruption of the lateral part of the bundle. This finding is the basis for pain therapy by selective lateral

rhizotomy. Presently, we are aware of the theory that all sensory fibers that penetrate the spinal cord via the dorsal horn are correct. It was demonstrated that pain sensation can also be produced by ventral tract stimulation. Thirty percent of the ventral fibers were found to be unmyelinated. It is presumed that the ganglion of the dorsal horn sends two processes – superficial and deep somatic projections. This finding is a reasonable explanation for the cutaneous distribution of deep visceral pain. Pain in the left shoulder and chest in heart attacks is a well-known example of this phenomenon. Most of the fibers terminate in the spinal gray matter of the same side, some extend contralaterally, and others reach one or two segments above or under the terminated segment. The gray matter was divided by Rexed into 10 laminae. Laminae 1–6 belong to the sensory dorsal horn, laminae 7–9 belong to the motor ventral horn, and lamina 10 contains interneuronal corrections building the area around the central canal of the cord. The pain fibers reach certain areas; the fine myelinated A_δ fibers travel into the medial portion of the dorsal horn and reach areas I, II, and V. A_δ and C visceral fibers terminate in areas I and V, but also reach the laminae IV, VI, and VIII.

The different kinds of neurons are found in the dorsal horn:

1. Neurons that respond to a mechanical and thermal input mode (LTT) with a low threshold to noxious and non-noxious stimulation.
2. Wide dynamic range (WDR) neurons found partially in deeper layers: the WDR neurons respond to different inputs of thermal, mechanical, and chemical stimuli. The WDR activity range is wide and nonspecific. They consist of one-third to one-half of the neurons of the ascending system and are the most common neuron type in the deep V lamina.
3. Specific nociceptive neurons with an exclusive response to pain. These neurons were found in lamina I and also in lamina V. They contain specific small and large cells (Wahldayer) of a different structure, which are divided into two subgroups – cells activated only by mechanoreceptive A fibers and those activated by mechano- and thermoreceptors of A_δ , as well as C fibers.

In examining these neuron groups, group 3 (NG) has a specific reaction to pain response. Group 2 (WDR) responds to pain and to other stimulations also, and group I (LTT) does not respond to pain at all. It seems that the WDR neurons have a central role in the modulation of the sensitivity of the nociceptive cells to pain stimulation.

It has been shown that WDR neurons can be inhibited by painful stimulation, a phenomenon known as diffuse noxious inhibitory controls (DNIC). This inhibition was suggested to be the main component of the pain signal function.

The neurotransmitters and receptors known to be involved in the synaptic transmission of the dorsal horn are as follows: (1) the two fast and active neurotransmitters of the glutaminergic ionotropic receptors – *N*-methyl-D-aspartate (NMDA) receptors and α -amino-3-hydroxy-5-methylisoxazole-4-propionic acid (AMPA); (2) the intense and sustaining active transmitter of substance P and calcitonin gene-related peptide (CGRP), activator of the CGRP1, CGRP2, and neurokinin 1 receptors; (3) the presynaptic receptors, including the voltage-gated calcium channel and the inhibitory effective α aminobutyric acid (GABA_A) and GABA_B receptors which also have postsynaptic

effects; and (4) the postsynaptic receptors of cannabinoid receptor 1 and various opioid receptors (μ , δ , and κ).

Ascending System

A pain message is transmitted from the periphery through the dorsal horn to the supraspinal structures almost entirely via the pathways of the anterolateral tracts. There are two types of ascending routes that characterize the ascending system and each one of them has a different anatomical physiological and phylogenetical origin. One of the tracts, known as the neospinothalamic system, is characteristic in humans and primates containing the most important spinothalamic tract which transmits the nociceptive impulses to specific areas in the thalamus to the ventroposterolateral (VPL) nucleus in the thalamus. Another spinothalamic tract is the ventrospinal, which is located in the anterior section of the spinal cord. This route was usually considered the only one for pressure and touch stimuli. It has been recently proved that the ventrospinothalamic tract is also involved in pain transmission explaining the occasional pain sensation that remains even after total dissection of the lateral pathways.

The second group of ascending tracts, known as the paleospinothalamic system, contains the medial part of the spinothalamic tract, known as the spinoreticular tract and the spinomesencephalic tract. These tracts are more paleogenetic in nature than the neospinothalamic system and transmit pain sensation into the nuclei of the brain stem and into the non-specific thalamic nuclei – the medial and interlaminar nuclei which are nonsomatotopic in nature. Fiber projections to the limbic system and the hypothalamus transmit this message to the emotional and autonomic centers. It appears that the paleospinothalamic system is responsible for the creation of the effective-motivation component of pain. The stimulus that terminates in the hypothalamus is responsible for the autonomic reaction to pain, sweat, and increase in blood pressure and pulse. The spinoreticular tract projects the stimulus from neuron cells in laminae VII and VIII of the spinal cord to the reticular formation in the midbrain, pons, and medulla. It seems that this tract has a connection with the arousal and motivation of the reticular system. The spinomesencephalic tract originates in the cells of laminae I and V and transmits the stimuli to various nuclei in the brain stem, especially to the periaqueductal gray matter. Its role is in the production of the emotional reactivity to pain and in the modulation of pain by the descending system.

We are aware of the fact that besides the neospinothalamic and paleospinothalamic system, there are other pathways that play a role in the transmission of nociceptive impulses. Their significance in the pain system is uncertain. One system, the propriospinal multisynaptic ascending system, is located almost entirely in the dorsal part of the spinal cord and presumably plays a role in chronic and visceral pain.

The dorsal columns, which are considered a completely proprioceptive, nonnoxious system, contain almost 7% of nociceptive-anxious fibers.

Pain and the Supraspinal System

The spinothalamic, spinoreticular, and spinomesencephalic tracts terminate in different nuclei in the brain stem, thalamus,

hypothalamus, and ventral forebrain. The neospinothalamic bundle terminates in the specific thalamic nuclei, while the paleospinothalamic system reaches the nuclei of the brain stem and the nonspecific medial and intralaminar nuclei in the thalamus.

Brain stem terminus

The paleospinothalamic system projects fibers of the nociceptive stimulus to the reticular formation in the medulla pons and mesencephalon. The periaqueductal gray matter is an important target of these fibers. The reticular formation is dissipated throughout the entire brain stem. It contains different kinds of neurons with short and long axons. A wide development of fibers with massive projection the thalamus, subthalamus, and hypothalamus structure causes a rapid integrative response when stimulation occurs in this system.

The periaqueductal gray substance is the main terminating target of the spinomesencephalic tract. This structure is connected to the gigantocellular substance of the reticular formation, the medial nuclei of the thalamus indirectly with the cortex (S_2 area) and the limbic system. It was demonstrated that the periaqueductal gray and the gigantocellular cells are almost entirely responsive to pain sensations. The integrative function of these structures and the dense interneuronal connections intensify the efficacy of these structures in mediation of the effective emotional component of pain sensation. The role of the brain stem in opioid and placebo mechanisms was also examined, as well as in pain processing. The modulatory effects on pain are created by activation of the network system converging in the brain stem nucleus cuneiformis.

Thalamus terminus

The thalamus is the relay center for afferent sensory inputs, beginning in the periphery and ending in the brain. The primary afferent pain fibers reach two areas of the thalamus – the neospinothalamic system and the trigeminothalamic tract which terminate in the VPL and the VPM nuclei. Most of the fibers originate in laminae I and V of the spinal cord and project into the subnuclei VPLo (oral) and VPLc (caudal) of the VPL group. The organization of the VPL and VPM is somatotopic and is transmitted to the primary and secondary cortex via thalamocortical fibers. These structures play a central role in the process of the specific discriminative aspect of pain. The paleospinothalamic tract terminates in the paleospinothalamic nuclei, the medial and interlaminar nuclei, and the nonspecific and nonsomatotopic portion of the thalamus. The ventral medial posterior nucleus (VMP), which lies on the spinothalamic insular pathway, has a special role in this mechanism. Selective damage to this pathway induces hyperactivity of the spinothalamic cingular pathway, which can reduce persistent and chronic central pain.

Some of the paleothalamic structures are exclusively sensitive to pain stimuli. Short nociceptive cells, which are activated by A_δ fibers, and long cells, responding to stimuli of C fibers, are found in the thalamus. The nonspecificity of this structure can be demonstrated by local electrical stimulation of the medial and interlaminar nuclei and a burning pain sensation, without exact anatomical localization, is produced. The projection from these nuclei reaches the cerebral cortex, mainly the limbic system. The wide, diffuse connections are part of

the nonspecific activation and modulation and the cognitive aspects of pain sensation.

The limbic system and pain

The limbic system, a paleogenetic section of the brain, plays the main role in the creation of affective and emotional expression. Wide reciprocal projections between the limbic system, cortex, brain stem reticular formations, and thalamus are responsible for modulating emotional and mood aspects of pain. A particularly important role in the creation of the pain process is played by the pathways between the brain stem reticular formations and the limbic forebrain structures, especially the amygdala, hippocampus, cingulate cortex, and the septal area. The hippocampus and the related forebrain structures have the main influence on the modification of pain-related behavior. Stimulation of these areas produces an evoked response to pain. Electrical stimulations of other limbic system areas produce aversive pain behavior depending on the intensity of the stimulation. Disruptions of the cingulum bundle between the hippocampus and the frontal lobe diminish the negative effect and increase the pain tolerance. The central role in pain-related affective behavior is the amygdala. It seems that the nonsomatotopical projections between the brain stem, hypothalamus, thalamus, and limbic system create a dynamic system of behavior changes, motivation, and emotional changes, according to the pain stimulus.

Pain and the cerebral cortex

Contrary to the limbic system, the cerebral cortex receives inputs mostly from the specific thalamus nuclei (VPL, VPM), and to a lesser extent, from the postero- and ventrobasal thalamic groups. The majority of the somatotopical sensory fibers, which originated in the VPL-VPM, reach the primary sensory area in the postcentral gyrus. The primary sensory area (SI) has a typical somatotopic pattern (a specific representation for each part of the body). The secondary sensory area (SII) is located near the Sylvian fissure in the parietal lobe and has pathways from SI and the postero- and ventrobasal thalamic nuclei. The sensory cortex, together with the specific thalamocortical fibers, has a central role in adapting the discriminative component of pain stimulations. The importance of the anterior parietal area is controversial. It is widely accepted that there is no direct pain sensation in the anterior section of the thalamus. Nevertheless, studies which examined traumatic injuries in this area have proved that there is a total disappearance of superficial pain and a partial decline in deep pain sensation. Vascular events and epileptic foci in this area are occasionally accompanied by severe pain. Intense pain, with the disappearance of superficial sensitivity, is known as thalamic pain (Dejerine-Roussy syndrome) in thalamic damage. Similar clinical features were described in corticoparietal lesions. Dejerine and Mouzon described another parietal lobe syndrome as a pseudothalamic syndrome with the disappearance of all modalities of sensation, including pain. The central role of this area in creating the discriminative pattern of pain is shown in the clinical picture of pain hemiagnosia. In this symptom, the paralytic patient reacts to pain stimuli on the same side only, with emotional and autonomic components, without even understanding the meaning of pain. It seems that this clinical feature is a result of selective activation only

of the thalamolimbic connections. In asymbolia of pain, the inability to understand painful sensations in the body is accompanied by the disappearance of any adequate emotional or autonomic reaction. It seems that in such a symptom, the lesion is of the posterior parietal lobe with a disruption of the transcortical tracts.

Other cortical pathways having an important influence on the pain adapting mechanism are the frontal lobe tracts reaching the input from the nonspecific thalamic nuclei, the limbic system, and particularly, the gyrus cingulate. Lesions of pathways projected to the orbitobasal area of the frontal lobe influence the personality and behavioral aspects of pain. Removal of the frontal lobe (lobotomy) as a surgical treatment for intractable pain results in the continuation of the pain without, however, the subjective, negative, and emotional aspects; one may feel the pain, but it does not disturb the person.

The corticotemporal area also receives the pain input mainly in connection with the amygdala and the hippocampus memory center. Its importance is probably in the emotional character and memory of pain experience.

The prefrontal cortex

The prefrontal cortex region plays a role in the decreasing of pain sensation by inhibition of the pathway between the medial thalamus and the midbrain. Activation of the dorsolateral section of the prefrontal cortex has occurred in the study of the mechanism of placebo action. This phenomenon is explained by the functioning of the prefrontal cortex maintenance and integration of the pain relief. The anterolateral section of the prefrontal cortex regulates the anticipatory anxiety of pain. The activation of the prefrontal cortex is mostly parallel to the activation of the periaqueductal gray and the ventral tegmental area, and also to the cortex, posterior insula, and the anterior portion of the cingulate gyrus.

The Descending Pain Control Mechanism

The existence of a pain-modulating control system was suspected since Reinolds demonstrated a loss of sensation produced by electric stimulation of the periaqueductal gray. This theory has been confirmed in recent years and was the basis for understanding the pain mechanism. Electrical stimulation by implantation of microelectrodes in diverse structure of the diencephalon and the brain stem demonstrated a stimulation-produced analgesia (SPA) by inhibition of neurons in laminae I-V of the spinal cord. The following are the two most important centers that play a central role in the modulating pain system:

1. The periaqueductal gray has an intense connection to cortical, limbic, and thalamic structures. Reciprocal connections exist with nuclei of the reticular formation in the brain stem. The role of the periaqueductal gray in the pain-modulating system is also proved by the increase of pain complaints in experimental local lesions.
2. The nuclei in rostral medulla, especially the nucleus raphe magnus (NRM) and the nuclei magnocellularis, are probably the most important relay centers of the descending modulating pain system. Electrical stimulation, injection

of morphine, and direct input from other supraspinal structures, especially the periaqueductal gray, evoke pain depression. The inhibitory stimulus is transmitted along the tracts in the dorsal portion of the lateral fasciculus. The inhibitory input reacts mainly on cells in laminae I, II, and V.

Besides the modulatory effect of the mesencephalon and medulla, there is evidence of a direct depression effect on the cortex. Stimulation of primary and secondary sensory centers (SI, SII) may have a pain inhibitory effect. It seems that the inhibitory modulation is transmitted by motor fibers of the corticospinal tract and extrapyramidal system. Electrical stimulation of the medial part of the hypothalamus may also decrease the pain sensation by direct activation of the hypothalamospinal pathway or via activation of the periaqueductal gray.

The neurochemistry of the descending system and the opioid analgesia

Two main descending pain control systems play a role in pain modulation: norepinephrine-containing pathway and the serotonin-containing system. These systems are activated and react upon a number of peptides and monoamines, and inhibitory and excitatory neurotransmitters. The epinephrine system transmits stimuli from the dorsolateral pontine nuclei to neurons in laminae I, II, IV–VI, and X in the spinal cord and have an inhibitory effect and an excitatory effect as well. The serotonergic descending system contains fibers from the rostro-ventral medulla which terminate in laminae I and II. Injections of epinephrine or serotonin antagonists given intrathecally may abolish the inhibitory effect and increase the pain sensation. Several peptides influence the descending modulating system.

A calcitonin gene-related peptide (CGRP) is localized in the dorsal root ganglion and in 5% of the lamina I cells. It is of therapeutic significance in cancer pain and nonmalignant bone pain, as in Paget's disease. The corticotropin-releasing factor (CRF) known as somatostatin and the gut peptide cholecystokinin (CCK) are other spinal neurotransmitters. The somatostatin was extracted for the first time from the hypothalamus. It is found in 10% of laminae I and III cells, has an influence on the pinprick sensation test, and no effect on opiates. CCK is a very common neurotransmitter and is frequently accompanied by substance P (SP) without having any specific effect.

SP, which is located in the dorsal horn and in the periaqueductal gray as well, is a specific excitatory peptide having major importance in the pain pathway. It has a hyperalgesic effect (excessive sensitivity to pain) and is inhibited by opiates.

Neurotensin has a role in the pain control mechanism by acting in the hypothalamus, periaqueductal gray, and dorsal horn. Experimental intracisternal injection of neurotensin produces a comparable analgesia.

Opioid analgesia

Opiates have a central role in the decline of pain sensation. Since Portoghesi postulated the cellular receptors for morphine, five main groups of opioid receptors were discovered. The μ receptor is mostly activated by morphine and highly naloxone-sensitive (morphine inhibitor). Other receptors are the κ , σ , δ , and ϵ . μ Receptors are heavily dissipated in the periaqueductal gray matter, brain stem, limbic system, and the dorsal spinal cord,

while other receptors are less active in the pain-modulating system. Three groups of endogenous opioid peptides were found: enkephalin, highly concentrated in the spinal and supraspinal systems; dynorphine, found in the hypothalamus, periaqueductal gray matter, reticular formation, and spinal dorsal horn; and β -endorphins, concentrated in laminae I and II and also, IV, V, and VI of the spinal cord. They inhibit the releasing of SP, reduce the site of the peripheral receptive fields, and act on the excitatory postsynaptic potential (EPSP). Their effect, is therefore, pre- and postsynaptic. The pain-transmitted C fibers are more sensitive to opioids than the A_δ fibers.

The Psychobiology of Pain

Acute and chronic pain are psychobiological experiences with essential effective and cognitive components which produce an intense alteration of emotions. Their intensity can also be modified by attention, mood, or changing of perception. Impressive examples of this modifying system are pop-out and spotlight, phenomena which define the ability to selectively choose different elements of pain and processing an interpretation. Autosuggestion and hypnosis are two clinical methods that use these phenomena for pain therapy.

Fear and anxiety are greatly influenced by mood, motivation, and cognitive factors. Anxiety, as a warning signal prior to a familiar recurrent threatening situation (trait anxiety), is much more cognitive and emotionally dependent than the anxiety that appears during the pain itself (state anxiety).

Personal-individual and socioenvironmental factors significantly influence the sensitivity to pain – the subjective meaning of the unpleasant element, especially the threshold to pain (the least recognizable pain sensation of a subject). Lack of sufficient information, uncertainty concerning the personal circumstances, helplessness, and the loss of individual orientation influence the sensitivity of pain and suffering. Social and environmental factors also modify the interpretation of pain. Various cultures, races, and religions tolerate pain in different ways. The ceremonial torture ritual in primitive cultures and the maturity accompanying the adolescent to manhood are proposed to elevate the threshold of pain. The various understandings to the meaning of suffering in the Judeo-Christian and Far Eastern cultures are expressed by the different personal relations to pain.

In childhood, logical thinking is developed only at the age of 11 since any formal logical thinking in youth is impossible. In early childhood up until the age of 9, there is no clear understanding of the motivation of pain, and until the age of 7, there is no understanding of the linkage between pain and illness. These factors are responsible for the different aspects of pain response in children. Their total dependence on adults makes the role of parents highly important and the social and individual aspects extremely significant in the modulation of pain in childhood.

The Theories of Pain

Several theories, some incompatible with the physiological facts, were published during the last 200 years. The specificity

theory, which indicated a specific pain receptor, pain pathways, and a pain center in the brain, contraindicated the intensity theory which postulated the nonspecificity of pain sensation. According to this theory, every type of intense stimulation may be expressed as a pain sensation. Both theories contradict the Aristotelian hypothesis of pain as an affective aspect.

An extremely important development in the search for a unique concept was the gate theory by Melzack and Wall in 1965. The first step in this theory was the finding that in a decerebrated cat, stimuli of C fibers induce a positive potential in the dorsal root and the stimulation of the A_δ fibers induces a negative potential. This hypothesis postulates that the small (C) and the large (A_δ) fibers have a different and eventually contrary physiological activity in the dorsal horn. They presumed that both fibers activate a T transmission cell which transmits the stimuli toward the brain. Simultaneously with the T cell activity, the C and A_δ fibers have a contrary effect on the interneuron known as I inhibitory cell. These I cells depress the T cells and, therefore, suppress the transmission of pain. A_δ and C have opposite reactions on the I cells. A_δ inhibits, while C fibers increase their activity. The mechanism of both fibers reflects the inhibitory effect of the A_δ fibers on the T cells with a decrease in the pain sensation and an increase on the C fibers with intensification of pain. This hypothetical explanation of the pain mechanism explains several phenomena, but fails to explain other clinical observations. The findings of certain dorsal root neurons (WDR) which are powerful inhibitors of pain stimuli, and the phenomenon of diffuse noxious inhibitory control, can be explained in connections with the gate theory. Transcutaneous electrical nerve stimulation (TENS), a therapeutical method of using a high-frequency, low-intensity stimulation for diminishing pain sensation, can also be explained by the pain theory.

In 1968, Melzack and Casey modified the pain theory by including the role of the ascending system. They suggested that there were three different aspects of pain – discriminative, motivation-effective, and cognitive – which ascend through different pathways – the paleospinothalamic and the neospinothalamic tracts. In 1982, Melzack and Wall expanded this theory by also taking into consideration a cognitive control and descending brain stem inhibitory control system which modulated the pain system in the dorsal root. The involvement of endogenous opioids (opioid analgesia system) in the inhibitory interneural system must also be considered.

The Pain Model

Pain was defined in 1979 by the International Association for the Study of Pain (IASP) as an unpleasant sensory and emotional experience associated with actual or potential tissue damage or described in terms of such damage. The definition was limited by an additional note: many people report pain in the absence of tissue damage or any likely pathological cause; usually it happens for psychological reasons. The pain model can be conceptualized in two different ways based on the various disease entities.

Biomedical model of disease

As defined by Engels, it is a simple cause-and-effect explanation by linear causality. A further explanation is that it is involved

in the expression of provable and detectable physical body processes. According to this theory, there is a direct relationship between the significance of the tissue damage and the intensity of pain complaints. This direct disease–brain connection can lead to expectation of pain and its intensity in the presence of various diseases.

Biopsychological model of disease

This archetype was conceptualized and was based on the earlier defined general system theory. It presents the theory that no system can exist in isolation, and the influence environment is an obligatory part of this existence. The primary local systems produce a hieratical continuum of a complex system which stays in equilibrium with the primary system. According to Engel's model, health reflects a high harmony of intersystems and intrasystems.

Types of pain models

Looser's framework

According to J.D. Looser, there are four interacting hierarchical systems – nociception, pain, suffering, and pain behavior. Each of them can have a key role in the genesis of pain and should be directly investigated and treated.

The Glasgow illness model

This form was conceived and eventually published by G. Waddell and colleagues. It includes a framework which defined four main domains: physical problem, psychological distress, illness behavior, and social interaction. The model underscores the importance of psychological distress and illness behavior as separate systems of interest and necessity for therapeutic intervention. It was originally postulated for specifically low back pain patients.

The psychological model of flor and herman

This type of model is based on the learning theory. It was determined that pain is the reflection of multicomponent behavioral responses to aversive stimuli. The remembrance of pain persists at the various levels of the central nervous system, unrelated to the primary physical noxious experience. The pain itself is responsible for the reorganizational changes in the central nervous system.

Siddall and cousin's persistent pain theory

According to their hypothesis, there are discernable objective pathological and anatomical changes along the central nervous system by continued input of pain stimuli (secondary pathology). Influencing factors, such as social and psychological conditions, but also genetic characteristics, are defined as tertiary pathology.

Pain as homeostatic emotion

This theory was researched and published by A.D. Craig and was based on the assumption that pain is an emotion and is, in general, a reflection of bodily changes. Pain was specifically characterized by Craig as follows: Pain is represented by an unforeseen novel pathway in the human brain being a part of a hierarchical system of interoception subserving homeostasis, a sense of physiological conditions of the body, and a subjective awareness of feeling and emotion.

Clinical Implications of Pain

Acute Pain

Acute pain is produced by a sudden injury and ischemic damage to the skin or a visceral organ. Acute cutaneous pain is characterized by two different stages of pain coined as double response (by Lewis). The first stage, which develops immediately after an injury and has a pricking sensation, is caused by the transmission of the pain signal via rapid myelinated fibers (A_δ). One or two seconds later, there is a burning, unpleasant pain which is characteristic of the second stage. This pain pattern is caused by transmitting the signal via slow unmyelinated fibers (C).

Acute visceral pain has an aching, sometimes, sharp, penetrating character – lightening pain, which also appears as a burning, unlocalized sensation, combined with referred pain. The diffuseness of this pain pattern is explained by the high proportion of C fibers which overlap the different receptive fields and wide innervation areas.

Chronic Pain

Chronic pain is a persistent painful sensation whose duration is longer than that of acute tissue injury. As a rule, the time limitation for this type of chronic pain is between 1 and 6 months. Chronic pain is directly related to psychological aspects, such as anxiety, especially the trait anxiety state, isolation, feelings of loss and helplessness, emotions often accompanied by chronic pain. These circumstances influence not only mood, but perception as well.

The pain learning and initiation processes are emphasized more in chronic than in acute pain. The cultural and socioeconomic factors also brutally influence the relation to prolonged pain. As the meaning of suffering and pain varies according to the different cultures, chronic pain depends not only on the individual's cognitive and emotional condition, but also on the socioenvironmental aspects. Autonomic responses (sweating, increase in blood pressure and pulse, and widening of the pupils) very often accompany acute pain, and rarely, the chronic form.

Central Pain

Central pain is defined as that which is associated with a disorder of the central nervous system. The pain may lead to extreme distress and be classified as an intolerable complaint. According to the most updated literature, this type of pain is more intractable to treatment. The pain begins generally days or weeks after a traumatic event. The pain manifestations can present just after the insult or even lifelong.

The anatomical classifications of central pain can be divided into the following:

1. Brain-related central pain – continues in a certain pattern which lasts for a long time or lifelong; has been classified as thalamic pain, pseudothalamic pain, super thalamic pain, or anesthesia dolorosa.

The most common neurological disorders associated with central pain are the following:

1. Stroke – central poststroke pain (CPSP); 90% of brain-related central pain is of vascular origin;

prevalence – ranges from 6% to 11% of stroke patients; some studies report a prevalence of 21%, 32%, and 35% after 4 and 16 months; males more frequent than females; increase of prevalence dependent on age.

2. Multiple sclerosis – 18% prevalence of pain among multiple sclerosis patients.
3. Cancer patients – prevalence of 2%.
4. Parkinson's disease.
2. Spinal cord injury pain (SCIP) – may change its characteristics during its duration; the most predominant cause is trauma, especially road accident – prevalence 20–25%; the most involved population is young adult.
3. Central sensitization pain.

Various clinical features of central pain

1. Constant spontaneous pain, with the following characteristics: aching, burning, lacerating cramping pain.
2. Spontaneous intermittent pain – lacerating pain; 10–20% of cases.
3. Evoked pain – allodynia, hyperalgesia, hyperpathia; elicited by mechanical or thermal stimuli; poor localization, manifestation of ipsi – or contralateral neurons.

Central poststroke pain (CPSP)

The characteristics of pain include the following: band-like muscle; constrictive pain; dysesthesia, hyperpathy, allodynia (in about 50% of patients), lacerating, circulatory, and visceral pain. According to the classification of the International Assessment for the Study of Pain, nociceptive pain is divided into the following: musculoskeletal muscle pain, bone, trauma, inflammatory, visceral pain, and nonlocalized neural pain.

SCI patterns of pain

1. Pain below the level of lesion (possible involvement of the posterior spinal cord tract).
2. Possible segmental band-like pain sensation.
3. Syringomyelia (a pattern that is posttraumatic or not traumatic in cystic enlargement of the spine central canal).

Pathophysiology of central pain

1. Isolated thalamic lesion theory. The theory that the isolated thalamic lesion is the only inducer of central pain (thalamic pain) was changed into the assumption that a lesion may involve various locations along the corticothalamocortical (CTC) pathway. These would include the primary sensory region (S_1), secondary sensory region (S_2), and nonspecific nuclei. In the thalamus, the most involved nuclei associated with central pain are the venteroposterior–inferior nuclei (VPI) (thermo-specific and nociceptive-specific) and the venteromedial (VM) nuclei. The last contain neurons which transduce input from skin by A_δ and C fibers toward layer 1 of the anterior cortex. Stimulation of these thalamus nuclei neurons induces pain. It is noteworthy that after selective damage of the venteromedial–posterior nuclei (VMp) in the thalamus, there is hyperactivation of the spinothalamic cingular pathway.
2. The deafferentation theory.
3. The dynamic reverberation theory. This is associated with dysarrhythmia-hyperactivity of bursting activation in the thalamus and sensory regions.

4. Neuropharmacological theory. This includes the derangement of GABA transmitters (gamma-aminobutyric acid – the inhibitory brain transmitter) by GABA cell loss following brain damage.
5. Neuroplasticity theory. This involves the anatomical features and location of brain activation changes with neuroplasticity reactions in the central nervous system following the deafferentation process.

Central sensitization

This is a condition of prolonged suffering from injury or inflammation with chronic continuous pain over 3+ months. It is a result of the pain facilitatory state and continued neuronal excitation in the dorsal horn of the spine and leads to chemical and structural neuronal changes localized in the pre-synapses and postsynapses of the dorsal horn of the spine and brain with mediation by NMDA downstream activity. The end result is a fixation of peripheral pain on the central–spinal and brain levels.

Intractable Pain

Intractable pain is a permanent severe pain condition mostly unaffected by drug administration. It can be the result of malignant or nonmalignant disease and also be associated with a psychiatric illness without any identifiable symptom. This type of pain in cancer patients is caused by direct penetration of the tumor mass into the diverse organs by nonmalignant complications of cancer (e.g., pathological fractures), neoplastic remote symptoms, and as a complication of chemotherapy or radiation (e.g., neuropathy). The psychological condition of the cancer patient is a very important factor in the development of intractable pain. The hopelessness of the situation and the depressive stage can intensify the pain sensitivity and even decrease the threshold of pain.

Causalgia

Causalgia is a pain disorder of the peripheral nervous system having a sustained obstinate burning character. It can develop after a traumatic peripheral nerve lesion such as complications of limb injuries which can occur from high-velocity missiles during warfare. The incidence of such a pain disorder in limbs of wounded soldiers is ~1.5–2%.

Causalgia is a very distressing and intense pain disorder which usually attacks patients severely during normal daily activities. It is usually combined with the median nerve injury in upper limbs and the sciatic nerve in the lower extremities.

Emotional and behavioral factors can distinctly influence this pain either by aggravating or relieving its intensity. It is certain that dysfunction of the sympathetic nervous system plays the main role in this disorder. It has also been proved that hypersensation of the WDR cells in the dorsal horn and dysfunctioning of the C and A_δ activities are the physiological changes in causalgia. The main role of the sympathetic system is demonstrated by the complete abolishment of pain sensation by total disruption of all sympathetic fibers to the injured limb. This finding is the basis for effective therapy of surgical sympathectomy in causalgia.

Referred Pain

Referred pain is one of somatic visceral origin which is projected to a fixed distant location. The best examples for this disorder are the projection of cardiac pain in the left shoulder and arm: pain in the right shoulder, pain in gallbladder diseases, and back pain in peptic ulcer. The explanation for the referred pain is a simultaneous activation of both processes of the dorsal root ganglion cells in the superficial skin branch and the deep somatic process. By stimulation of the visceral branch, the superficial branch activates and also depresses the activity of the visceral area. In the interaction between two different visceral pains (cardiac and gallbladder or pancreas and peptic ulcer pains), the fixed distant location moves in the vertical direction. This dislocation of the referred pain is known as aberrant referred pain. It very often happens when there are other defects in the same area occurring simultaneously with referred pain. The reflex paralysis is a well-known combination of limb, skin, pain, and muscle weakness in the same distribution. The close relationship between sensory and motor fibers explains this phenomenon.

Phantom Pain

Phantom pain, a postamputation disorder, is pain in the area of the body where a limb existed previously. This pain phenomenon is mostly associated with limb amputation, but can also develop after nose, ear, tongue, breast, or penis excision. This type of pain has no particular identifying character and may present in a burning, throbbing, aching, or crushing form. Its intensity and duration also vary radically from patient to patient. Very severe intractable pain, a mild unpleasant sensation, or a sensation without a painful component (phantom) may be the presenting symptoms. Cognitive, emotional, and behavioral factors play a role in the onset of this disorder. Patients suffering from emotional rigidity, in a depressive state, with feelings of helplessness and insomnia, are most likely to develop phantom pain, and possibly, with even more intensity.

Theories concerning the importance of preamputation factors, such as the last position of the leg before it was amputated, were previously reported. Currently, it seems that there is no relationship between phantom pain and preamputation conditions. The mechanism of phantom pain is uncertain. Peripheral, dorsal horn, supraspinal, and psychological causes were hypothesized. It seems that multifactorial causes are responsible for the development of this unusual disorder.

Medication (analgesics, antipsychotic, and antidepressant drugs), surgical intervention, physio- and psychotherapy, hypnosis, and acupuncture are investigated, but later were found to have only limited efficacy. The usefulness of each therapeutic method is individualistic in nature and varies from patient to patient.

Pain and Psychiatric Diseases

Many psychiatric diseases are associated with long-standing chronic pain. The intensity of pain in psychiatric patients can become intractable without even any evidence of physical lesions.

In neurosis and hysteria, pain is of a somatoformic phenomenon, resulting from an emotional dysfunction. Forty percent of neurotic and hysteric patients, mostly males, complain of having pain. In its extreme form, pain can be the presenting symptom of a psychiatric disorder and may be totally unresponsive to analgesic medications. This condition is usually associated with anxiety, fatigue, depression, or irritability, and sometimes with a neurological localized deficit, such as paralysis or an atypical pricking sensation of the limb. The complaints, in contrast to organic physical pain, may be of a very localized character, such as spot location in headache and the localized cardiac pain in cardiophobia. Prolonged, intractable pain often leads to medical misdiagnosis. In Briquet's syndrome (acute abdominal pain as a result of hysteria), many females, diagnosed as suffering from appendicitis, peptic ulcer, extrauterine gravidity, or even heart attack, may undergo unnecessary recurrent surgical intervention. Pain associated with muscle contractions, which is characteristic of many of these cases, aggravates the somatoformic pain in neurotic hysteric patients.

Pain is very closely related to anxiety which decreases the pain threshold. On the other hand, anxiety can be induced by pain, especially when it is of a visceral origin and associated with autonomic symptoms. In a situation of extreme stress with an overfunctioning of the sympathetic system, severe anxiety can be combined with the insensitivity and elevation of the pain threshold. War injuries, incurred at war during combat, mountain climbing, and road accidents, are examples of such stressful conditions.

Another, less common pain disorder in psychiatry is known as delusional pain which occurs in 2% of schizophrenic patients. In this case, it is difficult to differentiate between delusional pain and the extreme increase of the tolerance threshold to external pain stimuli. Schizophrenic patients with serious life-threatening medical conditions, such as heart attacks, perforation of peptic ulcer, or multiple injuries from road accidents, may be free of pain. Neurochemical mechanisms, such as changing of the serotonin or bradykinin levels, were postulated as the cause of this phenomenon. Delusional pain is mostly a part of a complex psychotic picture and is treated by the administration of antipsychotic medication.

Pain in the Elderly

The subdiscipline of pain in the aged is of increased interest. The characteristics of this elderly patient population are not yet clear. There is evidence of the intensity of pain between middle age and elderly subjects in the various modalities, even though special patterns of suffering are found in some of the clinical types of pain probably because the psychosocial factors are different for these two age groups. The pathway from catastrophic incidence to pain severity and the role of depressing fear of reinjury among the older subject may have a dominant effect on the specific pain features among these patients.

Each of the modalities has different characteristics. The threshold and tolerance to one modality are unrelated to the other. For example, the duration and affected area of the heat contact stimulus, which is transduced by the A δ and C polymodal nociceptors, are much shorter than that of the cold

pressure pain. Spatial and temporal summation of stimuli is another aspect of the pain stimuli analysis. The clinical pain's pathways are divided into the acute pain tract and the chronic pain tract. The most commonly used clinical acute pain type nomenclature are acute postsurgical pain, migraine pain, acute renal colic and acute abdominal pain, and postsurgical pain. The most commonly used clinical chronic pain type nomenclature are rheumatoid arthritis pain, low back pain, fibromyalgia, oral and facial pain, neuropathic pain, and cancer pain.

Pain – Sex and Gender

Data from previous clinical research have led to the assumption that males endure more pain, are less sensitive to it, and have a higher tolerance to all kinds of pain sensation. It was even determined that pain was an abnormal sensation for males. At the very least, this assumption was a result of the social-dependent expectation for each gender. However, it is well known that the prevalence of various chronic pain types is different in males and females. Among females, the prevalence of migraine, trigeminal and suboccipital neuralgia, causalgia, burning tongue, fibromyalgia, and proctalgia fugax is significantly higher than among males. On the other hand, it can be found that the prevalence of cluster headache, SUNCT syndrome, and postherpetic neuralgia is higher among males. In some of the other pain disorders, the dependency of gender is also age-dependent, such as in osteoarthritis which is more common after the age of 45 among females, and in males, up to the age of 45. The complete data of gender and sex dependency of pain sensitivity and tolerance is not yet clear, and additional study is necessary to fully investigate this subject.

Nevertheless, the results of some studies in this area have been informative. In 2007, a consensus report on pain was published. It was entitled 'Studying Sex and Gender Differences in Pain and Analgesia.' The report stated that the pain field has moved from debating whether sex differences in pain exist to recovering the influence of this difference. They recommended that all pain researchers consider testing their hypothesis in both sexes, or if restricted by practical means, only in females. It was also recommended to test pain sensitivity and tolerance across estrogen cycles in animals during the menstruation cycle, and in humans, to take into account various psychosocial factors, such as age, race, and ethnic cultural factors; plus the subject's individual history and clinical factors such as comorbidities, disabilities, medication usage, and cognitive and other affecting factors.

There have been some study vehicles that let us assume the tendency of sex and gender dependency in each of the clinical and experimental types of pain:

Sex differences in response to experimental stimuli pain

1. Pressure pain stimuli – females have lower pain threshold and tolerance and are more sensitive to this type of pain.
2. Ischemia pain stimuli – there is no evidence supporting the assumption that there is a sex difference in pain threshold or tolerance in this type of pain; however, there is a discrepancy between the results of the different studies.
3. Heat pain stimuli – there is evidence that females are more sensitive to heat stimuli; they define heat stimuli as more unpleasant in males and the females have lower

thresholds for tolerance; the minimal grade of temperature which induces pain is lower among females.

4. Cold pain stimuli – there is a sex difference with the induction of cold pain stimuli with lower tolerance and threshold.
5. Electrical pain stimuli – it seems that females are more sensitive to the electrical pain model.
6. Capsaicin-evoked pain – there is a high sensitivity to this type of pain among females; the sensitivity changed dependent upon the phase of the menstrual cycle; in the oral use of capsaicin, there is no difference between male nonusers of contraceptives females with contraceptive users having higher sensitivity.
7. Glutamate and hypertonic saline injections – females are more sensitive than males.
8. Temporal summation of pain – the temporal summation of pain is more significant among females.
9. Spatial summation of pain – there was not enough data to support any conclusion.

Sex differences in clinical pain trials

1. Cancer pain – there was no evidence in cancer pain; depression is more common among females.
2. Neuropathic pain – there was a greater sensitivity among females.
3. Lumbosacral pain – there was no difference in pain intensity and tolerance.
4. Osteoarthritis pain – there was a greater pain sensitivity among females and a higher intensity of depression.
5. Oral pain – there is a difference in sensitivity and tolerance among sex, especially in the age group of 45–65.6.
6. Abdominal pain – the data among abdominal pain was controversial.
7. Postsurgical pain – females report a higher intensity of postsurgical pain.

Children and adolescents

There is a higher prevalence of chronic pain, headache, and back pain in females than in males; the difference is more prominent during puberty.

Mechanisms leading to sex differences in pain

1. Hormonal factors – there was evidence of hormones playing a role in clinical pain; either the increase or decrease in estrogen level has an effect on activation of pain (e.g., in thermal stimulation). Different pain stimuli thresholds are dependent upon the phase of menstruation. Higher progesterone level may also lead to increased pain sensitivity (cold pain stimuli). The exact mechanism of effect is not yet clear. It may be an inflammatory and C fiber activation induction effect or activation of NMDA receptor, nitric oxide, and sympathoadrenal systems.
2. Endogenous opioid system – females have a greater opioid receptor activity and binding than males; higher estradiol-level response to increased μ -opioid receptor availability.
3. Dopamine – was found in fibromyalgia.
4. Serotonin – was found in migraine and inflammatory bowel syndrome.
5. NMDA receptors – there is a direct estrogen effect on NMDA and a sex-related NMDA receptor expressed in the dorsal root ganglia (DRG); the enhancement of opioid

antinociception is greater in males than in females in laboratory animal model studies. This phenomenon probably has an effect in the temporal summation of pain among both sexes.

6. Psychosocial cognitive and affective factors included coping, catastrophic sizing, effecting distress, and depression.
7. Anatomical brain physiology – there is an anatomical difference in the periaqueductal gray (PAG)-rostral ventromedial medulla and the dorsal horn of the spinal cord pathway between males and females. This pathway has an important role in the pain mechanism. Not only morphine, a μ -opioid receptor antagonist, but also κ and δ , have a direct effect on the PAG. The difference in activity between males and females by opioid receptor antagonists can be explained by the anatomical and structural difference of this system among sex.

Genetics

Data about genetic mutation influencing pain comes from animal model (mouse knockout and transgenic) studies and human ones (twin studies, SNP, and polymorphism analysis).

Conduction of Pain Genetics

Sodium channelopathy

Voltage-gated sodium channels play an important role in nociceptive transmission. The nociceptive stimuli depolarize the membrane, open the voltage-gated sodium channel transiently, and induce the flow of sodium ions apparently along the concentration gradient. This generates the action potential in the excitable cells and activates a transmission along the axons.

Voltage-gated sodium channels are heteromultimers which contain large pore-forming α -subunits and smaller β -subunits. The genes that decode voltage-gated sodium channels are as follows:

1. SCN 11A which encodes the voltage-gated sodium channel Na_v 1.9 and is activated near the resting membrane potential and plays a role in setting pain threshold. It is influenced by inflammatory mediators.
2. SCN 9A which encodes the voltage-gated sodium channel 1.7 and is located on chromosome 2. It is highly concentrated in the dorsal root ganglion and sympathetic ganglion; it amplifies small depolarizations and acts on the threshold and modulation of excitability of the channel. Mutations in the gene are responsible for the following diseases – paroxysmal extreme pain disorder (IEPD), along with extreme pain of the perirectal, perioral, and trigeminal area; plus, inherited erythromelalgia – a mechanical pain with episodic attacks in the foot and hand associated with chronic inflammation.
3. SCN 10A encodes the Na_v 1.8 channel and contributes to electrogenesis primary pain pathway and has a direct influence on inflammatory modulators and activation of cold pain stimuli.

The regulation of the voltage-gated sodium channel by transcriptional and post-transcriptional expression is by the following:

1. Neuron-restricted silencing element (NRSE) and its protein factor (NRSF) and repressor element 1 (RE1) and its protein REST.
2. Modulation of transmitter – KCNQ-encoded potassium channel. It acts in reducing excitability. Clinical importance is in hyperalgesia and allodynia.

Transduction of Pain

1. Heat pain sensation. Heterogeneous expression of mouse PIR1 enhances the channel of activity of transient receptor potential channels (TRPV₁) nociception, which responds to heat and capsaicin stimuli. It is located on chromosome 17p13. TRPV₂, vanilloid receptor (VR), is located on chromosome 17 and is detected by thermal sensory neurons which differ in this response threshold. TRPV₃, vanilloid-like receptor 3 (VRL), is located close to chromosome 17p13 and responds to temperature sensations and TRPV₄.
2. Cold pain sensation. Direct activation of TRP M8 and TRPA₁, inhibition of K⁺, and reduction of electrogenic pump activity. The TRP M8 gene is located on chromosome 2q37 and is related to VR1. Its expression is on cold metal receptor 1 (Cur1) and VR1 in the target cells and induces a temperature – cold or hot sensation. The mechanism was thought to be the cause of misinterpretation of noxious cold stimuli, such as burning pain modified by endogenous menthol-like ligand. TRPA₁ is located on chromosome 8p13 gene. It is an ankyrin-like protein with its transmembrane domains 1 (ANKTM 1) and is a cold-activated channel with lower activation temperature than normal. It is a cold and mental receptor and coexpresses in heat and capsaicin receptor II.
3. Mechanical pain sensation. It is initiated by direct activation of TRPV₄ and TRPC/P. TRPV₄ is located on chromosome 12q 2.1. Its main role is that of normal pressure detection. It has a high-threshold sensory complex and is also activated by heat pain sensation.
4. Acid sensing ion channel (ASIC) which is an activating mechanoreceptor.

Transient Receptor Potential Channels (TRPV)

TRPV – four subtypes

1. Type 1 – activated by a heat temperature more than 42 °C; proteins and endocannabinoids; located in dorsal root ganglion (spine), trigeminal ganglia, brain, and viscera.
2. Type 2 – activated by a heat temperature more than 52 °C, mechanical osmotic and diphenyl substance; located in the dorsal root ganglion, spinal cord, brain, and viscera.
3. Type 3 – activated by a heat temperature more than 34 °C, capsaicin, diphenyl, and camphor; located in the dorsal root ganglion, trigeminal ganglion, brain, spinal cord, and skin.
4. Type 4 – activated by a heat temperature more than 27 °C, osmotic, epoxylic, trienoic acid, and PVFA; located in the dorsal root ganglion, trigeminal ganglion, brain, and viscera.

TRPA

1. TRPA is activated by cold temperatures lower than 18 °C, mechanical stimuli, calcium ion, and icilin; located in dorsal root ganglion, and fibroblast and hair cells.

TRPM – two subtypes

1. Type 1 – activated by temperatures 15–35 °C, calcium ion; located in viscera.
2. Type 2 – activated by temperatures lower than 28 °C, menthol and icilin; located in the dorsal root ganglion, trigeminal ganglion, and viscera.

TRPC – two subtypes

1. Type 1 – activated by mechanical stimuli; located in viscera.
2. Type 2 – activated by diacylglycerol and exocytosis; located in the brain.

Synaptic transmission in pain

This occurs through the following:

1. Voltage-dependent Ca²⁺ channels (CACNA) 1A subunit 5 and located on chromosome 19 p13 and CACNA 2D₁.
2. Ionotropic glutamate receptor AMPA (α -amino-3-hydroxy-5-methyl-4-isoxazole-propionate)-GRIA 1 (location 5q33), GRIA 2 (location 4q32) and GRIA 3 (location Xq25-26) and GRIA 4.
3. Neurokinin 1 receptor = substance P receptor (location 2q11).
4. NMDA receptors and ionotropic glutamate receptor.
5. Kainate 1 (location 21q22), 2 (location 6q21), 3 (location 1p34–33), 4 (location 11q 22.3) and 5 (location 19q 13.2).

Genetic Mutations Decrease Pain

Hereditary syndromes

1. There are 13 currently identified variants of the SCN9A gene involving the voltage-gated sodium channel (2 subunits).
2. Others include hereditary sensory and autonomic neuropathy I–V.

Pain is reduced in the average population having the following:

1. Variation of micro-opioid receptor gene (OPRM 1), type Mu 1 (location 1 p 36.1 – p 34.3), and type delta 1 (1 p 36.1–p 34.3).
2. Variation of catechol-O-methyltransferase gene (COMT) associated with increased morphine sensitivity (location 14 q 22.1–q 22.2).
3. Variation of guanosine triphosphate cyclohydrolase 1/ dopa-responsive dystonia gene (GTP cyclohydrolase 1, GCH1) (location 14 q 22.1–q 22.2).
4. Melanocortin 1 receptor gene (MC1R) associated with increased opioid analgesia of micro-opioid receptor agonist and κ -opioid agonist (in females).

Intense opioid effect

1. Duplication of cytochrome P 450 206 gene
2. Melanocortin 1 receptor gene
3. Catechol-O-methyltransferase (COMT V 158 M).

Hereditary Sensory and Autonomic Neuropathy (HSAN)

Here are some hereditary disorders associated with the severe form of loss of pain.

1. HSAN 1 – gene location 9q22.1-q22.3; misuse mutation in serine palmitoyltransferase long chain base subunit 1 (SPLC 1); apoptotic loss of sensory and autonomic neurons; pain and heat less.
2. HSAN 2 – gene location on 12p 13; misuse mutations of protein kinase PRKWNK1.
3. HSAN 3 – familial dysautonomia; sensory cell loss; loss of sensation; Riley–Day syndrome; gene location q13; splicing deficit on IKB KAP protein; deficit in sensory neuron development; insensitivity to pain.
4. HSAN 4 – familial dysautonomia type II; gene location 1q21-q22; loss of functional TrKA receptor, small fibers neurons loss; insensitivity to pain; combined with amyloidosis.
5. HSAN 5 – gene is located 1p 13.1; congenital insensitivity to pain.

Assessment of Pain Therapy

The management of pain therapy depends on the efficacy of therapy modality and the physical and psychological condition of the patient. Drug treatment, surgical intervention, physiotherapy, psychotherapy, psychological management, including hypnotherapy and acupuncture, are categories of pain therapy.

Drug Therapy

Nonopioid analgesics

These drugs are nonselective cox inhibitors, such as acetaminophen, acetylsalicylic acid, (aspirin) and selective cox inhibitors or nonsteroidal anti-inflammatory agents – NSAIDs (ibuprofen, naproxen, indomethacin, suprofen, diclofen, celecoxib, and etoricoxib). The effect is mainly through their influence on the peripheral pain system. Most of the substances inhibit the prostaglandin synthetase enzyme and the kinin production. The central effect is also postulated, but only with a limited clinical importance. These drugs are usually administered in muscle and joint pain, rheumatic complaints, and inflammatory diseases associated with pain and headache, and some have a specific effect on migraine. This drug category does not induce tolerance, physical dependence, or influence mood and alertness.

Opioid analgesics

Opioid analgesics are agents which eliminate pain by activating the opioid analgesic system in the spinal horn and supraspinal structure. The analgesic effect is induced by binding the exogenous opioid substances of different opiate receptors, especially the μ receptor. Morphine, meperidine, methadone, codeine, and oxycodone belong to the exogenous opioids. Some of the drugs (pentazocine) have an agonist and antagonist effect on the system. Others have combined effects with antipain mechanisms (tramadol- μ -opioid receptor agonist and monoamine reuptake inhibition).

Opioid analgesics are very effective in severe, visceral, post-traumatic operation, and cancer pain. Its efficacy on the peripheral nerve lesion with causalgia, phantom pain, and psychiatric disorders is less prominent. The drug category is associated with side effects, such as vomiting, constipation,

and even respiratory distress, and is characterized by the development of tolerance to the substance and addiction. Addiction to these opiates is highly individual.

Antidepressants

The tricyclic antidepressants (amitriptyline, doxepin, and imipramine) are based on the effect of balanced monoamine reuptake inhibition and effective medications against peripheral-neuropathic pain, headache, and fibromyalgia. The effect of these drugs is associated with the psychiatric, antidepressive, sleep-regulating, and mood-stabilizing results with a specific effect on the serotonic and norepinephrine turnover by preventing the reuptake into cell bodies. A beneficial effect was also shown in antidepressants known as serotonin selective reuptake inhibitors (SSRI) and serotonin noradrenalin reuptake inhibitors (SNRI), for example, venlafaxine and duloxetine, which have to be investigated in patients with neuralgia, neuropathic pain, and fibromyalgia.

Serotonin agonists and antagonists

Serotonin receptors play a central role in the pain mechanism, especially in migraine headache. At least five different presynaptic and postsynaptic serotonin receptors (5HT receptors) are differentiated by dividing them into two groups – 5HT₁ and 5HT₂. 5HT_{1B} and 5HT_{1D} agonists (sumatriptan) have a strong antagonist (pizotifen) that has a preventive effect. α_2 , H₃, μ -opioid, and somatostatin were found in the trigemino-vascular fibers (fibers of the trigeminal nerve surrounding the cranial vessels) and may play a role in antimigraine therapy. Medication which has a direct stabilizing effect are as follows: voltage-gated sodium channel blockers (carbamazepine, phenytoin, and lamotrigine), α_{25} subunit of presynaptic voltage-dependent calcium channel blockers and reducers of presynaptic transmitter release, which was found to be efficient in peripheral pain, and inhibitors of glutamate release and the action of AMPA and kainate receptors, for example, Topiramate, which has been found to be effective especially in migraine and headache.

Other Antipain Methods

Surgical intervention is a radical, but nevertheless effective method in the treatment of severe, prolonged pain. Physiotherapy and psychological management are helpful in the elimination of aggravating emotional and cognitive-negative aspects of pain. Physiotherapy can help relieve muscle contraction and joint pain, which severely intensifies pain sensation from other origins. The use of TENS, a high-frequency, low-intensity stimulation, is effective in peripheral and spinal pain. This mechanism is independent of the opioid analgesic system and the effect is not reversible by administration of naloxone.

A prolonged inhibitory effect of TENS on the spinothalamic tract without abnormality in the peripheral nerve conduction and a spinal depressing activity by selective C/A fiber stimulus, according to the gate theory, are postulated as the mechanisms of TENS.

Acupuncture depresses pain sensation probably by activating the opioid analgesic system. A low-frequency, high-intensity stimulus has a similar effect; however, both physical therapies are partially reversible by naloxone administration.

Hypnotherapy and biofeedback are other options in pain management. The relaxin-imaginary exercises may influence the autonomic system and induce self-regulation of pain by controlling cognitive and autonomic functions. Other non-pharmacological treatments tried in refractory central pain have repetitive transcranial magnetic stimulation (rTMS), deep brain stimulation (DBS), invasive motor cortex stimulation, and vestibulocochlear stimulation.

Paranoia

A Fenigstein, Kenyon College, Gambier, OH, USA

© 2012 Elsevier Inc. All rights reserved.

Glossary

Delusions Faulty interpretations of reality that cannot be shaken, despite clear evidence to the contrary, and that are not shared by other members of the community.

Ideas of reference The misperception of oneself as the target of others' thoughts and actions; for example, a person seeing others laughing might relate the event to himself, and see himself as the target of their laughter.

Paranoia A disordered mode of thought that is dominated by a pervasive, exaggerated, and unwarranted suspiciousness and mistrust of people, and a corresponding tendency to interpret the actions of others as deliberately threatening or demeaning.

Paranoid illumination The point at which the paranoid realizes that he has been singled out for mistreatment, and

others are working against him; suddenly, everything begins to make sense.

Projection A psychological defense often associated with paranoid thinking, in which the individual attributes one's own unacceptable motives or characteristics to others.

Pseudo-community A delusional system in which the paranoid organizes a variety of unrelated persons into a structured group whose primary purpose is to engage in a conspiracy against him.

Self-focus A behavioral style characteristic of paranoia, in which the individual is especially prone to be aware of himself as an object of attention to others.

Therapeutic alliance A tactic frequently used in treating paranoids, in which the therapist acknowledges the patient's delusional beliefs as understandable, in an attempt to build trust.

Paranoia, although originally referring (in Greek) to almost any kind of mental aberration or bizarre thinking, is currently used to describe a disordered mode of thought that is dominated by an intense, irrational, but persistent mistrust or suspicion of people, and a corresponding tendency to interpret the actions of others as deliberately threatening or demeaning. Because of the general expectation that others are against them or are somehow trying to exploit them, paranoid persons tend to be guarded, secretive, and ever vigilant, constantly looking for signs of disloyalty or malevolence in their associates. These expectations are easily confirmed: the hypersensitivity of paranoids turns minor slights into major insults, and even innocuous events are misinterpreted as harmful or vindictive. As a result, a pernicious cycle is set in motion whereby expectations of treachery and hostility often serve to elicit such reactions from others, thus confirming and justifying the paranoid's initial suspicion and animosity. Of all psychological disturbances, paranoia is among the least understood and most difficult to treat.

Paranoid Syndromes

Paranoid features are found in a variety of different psychological conditions. Although these conditions are often regarded as distinct, the criteria for distinction are not entirely clear and the practical utility of the distinction, in terms of etiology or treatment implications, has not been established. Thus, it may be useful to consider the different paranoid disorders as related syndromes existing along a continuum which varies in terms of the frequency and severity of paranoid thoughts, the degree to which reality is allowed to influence perceptions, and the extent to which functioning is impaired. The continuum extends from paranoid personality disorder, which is

nondelusional, but where suspicion and its sequelae occur so regularly that work and family life are often disrupted; to delusional (paranoid) disorder, involving a chronic, dysfunctional delusional system, although apart from the delusion, reality testing is good and behavior is not obviously odd; and finally, to paranoid schizophrenia, a severe, incapacitating psychosis, involving a serious loss of contact with reality in which all thought is affected by the delusion.

Paranoid Personality Disorder

Anyone starting out in a new situation or relationship may be cautious and somewhat guarded until they learn that their fears are unwarranted. Those with paranoid personality disorder cannot abandon those concerns. Although not of sufficient severity to be considered delusional, theirs is a rigid and maladaptive pattern of thinking, feeling, and behavior, usually beginning by early adulthood, which is built upon mistrust, vigilance, and hostility. The conviction that others 'have it in for them' represents their most basic and unrelenting belief; they feel constantly mistreated, and have a high capacity for annoying and provoking others.

Seeing the world as a threatening place, these individuals are preoccupied with hidden motives and the fear that someone may deceive or exploit them. They are inordinately quick to take offense, slow to forgive, and ready to counterattack at the first sign of imagined criticism, even in their personal relationships. Disordered paranoid personalities see references to themselves in everything that happens. If people are seen talking, the paranoid knows they are talking about him. If someone else gets a promotion, that person's advancement is seen as a deliberate attempt to humiliate him and downgrade his achievements. Even offers of help and concern are taken as implied criticisms of weakness or as subtle manipulations of

indebtedness. The constant suspicions and accusations eventually strain interpersonal relations to the point where these individuals are in constant conflict with spouses, friends, and legal authorities.

Given their hypersensitivity, any speck of evidence that seems to confirm their suspicions is blown out of proportion, and any indication to the contrary is ignored or misinterpreted. Trivial incidents become accumulated and unconnected 'facts' are fit together to create false, but unshakeable beliefs regarding their mistreatment. Because of their conviction that others are undermining their efforts or ruining their achievements, they tend to see themselves as blameless, instead finding fault for their own mistakes and failures in others, even to the point of ascribing evil motives to others.

Those with disordered paranoid personalities also tend to overvalue their abilities, and have an inflated sense of their rationality and objectivity, making it extraordinarily difficult for them either to question their own beliefs or to accept or even appreciate another's point of view. Unable to recognize the possibility of genuine dissent, simple disagreement by others becomes a sign of disloyalty. The resulting obstinacy, defensiveness, and self-righteousness exasperates and infuriates others, and elicits responses that exacerbate the conflict and confirm the original paranoid expectations.

In addition to being argumentative and uncompromising, paranoids appear cold and aloof, and emotionally cut off from others. They avoid intimacy, partly because they fear betrayal, partly in an attempt to maintain total control over their affairs, and partly because of profound deficits in their capacity for joy, warmth, and nurturance. The resulting social isolation, by limiting the opportunity to check social reality and learn from others, only reinforces their egocentric perspective.

Compared to some other paranoid pathologies, those with disordered personalities tend not to progressively worsen, but rather reach a certain level of severity and stay there. They show considerably less disorganization of personality, and they do not develop the kind of systematic and well-defined delusions found in delusional disorders. However, the proverbial kernel of truth is often greater in the suspicions of disordered paranoid personalities than in those with delusional disorders; their accusations have more plausibility and their paranoid attitudes are more diffuse. Because of the complexity and pervasiveness of personality disorders, these individuals may have more impoverished lives, although some do manage to function adequately in society, often by carving out a social niche in which a moralistic and punitive style is acceptable or at least tolerated.

Delusional (Paranoid) Disorder

The cardinal feature of this disorder is the presence of a delusion that is so systematic, logically developed, well-organized, and resistant to contradictory evidence, that others are often convinced by it. Delusions are faulty interpretations of reality that cannot be shaken, despite clear evidence to the contrary. Although the delusions in this disorder are nonbizarre (unlike those found in paranoid schizophrenia) and involve situations that may occur in real life, in fact they have no basis in reality, and are not shared by others in the culture. Delusional systems are usually idiosyncratic, but some themes or combination of

themes are more frequently seen than others, and psychiatric diagnoses of this disorder are now specified by the predominant theme of the delusions present.

Delusions of persecution, in which the paranoid believes that 'others are out to get me,' are the most common form of this disorder. While those with a paranoid personality disorder may be suspicious that colleagues are talking about them behind their backs, persons with delusional disorder may go one step further and suspect others of participating in elaborate master plots to persecute them. They often believe that they are being poisoned, drugged, spied upon, or are the targets of conspiracies to ruin their reputations. Many of them tend to be inveterate 'injustice-detectors,' inclined to take retributive actions of one sort or another, and are constantly embroiled in litigation or letter-writing campaigns, in an attempt to redress imagined injustices.

Persons with delusions of grandiosity have an exaggerated sense of their own importance. In some cases, these beliefs are related to persecutory delusions, in that the paranoid eventually comes to feel that all the attention he is receiving is indicative of his superiority or unique abilities. Such exalted ideas usually center around messianic missions, extremist political movements, or remarkable inventions. Persons suffering from delusions of grandeur often feel that they have been endowed with special gifts or powers and, if allowed to exercise these abilities, they could cure diseases, banish poverty, or ensure world peace. When these efforts are ignored or thwarted, as they almost inevitably are, the paranoid may become convinced of a conspiracy directed against him.

Another theme frequently seen is that of delusional jealousy, in which any sign – even an apparent wrong number on the phone or a short delay in returning home – is summoned up as evidence that a spouse is being unfaithful. When the jealousy becomes irrationally pathological, and the paranoid becomes convinced beyond all reason that his spouse is cheating and plotting against him in an attempt to humiliate him, he may become violently dangerous.

An erotic delusion (also known as erotomania) is based on the belief that one is romantically loved by another, usually someone of higher status or a well-known public figure, although the other, presumably, cannot acknowledge it openly. Because of unrealistic expectations about the likelihood of living with the celebrity, these delusions often result in stalking or harassment of famous persons through incessant phone calls, letters, visits, and surveillance. When their love is not returned, these delusional individuals feel a sense of betrayal that may turn to rage and hatred. Although this disorder has been reported most often in women, it occurs in men as well (perhaps the best example being John Hinckley, whose erotomanic delusions involving the actress Jodie Foster led to his attempted assassination of then-President Ronald Reagan).

Those with somatic delusions are convinced that there is something very wrong with their bodies – that they emit foul odors, or have bugs crawling inside of them, or are misshapen. These delusions often result in an avoidance of others, except for physicians who, despite being accused of conspiring to deny the problem, are consulted continuously regarding the imagined condition.

The thinking and behavior of these individuals tend to become centered around the delusional theme in a pathological

'paranoid construction' that, for all its distortion of reality and loss of critical judgment, provides a sense of identity, importance, and meaning not otherwise available. The meaningfulness of delusions is also suggested by the fact that they often reflect the person's position in the social universe: women and married men are most likely to have delusions with sexual content; foreign immigrants are most prone to have paranoid delusions; and people from higher socioeconomic levels are the most likely to have delusions of grandeur.

Once the basic delusion is accepted, other aspects of behavior, including emotional responses, may be described as appropriate and more or less conventional. Delusionally disordered persons do not suffer hallucinations or indications of other mental disorders, and their personalities do not change drastically; there are few exacerbations or remissions. There is a relatively high level of cognitive integration skills in areas that do not impinge on the delusional thought structure. Despite their mistrust, defensiveness, and fear of being exploited, they can sometimes function adequately, especially when their suspicions are limited to one specific area; for example, if they suspect poisoners everywhere, they may be satisfied if they can prepare all their own food. Their lives may be very limited and isolated, but they are just as likely to be regarded as harmless cranks than someone requiring the help of a mental health professional.

Sometimes, however, the consequences of the delusions are debilitating and not so easy to manage; for example, a person suffering from delusions of persecution may assault an imagined persecutor or spend a fortune fleeing enemies and pursuing redress for imagined wrongs. In other instances, the disorder may be dangerous. In particular, paranoid delusional disorder may be overrepresented among fanatical reformers and self-styled prophets and cult leaders. These individuals may be especially attracted to an enterprise that encourages blaming others, regarding themselves as a victim, and putting themselves at the center of things. Especially in times of social cataclysm or uncertainty, their grandiosity and moralistic tendencies, as well as the logical and compelling presentation of their messianic or political delusions, can often attract disciples. In addition, their garrison mentality is quite capable of provoking events which then serve to confirm their apocalyptic prophecies.

Much of the difficulty involved in diagnosing paranoid disorders is because of the slipperiness of the concept of delusion. Even in the real world, it is not always possible to determine the truth or falsity of an idea: Does the government keep track of unsuspecting individuals? Is our air and water filled with unseen toxins? Does our boss really have our best interests in mind? Some ideas that are patently false are held with sincere conviction by many; and even when an idea is held as preposterous by the majority, that majority may be wrong. How, then, do we evaluate the irrationality of an idea, or decide whether clearly eccentric and convoluted thinking merits the designation 'delusional?' Although it may be difficult to distinguish reality from illusion, particularly when the belief system develops around a potentially real injustice, other indications may be diagnostically helpful. An inability to see facts in any other light or to place them in an appropriate context, a glaring lack of evidence for far-reaching conclusions, and a hostile, suspicious, and uncommunicative attitude when delusional ideas are questioned usually provide clues of pathology.

Paranoid Schizophrenia

This major mental illness is one of the most common types of psychotic disorders. Paranoid schizophrenics may be distinguished from those with delusional disorder on the basis of the extreme bizarreness of their paranoid delusions, such as the belief that their thoughts or actions are being controlled by external forces, and by the presence of hallucinations (e.g., hearing voices) and other indications of a serious break with reality. The delusions of schizophrenics are not organized and systematic, but fragmentary and unconnected. Although these individuals may be suspicious and very much threatened by outside influences, their reaction, unlike that of the disordered paranoid personality, is usually hesitant and confused; their anger has no concentrated intensity. The behavioral, cognitive, and perceptual disorders of paranoid schizophrenics are so dysfunctional that performance on the job or at home almost invariably deteriorates, and emotional expressiveness becomes severely diminished.

These individuals commonly suffer from delusions of persecution, wherein they are convinced that they are constantly being watched or followed, and that strangers or government operatives or even alien beings are plotting against them with fantastic machines, undetectable poisons, or extraordinary mental powers. Of course, given the exceptional cunning and duplicity of these diabolical forces, virtually anything – a look, a sound, a bodily sensation, for that matter, even the absence of anything, a particularly shrewd maneuver – is seen as confirmation of one's suspicions. When the schizophrenic experiences the 'paranoid illumination,' and recognizes that all this overwhelming evidence fits together, the sense of his own visibility and vulnerability is profoundly increased, as is the tendency to misperceive himself as the target of other people's stares, comments, and laughter. In some cases, persecutory beliefs are accompanied by delusions of grandeur: that they are the target of these forces is only because they are special or powerful or dangerous. They may recognize that others reject them and their message, but they interpret these negative reactions as persecution based on jealousy, hostility, or enemy conspiracies.

Some paranoid schizophrenics avoid detection for long periods because their extreme suspiciousness encourages them to keep their 'precious knowledge' secret. Moreover, although these individuals are deeply disturbed and are subject to intense panic (given their sense of imminent danger) and extreme excitement (over their irrational 'discoveries'), many of them are not overtly bizarre or belligerent.

Other Paranoid Disorders

Some paranoid thinking manifests itself in a less persistent form. Acute paranoid disorder, in which delusions develop quickly and last only a few months, sometimes appear after a sudden, stressful social change, such as emigration, prison, induction into military service, or even leaving a family home. Although these conditions are multifaceted, they all are associated with extreme social isolation, unfamiliarity with the appropriate customs and rules of behavior, a sense of vulnerability to exploitation, and a general loss of control over life, psychological factors which may play an important, albeit temporary, role in inducing episodes of paranoia.

Paranoid symptoms may also be a byproduct of physical illness, organic brain disease, or drug intoxication. Among organic illnesses, hypothyroidism, multiple sclerosis, Huntington's disease, and epileptic disorders, as well as Alzheimer's disease and other forms of dementia are common causes of paranoia. In some people, alcohol stimulates a paranoid reaction even in small doses, and paranoia is a common feature of alcohol hallucinosis and alcohol withdrawal delirium. Chronic abuse of drugs, such as amphetamines, cocaine, marijuana, PCP, LSD, or other stimulants or psychedelic compounds may produce some of the symptoms of paranoid personality disorder, and in high doses, may cause an acute psychosis that is almost indistinguishable from paranoid schizophrenia. These drugs may also exacerbate symptoms in persons already suffering from a paranoid disorder.

Prevalence

It is difficult to estimate the frequency of paranoia in the general population because many paranoids function well enough in society to avoid coming to the attention of professionals and because their suspiciousness and intellectual arrogance usually prevent them from volunteering for treatment. While clinical diagnoses of paranoid disorders are rare, a more realistic picture of its actual occurrence is suggested by the many exploited inventors, morbidly jealous spouses, persecuted workers, fanatical reformers, and self-styled prophets who are often able to maintain themselves in the community without their paranoid condition being formally recognized.

Estimates of prevalence are further complicated by the fact that almost everyone engages in paranoid thinking at one time or another. Most people can think of an occasion when they thought they were being watched or talked about, or felt as if everything was going against them, or were suspicious of someone else's motives without adequate proof that such things had actually occurred. Recent studies have shown that for a significant number of people, these paranoid beliefs represent a relatively stable personality pattern. Such paranoid personalities – although characterized by suspiciousness, self-centeredness, scapegoating tendencies, and a generally hostile attitude – apparently are capable of functioning reasonably well in society.

Causes of Paranoia

Biological Bases

Genetic contribution

Although there is little research on the role of heredity in causing paranoia, there is some evidence from twin studies indicating that paranoid symptoms in schizophrenia may be genetically influenced. In addition, family studies suggest that features of the paranoid personality disorder occur disproportionately more often in families with members who have either delusional disorders or paranoid schizophrenia, suggesting that these syndromes may be genetically related.

Biochemistry

No identifiable biochemical substrate or demonstrable neuropathology relates specifically to paranoid thought or delusions; that is, there is no brain system whose dysfunction would

specifically produce the psychological characteristics associated with paranoia. Although the abuse of drugs, such as amphetamines, may lead to paranoid symptoms, thus suggesting a possible biochemical pathway, no such pathway has been identified; whatever drug effects have been found may be psychologically, and not biochemically, mediated.

Psychological Bases

In the absence of a clear organic basis or effective drug treatment for paranoia, most researchers have sought to identify the psychological mechanisms that explain how paranoid ideas become fixed in the mind.

Psychodynamic theory

Of all psychological theories, Freud's is perhaps the best known, although it is increasingly challenged. He believed that paranoia was a form of repressed homosexual love. According to Freud, paranoia arises, at least in men, when a child's homosexual feelings for his father are preserved but driven into the unconscious, from which they reemerge during an adult emotional crisis, converted into suspicions and delusions by projection – the attribution of one's own unacknowledged wishes and impulses to another person. That is, before reaching consciousness, the impulses undergo some kind of transformation that disguise their homosexual origin; for example, a man suffering from paranoid jealousy, unable to acknowledge that he himself loves another man, projects that feeling onto his wife, and becomes convinced that it is his wife who loves the man.

Although Freud's theory of unconscious homosexuality has been largely discredited, projection is still recognized as a basic mechanism used by paranoids to defend against their feelings. Paranoids will explain their sense of helplessness by pointing to the control exerted by others; or self-critical ideas are transformed into the belief that others are criticizing them. Viewing others as hostile not only justifies the paranoid's feeling of being threatened, it may actually elicit the other's anger, thus confirming the paranoid's original assumption. As a result, paranoids are left feeling weakly vulnerable, but morally righteous.

Faulty development

Rather than emphasizing unconscious dynamics, other approaches have viewed paranoid thinking as the outcome of a complex interaction of personality traits, social skills, and environmental events, some of which may be traced to early family dynamics. Paranoids, even as children, are often described as aloof, suspicious, secretive, stubborn, and resentful of punishment. Rarely was there a history of normal play with other children, or good socialization with warm, affectionate relationships. Their family background was often authoritarian, and excessively dominating and critical. Paranoid persons may dread being watched and judged because, it has been suggested, it reminds them of their parents, who were distant, demanding, and capricious.

This inadequate socialization may have kept them from learning to understand others' motives and points of view which, in turn, may have led to a pattern of suspicious misinterpretation of unintentional slights. Social relationships

tended to be suffused with hostile, domineering attitudes that drove others away. These inevitable social failures further undermined self-esteem and led to deeper social isolation and mistrust. In essence, these individuals emerged from childhood with deeply internalized struggles involving issues of hostility, victimization, power, submission, weakness, and humiliation. In later development, these early trends merged to create self-important, egocentric, and arrogant individuals, who maintained their unrealistic self-image and a sense of control by projecting blame for their problems onto others, and seeing weaknesses in others that they could not acknowledge in themselves. Their suspicion and hypersensitivity were made even more problematic by their utter inability to see things from any viewpoint but their own.

The paranoid 'illumination' and the paranoid pseudo-community

Other theorists have focused, not on early family history, but on the later emergence of a fixed, unyielding paranoid belief system. Given the paranoid's rigidity, self-importance, and suspiciousness, he is likely to become a target of actual discrimination and mistreatment; and ever alert to such occurrences, the paranoid is likely to find abundant 'proof,' both real and imagined, of persecution. The cycle of misunderstanding is then perpetuated by the paranoid's subsequent responses. The belief that others are plotting against him results in hostile, defensive behavior. This in turn elicits the others' anger and irritability in response to the paranoid's apparently unprovoked hostility, thus confirming the paranoid's original suspicion that they are out to get him. This cycle of aggression and counteraggression has also been offered as one explanation for the greater prevalence of paranoia among males than females. The paranoid's inability to consider the others' perspective – that the other may be operating out of defensiveness against the paranoid's antagonism and belligerence – only exacerbates the conflict.

As failures and seeming betrayals mount, the paranoid, to avoid self-devaluation, searches for 'logical' explanations. He becomes more vigilant in his scrutiny of the environment, looking for hidden meanings and asking leading questions. Eventually, a meaningful picture, in the form of the 'paranoid illumination,' crystallizes and everything begins to make sense: he has been singled out for some obscure reason, and others are working against him. Failure is not because of any inferiority on his part, but rather because of some conspiracy or plot directed at him. With this as his fundamental defensive premise, he proceeds to distort and falsify the facts to fit the premise, and gradually develops a logical, fixed delusional system, referred to as the 'pseudo-community,' in which the paranoid organizes surrounding people (real and imaginary) into a structured group whose purpose is centered on his victimization. As each additional experience is misconstrued and interpreted in light of the delusional idea, more and more events, persons and experiences become effectively incorporated into the delusional system. Because the delusion meaningfully integrates all the vague, disturbing, amorphous, and unrelated 'facts' of his existence, the paranoid is unwilling to accept any other explanation and is impervious to reason or logic; any questioning of the delusion only convinces him that the interrogator has sold out to the enemy.

Anomalous perceptions

Another theory offers the intriguing hypothesis that delusions are the result of a cognitive attempt to account for aberrant or anomalous sensory experiences. For example, research has shown that persons with visual or hearing loss – because of both heightened suspiciousness and an attempt to deny the loss – may conclude that others are conspiring to conceal things from them. The experience of many elderly people, who are a high risk group for paranoia, provides a particularly good example of this phenomenon. These individuals, because of physical disability or social isolation, often feel especially vulnerable. These realistic feelings may be converted to paranoia by an unacknowledged loss of hearing. That is, an awareness of oneself as a potential victim of greedy relatives or petty criminals, together with an increased sense that others are whispering, may contribute to a growing suspicion that others are whispering about them, or harassing them, or perhaps planning to steal from them. When the others angrily deny the accusation, it only reinforces the conspiratorial delusion, and intensifies the cycle of hostility and suspicion.

The occurrence of paranoia in those with degenerative brain disorders, such as Alzheimer's disease, may be explained through a similar process. These diseases commonly involve a disruption of memory that victims may be unwilling to acknowledge. As a result, failures of memory become an anomalous experience that needs to be explained. For example, not being able to locate one's keys is transformed into the belief that someone else has stolen or misplaced them. This suspicion may then be incorporated with actual perceptions, such as seeing one's child speaking to the doctor, to produce the conviction that others are conspiring to confuse the patient in order to put them away.

The general hypothesis that anomalous experience may be the basis for paranoia assumes that the process by which delusional beliefs are formed is very similar to the process that operates in the formation of normal beliefs; that is, delusions are not the result of a disturbed thought process, but arise because of abnormal sensory or perceptual experiences. Anomalous experiences demand an explanation, and in the course of developing hypotheses and testing them through observations, the delusional insight is confirmed through selective processing of 'evidence.' This explanation offers relief in the form of removing uncertainty, and the relief in turn works against abandonment of the explanation.

Stress

A related explanation may account for the often observed association between paranoia and stressors such as social isolation, economic deprivation, and abrupt situational changes. These conditions generally involve feelings of confusion, vulnerability, and a loss of control, suggesting that, in some ways, paranoid thought may serve to impose meaning and control in an otherwise uncertain and threatening environment. The paranoid belief that others are responsible for one's own misfortune, although threatening and irrational, may still be preferable to the belief that one is responsible for one's own misfortune or that such misfortune is a purely random event. In this regard, it is possible that the paranoid thinking which often develops as a result of acute drug intoxication (e.g., amphetamine abuse), or aging (and its concomitant sensory

loss and social isolation), or degenerative brain disorders (such as Alzheimer's Disease), may be mediated by the confusion and vulnerability often found in these conditions.

Biases in information processing

Some of the approaches discussed thus far have emphasized the fact that, apart from the paranoid construction itself, the cognitive functioning of paranoids is essentially intact. In fact, given their delusional system, paranoid reactions are not unlike the biased tendencies of many individuals with strong belief systems, who are likely to exaggerate, distort, or selectively focus on events that are consistent with their beliefs. Once the paranoid suspects that others are working against him, he starts carefully noting the slightest signs pointing in the direction of his suspicions, and ignores all evidence to the contrary. With this frame of reference, it is quite easy, especially in a highly competitive, somewhat ruthless world, for any event, no matter how innocuous, to be selectively incorporated into the delusion. This, in turn, leads to a vicious cycle: suspicion, distrust, and criticism of others drives people away, keeps the paranoid person in continual friction with others, and generates new incidents for the paranoid to magnify.

Although these information processing biases serve to maintain the paranoid's beliefs once they are established, they do not address the question of the origin of paranoid beliefs. That origin, however, may also be related to cognitive biases. The essence of paranoia is a malfunctioning of the capacity to assign meanings and understand causes for events. Ordinarily, these cognitive processes operate in a reasonably logical and objective fashion. In paranoia, such objective assessments are overwhelmed by judgments and interpretations that bear little relation to what actually happened, but instead are perverted in accord with the paranoid's own concerns and interests. The persistent misperception of oneself as the target of others' thoughts and actions, referred to as an idea or delusion of reference, is the hallmark characteristic of almost all forms of paranoid thought. Even when there is no basis for making any connection, paranoids tend to perceive others' behavior as if it is more relevant to the self than is actually the case as, for example, when the laughter of others is assumed to be self-directed, or the appearance of a stranger on the street is taken to mean that one is being watched or plotted against. Why does the paranoid consistently feel singled out or targeted by others?

Paranoia and self-focus

Part of the answer may lie in the characterization of paranoia as a very self-focused style of functioning. Recent studies have suggested that self-awareness, or the tendency of the individual to recognize himself as an object of attention, heightens the likelihood of engaging in paranoid inferences. In essence, to see oneself as an object of attention, particularly to others, leaves a person susceptible to the paranoid idea that he is being targeted by others. Apparently, as a result of recognizing the self as an object of attention, the self is more likely to be interjected into the interpretation of others' behavior, thus transforming insignificant and irrelevant events into ones that appear to have personal relevance for the self. Self-focus not only relates directly to paranoid ideas of reference, it has important implications for other critical aspects of paranoid thought.

Personalism and intent

Unfortunate things happen to everyone, and usually they are dismissed as random or chance events. But paranoids rarely accept the idea that bad things just happen; because of their self-focus, they are likely to perceive those negative events as the result of someone else's intentional doing. Research has suggested that when events are taken personally, or are seen as uniquely targeted toward the self, they are more likely to be understood in terms of others' personal characteristics or intentions. For the paranoids, the negative event itself is evidence for others' malevolent intentions toward them. Eventually, the accumulation of such events constitutes evidence for a fundamentally irrational view of the world as a hostile and threatening place. Once the assumption of ubiquitous danger is accepted, the other manifestations of paranoia become comprehensible: suspicion and guardedness; selective attention and memory for signs of trickery or exploitation; misinterpretation of apparently harmless events as malevolent; and blaming others for all of one's difficulties. Moreover, when negative events are seen, not as fortuitous occurrences, but as personally intended by others, hostilities become intensified and enemies are found everywhere.

Egocentricity

One of the critical elements of paranoid thinking is the utter inability to understand the motivations and perspectives of others. Not only are paranoids more likely to misinterpret other's behavior, they are less likely to correct that misinterpretation by altering their point of view. The narrowness and rigidity of paranoid thought – the failure to examine events critically or in a broader context, the ability to fit anything into one's belief system, the unwillingness to ever consider changing one's mind – are, in large part, the result of being locked into one's own perspective. Although social isolation may account, in part, for this deficit in role taking, self-focused attention may also contribute to the self-centeredness of paranoids. Attention directed toward the self interferes with the ability to take the role of another or appreciate the existence of alternative perspectives. As a result, paranoids are likely to assume that others share their own view of events, and fail to appreciate the way in which their own actions are viewed by others. Thus, in a typical encounter, they are unlikely to consider the way in which their own behavior provokes the hostility of others, but instead are likely to see themselves as the innocent victim of the other's hostility. Self-focus may also play a role in the egocentric tendency of paranoids to project their own characteristics onto others.

Treatment of Paranoia

Treatment of paranoia is extraordinarily difficult for a number of reasons. First, little is known about the causes that presumably are to be treated. Secondly, it is difficult for the paranoid to recognize a problem when he is locked into his own perspective and is reluctant to accept another's viewpoint. Finally, it is nearly impossible for therapists to penetrate the barrier of suspiciousness. For all these reasons, paranoids are unlikely and unwilling to enter therapy; and once in therapy, their wariness often leads them to sabotage treatment, or break it

off prematurely. Paranoids also generally refuse to take responsibility for their treatment because the only problems they see are those created by the people intent upon harming them. In addition, those aspects of therapy that require disclosure of personal information may represent a loss of control, especially to male paranoids.

Mistrust obviously serves to undermine the therapeutic relationship. Any expression of friendliness or concern by the therapist is likely to arouse suspicion or be taken as confirmation that others are trying to humiliate the paranoid client. Questions or suggestions are seen as criticisms or attacks. Even if therapy improves other aspects of the paranoid's functioning, their delusional system is so strenuously defended, and so easily confirmed by 'clues' detected in the therapeutic situation, that it often remains intact, yielding a highly unfavorable prognosis for complete recovery.

Because of the paranoid patient's guardedness and insistence on their own correctness, an effective therapeutic approach usually focuses on trust building rather than direct confrontation of the delusional beliefs. Perhaps the most powerful strategy is to establish a rapport by forming a 'therapeutic alliance' in which the therapist recognizes whatever kernel of truth exists in a paranoid system, and acknowledges the delusional beliefs as powerful, convincing, and understandable. The therapist may then try to identify the ways in which these beliefs may interfere with the patient's goals or create frustration for others as well as for the patient. The patient's paranoid reactions have usually driven others away or incited them to counterattack, heightening the cycle of suspicion and hostility. The therapist can sometimes bring about change by providing a different, empathic response that serves as a model of nonparanoid behavior. The task is then to help the paranoid become more competent at discriminating real threats from perceived ones, and the final step is the development of more adaptive responses to real or even ambiguous threats.

Behavioral theory assumes that paranoids have learned to be hypersensitive to the judgments of others and, as a result, they behave in ways that invite just the sort of reaction they anticipate and fear. As others begin to avoid them, they

become socially isolated and develop increasingly elaborate suspicions that maintain the isolation. Behavior therapy tries to break the cycle by first using relaxation and anxiety management to teach the patient to be less sensitive to criticism, and then improving social skills by training the patient to act in ways that will not invite attack or avoidance. The patient can also be given help with recognition and avoidance of situations that produce or increase delusions. Paranoid thinking can in some cases be altered by aversive conditioning or the removal of factors that reinforce maladaptive behavior.

Glossary

Internalization of values When children's compliance with the attitudes or values of the social or cultural group is motivated by internal factors and not external factors (such as fear of punishment).

Mutual reciprocity/responsiveness A quality of a dyadic relationship that is characterized by high rates of reciprocity and feelings of mutual obligation to other.

Negative reinforcement When a behavior is strengthened by the removal of a negative or aversive condition or stimulus.

Proactive regulation A parenting technique in which parents anticipate sources of conflict for the child

and structure or control the environment in such a manner to limit this conflict. For example, mothers may anticipate conflict in particular isles in the supermarket and avoid these isles.

Security Feelings of trust in the caregiver's responsiveness in times of stress and protection.

Socialization When parents or others assist with the acquisition of the knowledge and skills necessary to participate in social and cultural groups.

Warmth Noncontingent displays of affection between partners.

There is little doubt that parents play a number of significant roles in the lives of children. Parents are sources of comfort and protection; sources of warmth, affection, and support; providers of control and discipline; and teachers who guide children's learning. Ultimately, parents are responsible for ensuring that children acquire all of the social and cultural knowledge and skills that they will need to be successful within the broader cultural setting. Thus, it is not surprising that the role that parents play in shaping children's development has captivated scholars from all theoretical perspectives throughout the history of psychology, including (but not limited to) psychoanalytic theorists who were interested in the role that parents played in managing children's psychosexual impulses; behaviorists who were interested in how parents shape children's behavior through reinforcement and punishment; and more modern parenting theorists who have focused on the styles, dimensions, and practices that parents use to socialize children.

Contemporary research on parenting and socialization has changed little in its conception of the types of parenting that are assumed to promote optimal child outcomes. In general, research has supported the idea that authoritative parenting, that is, parents who are warm and nurturing and who use reasonable behavioral control with children, generally have children who are the best adjusted. Parents who are warm and too lax in control (permissive) or who are more strict and less warm (authoritarian) raise children with less optimal outcomes, although the effects of each of these parenting styles depend to some extent on the cultural and socioeconomic status of the family. Despite the fact that the research on parenting styles continues to dominate some portion of the current research, more cutting-edge conceptions of parenting have argued that it is too simplistic to focus on the effects that parenting styles have on children. These researchers have argued that parenting styles tell us little about what it is that actually influences child outcomes (e.g., is it warmth or flexible control that matters?). Similarly, such an approach has been criticized because although it tells us something about the

emotional climate that children are raised in, it tells us relatively little about how the specific practices parents use (e.g., corporal punishment) actually influence child outcomes. In addition, it seems likely that the specific practices that parents use are moderated by the broader emotional climate of the family. For instance, the occasional use of corporal punishment in the context of an otherwise warm and supportive relationship has a different meaning to a child than corporal punishment in a harsh and rejecting parent-child relationship. Finally, traditional work on parenting styles has been criticized for being too unidirectional in its focus (assuming that parents influence children and not the reverse). More modern conceptions of parenting and socialization have taken a more bidirectional approach to parenting, highlighting how children influence parents and how children take an active role in shaping and interpreting the nature of the interaction between the two.

Ultimately, both traditional and modern socialization theories argue that parents have broad influences on children and a total review of the entire literature on parenting is beyond the scope of this article. Instead, we try to focus on a narrower range of topics. We begin with a discussion of parental goals and briefly discuss the role that goals play in influencing parenting practices and approaches. We then highlight the recent research and theorizing on the role that emotion plays in influencing parenting. We then discuss three broad indicators of relationship quality between parents and children that have been implicated as important influences in socialization: attachment security, warmth, and mutual responsiveness. Following this, we discuss the complex issue of parental control and then highlight some of the specific practices that parents use to socialize children, including reinforcement and punishment, modeling, proactive regulation, parents' use of routines and rituals, and guided learning. We end with a brief discussion of the active role that children play in interpreting, evaluating, and accepting or rejecting parental attempts at socialization.

Parenting Goals

Modern theories on parenting have emphasized the influential role that parenting goals play in shaping the practices that parents use to socialize children. Original research in socialization operated as if parents had only a single goal, that is, children's internalization of parental values and compliance with these values in the absence of the parent. More recent theorizing on the influence of parental goals has recognized that many parents have varied long-term goals for their children. For example, whereas some parents may desire children's internalization of values, other parents may be more interested in maintaining relational harmony with children, fostering children's abilities to make good choices with regards to values, and/or fostering children's abilities to compromise or negotiate. This different perspective on the varied types of goals that parents have leads to very different assumptions about how children's noncompliance is viewed. Originally, children's noncompliance with parental requests was assumed to be an indicator of a failure of socialization, but this is no longer believed to be the case by most modern socialization theorists. Instead, there are good reasons to believe that parents might be willing to accept only partial compliance with their requests (or in some cases even noncompliance), especially if parents are committed to maintaining positive relationships with children and are more interested in fostering autonomy than compliance. Thus, the types of behaviors that parents see as acceptable change depending on the type of goals that parents have and the relative importance parents assign to those goals. Parents who are interested more in fostering autonomy (than promoting acceptance of their values) might be willing to tolerate some degree of negotiation with regards particular values, especially within domains that they do not view as extremely important. However, even these parents may require more strict compliance in domains such as safety, health, and morality, in order to ensure children's survival and cultural success. In contrast, parents who are more concerned with children's internalization of values may take a more strict approach to parenting across all domains.

It is important to realize that parents have a number of both short-term (e.g., getting the child to school on time in the morning) and long-term goals (e.g., fostering academic achievement) that guide their interactions with children. In addition, it is important to realize that some of the goals that parents hold may be self- or parent-oriented (e.g., getting the child to school on time to make it to work on time), some may be child-oriented (e.g., teaching the child an important value), and some may be relationship-oriented (e.g., maintaining strong bonds with children). It is not particularly clear which of these goals predominate in any given interaction between parents and children, but some research suggests that the context of the parent-child interaction. Parents are more likely to focus on short-term and more parent-centered goals in public situations and are more likely to focus on long-term child-centered socialization goals in the context of private interactions. In addition, there seems to be individual variation in the relative focus of parents (between parent-focused vs. child-focused goals) and these differences in the tendency to prefer parent- versus child-centered goals are likely linked in meaningful ways with the techniques that parents use. Parents

who report more child-centered goals tend to use more reasoning and less power-assertive techniques with children. Parents who report being more concerned with immediate and parent-centered goals tend to use more power-assertive techniques to ensure children's immediate compliance.

Parenting and Emotions

As anyone who has ever been a parent knows, parenting is an intensely emotional experience. Children have the capacity to evoke both strong positive emotions (e.g., joy, pride, and love) and strong negative emotions (e.g., anger, fear, distress, and anxiety) in parents, and there is little doubt that the emotions evoked in the context of parenting influence the quality of the parenting that children receive and children's outcomes. For example, high levels of positive emotions in parents have been linked with parental sensitivity and responsiveness and with children's prosocial and empathic behavior. In contrast, parents who are depressed or who experience high levels of distress or anger are prone to being hostile, rejecting, insensitive or abusive and have children who experience externalizing and internalizing problems. Thus, a number of researchers have argued that the emotional health of parents reflects the broader emotional climate and success of the family.

The links that emotion has with parenting are likely more complex and have not been sufficiently examined by researchers. However, a number of researchers (especially Theodore Dix) have written extensively on the role that emotion likely plays in influencing parenting, and thus, a number of conclusions can be drawn. First, stress outside of the parent-child relationship (including marital problems, occupational concerns, and financial stress) can undermine the quality of parenting, mainly because of the effects that these stressors have on parental emotion. Second, the emotions evoked in the parent by the child in any given interaction depend upon the goals that parents have in any given situation. Whether parents experience positive versus negative affect in any given interaction with a child depends on whether or not both the long-term and short-term goals of the parents are met by the behavior of the child and how significant these goals are to the parent. Parents can facilitate their own goals and promote positive affect by adopting empathic strategies and coordinating their interests and goals in ways that are compatible with the goals and behaviors of their children. When interests conflict, however, parents can either elicit the cooperation of the child (maintaining positive affect in the parent and child) or they can use more forceful strategies to ensure that their short-term and long-term goals are met. If children comply with these more forceful strategies, it is less likely that negative affect will be evoked in the parent. Over time, however, such forceful strategies likely evoke resistance on behalf of the child. Such resistance may create negative emotion in the parent, particularly in situations in which parents have a strong commitment to a particular goal.

Once emotions are aroused in parents, there are good reasons to believe that such emotions influence parenting. First, emotions motivate parental responses and influence behavioral response tendencies. In the context of negative affect, parents are motivated to comfort, protect, and potentially discipline

children. In the context of positive affect, parents are motivated to engage, respond, and play with children. Second, emotion also influences parental perception and interpretation of events. Negative emotion can lead to more negative expectations and evaluations of children's behaviors and it can disrupt parental attention, monitoring, and problem solving. Positive emotions likely have an opposite effect on parental attention, monitoring, and problem solving, although the effects of positive emotions have been given less thoughtful attention by researchers. Finally, parental emotion likely influences the nature of the communication between parents and children. Emotion serves communicative functions and sends important messages to children. For example, parental anger can signify to a child that their behavior is not acceptable. Moreover, the parent's emotional state influences the child's emotional state through contagion and modeling. Finally, emotions theorists have argued that beyond motivation, particular emotions are also directly associated with behavioral responses that influence parenting. For example, anger is linked with harsh and aggressive behavior (e.g., yelling, condemning, punishing, and striking), and thus, in parents likely evokes similar types of behavior directed toward the child. In contrast, the emotion of joy is linked with engagement with the environment and likely leads to parent's engagement with children's needs.

Indexes of Relational Quality

Relationships between parents and children differ in broad qualitative ways, including in the amount of warmth and affect exchanged between partners, in the amount of shared trust or security, and in the amount of reciprocity and shared positive affect between partners. Although these three constructs (security, warmth, and mutual responsiveness) have often been used interchangeably in the literature and have often been measured together in the context of research on parenting, recent research suggests that when they are assessed independently, they are empirically distinctive and sometimes not overlapping constructs. In fact, in conceptualization, they are quite different constructs. Warmth involves noncontingent displays of affection between partners, whereas security is believed to derive from parental sensitivity or responsiveness to children's needs for comfort or protection (thus, in situations involving negative affect). Mutual responsiveness, in contrast, is a fully dyadic construct that is assessed in situations of low stress and threat. Thus, although all three constructs are indicators of relational quality that have been well-studied in the literature on parenting, there have been recent calls to keep these processes clearly delineated in the literature on parenting, because they may have unique effects on children.

Security

Attachment theorists argue that a child's need for comfort and protection are biologically based motives that are deeply rooted in the human species as a result of evolution. A caregiver's sensitivity, especially in times of threat and stress, offered protection and nurturance that enabled a human infant to survive in the savannah grasslands of human evolution. Moreover, the child's confidence in the adult's protection, in

turn, fostered exploration and competence. Ultimately, the confidence provided by a secure attachment to explore the environment has implications for a modern child's socialization, because it affords a secure base from which to explore other interpersonal relationships and the broader environment. In addition, attachment research has suggested that children in secure relationships with caregivers are more receptive to the socialization attempts of caregivers, more compliant with requests, and more likely to internalize values. In addition, because securely attached children are more socially competent, they experience closer interpersonal relationships with others. These close interpersonal relationships with others provides secure children more opportunities for socialization in the context of other close relationships (e.g., with peers and teachers).

Finally, attachment security is presumed to color a child's approach to subsequent relationships, especially close ones. As a result of their experiences with sensitive care (or insensitive care) in situations of stress, children create mental representations of relationships, or internal working models. These internal working models are filters through which children interpret their relational experiences with others in ways that are consistent with their expectations from past relationships. In addition, these expectations cause children to respond to others in ways that may evoke the kinds of responses from others that confirm their expectations. Thus, a securely attached child may respond to others with compassion, which in turn evokes a positive response from others, cementing the child's trust in the responsiveness of others. In contrast, an insecure child anticipating another's unfriendliness may remain distant and unengaged, which in turn evokes an unfriendly response from a relational partner, and confirms the insecure child's relational expectations. These internal working models also influence children's understanding of others (e.g., other's emotions and intentions), relationships (e.g., through biases and attributions), and themselves (including feelings of self-esteem and worth). Although internal working models are difficult to study, research does suggest that securely attached children show advantages in emotional understanding, social attributions, theory of mind, social problem solving, and self-esteem.

Warmth/Support

Warmth, or noncontingent displays of affection, has been universally recognized as an important influence in socialization in almost all traditional and modern formulations of parenting. In traditional formulations, warmth has been conceived of as characteristic of the parent; however, in more recent formulations of parenting, warmth has been portrayed as a dyadic and relational construct, involving high levels of 'shared positive affect' between parents and children. Either way, warmth and support are influential in socialization for several reasons. First, warmth and support from parents give children the sense that they are loved, respected, and of value. As a result, children develop a willingness to participate in further activities with the caregiver, to share feelings, and to take part in other features of interpersonal experience that provide children with rich opportunities to appropriate cultural values. Second, warmth enhances children's motivation to cooperate and comply with parental directives, in part through their identification

with parents. Finally, high amounts of positive affect and warmth in the context of close relationships with parents promotes positive moods in children, making children more likely to be responsive to the needs of others. In addition, research suggests that children who are in a positive mood are more likely to comply with parental requests and directives.

Mutual Responsiveness

A related, but slightly different portrayal of the influence of parent-child relationships on socialization has been proposed by a number of researchers who argue that parents who are reasonably compliant with children's needs, wishes, and requests elicit from children cooperation with parental requests and directives. This type of relationship has been coined one of 'mutual reciprocity,' in which both partners feel a mutual obligation to the other. Young children who are part of a relationship with mutual reciprocity feel an obligation to respond constructively to socialization initiatives, to accept parental values, and to maintain relational harmony with the parent. Thus, children who are part of a mutually reciprocal relationship are in essence, eager and willing to be socialized by a parent, because they have internalized an obligation to respond to parental initiatives as a result of their history of responsive care from parents. Research does support the idea that children are in fact more likely to comply with parental directives in a cleanup task following an episode of mutually reciprocal play.

Parental Control

The study of the effects of parental control over the years has been complicated by the fact that researchers have used the same word to refer to qualitatively different phenomena. Over the years, some researchers have used parental control to refer to demands for maturity, such as Baumrind's work on parenting styles, and others have used to refer to the way demands are communicated. Probably, one of the most useful distinctions to make, however, is between behavioral control and psychological control. Behavioral control, or control that involves reasonable limit setting and enforcement of rules (as well as parental monitoring), is the type of control that has been considered to be a part of authoritative parent rearing and which has been linked with optimal child outcomes among most children. Excessive use of behavioral control, however, can be associated with poor adjustment in children, especially if it involves feelings by the child of being controlled. For behavioral control to lead to positive child outcomes, control needs to be autonomy supporting, which means that children need to feel as if their own behavior is self-initiated and that they have some control over the outcome experienced. Psychological control, which involves attempts to influence children through affecting the child's emotional state, especially through ways that are manipulate or insensitive, is typically associated with maladjustment in children. Children with psychologically controlling parents typically suffer with regards to self-esteem, are at risk for internalizing and externalizing problems, and tend to exhibit poor academic achievement. Ultimately, psychological and behavioral control are considered to be two conceptually distinct concepts that are differentially related to children's outcomes.

In addition to behavioral control, parents use a number of specific practices to socialize children's behavior including rewards and punishment, modeling, proactive regulation, routines and rituals, and guided learning. These specific parenting practices are considered next.

Parenting Practices

Reinforcement and Punishment

The significance of parental rewards and reinforcement for shaping children's behavior has long been recognized in the literature on parenting. Even before children are verbal, the parent's warmth and affection contribute to children's developing self-esteem and provide the motivation for children to comply with parental requests in attempt to please the parent. Thus, such displays of warmth and affect are reinforcing of the child's desire to be socialized. Negative reinforcement also has powerful effects on child behavior, as the research on children's aggressive behavior suggests. Parents who end aggressive or coercive family conflicts with children by giving in and withdrawing reinforce children's aggression. Ultimately for reinforcement and punishment to be effective as children get older, parents need to be subtle in their use of incentives. Research suggests that children need to respond to internal (i.e., self-derived) incentives rather than external reinforcement of competent behavior. If children attribute their compliance to external rewards (e.g., receiving money for chores) children may comply in the presence of the parent in anticipation of the reward, but are unlikely to comply with parental rules in absence of such a reward. Thus, internalization of values is inhibited by the presences of obvious rewards and punishments.

The role of punishment, particularly corporal punishment, in affecting children's outcomes has been a hotly debated topic in the history of developmental psychology. A number of researchers have argued that parental use of physical discipline has no beneficial effects for children beyond immediate compliance and is associated with children's angry and aggressive behavior. Moreover, a number of researchers have argued that physical discipline undermines the parent-child relationship by creating anger and humiliation in the child and that parent's use of physical discipline puts the parent at risk for abusive parenting. In contrast, other researchers have argued that the effects of an occasional use of mild corporal punishment (spanking) as a backup discipline method has not been sufficiently explored in the literature. These researchers have argued that in the research, the effects of mild corporal punishment have been confounded with more punitive and harsh forms of discipline. These same researchers have argued that spanking can in fact be an appropriate discipline technique if it is coupled with reasoning, not administered in anger, and employed as a last resort when other discipline methods have failed. To complicate the debate on either side, the effects of corporal punishment likely vary by culture and are likely moderated by the child's temperament, age, and the broader relational context in which the corporal punishment is applied. Thus, spanking may have significantly different outcomes depending upon whether it is applied in the context of an otherwise loving parent-child relationship and in context of reasoned

child-centered discipline, as opposed to when it is applied in the context of an angry confrontation between a parent and child in the context of a frequently hostile relationship. The broader question, however, depends upon what type of emotional climate prevails when spanking is used as an everyday discipline strategy.

Other types of parental discipline have been less debated by psychologists. Inductive discipline, which involves discussing the effect of the child's actions on others, has long been a discipline method that is assumed to promote children's development of empathy, guilt, and moral behavior. Research has suggested that parents who use inductive discipline have children who experience high levels of moral emotions (especially guilt and empathy) and who internalize parental values. Inductive discipline is presumed to be an important socialization strategy for a number of reasons. First, by discussing the effects of children's actions on others, parents induce feelings of guilt in children, which in turn promote the children's internalization of parental values. In addition, inductive discipline promotes children's abilities to understand the consequences of their actions on others and this promotes the development of children's empathy. Finally, inductive discipline is optimally arousing in the context of discipline encounters, fostering enough empathy and guilt to promote the child's reflective thinking upon the issues that parents raise in the discipline encounter, but not so arousing that it interferes with the child's processing of parental messages. Other types of discipline, especially those that involve high levels of power assertion or love withdrawal, often evoke so much negative emotion on behalf of the child that the child is not capable of processing parental messages conveyed in the context of discipline.

Beyond power assertion and inductive discipline, other methods of parental discipline have been less studied by researchers. Behaviorists, however, have argued and found some limited empirical support for the idea that other types of punishment, such as the withdrawal of privileges and 'time outs,' are effective sources of discipline, although most of the research is conducted with clinical populations. Some research with nonclinical populations suggests that these two discipline techniques are most effective if they are coupled with parental reasoning and induction. It is important to note, however, that nonbehavioral-oriented psychologists tend to view all forms of aversive punishment (including withdrawal of privileges, corporal punishment, and time outs) as less effective methods of control than parental inductive discipline and use of subtle rewards. Clearly, more research on these alternative discipline techniques in nonclinical settings is needed.

Most of the modern research on parenting acknowledges the fact that parents seldom use a single discipline strategy to socialize children. Parents ultimately adopt and choose specific types of discipline based upon features of the child and the current situation. Research, for example, suggests that parents' discipline techniques vary based on the nature of the misdeed. For example, parents are more likely to use both power assertion and reasoning when children commit antisocial acts, such as lying, and are more likely to use reasoning alone when children fail to show adequate concern for others. Moreover, if given strategy is not effective or based upon children's reactions, parents will often modify, adapt, or change strategies all together. In addition, children respond to parents' discipline

strategies differently depending upon their age and intellectual level, their mood (and broader temperament), their rapidly changing emotions within the discipline encounter, and their interpretations of parental intentions and communications. Thus, every discipline encounter between parents and children is influenced by both partners and effective parenting does not consist of a single discipline strategy used by a parent. Instead, effective parenting likely involves the parent's ability to flexibly adapt his or her discipline strategies within any given context based upon the child's needs and behaviors and based upon their own parenting goals.

Modeling

Imitation has also been considered an important way in which children learn culturally relevant behavior. Although young children are more likely to model the behavior of siblings and peers, evidence still suggests that children model the behavior of their parents as well. A number of theorists have argued that infant's imitation in particular contributes to their emergent understanding of persons. These early episodes of imitation are cognitively complex and involve sophisticated inferences about the parent's intentional activity, including his or her desires and goals. The parent's responsiveness to the infant's imitative efforts engages the child emotionally and contributes to a sense of interactive control. In addition, there is some suggestion in the research that young children's willingness to engage in responsive imitation reflects the child's motivation to accept socialization efforts by the parent. These researchers emphasize that imitation entails the child's active interest in emulating the parent's actions and argue that this same interest underlies young children's responsiveness to other aspects of parental socialization.

Beyond infancy, there is good evidence that children also model parents in a variety of different ways. A good example of the types of processes involved comes out of the literature on emotional expressiveness. This literature suggests that parents are key models of emotional expressiveness, and that exposure to particular profiles of expressiveness by parents appear to promote children's own expression and experience with similar emotions. Parents who frequently experience and express positive emotions have children who exhibit similar profiles of positive expressiveness, and as a result, are well-liked by peers. In contrast, children exposed to parents who frequently express negative, particularly hostile emotions like anger, express similar types of emotion, have trouble regulating negative affect, and are prone to externalizing and internalizing problems. Overall, the processes assumed to underlie these effects are modeling and emotion contagion.

Proactive Regulation

Parents also have an important influence on children's socialization by controlling the environment in such a way to create a desired outcome. Ultimately, there are plenty of examples of the ways in which parents do this. For example, parents may 'child proof' a home in such a way to prevent accidents and injuries. Furthermore, parents may anticipate sources of conflict, such as forbidden objects or tempting isles in a supermarket, and avoid such objects and/or locations. Such proactive

techniques may benefit both the child and the parent. Proactive techniques may lessen the amount of conflict in the parent–child dyad and scaffold the environment in such a way to enhance children’s understanding of appropriate conduct.

In addition, as children get older, parents may also use proactive strategies to help influence children’s values. For example, parents may ‘pre-arm’ children against competing values from others outside of the family by, for instance, giving children exposure to the value conflicts that they will face and by helping children understand the reasons behind their own value adoption. Parents can also monitor children’s exposure to values by monitoring and controlling exposure to media. Finally, when children are young, parents manage children’s exposure to peers and others, by regulating both children’s access (e.g., through transportation) and permission, and by supervising children’s activities when they occur.

Structuring of Routines and Rituals

Parents are also influential in guiding children’s learning and understanding by establishing and structuring the routines and rituals in which children take part on a daily basis. The structure of daily life is important for young children who seek predictability and control and parents vary with regards to the extent in which they provide this structure. Routines are recurrent patterns of family activity in which some or all members of the family participate (e.g., bedtime or meal routines). Rituals are routines that assume meaning for family members, because of their emotional and symbolic significance, such as birthdays, weddings, or anniversaries. Family routines are unique to every family, are heavily influenced by culture, and are one important way in which children learn culturally relevant information. As children get older, children’s participation and negotiation of these routines and rituals increases. Family routines and rituals become one important avenue through which family roles and responsibilities are defined and assigned by parents, family values are communicated, and expectations about everyday events are formed.

Guided Learning

In addition, parents play an important role through guided learning in supporting children’s acquisition of cognitive, social, and emotional skills that are needed for success in their cultural group. Guided learning, involves parents scaffolding the child’s learning by adjusting the amount of support that parents provide to match the child’s level of understanding. Parents who are successful in this process are able to provide sufficient levels of support for the child to promote optimal learning. Although much of the research in this area has highlighted the role of parents in promoting cognitive development (e.g., by parents providing the structure during a storybook reading), there is good reason to believe that parents are also influential in promoting social and emotional understanding through guided learning as well. For example, a number of researchers have argued and found empirical support for the idea that parents who coach children in how to deal with negative affect have more advanced emotional development. Emotion coaching involves not only parents being aware of the negative emotions of their children, but also being

willing to validate, label, and openly discuss and problem solve with their children about how to deal with negative emotion. Children whose parents are willing to directly coach them on how to cope with negative emotion acquire scripts on how to manage and handle negative emotions, and these children have more success with peers and are more psychologically competent. Similarly, parents who talk to children about their past emotional experiences and scaffold these conversations in such a way to provide detail, structure, and feedback have children who have more advanced understanding of emotions and relationships.

The Influence of the Child on Parenting

There has been increasing recognition of the role that the child plays in influencing the effects of parenting on children’s outcomes and on the type of parenting that they receive. Theorizing by Joan Grusec and Jacqueline Goodnow suggests that part of the reason that the past research on parental discipline and control has been so inconsistent is because researchers have failed to take into account the active role that the child plays in accepting or rejecting parental attempts at socialization. For children to embrace parental messages in the context of any discipline encounter, these researchers argue, parental messages need to be both accurately perceived by the child and accepted by the child. Parents can actively influence children’s attempts at accurate perception in a number of ways. If parents frame messages in a way that is developmentally appropriate, that captivates the child’s attention, and that signifies the importance of the message being conveyed, accurate perception is possible, provided the child has resources available to process the message. However, with regards to acceptance, the numbers of variables that intervene are more complex. First, children need to judge that the parental reaction and discipline is appropriate. A number of considerations likely figure into children’s assessments of appropriateness, including whether the punishment matches the misdeed, whether they feel as if they were treated fairly, and whether they see the parent’s actions as being well-intended. Second, children need some motivation for accepting the parent’s message. Broad relational qualities, such as security, mutual reciprocity, and warmth, provide some motivation to accept parental messages and values, but other factors also may play a role. Messages that are inductive and promote empathy and relational understanding likely provide motivation to internalize parental values, and messages that threaten the child’s autonomy and security likely undermine internalization. Finally, children need to feel to some extent that the value is self-generated. Thus, parents need to use punishments and rewards in such a way that reduces the salience of external pressure and that makes sure that children attribute their willingness to comply based upon self-generated motives and not because of external pressures.

Furthermore, there is accumulating evidence that characteristics of the child influence parenting. Most of the research that has been done has looked at how’s children’s temperament evokes different approaches to parenting. For example, there is accumulating evidence that children’s negative emotionality, that is, their proneness to distress, anger, and fear, evokes less

responsive and sensitive parenting from parents. In turn, less supportive and responsive parenting only seems to increase the amount of negative emotionality in children. The links between harsh parenting and negative emotionality are especially problematic with parents who are already at risk for poor parenting (i.e., because they are depressed or economically distressed). In addition, there is some indication that positive temperamental traits are associated with more sensitive and responsive parenting. For example, high levels of effortful control and self-regulation have been linked with more elaboration by mothers in the context of reminiscing and less restrictiveness in terms of parental control.

Conclusions

There is growing recognition of how complex the links between parental behaviors and child outcomes truly are. In the last 20 years, researchers have moved beyond using simplistic parenting styles in attempt to understand how parents socialize children. Instead, modern research on parenting has shifted to trying to understand how parents' goals, cognitions, and emotions shape and influence the nature of the interaction between children and parents. In addition, there has been a recent call by researchers to be clearer about the broad relational qualities they are assessing, in order to understand how different types of relational qualities differentially relate to child outcomes. Furthermore, there is a growing interest in examining how more specific types of parenting practices influence children's behavior and are moderated by the broader emotional climate of the family. Finally, there is a growing recognition of the bidirectional nature of the parent-child relationship and an increasing interest in understanding how children actively interpret, evaluate, accept, and influence parental initiatives.

Glossary

Autonomy Independence or self-reliance; the ability to make appropriate decisions for oneself by oneself.

Conflict The state in which two people, or forces, stand in opposition to each other.

Corporal punishment The deliberate use of physical force to cause the child pain for the purposes of disciplining or to deter wrongdoing.

Internalization The process whereby the child assumes personal responsibility for enacting taught values, rules, and behaviors.

Meta-analysis A statistical method that combines the results of multiple different research studies on the same or related topics to produce a stronger understanding of the overall findings.

Physical abuse Any nonaccidental physical injury inflicted on the child, or any action that results in the child's physical impairment.

Socialization The process by which parents instill in their child societal values and norms of behavior.

Parent–offspring conflict can be defined as a state in which parents and children stand in opposition to one another. The source of conflict between parents and children can vary significantly from relatively trivial issues such as clothing choice or bedtime routine to very serious issues relating to the safety and well-being of the child. One of the principal goals of parenting is the socialization of the child – the process by which parents instill in their child the values and behaviors appropriate to a member of society. That this socialization process frequently leads to conflict if the child resists parental attempts to modify their behavior highlights several truths about parent–child conflict. To begin with, parent–child conflict is inevitable. Parents cannot engage in the socialization process without having to occasionally confront their reluctant child, and children cannot test the boundaries of their developing autonomy without occasionally frustrating their parents.

A second, and perhaps surprising, truth about parent–offspring conflict is that it is not necessarily a negative occurrence. Although we often think about conflict as something to be avoided, there is growing evidence that it may serve as a critical catalyst for children's social cognitive development. Conflict often forces children to take another person's perspective (in order to understand precisely what is upsetting them about the situation), to practice burgeoning negotiation skills, to understand moral and social values, and to effectively regulate their emotions in order to avoid escalating the conflict further.

A final point is that parent–offspring conflict is not a singular phenomenon. The nature and frequency of conflict changes as children develop, as do the strategies for handling conflict. A parent trying to manage their toddler's nap schedule is going to face different challenges than a parent trying to manage their adolescent's curfew. As children develop, they become both more receptive to recognizing and complying with their parents' perspective on issues and more capable of negotiating and resisting their parents' instructions. Likewise, parents' expectations for their children's behavior during conflict situations, as well as their perspective on their own role as a socializing agent, will change as their child develops. With that said,

there also appears to be great continuity in how dyads manage conflict. When a pattern of mutually responsive, effective conflict management in which both partners are free to express their differing viewpoints and work together to resolve the issue is established early in life, it is likely to persist across childhood despite the changing nature of parent–child conflict.

Parent–child conflict is a topic that has received considerable theoretical attention. Therefore, this article begins with a brief comment on theoretical perspectives on parent–offspring conflict. In the following sections, research on the antecedents and outcomes of parent–child conflict is reviewed. We adopt a developmental perspective that focuses on the bidirectional influence of both parent and child behavior during conflict interactions. We conclude this article with a discussion of parent–child conflict that exceeds what can be considered developmentally normative – either because it occurs with greater (or less) frequency than is typically seen, or because it escalates into coercive patterns of interaction or child maltreatment. This focus on nonnormative parent–offspring conflict has particularly practical implications, as the development of successful interventions for families overwhelmed by conflict is of great importance.

Historical Perspectives on Parent–Offspring Conflict

There is a rich variety of developmental theories addressing the role of parent–offspring conflict in child development. Conflict has been proposed to play a significant role in a diverse range of developmental domains, including personality development, emotional development, moral development, and even cognitive development. Although a review of all theories that include parent–child conflict in their developmental model is outside the scope of this article, it should be appreciated that this is an issue that has long held a place in the thinking of psychologists.

To give just one example of the function of parent–offspring conflict in developmental theory, we can examine the work of Viennese neurologist, Sigmund Freud. Given that

Freud's theories are arguably foundational to many current theories of human development, his focus on the role of parent–offspring conflict in shaping personality development suggests the importance of this topic. According to Freud's theory of psychosexual development, adult personality emerges through a series of four stages (oral, anal, phallic, and genital) where children face some sort of conflict between wanting to fulfill their bodily desires and the constraints that society places on their ability to satisfy those desires. Importantly, early in life, these societal constraints come primarily from the child's parents, and thus, Freud believed that parental behavior during these conflicts played a central role in determining whether each stage would have a positive or negative impact on that child's developing personality.

During the toddler years, for example, Freud argued that children in the anal stage of development faced a great conflict between their desire to gratify themselves by emptying their bowels and the newly placed constraints on this behavior as their parents attempt to toilet-train them. If parents are too rigid or too lax in their application of toilet training, children could grow up to become either excessively fixated on cleanliness and organization, or slovenly. Appropriate management of conflict during toilet training, on the other hand, would allow the child to move optimally forward to the next stages of development.

Although many of Freud's ideas, including his stages of psychosexual development, have not been empirically generative, his argument about the lasting impact of early experience, including the experience of conflict between children and their caregivers, remains fundamental to developmental science. Importantly, several neo-Freudians, including Erik Erikson, also carried forth the idea that parent–child conflict is essential to personality development in their theories. Other developmental theorists, including Jean Piaget, Lawrence Kohlberg, and Lev Vygotsky, have likewise described parent–child conflict as an important catalyst for cognitive growth, moral development, and the growth of cultural skills. Furthermore, the research reviewed in the next section largely supports these theories about the transformative role of parent–child conflict.

A Developmental Overview of Parent–Offspring Conflict

As mentioned earlier, one of the major tasks for parents is to instill into their children their own system of values and beliefs. This is accomplished through internalization, whereby the child commits to the value or behavior and takes personal responsibility for enacting it independent of external reinforcing influences. The process of internalization is a major theme of parent–child conflict as the parent strives to shape the child's way of thinking and acting. Traditional considerations of parent–child conflict have focused on this unilateral influence of the parent on the child. A common approach has been to examine which styles of parenting and parental discipline are best able to accomplish the parent's objective of socialization smoothly and with the least resistance from the child. This perspective overlooks the child's active role in parent–child interactions, and an alternative approach has emerged that considers the bidirectional influences of the parent and the child on conflict interactions. The following discussion of

parent–child conflict during each phase of the child's development employs this relational perspective and examines the contributions of both members of the parent–child dyad.

Conflict in Infancy and Toddlerhood

During the first weeks and months of life, the potential for parents to feel as though they are engaging in conflict with their infant stems from the infant's nearly complete reliance on the parent to provide for all of their needs. It is not that the infant behaves in a way that is deliberately oppositional to the caregiver, but rather that the infant's needs often stand in opposition to that of the parent's (e.g., the infant's need for nighttime feedings is in conflict with the parent's need for an uninterrupted night of sleep). The burden falls largely on the parent to minimize this felt conflict by responding appropriately to the infant's signals regarding need states. This parental sensitivity to the infant's rudimentary bids at communication helps establish synchronized parent–infant interactions wherein both partners are attuned to each other and responsive to communications from the other. In contrast, when parents are unable to interpret their infant's signals accurately or meet their needs appropriately, infants become distressed. In these dyads, a cycle of interactions may develop, which is upsetting and frustrating for both members.

Over time, a pattern of synchronized parent–infant interactions builds what is called a mutually responsive orientation between parents and their children. Studies have shown that young children with a mutually responsive relationship history more readily adhere to parents' directives with less likelihood of dispute. Across the toddler and early childhood years, these children internalize parental values and behavioral rules more firmly and with less resistance than children who lack this history of relational experience. Within the first year of the child's life, the parent and the child begin to establish an understanding of their relationship, which will be critical to the tenor of their future disputes. For mutually responsive dyads, the understanding is that, regardless of the details of any specific conflict, both individuals are on the same team and ultimately want what is best for each other.

The child's continual developmental achievements create new potential points of contention between the child and the parent. When children begin to crawl after 6 months of age and walk at the end of the first year, issues of safety become paramount and parents remove dangerous objects but also expect their children to comply with cautionary warnings. Children at this age also form a more sophisticated sense of the self and it emerges, in part, through assertions of autonomy. Toddlers are motivated to take nearly every opportunity to exercise their newly acquired skills, but their burgeoning abilities to fulfill their own desires (by drawing on the walls with a crayon or climbing on the table to reach an interesting object) thrust them into confrontations with parents who may hold directly opposing desires. The regularity with which parents and toddlers seem to conflict about issues such as these have made this age period a challenging one for many parents, but parent–toddler conflicts actually provide important opportunities for children's social cognitive development.

From the toddler's perspective, the reality that the mother does not want you to do the exact thing that you want to do

highlights powerfully the difference between the mental states of yourself and another. Mental states like desires, goals, or intentions are often stated outright during the course of conflict and the emotions evoked make the situation particularly salient. The toddler has a strong personal stake in obtaining his or her desired outcome, while the close, interconnected nature of the parent-child relationship puts a premium on a positive resolution. These features make conflict a uniquely rich setting for toddlers to learn about their influence on others' thoughts, feelings, and reactions and to develop perspective-taking skills. Toddlers carry what they learn about interpersonal interactions during conflict with their parents into other relationships. Their experiences also contribute to their ongoing understanding of the parent-child relationship – whether it is a relationship of mutual understanding or a relationship of competing goals.

Over the second and third year, children's conflict behavior shifts from a reliance on passive noncompliance and direct defiance to negotiation, compromise, and attempts at manipulation. Parents' behavior mirrors this change, with physical intervention giving way to negotiation and persuasion. With the child's mastery of language, the complexion of parent-child conflict changes. Research shows that when mothers engage their toddlers with verbal strategies like compromise, bargaining, or justification during conflicts, their children demonstrate greater internalization of the mother's directives 6 months later. This may occur because these verbal strategies provide children with an explanation of the mother's requests. A similar link has been found between the back-and-forth with which mothers and toddlers discuss past conflicts and children's later internalization. Reminiscing conversations about previous conflict episodes may be particularly useful for children's developing understanding of values and appropriate behavior because they allow children some distance from the emotional intensity of the conflict as they process parents' messages. As the infancy and toddler period comes to an end, verbal communication transforms the ways in which parents and children connect and conflict with each other. This further enriches the unique opportunities conflict provides young children to learn about themselves in relation to important others.

Conflict in Childhood

Parent-offspring conflict during the preschool and elementary school years increases in complexity, as children develop still greater skills to cooperate, negotiate with and defy their parents, as well as the ability to deliberately deceive them. Parents must also update their repertoire of conflict strategies to keep up their children's changing abilities. One such strategy is corporal punishment. Research suggests that a majority of American children experience some form of corporal punishment as a function of parent-child conflict. The phenomenon is particularly common during the preschool years. Research studies have focused on the short-term effectiveness of this kind of discipline as well as on its more general effects on children's well-being. Meta-analyses show that, while corporal punishment may be effective for achieving immediate compliance from children in the given situation, it is not associated with the internalization of parental values in other settings.

Furthermore, the experience of corporal punishment is associated with increased anger and frustration in children, and children whose parents frequently use corporal punishment also act more aggressively with their peers. These findings indicate that the negative consequences of corporal punishment deserve important consideration.

There are limitations to the understanding of the effects of corporal punishment on children, however. Corporal punishment refers to discipline involving mild to moderate hitting, slapping, or spanking, but the point at which physical punishment becomes physical abuse can be unclear both conceptually and in practice. Thus, the frequency or severity of the punishment that drives the association with negative child behaviors is not well understood and deserves greater empirical attention. The relationship between the two may also be explained by other contextual factors that affect both parent and child behavior (e.g., marital discord) or it may be that aggressive children elicit stronger forms of parental discipline like physical punishment than do nonaggressive children. These possibilities challenge a clear causal relationship between corporal punishment and children's problem behaviors. There is also an argument that mild corporal punishment may be effectively used secondarily to other forms of parental discipline.

Power assertion is a form of parental discipline that involves the restriction of privileges and threats as well as corporal punishment. When used alone during the course of parent-offspring conflict, power assertion does not effectively encourage children's internalization of values or stave off future conflict. In contrast, the use of parental induction or reasoning has been linked to desired child behaviors including compliance and internalization of values. In line with toddler research, parent-child discourse on the causes and consequences of the conflict helps transform these situations into constructive socialization experiences in which the child is made a partner in the exchange. Parents who tend to rely on induction during parent-child conflict provide opportunities for children to articulate their own perspective and engage with the parent in a discussion of values leading toward a mutually satisfying resolution. Still, induction is not suited for all conflict scenarios, and effective management of conflict with children involves parents' accurate reading of and flexible adaptation to the situational demands of the child's state and the specific context.

As they develop greater social cognitive sophistication, children distinguish between moral transgressions (e.g., hurting another person) and transgressions of social convention (e.g., not saying thank you), and they evaluate adults on the appropriateness of the match between the punishment and the misbehavior. Thus, an adult who punishes a child for leaving his seat without asking is viewed as being more unfair than an adult who punishes a child for hitting a classmate. At this age, children also establish nuanced expectations of their parents and their behavior within the parent-child relationship just as parents have expectations for their children. Parents adjust expectations of their children's behavior in relation to their developmental abilities, but children also modify their expectations of parental behavior over time. A violation of expectations by either partner often results in conflict. Parents may react more strongly, escalating conflict, when the point of contention has been discussed in the past, and it is believed

that the child should know better. Similarly, children may become particularly recalcitrant when they perceive their parents' discipline as unfair or inconsistent with past behavior, or when parents regulate children's conduct that should be the child's decision alone (e.g., what to do during leisure time). Both parents and children take active roles in maintaining the terms of their relationship and navigating together those times when things go awry.

Conflict in Adolescence

Parent–child conflict often increases during adolescence. Youth pursue more independent and adult-like roles for themselves and these efforts toward autonomy can be especially challenging for the parent–child relationship. These problems stem, in part, from inherent qualities of the parent–child relationship. Compared to peer conflicts, the hierarchical power structure of the family tends to generate disputes involving issues of authority, control, and obedience. This may become more salient and troubling for the child during adolescence than at earlier developmental stages.

A comparison of parents' and adolescents' evaluations of misbehavior and parental authority sheds light on the sorts of situations that spur parent–adolescent conflict. Parents and adolescents agree on parental authority over moral and social conventional transgressions, but differences emerge with regard to the domain of personal preferences. Younger adolescents tend to perceive behaviors like sleeping late on the weekend or not cleaning up one's room as personal preferences that do not fall under parental authority, while their parents often perceive themselves as having authority over these behaviors. The potential for conflict over these everyday issues is obvious, but this also changes with time. The parents of older adolescents more often view these kinds of behaviors as the personal preference of the adolescent. The contrast between how parents and adolescents evaluate the same set of behaviors reiterates the significance of violations of expectations for conflict. The shift in parents' thinking that occurs with adolescent maturation, bringing the parental perspective to a greater alignment with the adolescent perspective, illustrates the critical interplay between both members of the relationship as well as the central role of developmental level in understanding conflict between parents and children.

Despite the common perception of adolescence as a highly troubled and conflictive phase, the empirical evidence for this idea is equivocal. Overall, the picture of parent–child conflict across development is one of continuity rather than discontinuity, and families that struggle with serious and destructive conflict during adolescence most likely struggled with this sort of conflict during childhood as well. While meta-analyses do reveal that the rate of parent–child conflict is elevated during early adolescence, that rate falls during mid-adolescence and again during late adolescence. With regard to negative affect, there is an increase from early to mid-adolescence followed by a decrease in late adolescence. For most families, this is a period when previously established closeness and reciprocity between parents and children are maintained. When parent–adolescent conflict takes the form of a challenging discussion within a supportive, mutually responsive setting, it is associated with an increased sophistication with which adolescents understand

themselves and their relationships with others. Thus, parent–adolescent conflict is often less severe than stereotypes indicate and is an important component of adolescents' developmental transition toward adulthood.

Atypical Parent–Offspring Conflict

As has been discussed, parent–offspring conflict is a normal, and perhaps even essential part of development, spurring on the child's internalization of the parent's rules and values, and providing a context to develop vital social cognitive skills such as perspective-taking and negotiation. And while conflict may escalate during certain periods of development (primarily during the toddler years and early adolescence), it should never become the primary style of interaction between parent and child, nor overwhelm the family environment with negative affect that is not easily resolved. Yet, for some families, this is precisely what happens, and excessive conflict becomes an agent of atypical development and a host of negative outcomes for both children and parents.

Why do certain families experience higher levels of conflict than others? Stressors appear to play a major role. For example, several recent studies have demonstrated elevated conflict in families where the child is experiencing a psychological disorder such as substance abuse or disordered eating. In these studies, conflict did not predict the onset of these problems, but rather seemed to occur as a result of them. This is especially problematic because elevated family conflict has also been shown to disrupt the effectiveness of therapeutic interventions for children's mental health problems. The stress of ongoing angry conflict between parents also appears to contribute to increased parent–child conflict. Socioeconomic stress and lack of social resources appears to play a particularly significant role in predicting an increase in parent–child conflict that results in child maltreatment. The overall quality of the parent–child relationship may also play a role in determining rates of conflict. Insecurely attached children, for example, have been found to initiate more conflicts with their parents than do securely attached children.

Research has also demonstrated that suppressed conflict within the family environment can also be harmful. For example, children from families where conflict is avoided even when it would otherwise be appropriate, or where conflict is entirely one-sided as parents deny children any attempts to express themselves or to dissent, may be at an increased risk of peer victimization. Parent–offspring relationships must, therefore, strike the delicate balance of conflict occurring frequently enough to allow children to practice crucial conflict management skills in a safe, supportive context, but not so frequently as to interfere with the overall functioning of the family. The remainder of this section focuses on two family contexts in which conflict becomes a destructive rather than a beneficial agent of development – when conflicts become part of a coercive cycle of parent–child interactions and when child maltreatment occurs as a result of conflict.

Coercive Family Processes

In the parent–child relationship, there is a hierarchy of power that favors the parent. While children may find this power

differential frustrating, especially during conflict situations, it is also developmentally appropriate and supports many of the positive outcomes of conflict such as negotiation, compromise, and placing limits on potentially risky child behavior. For certain families, however, this power hierarchy becomes reversed, with children having the upper hand during conflicts. This reversal has been referred to as coercive family processes and can have devastating effects on both the family dynamic and children's broader social–emotional development, including their use of conflict in other relationships.

Parent–child conflict within coercive families involves mutually escalating cycles of negative behavior between parent and child. It begins in much the same way as any other conflict interaction – one member of the dyad does something that is aversive to the other. The parent, for example, may insist on the child finishing dinner before dessert. The child then responds with another aversive behavior (e.g., noncompliance), to which the parent escalates the demand (e.g., requiring the child to sit at the table until dinner is finished), to which the child is more resistant (e.g., leaving the table without permission), and the cycle continues. The conflict is resolved only when one partner gives in to the other (e.g., the parent allows the child dessert). If the parent is consistently the one to withdraw from these conflicts, he or she is negatively reinforcing their child's aversive behavior, showing the child that escalating the conflict can lead to the child's desired outcome, and thus is increasing the likelihood that this cycle will occur again in the future. Moreover, when the child 'wins' and calms down, the parent's acquiescing is also negatively reinforced by the child's calm compliance. Thus, coercive family interaction is mutually reinforcing and self-perpetuating, and can lead to entrenched patterns of negative parent–child interaction.

Interestingly, at least in some cases, these coercive cycles appear to have their origins in infancy. Research has demonstrated that infants who are temperamentally demanding (typically those who are most reactive, negative, and persistent in their attention seeking) and who have mothers who are non-responsive demonstrate more coercive behaviors during the toddler and preschool years. Other studies have demonstrated that certain parent characteristics, such as irritability, correlate with sustained, coercive interactions. These findings support the bidirectional model of conflict we have applied throughout this article, and also reflect the significance of the earliest parent–child interactions in setting up patterns of conflict.

As coercive interactions continue throughout early childhood, the normative balance of power favoring the parent shifts, as children 'win' more and more conflict interactions. With time, parents may even stop setting clear and appropriate limits for their children's behavior, in order to avoid further conflict, and develop other kinds of unconstructive parenting practices (e.g., expecting hostility from their offspring before it occurs). The impact of this coercive cycle on children's development is far-reaching. To begin with, children may gain a precocious and inappropriate sense of control and power over their interpersonal relationships. With time, this can extend beyond the parent–child relationship and impact how they interact with peers, teachers, and other important social partners. Unfortunately, many of the other positive aspects of social cognitive development that are spurred on by appropriately resolved parent–child conflict can also be delayed.

Deficits in perspective-taking, empathy, or negotiation and compromise may also contribute to one of those most troubling outcomes of coercive family processes – increased childhood aggression.

Children who lack other strategies for ending conflict may choose to escalate their aversive behavior to physical aggression in order to fulfill their goals in the interaction. Children from coercive families are more likely to bully and victimize their peers, and may be particularly likely to be ineffectual aggressors – children who engage in protracted, aggressive conflict but typically wind up losing the fight. Aggressive behavior appears to be both a consequence of coercive family processes and a catalyst for it, with aggressive children being found to exhibit more frequent episodes of noncompliance with parental demands, to persist in aversive behavior once a conflict has begun, and to be the one to initiate conflict more often than their nonaggressive peers. Unsurprisingly, coercive family processes are also associated with increased rates of externalizing problems, and, as children reach adolescence, become associated with delinquency and even criminal behavior.

Child Abuse

Distinguishing between appropriate corporal punishment and physical punishment that constitutes child abuse is a difficult task. One distinction is that physical abuse results in nonaccidental physical injury to the child, while corporal punishment may cause temporary discomfort, but should not result in lasting harm. What is clear, however, is that parent–offspring conflict plays an important role in several different types of child maltreatment, including physical abuse.

When research has focused on parent–offspring conflict and physical abuse, several patterns of findings emerge. To begin with, abuse frequently seems to result from poor parental management of conflict. Parents often report losing control during the course of a conflict episode and resorting to physical violence. This escalation appears to be profoundly related to coercive family processes. Abusive parents are more likely to report perceiving their children as holding the majority of power during conflict situations, and thus feel the need to reassert their dominance through physical means. Furthermore, aggressive behavior in children has also been found to provoke aggression in parents. What may distinguish abusive families from those characterized by the coercive family processes described previously is that in an abusive family, the cycle of escalating aversive behaviors is terminated, not by the parent abandoning the conflict, but instead by responding with physical aggression against their child.

As with all investigations of parent–child conflict, a developmental perspective is important. As children develop, the eliciting events for abuse may change. During the infant and toddler years, the majority of conflict-to-abuse incidents revolve around the child's need for nurturance (e.g., conflict around feeding routines) or the toddler's inability to regulate their behavior in response to parental instructions (such as during toilet training). In middle childhood, abusive incidents more often revolve around the child's refusal to comply with social standards, such as lying to their parents. As would be anticipated, as adolescents gain both more freedom and more

responsibility, abuse during this developmental period tends to stem from conflicts around obedience and compliance. Rates of abuse also appear to increase as children get older, with more than 25% of reported abuse cases concerning adolescents. Indeed, abusive patterns of interaction may emerge for the first time during adolescence as parents find the balance of power shifting and their previous strategies for discipline and conflict management ineffective against their newly autonomous adolescents.

Conclusion

What becomes clear from even this brief review of parent–offspring conflict is that it is a topic seemingly full of contradictions. Conflict, in general, appears to be a vital catalyst of children’s social cognitive development, but too much (or poorly managed) conflict within the family context can quickly come to hinder these developmental processes. How parents and children perceive and manage conflict is subject to both great continuity and great change as children develop from helpless infants to independent adolescents. For example, previously held views that certain periods of development, such as adolescence, are highly conflictual receives only equivocal evidence from the empirical literature. Instead it appears that, while overall rates of conflict may increase somewhat early in adolescence, families which have a long history of successfully managing conflict will weather this period unscathed.

Another thing that is clear from this review is that much future work is needed. The positive role that parent–offspring conflict can play in development is a topic that has received insufficient empirical investigation, despite long being a cornerstone of developmental theory. Research on parent–offspring conflict is critical for our understanding of both typical and atypical child development, and deserves greater consideration than it has received thus far.

Glossary

Clique A small group of friends.

Crowd A reputation-based peer group.

Friendship A voluntary, close relationship reciprocally recognized by two individuals.

Homophily A phenomenon in which social contact is higher among people who are similar rather than dissimilar.

Hostile attribution bias The tendency to interpret ambiguous harm as being intentionally caused.

Peer acceptance Refers to how much a child is liked by peers.

Peer rejection Refers to how much a child is disliked by peers.

Perceived popularity Refers to how much a child is perceived as 'popular,' or socially prominent, by peers.

Rejection sensitivity The tendency to defensively expect, readily perceive, and overreact to rejection.

Relational aggression Aggression meant to manipulate or disrupt relationships, often initiated covertly.

Social information processing (SIP) theories Theories devised to explain online processing and decision-making that happens before, during, and after social interactions.

Sociometric assessments Measures in which children are asked to report on how much they like or dislike their peers.

Temperament A biological basis for the affective arousal, expression, and regulatory components of personality.

Working models Expectations and assumptions about interactions and relationships with other people which affect behavior in social interactions.

Introduction

Typically, children and adolescents spend considerable amounts of time interacting with peers, in and outside of school. Although much research in developmental psychology has focused on the influence of parents and family, peer relationships are of significance for positive social and emotional development. In fact, the ability to initiate and maintain positive relations with peers and friends is an important developmental accomplishment. Through peer interaction, children learn about their social worlds, establish identities, and develop close, intimate friendships. Children who experience success with peers are on track for adaptive and psychologically healthy outcomes whereas those who have difficulty are considered at-risk for all manner of adjustment problems.

In this article, we survey the literature on child and adolescent peer relationships. First, descriptions of children's friendships, characteristics of children who have friends, and the consequences of friendship for adjustment are examined. Next, the article focuses on peer groups, cliques, and crowds. Following this, the behavioral, social-cognitive, and affective correlates and longitudinal outcomes of being liked or disliked by peers and of being considered 'popular' are reviewed. Then, a discussion of cultural variation in peer relationships is presented. Finally, both the biological and parental origins of peer relationships are examined, and subsequently, a brief discussion of peer influence processes is described. The article begins, however, with an overview of relevant theory pertaining to child and adolescent peer relationships.

Theoretical Perspectives

Theoretical discussion of the importance of child peer relations can be traced back to the early decades of the twentieth century. Jean Piaget proposed that, in contrast to relationships with parents, children's peer relationships were more balanced and egalitarian. Thus with peers, children experience opportunities to examine conflicting ideas, to negotiate and discuss their perspectives, and to compromise with the ideas held by age-mates. Harry Stack Sullivan also theorized that children gained understandings of mutual respect, equality, and reciprocity from peer interaction, but he additionally emphasized the significance of best friendships in the process through which children develop abilities to recognize and value each other's personal qualities. George Herbert Mead contributed the idea that peers help children to develop the ability of self-reflection and a sense of identity through social comparison.

Social learning theory, ethological theories, and group socialization theory have also guided current research on children's peer relationships. The main contribution of social learning theory has been the principle that children learn about their social worlds, and how to behave within these contexts, through direct peer tutelage and through observation of their fellow peers. Additionally, peers can affect and change the behavior of each other through punishment (e.g., ignoring, criticizing) and reinforcement (e.g., smiles, laughter, attention). Ethological theorists, such as Robert Hinde, have also provided valuable perspective in the study of children's peer relations. They argue that social behavior and social structures are limited by biological constraints and serve evolutionary

functions insofar as personal and group relationships are concerned. Moreover, with contemporary ethological theory came renewed emphasis on observing children in natural settings, adding more objective descriptive information about behavior within peer contexts. Relatively recently, Judith Harris proposed Group Socialization Theory in which she challenged the view that parents are the primary agents of socialization for their children. Instead, she suggested that peers play a significant role in personality development. In short, the theory hypothesizes that, beyond genetic contributions, peer group norms influence behavior and identity more so than parents. Altogether, many theoretical perspectives have contributed to peer relations research, each highlighting the significance of peer interactions and groups for development. Of particular significance in childhood, adolescence, and throughout life is the close, dyadic peer relationship of friendship.

Friendships

Friendships are voluntary, close relationships reciprocally recognized by two individuals. Peer relationship researchers measure friendships by asking children or adolescents to nominate their friends or best friends. If two individuals nominate each other, it is considered a reciprocal (or mutual) friendship. Typically, ~75% of children have at least one mutual friend and about 50% of children have a mutual best friend. Friendships, especially best friendships, are typically stable over the school year, with friendship stability increasing as children get older.

Friends, especially best friends, are typically of the same sex, although cross-sex friendships increase with age. Additionally, friends tend to be similar to one another on both demographic characteristics (e.g., race), behavioral characteristics (e.g., social competence, aggression), and interests (e.g., music). Homophily in friendship may stem from both initial attraction (i.e., children are attracted to those similar to themselves) and socialization (i.e., as friends spend time together, they influence each other). For additional information on socialization and peer influence (see the sections 'Socialization Within Peer Groups' and 'Peer Influence').

Descriptions of friendships change with age, indicating that the functional benefits of friendships may vary by age as well. When young children are asked to describe friendships, their narratives focus on play and companionship. Shared-play allows children the opportunity to develop self-regulation skills. In middle-through-late childhood, friendship descriptions center on sharing, cooperation, and help, and gradually develop into an emphasis on similarity and loyalty. Friendships during this period provide opportunities for children to learn about social norms, provide support, and help them to learn the interpersonal skills necessary for later intimate relationships. Finally, adolescents' friendship descriptions include expectations for shared intimacy and emotional support, and ultimately friendships at this age provide a context to express and regulate emotion and establish identity.

The benefits of friendship are evident when comparing the social and emotional adjustment of children who do and do not have close friends. Children who have friends report less

loneliness and higher self-esteem than children without friends. Children with friends are also less likely to be victimized by peers than are children without friends. Friendships are also beneficial for children normally considered 'at-risk.' Having friends seems to protect children who do not have supportive parents or who have stressful home lives from later maladjustment.

The quality and stability of friendships is also a determinant of the benefits derived from them. The degree to which a child's friendships are high in emotional and instrumental support, intimacy, validation, and conflict resolution is related to positive adjustment. Children with high-quality friendships are less lonely, exhibit fewer externalizing or internalizing problems during life stressors, and are better adjusted after school transitions. Children with stable friendships are also less lonely compared to their peers with unstable friendships.

Groups

Beyond friendships, children also spend a large proportion of their time in both informal and formal group settings. In childhood, small groups of friends, or cliques, are predominant. However, in adolescence, participation in reputation-based crowds becomes more prevalent. Crowds are larger collections of individuals who share the same image or status among peers, even if they spend little time interacting with each other (e.g., 'jocks,' 'geeks,' 'populars,' 'goths,' 'loners,' and 'druggies'). These changes in group structure suggest that older children rely on a group of trustworthy peers for social support, whereas adolescents strive to acquire a sense of group identity that is different from their parents.

Groups can be measured in several ways, but the most popular techniques include social network analysis (SNA) and social cognitive mapping (SCM). With SNA, children are typically asked to list up to ten friends with whom they hang out most often in the school. A computer program, NEGOPY, then clusters children into groups who report having relatively high contact with one another. With friendship nominations, NEGOPY can report group members, liaisons, dyads, and isolates. Group members are those individuals who belong to a rather exclusive social group, with at least three individuals who have at least half of their friends in the same group and who are all connected within the group. Liaisons are individuals who have friendships with group members, but are not group members themselves. Dyads are individuals who have one reciprocated friendship link, either to each other or to another individual. Isolates are children who have no reciprocated friendships.

In contrast, the SCM technique assesses peer groups by asking children to report on peers who 'hang around together a lot' and whom they, themselves, 'hang around with.' Based on the reports of all children, a matrix is constructed based on the number of occasions that any two individuals are named as being in the same group. Each participant's group-membership profile is generated based on the frequencies of nominations of group-membership with every other child in the class. A profile similarity index is derived by correlating pairs of individual group-membership profiles and then children with similar group-membership profiles are clustered into the same group.

Socialization Within Peer Groups

The peer group represents a social context influenced by the collective functioning of members based on group norms and values and is not simply reducible to the characteristics of the individuals who compose the group. Children in the group are bound together, constrained by common interests and group norms. Thus, these group norms guide how children and adolescents behave in various social situations.

Interactions within peer groups socialize children and adolescents in several major ways. For example, from group activity, children learn how to cooperate to achieve collective goals and the skills needed to both lead and follow others. Youth learn how to control aggression toward their fellow group members, and simultaneously, how to direct aggression toward out-group members. Groups also forge emotional connections among members and serve as sources of social support. In short, frequent contact, common activities, and affective connectedness among group members may make children's groups a particularly strong socialization influence.

Crowd membership contributes to adolescents' social functioning, partly because of its influence on social contacts. For example, the stigma associated with certain crowds constrains adolescents into relationships with members of their own group, and prevents changes in group membership. Crowd membership also leads to the stereotyping of peers; adolescents are biased in their use of reputational information about particular groups, especially when presented with social information about those groups that is ambiguous.

Thus, peer groups may have far-reaching effects on individual social, emotional, and behavioral functioning and adjustment. Although peer groups may initially be formed based on child characteristics, the profile of peer networks significantly predicts subsequent adjustment. For example, peer groups contribute to school motivation, school drop-out, pregnancy, and delinquency. See the section below on peer influence for additional information.

The prevalence of larger peer groups declines in the late adolescent years, partly due to increased cross-sex groups and dyads. Eventually, groups divide into couples and adolescents feel more comfortable approaching each other, even without support from a crowd. Additionally, in late adolescence, youth become more secure creating their own identity and deciding on their own personal values and morals apart from a crowd.

Peer Acceptance and Rejection

Often used as an indicator of child adjustment, peer acceptance and rejection refer to how liked or disliked a child is by his or her peers. In this section, methods of measuring peer liking and disliking are briefly surveyed. Second, the behavioral and social-cognitive characteristics associated with acceptance and rejection are reviewed, followed by a discussion of the long-term outcomes of peer rejection.

Peer acceptance is typically measured through a sociometric assessment, in which children are provided with a class roster and are requested to nominate up to three classmates with whom they like to play or work, or whom they simply like the most. Children are also asked to nominate peers with whom they do not like to play or work, or those whom they

like the least. Some researchers limit the number of nominations that children can make for 'liked most' and 'liked least' to three, whereas others allow children to make unlimited nominations. The number of nominations a child receives is summed and then divided by the number of possible raters to compute a proportion of how many classmates (or grade-mates) like and dislike each child. Scores are standardized within each class (or grade) to control for group size. Children who receive few 'liked most' nominations and many 'liked least' nominations are labeled as 'rejected' whereas children who receive many 'liked most' nominations and few 'liked least' nominations are labeled as '(sociometrically) popular' or as 'well-accepted.' Other groups of children can also be identified, including children who are 'average' (near the mean on liked and disliked nominations), 'controversial' (many liked and disliked nominations), and 'neglected' children (few liked and disliked nominations). As an alternative to using nominations, it is also possible to measure acceptance using a rating-scale sociometric procedure. Children are provided with a class roster and asked to rate each classmate on a scale (e.g., 1 = 'not at all' to 5 = 'very much') pertaining to how much they like to play or work with each person.

Not to be confused with sociometric popularity (being liked or accepted by peers), perceived popularity, or social prominence, is the degree to which children are labeled as 'popular' by peers. Perceived popularity is measured by standardized, proportioned nominations of 'most popular' and 'not popular.' The proportion of 'not popular' nominations received by each child is subtracted from the proportion of 'popular' nominations, and this score is standardized within class (or grade and sometimes gender). Teacher nominations of popularity have also been used to study perceived popularity. The association between perceived popularity and sociometric popularity ranges from moderate to strong, but generally decreases in magnitude during adolescence.

Behavioral Correlates of Peer Acceptance and Rejection

In an effort to understand why some children are liked versus disliked by peers, research on associations with child behavior has been prominent. Child behavior can be measured in numerous ways, including peer-, teacher-, parent-, and self-reports, as well as through observational methods. In the peer relations area, child behavior is most commonly measured through peer reports of behavior. Children nominate classmates who fit different behavioral descriptions (e.g., 'starts fights,' 'shy,' and 'helps others'). These nominations are also proportioned and standardized within class.

Observing children in naturalistic or laboratory settings is another method to measure child behavior, which may offer more objective assessments compared to peer-, teacher-, parent-, or self-reports. Laboratory or analogue assessments are useful for observing behaviors that may be hard to detect or may occur less frequently in natural settings. From these observations, researchers can deduce what is age and gender typical in social situations. Behaviors that deviate from these norms are typically associated with peer rejection.

Generally, sociometrically popular (or well-accepted) children are identified by peers as being skilled communicators and good leaders. Well-accepted children are also perceived

by peers as being sociable, helpful, sensitive, agreeable, and cooperative. They also tend to be good athletes, good students, and have good senses of humor. Further, observations of sociometrically popular children have revealed that they are more successful at entering group activities than rejected children, likely because they take the group's frame of reference and say something on topic without drawing undue attention to themselves. Further, in conflict, well-liked children are more likely to negotiate and compromise than their disliked peers.

In comparison, there is more heterogeneity in the characteristics of peer-rejected children. Between 40% and 50% of rejected children are considered aggressive by their peers. Observations of the interactions of unfamiliar children over time have shown that the behavior that most clearly predicts whether peers increasingly dislike a child is how much that child uses instrumental and reactive aggression in his peer interactions. Additionally, if children are both aggressive and disruptive, the likelihood of being rejected by peers increases greatly. However, aggressive behavior and peer rejection are correlated more within groups of younger children than within groups of older children.

Further, if children have other peer-valued characteristics, then the association between aggression and peer rejection decreases. For example, aggressive children and adolescents who are also considered athletic and 'cool' may not be rejected by peers. In fact, the group of 'cool,' aggressive children may be part of the group of children that was described above as being perceived as popular. Perceived popularity has been linked to a diverse list of characteristics, including aggression and dominance, as well as prosocial behavior, academic and athletic abilities, having a good sense of humor, and being attractive, stylish, and wealthy.

This mix of valued characteristics with dominant/aggressive behavior may be what distinguishes the perceived popular group from other status groups. Longitudinal research has found that youth who become perceived as popular by peers subsequently increase their use of aggression, particularly relational aggression, perhaps as a means to maintain their status during adolescence. Relational (also sometimes labeled indirect or social) aggression is meant to manipulate or disrupt relationships and is often initiated covertly. Although, overt aggression (i.e., direct physical or verbal aggression) has also been associated with perceived popularity, these associations have been explained through the relations of both constructs with relational aggression.

Returning to the behavioral characteristics of rejected children, ~10–20% of these children are shy, withdrawn, and/or socially anxious. Withdrawn children are not likely to approach unfamiliar peers, they appear overly compliant to peers' requests, and seem unconfident and wary in the company of peers. They are also more victimized by peers, perhaps because they are viewed as 'easy marks.' Additionally, withdrawn boys are more likely to be rejected than withdrawn girls, perhaps because withdrawn behavior violates male gender norms.

Withdrawn behavior has been differentiated into three forms, each of which is differently related to peer rejection. Solitary-passive behavior comprises solitary exploration and/or constructive activity in the company of others and is

considered normal for young children, but becomes increasingly associated with peer rejection with increasing age. Solitary-active behavior comprises the display of solitary sensorimotor activity and/or dramatic play in the company of others. It is viewed as abnormal throughout childhood and is associated with peer rejection as early as preschool. Finally, reticence consists of watching others from afar and avoiding social activity altogether. Reticence has been found to reflect internalized feelings of social anxiety and, beginning in early childhood, also elicits peer rejection.

Once a child is rejected by peers, the experience may reinforce both aggressive and withdrawn behavior in those children who are predisposed. For example, anxious-solitary children who were excluded early in kindergarten evidenced more stability in their behavior over time compared to peer-accepted anxious-solitary children, whose anxious solitude decreased over time. Similarly, researchers have found that peer rejection predicts increases in aggressive behavior over time, especially for children who are initially more aggressive than peers. In this regard, there appears to be a dialectic relation between behavior and rejection. Behavior may initially result in peer rejection, but the experience of rejection evokes greater maladjustment.

Social-Cognitive Correlates of Peer Acceptance and Rejection

Researchers have investigated the social cognitions of children in the different sociometric status groups and of children with different behavioral tendencies. Social information processing (SIP) theories explain online processing and decision-making that occur before, during, and after social interactions. Most SIP models suggest that individuals enter social situations with unique interpersonal histories, which include beliefs, schemas, scripts, and working models, all of which influence how they interpret social interactions and how they behave. Typically, SIP models also outline a series of sequential steps that explain how children attend to, encode, and interpret social information and how they choose, evaluate, and enact both goals and behavioral strategies. Recent revisions of these models also include temperament, emotional regulation, and affective reactions as contributors to cognition and subsequent behavior in social interaction.

Generally, rejected children are less likely than their well-liked counterparts to formulate prosocial goals and generate sophisticated strategies. However, a majority of SIP research has focused on children who are both rejected and aggressive. Typically studied by asking children to respond to vignettes in which they are harmed but is unclear whether the offense was intentional (e.g., someone bumps into you in the cafeteria and your milk is spilled on your shirt), rejected-aggressive children are more likely to judge an ambiguous harm as being intentionally caused and respond in a hostile manner. This tendency has been termed the hostile attribution bias.

Children who are both aggressive and rejected are also more likely to choose aggressive/hostile goals and strategies in social situations. For example, these youth are more likely to endorse revenge and dominance goals as well as aggressive behavioral strategies in both ambiguous situations and very minor conflicts of interest. Aggressive children also view aggression as a more legitimate response in social situations,

anticipate greater rewards and fewer consequences for aggression, and they expect that aggression will lead them to feel better about themselves and will be less hurtful to victims.

In comparison, far less research has examined the SIP patterns of withdrawn children. Research that has focused on this group finds that withdrawn children are more likely than aggressive or typical children to anticipate failure in social situations. When withdrawn children do encounter social rejection, they are more likely to attribute it to their own dispositional characteristics rather than to external causes. Additionally, withdrawn children are more likely to suggest adult-dependent and avoidant strategies and less likely to generate assertive social strategies to resolve interpersonal conflicts.

Interpersonal schemas may also predict how children react in peer situations, and ultimately are related to their sociometric status. For example, rejection-sensitivity, defined as the tendency to defensively expect, readily perceive, and overreact to rejection, has been associated with peer rejection and child behavior. First, peer rejection predicts increases in rejection sensitivity over time. Furthermore, angry expectations of rejection are positively associated with teacher-rated aggression and negatively linked with social competence. Moreover, child and young adolescent anxious expectations of rejection have been linked with social anxiety and social withdrawal. While this is still a relatively new topic of investigation, it seems that rejection-sensitivity is a construct that may prove useful in further SIP-guided research.

The self-system

Henry Stack Sullivan argued that peer relationships shape children's self-concepts. In support, researchers have found that rejected children view themselves as less socially competent and have lower self-worth than nonrejected children. Further, it appears as if peer rejection predicts decreases in social self-concept over time. However, not all rejected children have negative self-views. Aggressive-rejected children tend to think more positively about themselves and underestimate how disliked they are compared to nonaggressive-rejected and withdrawn-rejected children. Aggressive-rejected children may be less likely to be treated poorly by peers, or perhaps, they are more likely to employ self-protective mechanisms and ignore negative feedback.

Loneliness

It is not surprising that rejected children are generally lonelier than typical or nonrejected children. Examining subgroups of rejected children, submissive/timid/withdrawn-rejected children, when compared with average-status and aggressive-rejected children, report higher levels of loneliness. Additionally, those whose rejected status is stable over time become increasingly lonely over time. The association between peer rejection and loneliness may be explained, in part, because rejected children have fewer friends and are more likely to be victimized by peers.

Outcomes Associated with Peer Rejection

Focusing on both externalizing and internalizing problems, this section briefly reviews research on peer rejection and later adjustment outcomes. Research in this arena has been

guided by several theoretical models, proposed to explain how sociometric status, behavior, and later adjustment are related. The 'causal model' states that rejected peers interact with their peers in a negative manner causing them to receive poorer treatment which eventually leads to subsequent adjustment difficulties. The 'incidental model' assumes that peer rejection does not affect later adjustment but is only a by-product of the child's behavioral style and it is behavior, alone, that affects later adjustment. More recently suggested, the 'additive model' states that relational risk factors, like peer rejection, increase the likelihood of later dysfunction beyond the risks associated with behavioral characteristics. Alternatively, the 'moderated risk-adjustment model' suggests that relational risks (e.g., peer rejection) exacerbate maladjustment among children who are behaviorally at risk. Finally, examining forces outside of the child and the peer group, the 'transactional model' proposes that the child's dispositional and biologically based characteristics, parents' socialization practices, relationships within and outside of the family, and culture, stress, and social support determine both peer relationships and the positive or negative outcomes that follow.

Externalizing problems

Externalizing difficulties comprise behaviors that are disruptive, destructive, harmful to others, and in violation of societal norms (e.g., delinquency, aggressive behavior, criminal involvement). Children who are rejected by peers are at an increased risk for externalizing difficulties in adolescence and beyond. Theoretically, research about how peer rejection and aggression are associated supports components of the additive, interactional, and causal models. For example, peer rejection in early childhood has been linked with later misconduct and conduct problems, even after controlling for initial levels of behavioral problems. In some cases, the pathway from peer rejection to conduct problems is exacerbated by the initial level of behavioral problems. It may be that social rejection serves as a social stressor, increasing children's tendencies to behave aggressively beyond their initial tendencies.

Internalizing problems

There is much evidence for both concurrent and longitudinal associations between anxious-withdrawal and internalizing problems. Withdrawn behavior early in childhood is related to depression, loneliness, anxiety, and negative self-worth years later and, empirical support has been found for the causal, additive, moderated risk-adjustment, and transactional models. For example, because peer rejection and anxious-withdrawal are associated, researchers have proposed that the combination of anxious-withdrawal and peer rejection is associated with an increased risk for later internalizing issues. Indeed, anxious-solitary children who are also excluded by peers subsequently display more depressive symptoms years later than anxious-solitary children who are not excluded by peers.

In conclusion, peer-rejected children are at risk for both externalizing and internalizing problems. Children who act aggressively or are withdrawn are likely to be rejected, and peer rejection exacerbates these behavioral tendencies. In combination with these behavioral risk factors, peer rejection is associated with an increased likelihood of later maladjustment.

Culture and Peer Relationships

Most of what has been learned about child and adolescent peer relationships has been based on research from North America and Europe. However, child behavior, social and behavioral norms, and the formation and function of peer relationships and peer groups are directed by cultural conventions, norms, and values, and thus, vary cross-culturally. This section briefly focuses on cultural variation in the meanings and correlates of peer acceptance, friendships, and peer groups.

Although it appears to be a universal finding that children who are cooperative, friendly, and sociable are well-liked by peers, cultural values greatly influence standards for rejection of children who are prototypically aggressive or withdrawn among their peers. Whereas aggression is typically associated with peer dislike, when the larger group within which the child is a member is aggressive, its association with peer rejection is nonsignificant. Interestingly, aggressive behavior is associated with loneliness in China but is not in Western cultures. As aggressive and dominant behavior has been linked to perceived popularity in the United States, there may be fewer social sanctions against it, whereas in China, aggression is more prohibited.

Furthermore, social withdrawal is associated with peer rejection in cultures that value assertiveness, expressiveness, and competitiveness. Thus, social withdrawal is associated with peer rejection in countries such as Argentina, Canada, Greece, Italy, the Netherlands, and the United States. Yet in China, research in the 1980s and 1990s indicated that shy and inhibited behavior was positively linked with peer acceptance; it was argued that in China, quiet, reserved, compliant behavior was a reflection of self-regulation. More recently, with historical changes occurring such that the Chinese economy and political climate is becoming more similar to Western nations, researchers have noted that shy, reserved, and especially socially withdrawn behaviors are becoming more associated with peer rejection among urban Chinese elementary school children. The same findings have not been reported for children residing in traditional, rural regions.

The functional roles that children's friendships fulfill may vary across cultures as well. For example, whereas friendship is considered voluntary in Western cultures, friendships may not be freely chosen everywhere, but instead may be considered predetermined or permanent. Additionally, the salience of friendship provisions may vary as defining features of friendship. For instance, intimacy is a more important criterion in the friendships of Korean adolescents than their US counterparts. Furthermore, whereas children from both Indonesia and the United States rate intimacy as being similarly important to friendships, American children also define friendships by companionship whereas Indonesian children derive companionship more from their family members than from their friendships.

Researchers have just begun to explore variation in friendships by race and ethnicity within culturally diverse nations. In one US study, ethnic minority adolescents, from low-income, urban contexts, conceptualized and expressed intimacy with friends differently than their white or middle-class age-mates. Low-income urban adolescents stressed instrumental aid (e.g., sharing money and other resources) with friends as a powerful signifier of trust and closeness, whereas middle-class white adolescents traditionally focused more on intimate disclosure.

Without additional research, it is not possible to know whether these differences were due to race, ethnicity, socioeconomic status, or other community features.

Biological and Parental Influences on Peer Relationships

As noted above, children's social skills are associated with, and predictive of, the quality of their peer relationships. Thus, knowledge about the origins of these skills is valuable and may be used to develop prevention or intervention programs for those at risk for peer rejection and its negative consequences. In this section, we briefly review research on the origins of these skills, focusing on biological or dispositional factors, such as temperament, as well as parent-child relationships and parenting behaviors.

Temperament

Temperament is defined as a biological basis for the affective arousal, expression, and regulatory components of personality. Temperament seems to play a powerful role in social skill development; longitudinal evidence following children from early childhood through adolescence indicates that about half of the variation in social skills may be accounted for by temperamental characteristics.

Focus has been on three main groups of traits: manageability, reactivity, and inhibition. Children low on *manageability* lack attention regulation, are low on agreeableness, and have trouble ignoring rewarding stimuli. These children tend to be boisterous, socially immature, and unresponsive to parents' and teachers' attempts to regulate their activities. With peers, these children are socially unskilled and are more likely to display other externalizing problems. Children who are highly *reactive* are easily angered, frustrated, and provoked by peers, and have difficulty controlling the expression of negative emotions. The probability of these children being rejected and of developing externalizing and internalizing difficulties is much greater than for children low on temperamental reactivity. Finally, *inhibited* children refrain from interacting with unfamiliar peers because of dispositionally based fear or anxiety. As noted above, shy, inhibited children are more likely to be rejected and develop internalizing problems, in part because they act less competently and employ less active coping strategies. Finally, children who are well-regulated emotionally and are sociable develop those social skills that endear them to their peers and friends.

Parent-child relationships

Parents serve many influential roles in their children's development of social skills and positive peer relationships. As outlined in attachment theory, the parent-child relationship provides a 'secure base' allowing the child the freedom to explore his or her social environs, thereby enhancing the development of social competence. Additionally, within parent-child relationships, children begin to develop 'working models,' or expectations and assumptions about interactions and relationships with other people that subsequently affect their behavior in social interactions. According to attachment theorists, parents who recognize their young child's emotional signals, consider their child's perspective, and respond contingently to their child's needs have children who rely on their parents for protection,

nurturance, comfort, and security and who develop the belief systems that others are generally trustworthy and that the self is worthy of positive treatment. When parents do not meet these standards, children may develop insecure attachments to parents, and subsequently, working models that interpersonal relationships may be rejecting or neglectful.

Research linking attachment and peer relationships abounds. In both childhood and adolescence, youth who experience a secure relationship with their primary caregivers (usually mothers) are rated by peers and teachers as more likeable and sociable compared to insecurely attached peers who are reported to be more aggressive or withdrawn. Longitudinal research has also revealed that infants identified as being insecurely attached to mothers are more likely than their secure counterparts to display aggressive or socially wary and withdrawn behavior years later. Security of attachment has also been related to subsequent friendship formation and maintenance; children with insecure attachment relationships have fewer friends and have poorer quality friendships compared to children with secure attachments.

Parenting behaviors

Parenting behaviors influence child social skills and peer relations in many ways. Here, we focus on two primary means: (1) parental warmth and control, and (2) parental provision and monitoring of opportunities for peer interaction. First, much of the research on parenting and peer relationships has examined two dimensions of parenting: warmth and control. Warmth refers to parental praise, encouragement, physical affection, both physical and psychological availability, and approval. Control refers to the consistent enforcement of rules accompanied by an ability to make age-appropriate demands on the child. Researchers consistently find that parents of peer-rejected children use more harsh and authoritarian disciplinary and socialization practices compared to parents of well-liked children who use more feelings-oriented reasoning, warm control, and are more positive during communication. The association between parenting behaviors and peer acceptance is likely accounted for by the child's behavior with peers. For instance, parents who are more physically punitive and rejecting or are overly permissive have children who are more aggressive with peers. Additionally, parents who are overprotective and overcontrolling have children who are shy or withdrawn with peers. In fact, parents may inadvertently exacerbate childhood aggression or shyness and social anxiety by serving as models of these behaviors.

Second, parents affect children's peer relations by providing opportunities to interact with peers (especially in early childhood), monitoring their peer activities, and by coaching them through difficult peer tasks. Young children whose parents arrange play dates have more play partners, are more socially competent, and are better liked by peers. Further, children whose parents monitor their peer contacts are less likely to be aggressive or delinquent in adolescence. Finally, parents can offer helpful advice about how to handle challenging peer interactions; mothers of well-liked children encourage them to employ positive and assertive strategies for handling interpersonal problems involving peers in comparison to mothers of rejected children who support more avoidant coping strategies.

Peer Influence

There is a rather strong and consistent association between the individual child's own behaviors and those of their peers. As noted above, friends tend to both befriend similar peers (i.e., selection) and become more like their friends over time (i.e., socialization). In this section we focus on peer influence processes, sometimes referred to as peer contagion, and how peer relationships and the characteristics of friends shape adolescent behavior.

Several mechanisms for peer influence have been offered. The first is peer pressure, in which children and adolescents directly try to influence each other's behaviors and attitudes. Second, based on social learning theory, another influential factor may be peer modeling, or peers mimicking each other's behaviors; this is especially true for the modeling of peer group leaders' behaviors. Third, youth may also use antagonistic behaviors, such as teasing, ridicule, or even bullying to control each other's behavior. Fourth, peers may create structural opportunities that facilitate behavior without directly encouraging it. Fifth, when an adolescent is labeled by peers as being a part of a certain crowd, this label may lead them to act in ways that are self-fulfilling. And finally, friends and peers may subtly reinforce and encourage each other to continue or increase behaviors in which they are already engaging.

Peer influence is prevalent in early childhood and throughout adolescence, affecting youth aggression, risk-taking behaviors, social attitudes, and much more. For example, aggressive children tend to interact with other aggressive children, escalating their aggression over time. The subtle ways that deviant friends encourage each other are revealed through observations of their discussions. When deviant or aggressive children interact, they reward each other for talking about deviant behaviors, through laughter and extended discussion. This has been termed 'deviancy training' and has been observed in the interactions of children as young as 5 years old.

Social influence can be both harmful and healthy, depending on the characteristics of peers. For example, longitudinal research indicates that the academic performance of a child's friends is associated with the later academic performance of the child. More specifically, if a child's close friends obtain higher grades, the child is more likely to demonstrate academic improvement; however, if the child's close friends perform poorly, then the child's performance is likely to suffer. Peer crowds are also important. Highly motivated students receive more reinforcement from their crowd members for on-task behavior, whereas low-achieving youth are rewarded more by their crowd members for off-task behavior.

The extent of peer influence depends on both individual characteristics as well as situational and relational factors. For example, at the individual level, those with low self-esteem are more susceptible to peer influence. A youth's perception of social norms is also significant; for example, teenagers adjust their alcohol consumption to be similar to their perceptions of group norms. Contextually, the power dynamics of a relationship affect which individuals are more susceptible to group influence. Peers are more likely to be influenced by higher status peers than they are by low-status peers. Moreover, interactional processes between friends affect subsequent adjustment. For example, co-rumination, or joint, extensive

discussion about negative events in each other's lives, is associated with increased depressive symptoms among girls.

In conclusion, we have surveyed the literature on child and adolescent peer relationships. We have found that friendships provide youth a safe, supportive relationship in which they gain self-regulatory skills, and learn about social norms and themselves. Peer cliques and crowds are also socializing agents, providing a source of identity in adolescence. Further, the extent to which children are liked or disliked by the larger peer group is influenced by their behavior and social cognitive skills, which in turn are also affected by cultural norms, child temperament, parent-child relationships, and parenting behaviors. Thus, from our reading of the literature, it would appear safe to conclude that peer relationships significantly influence social, emotional, relationship, and academic development.

Perceived Control

J G Chipperfield, R P Perry, and T L Stewart, University of Manitoba, Winnipeg, MB, Canada

Glossary

Learned helplessness The 'giving-up reaction' or 'quitting response' that results from believing that behaviors do not produce desired responses.

Perceived control Classic definitions focus on beliefs involving *influence*, including beliefs in *influence* over one's own actions and contingency beliefs that a given response will *influence* an outcome.

As a Darwinian imperative, survival is predicated on 'cause-effect' associations. An animal will not survive unless it engages in the necessary behaviors to catch its prey. *Objective control* is used to describe these cause-effect relationships in which a given response influences or produces an intended outcome. A desire to exert influence over one's environment has even been proposed as a basic human motive. The motive to strive for control is reflected in folk expressions that permeate our day-to-day language, such as 'The early bird gets the worm' and 'If at first you don't succeed, try and try again.' Striving for control is also a central theme in literature and poetry, as illustrated by the common refrain 'I think I can, I think I can' in Piper's famous bedtime story about the *Little Engine that Could*, and in the advice to pray for 'the courage to change the things I can' in Niebuhr's *Serenity Prayer*.

Successfully producing a desired outcome (objective control) is invariably accompanied by beliefs or *perceptions of control* about one's influence over such outcomes. Unlike objective control, *perceived control* is phenomenological. Often times, it is the subjective perceptions that predict subsequent behavior, not the objective reality of whether one can actually produce an outcome. The focus of this article is on control at the subjective level, *perceived control*.

Historical Development of Perceived Control

Perceived control arose as an area of scientific inquiry with the emergence of the 'cognitive revolution' in the mid-twentieth century. Perceived control has been featured in many broad theories of human motivation and behavior, such as in Rotter's original *Locus of Control Theory* and, more recently in Pekrun's *Control Value Theory*. During the 1980s, the construct was embraced by researchers studying health, as is evidenced by its inclusion in the *Health Belief Model*, the *Protection Motivation Theory*, and the *Theory of Reasoned Action*, later revised to the *Theory of Planned Behavior*. Finally, many theories imply the importance of perceived control even though it is not explicitly stated. This is the case, for example, in Weiner's *Attribution Theory* of motivation and emotion in which individuals seek causal explanations (attributions) in an attempt to understand the 'rules' that govern cause-effect relationships.

Conceptual and Theoretical Developments

During the second part of the twentieth century, many theorists and researchers contributed to the conceptual and

theoretical developments in perceived control. In 1959, White introduced his theory of *effectance motivation* that portrayed humans as possessing an innate need to investigate, master, and effectively handle their environment. In the 1960s and 1970s, a seminal body of animal research that examined objective control contingencies provided a backdrop for one of the major theoretical contributions in the field. In this research, dogs were exposed to learning conditions in which their responses to influence a desired outcome (escape of a shock) were futile. This led to an expectancy that generalized to other new learning situations: having previously learned that their attempts to escape a shock were futile, the dogs simply gave up trying to escape future shocks. Seligman coined the term *learned helplessness* to describe the pattern of passive, withdrawn, and apathetic behavior that ensued.

Following these animal studies that expressly manipulated *control contingencies* and focused on observed behaviors, the 'learned helplessness' paradigm was extended to the study of humans. Experiments exposed participants to uncontrollable noxious conditions, including electric shocks, loud noises, and painful stimuli like cold water. For example, in one experiment that exposed participants to an aversive stimulus (electrical shocks) while working on a task (puzzle), participants were informed that solving the puzzles would terminate the shocks. This study showed that it was not the objective influence over the termination of shocks that affected cognitive and physiological stress responses, it was the belief their responses (solving the puzzle) influenced the outcome (shock termination).

In addition to Seligman, many others have contributed to the conceptual and theoretical advances in the study of perceived control. The two others who are most often credited are Rotter and Bandura. Rotter's pioneering work on the *locus of control* construct separated beliefs about the causes of environmental outcomes into those controlled by *internal* factors (one's own actions and characteristics) or by *external* factors (powerful others, luck, chance, etc.). Subsequently, Bandura argued that individuals need to believe that an outcome is contingent upon a certain course of behavior or response (outcome efficacy), but that it is equally (if not more) important to believe they possess the capacities to produce that behavior/response (self-efficacy). Because *self-efficacy* involves beliefs about the possession of the abilities/skills/tools/behaviors necessary to influence a desired outcome, it presumably provides the incentive to act. Bandura argues that "there are countless response-outcome pairings that people understand but do not pursue because they judge themselves to lack the

capabilities for them . . .,” implying that self-efficacy is even a ‘better’ predictor of behavior than is ‘outcome efficacy.’

Definitions of Perceived Control

Beyond locus of control and self-efficacy, other classic concepts such as *mastery*, *agency*, and *self-determination* emerged that are all generally subsumed under the umbrella term ‘perceived control.’ Skinner developed a taxonomy that helped to differentiate the subtle variations between these concepts. Each can presumably be classified in relation to its emphasis on the ‘agent–means–end’ sequence, in particular whether it describes an ‘agent–means,’ ‘agent–ends,’ or ‘means–ends’ relationship. The ‘agent’ refers to beliefs about the agent of control (the role of the self); the ‘means’ refers to beliefs about the way in which control is exerted; and the ‘end’ refers to the desired outcome over which control is exerted.

Despite the different emphases in the classic concepts, the definitions share a common core: each focuses on beliefs about *influence*. The focus might be on a belief that certain actions will generally *influence* an outcome (running fast will allow one to escape from an attacking bear) or on whether one believes he/she possesses the essential qualities to *influence* his/her actions (I believe I have the strength and endurance to run fast) and/or whether this allows for one’s *influence* over outcomes (running fast will allow me to escape from an attacking bear).

Some researchers continue to use the *perceived control* label in the classical way to refer to beliefs about *influence*; whereas, others use it more liberally to describe a psychological state of control, that is, whether one feels ‘in control’ or ‘out of control.’ Beliefs about influence are tied to specific outcomes, but the psychological state of control is broader. Just as people can report whether a specific outcome produces happiness, they can also report a broader, overall state of happiness that extends beyond the outcome.

To avoid confusion in this article, when it is useful to distinguish *perceived control* from the broad psychological state of control, we adopt *sense of control* as a label to refer to the psychological state. We subsequently use the *perceived control* label in its narrowest, classic manner (i.e., beliefs about influence), not as an endorsement of this classic view, but rather, to avoid confusion.

Perspectives and Approaches to Studying Perceived Control

A researcher’s approach to studying perceived control is partly determined by the extent to which it is viewed as a trait, or as a state. The *trait perspective* regards perceived control as being much the same as a dispositional or personality characteristic, conforming to a *generalized* individual difference. Thus, at a global level, these perceptions may serve as ‘self-fulfilling prophecies’: If you believe you can, you can! Because these traits generalize across time, if one perceives control over her academic performance today, her perception will be the same tomorrow. However, these traits need not generalize across domains; a student might believe she can influence outcomes in the academic domain, but not in the health domain.

In contrast, the *state perspective* regards perceived control as arising, not only from beliefs that can change from domain to domain (or setting to setting) but also from moment to moment. Thus, the state perspective could, not only lead to predictions about domain-specificity in that perceived control can vary across situations (e.g., a student can believe he has considerable influence over getting a good grade on an upcoming exam but believe he cannot influence his weight loss), but also to predictions about the time dimension (lifespan trajectories).

Domain Specificity

Variations in perceived control have been examined in a wide range of domains, such as stress, social relationships, occupations/workplaces, housing, athletics, advertising, decision making, leisure activity, intellectual development, memory, and academic achievement. Although the research findings are not definitive, Lachman and Weaver showed that adults’ reports of perceived control were higher in some domains than others. The least perceived control was reported over sex life and finances and the most over marriage and life overall.

The most frequently studied domain in which perceived control has been assessed is health. Wallston’s *Health Locus of Control* scale is perhaps the most commonly used domain-specific scale that assesses perceived control over health in general. Other measures have also been developed within the context of specific health problems such as arthritis. Moreover, perceived control has been studied among individuals with a variety of specific health conditions, including AIDS, Parkinson’s disease, cancer, and arthritis, to name a few.

Lifespan Approaches

Although the research is insufficient to allow conclusions about changes over the *life course* in perceived control, some studies do suggest a shift toward externality in later life. A lifespan pattern is proposed by Wolinsky and Stump in which perceived control (i.e., mastery) gains strength throughout childhood and into early adulthood, plateaus in mid-life, and declines in later life as people experience losses. Specifically, they identified an ‘inflection point’ around the age of 50, at which time increases in perceived control were shown to wane and eventually decline.

Despite the limited empirical evidence, it is logically plausible that shifts in perceived control might occur over the life course. Although each person’s perceived control trajectory would develop in unique ways, some overall patterns may indeed exist. The following developmental trajectories serve as illustrations of such hypothetical patterns.

Response-outcome contingencies clearly begin to emerge at the earliest stages of development when a baby learns that his cries will result in feeding or when an infant learns to use her hands to manipulate an object. The pride on a child’s face when she accomplishes even the simplest task of tying her shoe suggests that she believes she is influencing/controlling an important outcome. Thus, the infant becomes more capable of exerting influence over more outcomes, and the young child increasingly gains proficiency at achieving goals through contingent response-outcome pairings.

Response-outcome pairings have traditionally been viewed as distinct, disconnected episodes. However, a developmental perspective suggests that the frequent and sequential response-outcome pairings become consolidated into ingrained series that constitute ‘contingency chains.’ Contingency chains may also produce expectations about influence over future outcomes. If contingency chains are only beginning their consolidation during infancy, infants should perceive very little control (influence) over their environments. Interestingly, however, infants are rarely depicted as being ‘out-of-control,’ a description that is reserved for later points in development.

Although infancy and young childhood would generally be regarded as a time when response-outcome contingent pairings and perceived control are increasing, these patterns presumably change during development. For example, contingency in response-outcome relationships might become more pronounced as adolescents or young adults begin to navigate their social worlds; their approaches to pursuing relationships might not always produce favorable outcomes. Moreover, during adulthood, limits are imposed when there are only brief windows of opportunity for objective control over important life goals, such as selecting a career or having children. Outside these windows of opportunity, contingency is likely to be eroded when responses do not produce the intended outcome.

Perhaps the *contingency limit* is most pronounced in late life when aging is often associated with a loss in resources (e.g., financial capacity), physical and functional capacity (e.g., immune system capacity; inability to perform daily activities), and social supports (e.g., loss of loved ones). Although the largely (objectively) uncontrollable environment would predict that perceived control should decline, Lachman and Weaver’s analysis shows that this is not universally true in all domains. Paradoxically, many older adults continue to report perceived control (influence) in some domains.

Antecedents of Control

Figure 1 provides an organizational heuristic to link our discussion of the next two sections on the ‘Antecedents of Control’ and the ‘Consequences of Control.’ Specifically, we consider the antecedents of the psychological *sense of control* (Path A), allowing for an inclusive approach that extends beyond the classical focus on *influence*. Although an analysis could consider a wide range of antecedents such as demographic characteristics, social resources, or cultural and societal factors,

we instead focus on the cognitive antecedents, drawing on conceptual and theoretical work in three areas: beliefs about *influence*, *explanatory (causal) thinking*, and *control beliefs* (see Figure 1).

Beliefs About Influence

When a response-outcome contingency exists such that a response *influences* an outcome, a psychological sense of control will arise (Path A, Figure 1). Even the *perception* that one can influence the outcome fosters the psychological sense of control. That is, even in the absence of true influence, one can believe he can control outcomes. This is captured in Taylor and Brown’s notion of the *illusion of control* that can exist when influence over an outcome is thought to be possible but, in reality, it is not. In essence, one’s beliefs about influence are not always aligned with reality.

Beliefs about objective influence that are based on response-outcome contingency clearly contribute to a psychological *sense of control*, yet, they are not the sole antecedent. In fact, a singular focus on beliefs about influence could oversimplify the cognitive processes that individuals engage in when attempting to understand cause–effect relationships. This would ignore the possibility that the perceiver engages in an in-depth cognitive analysis of outcomes, suggesting a need to consider individuals’ appraisals of the causes of outcomes.

Explanatory (Causal) Thinking

A consideration of explanatory (causal) thinking could provide further insight into the antecedents of a sense of control (Path A, Figure 1). Weiner’s *Attribution Theory* offers a compelling example of how causal thinking might foster people’s beliefs about influence and, in turn, their psychological sense of control. To the extent that individuals attribute failure outcomes to uncontrollable causes, beliefs about personal influence are likely to be eroded. For example, upon failing an exam, one might engage in causal search, appraising the cause of failure as bad luck. This presumably undermines beliefs about perceived control (influence) over future performance. In contrast, attributing a poor grade to insufficient effort fosters a belief that future grades can be influenced if one exerts more effort. Habitual attribution patterns may even shape beliefs about influence over time and the accompanying sense of control.

Little is known about the developmental sequence of the link between attributions and beliefs about perceived control

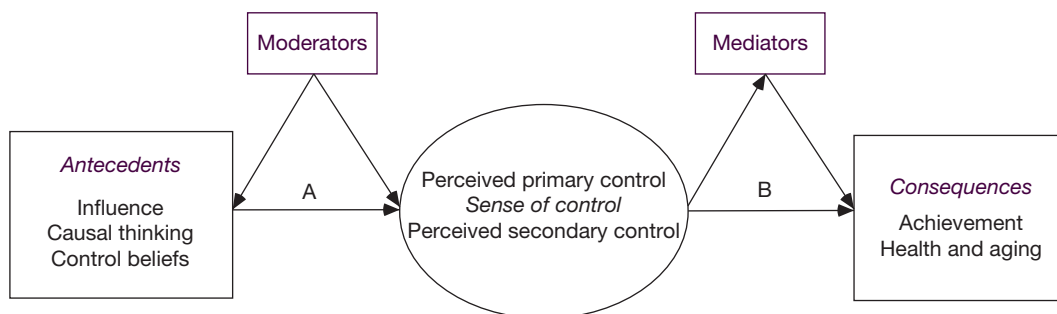

Figure 1 Antecedents and consequences of sense of control.

(influence). So, for example, although we present causal thinking (attributions) as an antecedent, the relationship to perceived control (influence) might indeed be reciprocal. Individual differences in preexisting beliefs about influence might promote the selection of specific causal attributions, and causal attributions might then refine and reshape an individual's subsequent perceptions about whether they can influence outcomes.

Control Beliefs

Rothbaum, Weisz, and Snyder's *two-process model of control* provides additional unique insights into causal beliefs as antecedents to the sense of control (Path A, Figure 1). This model identifies *primary control* beliefs that correspond to the classical view involving beliefs about 'influence' over behaviors/outcome (e.g., beliefs about effort, persistence, R-O contingency, etc.). However, the *two-process model* also identifies complementary *secondary control* beliefs that operate when direct influence cannot be achieved. Secondary control thinking involves cognitive reinterpretation through the adjustment of beliefs, hopes, goals, interpretations, and attributions, presumably allowing an individual to achieve a 'goodness of fit' with the environment and simply 'go with the flow.' Examples of how one reinterprets negative outcomes include, for example, optimistically comparing oneself to worse-off others; positively reappraising a situation to find benefit; and downgrading personal expectations or accepting personal limitations.

What was most provocative about the notion of secondary control is that these beliefs were presumed to bolster the psychological sense of control. This was the first acknowledgment that an overall sense of control could arise, not only from primary control beliefs about influence but from complementary secondary control beliefs that exist even in the absence of beliefs about direct influence. Although Rothbaum et al. did not propose that primary versus secondary control beliefs led to different and unique psychological states, we adopt the labels *perceived (primary) control* and *perceived (secondary) control* to differentiate between them.

To illustrate, an elderly man suffering paralysis following a sudden heart attack might believe he is incapable of exerting direct influence over many daily activities, thereby leading to a lack of *perceived (primary) control*. However, he might believe he is 'better off' than his neighbor who has terminal cancer, fostering his *perceived (secondary) control*. Thus, despite being unable to influence his daily activities and having low perceived (primary) control, he would feel that things are under control and that life is indeed still manageable. In short, if an assessment of his overall sense of control were based only on beliefs about influence over outcomes (and the accompanying perceived primary control), it would ignore the control-enhancing effect of secondary control beliefs that operate in the absence of influence. This would result in an underestimate of his overall psychological sense of control.

Rothbaum et al.'s theory departed from other views that regarded beliefs about influence as the single antecedent of the psychological sense of control. A radical shift in the study and definitions of perceived control accompanied the recognition that the sense of control can exist *both* when influence *is* and *is not* possible. Moreover, this acknowledgment that secondary control beliefs can act as antecedents to the sense of control

facilitated our understanding of how people face challenge. For example, this helps to explain what we refer to as the *control paradox*: even when exposed to a barrage of objectively uncontrollable outcomes in which influence is not possible, older adults paradoxically retain a psychological sense of control.

As implied in Figure 1, the role of these antecedents on the sense of control may be *moderated* by other factors. For example, secondary control beliefs might be more strongly linked to a sense of control for women than men. This linkage might also be stronger in later life, relative to earlier points in the lifespan. Although we know of no studies that have directly examined the potential moderating role of these antecedents on the sense of control, studies have examined the moderating effects of these antecedents (e.g., control beliefs) on more distal outcomes, as suggested in the next section on consequence of control.

Consequences of Control

Figure 1 depicts a model in which beliefs about influence are *antecedents* to the *overall sense of control* (Path A) that, in turn, has *consequences* on outcomes (Path B). Because research on the consequences of gaining, maintaining, and losing control have relied on classic control conceptions (e.g., internal locus of control, mastery, and self-efficacy), we restrict our review of these studies. Overall, the findings that examine the classical conception of perceived control are overwhelmingly consistent with regard to both the *beneficial* consequences of gaining and maintaining control, as well as the *detrimental* consequences of uncontrollability.

These effects have been replicated across many contexts. However, due to space limitations, we present only selected findings in two dominant contexts: *achievement* and *health and aging* (Figure 1, Path B). Embedded in this review are also examples of conditions under which the effects of perceived control (or perceived primary control) are qualified (*moderators*) and of the mechanisms (*mediators*) that may explain the effects.

Consequences for Goal Attainment in an Achievement Context

Generally speaking, the more one believes he/she can influence outcomes (i.e., the stronger the perceived control), the more motivated he/she will be to engage in goal-directed behavior, making goal attainment more likely. This applies to a broad array of human endeavors where goals are pursued, from dating (social settings) to goal performance (athletic and achievement settings). A well-developed body of literature on the consequences of perceived control (influence) for goal attainment exists in settings that consider academic achievement.

This relationship between perceived control and achievement is intuitive to the extent that beliefs about being able to influence outcomes will promote proactive academic behaviors such as studying, attending class, and taking notes that, in turn, positively affect achievement. Indeed, research shows that classical measures of perceived control are correlated with higher grades, greater persistence, and more adaptive learning strategies, including critical thinking and elaboration. The consequences of this notion of perceived control are also indirectly implicated through the application of remedial, control-enhancing interventions.

Attributional retraining (AR) was introduced as a remedial, cognitive treatment intervention designed to restructure individuals' explanations about the causes of negative outcomes by replacing certain uncontrollable attributions that are maladaptive and self-defeating with more controllable, adaptive, attributions. For example, in an academic achievement setting, individuals are encouraged to take personal responsibility for failure by attributing performance to controllable factors such as effort or strategy that involve influence. At the same time, students are discouraged from making uncontrollable attributions for failure, such as low ability or bad luck. Thus, dysfunctional attributions are replaced with attributions that are more adaptive and self-enhancing.

AR research in elementary schools confirms that persistence is enhanced by teaching children to attribute academic outcomes to controllable causes, such as effort rather than to uncontrollable causes, such as ability level. AR interventions are also effective in secondary school students. For example, adolescent girls who were encouraged to attribute achievement to their own level of effort reported greater perceived control, improved self-concept, and better performance in traditionally male-dominated subject areas such as chemistry and physics.

Research by Haynes, Perry, Supnisky and Daniels demonstrates positive AR effects with young adults in competitive achievement settings. Positive effects are shown on cognitions, motivation, behavior, and performance (see review by Haynes). College students who received AR reported stronger perceived control (influence) as assessed by Perry's classic measure of perceived academic control; they engaged in more critical thinking; they were less likely to withdraw from courses; and they outperformed their no-AR counterparts in terms of homework assignments, final grades in Introductory Psychology, first-year grade point averages, and overall cumulative grade point averages. Students who received AR attained cumulative grades that were over a full letter grade higher than students who did not receive AR! The assumption in this research is that by fostering adaptive attributions students can come to believe they have influence over outcomes, ultimately improving their achievement.

Consequences for Health in an Aging Context

Early animal experiments that manipulated objective influence provided insight into the health consequences of the classic notion of perceived control. Negative health-related physical changes were systematically documented in experiments that exposed animals to R-O noncontingency that produce uncontrollable environments. R-O noncontingency resulted in various deficiencies, such as suppression of tumor rejection, increases in tumor growth, gastric ulceration, unhealthy autonomic reactivity, and increased catecholamine levels. Some of these effects were replicated with humans who were exposed to uncontrollable stimuli. They experienced increases in blood pressure and magnitude of skin conductance responses; impairments in cellular components of immune function; and increases in stress-related hormones. Catecholamine levels were elevated and the ability of helper cells to mobilize effective responses was suppressed.

Consistent findings were produced from human studies that involve large-scale, longitudinal field studies employing descriptive survey designs and epidemiological approaches.

The findings fully support the conclusion that classic measures of perceived control (e.g., mastery, self-efficacy) have protective consequences for subsequent health in general as well as for health outcomes in the context of specific diseases, such as cardiovascular disease and arthritis. The positive consequences appear to extend to outcomes in the context of disease etiology, course of illness, management of symptoms, recovery from surgery, and adaptation to medical procedures as well as to psychological well-being. It has been shown, for example, that believing one has control is associated with life satisfaction, morale, self-esteem, psychological adjustment, quality of life, happiness, and positive emotional profiles more generally. Moreover, the debilitating effects of uncontrollability have been documented in terms of negative emotions, ruminative thought, anxiety, depression, distress, boredom, and stress.

Much of the research on the health consequences of perceived control has examined older adults, in part, because health problems are common in later life. It is typical for older adults to simultaneously struggle with multiple chronic health problems such as cancer, arthritis, and diabetes, providing a unique opportunity to assess the effects of perceived control when health is compromised. That perceived control is a critical personal resource in later life underscores the strategic importance of its relevance in gerontology. This is further implied in that perceived control is characterized as a 'cornerstone' of successful aging.

Langer and Rodin conducted one of the pioneering intervention studies that manipulated objective control by encouraging institutionalized seniors to care for a potted plant and to take responsibility (exert influence) for the scheduling of daily events. The study showed that health was better for older adults who received (vs. did not receive) the intervention, presumably due to their enhanced perceived control. Perceived control was even shown to be associated with longevity: those receiving the control-enhancing intervention had a greater likelihood of surviving at 18 months follow up than those who had not received the intervention.

Although Langer and Rodin's conclusions were limited by sample size, Chipperfield's subsequent analyses of a large, representative sample of community-dwelling adults (age 65–111) replicated the link between perceived control and longevity. Compared to those adults who perceived they had influence/control over managing their health care, those who perceived little control had an increased odds of mortality 12 years later. Krause and Shaw also replicated this effect when examining older adults' beliefs about influence over important roles such as spouse, grandparent, and friend. Interestingly, they showed that a lack of control predicted mortality, but *only* with regard to perceived control over the role deemed as most important by the participant. This finding implies that the consequences of perceived control on health-related outcomes are qualified or *moderated* by other factors, as depicted in [Figure 1](#).

Two conclusions have emerged from studies that have examined what *moderates* the consequences of control on outcomes. First, the findings from a set of studies by Chipperfield and colleagues indicate that the salutary effects of believing one can influence health are restricted to those who are most compromised. Although perceived inability to manage health care (perceived uncontrollability) predicted 12-year mortality,

this was *only* true among individuals whose health was initially comprised. In another study of older adults with arthritis, being lower on internal locus of control was associated with more frequent hospitalizations, but *only* for those adults who were highly restricted by their arthritis. A final study suggested that the relationship between perceived control and health was limited *only* to those with functional impairment. Moreover, this relationship was shown to be further moderated by age: it appeared *only* among the very oldest individuals. Taken together then, these findings suggest that the consequences of controllability are most evident when this protective resource is most needed.

Second, a few studies lead to an opposing conclusion: that there may be conditions under which perceived control is detrimental. This might happen, for example, if perceived control is enhanced but subsequently eroded, as suggested in an early study by Schulz and colleagues who allowed participants influence over scheduling social visits and then withdrew this. Potential detrimental effects might also arise when an 'exaggerated' perception of control (influence) is at odds with reality. In such a case, the unrealistic perception of control fosters proactive approaches that doom one to fail. That exaggerated perceptions of control can lead to repeated failure might explain why increasing levels of perceived control among adults with severe pain was found to be associated with deficits in daily mood. Perhaps it is dysfunctional to hold false beliefs that one can influence pain when this is not possible.

Although a handful of studies have documented conditions under which perceived control might be detrimental to health, it is overwhelmingly shown to predict a broad range of positive health-related outcomes in older adults, from better global self-reported health and fewer chronic conditions to objective measures of fewer physician visits and hospitalizations. Thus, the robust finding and the clear conclusion from this body of work is that perceived control is beneficial for health. The financial implications of this relationship are illustrated by Chipperfield's research on older adults with arthritis-related restrictions. Those adults with low perceived control were hospitalized more frequently than their high-control counterparts, and the estimated costs for their hospital stays were *double*!

In addition to examining moderators of perceived control, researchers have asked what *mechanisms* might explain the consistent effect of these classic measures of perceived control on the quality and quantity of life. In technical terms, this is a question of what *mediates* the relationship between perceived control and health outcomes (Figure 1). As previously described, physiological factors such as hormones and immune functioning have been proposed as potential mechanisms to explain why perceived (primary) control so consistently predicts health, well-being, and survival. Other possible mediators are emotions, for example, perceiving little control can lead to emotions like hopelessness and boredom.

Still other potential mediators are motivational/behavioral factors, such as health behaviors. Animal studies showed that inescapable shock in animals produced sickness behaviors including decreased intake of food/water and reduced physical activity. The underlying premise in theories such as the *Health Belief Model* is that perceived uncontrollability (perceived lack of influence) produces behavioral apathy and/or that perceived controllability promotes proactive behaviors that,

in turn, foster health. The viability of this premise is illustrated by findings in which individuals who believe they are responsible for their own health outcomes are more likely than their counterparts to seek out health information and engage in adaptive health behaviors (regular check-ups, taking prescribed medications, etc.).

Complexities, Controversies, and Challenges

The research on perceived control has been complicated by definitional and operational confusion and theoretical controversies. Opposing theoretical views of the meaning, role, and definitions of secondary control have added further complexity. The field will have much to gain if researchers embrace a challenge to resolve some of labeling confusion and remain receptive to the merits of various theoretical positions.

Conceptual and Operational Challenges in Studying Perceived Control

As the field evolved, confusion arose due to the linguistic tendency to use the words *control* and *influence* interchangeably. Some researchers have continued to use the perceived control label interchangeably with beliefs about influence; some use it to refer to the psychological state that is determined by beliefs about influence; and others use it in its the broadest way to describe a psychological state that can be achieved both when influence *is* and *is not* possible. This signals the need for researchers to clearly articulate their meaning of the label *perceived control*.

Instead, researchers could consider the potential value of adopting a separate label to depict the overall psychological state of control. *Sense of control* seems a suitable descriptor in that it avoids the implication that the psychological state is simply about influence. However, because the sense of control label has also been used interchangeably with perceived control, researchers would again need to clearly articulate their conceptual meaning of the label.

Of course, many other alternative labels could be introduced. Any attempts to do so, however, should seek a label that is broad enough in scope to depict both primary and secondary sources from which the psychological state of control originates. The approach in this chapter provides an example of the use of separate labels to capture the psychological state that can arise from proactive beliefs and behaviors involving influence (*perceived primary control*) and from the complementary beliefs and behaviors that do not involve influence (*perceived secondary control*).

These conceptual and labeling complexities are accompanied by measurement challenges. To the extent that there is an overall psychological state of control that we call sense of control, how can it be assessed? One possibility is to simply ask about the degree to which individuals feel 'in control' or 'out of control.' This would potentially capture a sense of control that is derived both when one believes he/she *can* and *cannot* influence outcomes. New operational definitions of this broad state of control should avoid measures that capture only perceived primary control since this would underestimate the role of secondary control beliefs that operate when influence is not possible.

Conceptual and Theoretical Issues in Studying Secondary Control

The secondary control concept, as originally proposed by the *two-process model of control*, has more recently been featured in the *lifespan theory of control (LTC)*. By conceiving secondary control in terms of strategies, the LTC has bought about a shift in emphasis to control *striving*. Researchers from this perspective typically see no need to study a psychological state of control because the function of secondary control striving is *not* to facilitate a psychological sense of control, but rather to protect self-esteem and to promote the motivation for primary control striving.

The introduction of the LTC has resulted in perceived control losing its prominence in control theory. The field has since become divided into proponents of the *two-process model of control* or the *LTC*. However, Morling and Evered recently provide an analysis that may undo the theoretical schism. They contrast *control-focused secondary control* that promotes the potential for control striving and is consistent with Heckhausen and Schulz's theory with *fit-focused secondary control* that encompasses 'adjustment' and 'acceptance' and is consistent with Rothbaum et al.'s theory that emphasizes how individuals psychologically 'fit into' an objectively uncontrollable environment.

Concluding Comments

Schulz and colleagues point to the positive impact of perceived control; they describe it as representing 'one of the most impressive success stories in the social sciences,' having had 'positive impacts on large numbers of individuals of all ages.' Although the consequences of perceived control have been demonstrated for outcomes in many areas, we limited our analysis to the areas of academic achievement and health and aging. Clearly, the promotion of perceived control (and the associated sense of control) has implications for the intellectual capital of our youth and the health of seniors, both of which society cherishes. This may even have implications for the future financial strains on the health care system that will accompany the demographic shifts in our aging population.

Western cultures as well as others value the persistence and effort that is embodied in mastering our environment. The *little steam engine's* effort and determination to reach the summit was driven by the belief in his (or her) capacity to influence the outcome. Although this profound metaphor for the American dream accurately captures the value we place on primary control striving, it can overshadow the adaptive value of secondary control.

Just as the value of primary control is captured in everyday folk beliefs (e.g., 'the early bird gets the worm'), so too is the value of secondary control (e.g., 'every cloud has a silver

lining'). Likewise, the message in Niebuhr's *Serenity Prayer* to develop 'the courage to change the things I can,' is counterbalanced with the idea of striving for the 'serenity to accept the things I cannot change.' The combined message is that it is not adaptive to *always* and *under all conditions* strive to control (influence) every outcome. Rather, it appears adaptive to know how to accept uncontrollable outcomes and reinterpret them to soften the blow. In other words, despite an ongoing scholarly debate over definitions of secondary control, it is generally agreed that there is wisdom in knowing when to exert primary control and when to shift to secondary control.

Glossary

Constructivism A theoretical approach that posits that individuals construct reality and meaning from prior experiences.

Core principle An innate, genetic, endowment that guides humans in reaching their understanding of new objects or events.

Differentiation The active search for stable features of the environment that exist in a constantly changing world.

Habituation The gradual waning of a response through repetitive stimulation. Dishabituation is a return to the original level of attentive responding.

Maturation The unfolding of biological and genetic influences that impact an individual's development relatively free of experience.

Module Specialized information processing systems that share many characteristics, such as speed, autonomy, and output of perceptual categorical information that can be accessed by consciousness.

Phoneme Individual sounds within a particular language used to form words.

Selective attention The focusing of one's mental efforts toward one aspect of the environment while simultaneously ignoring others.

Recently, an experiment was reported by Yale and Duke University developmental psychologists, simple in design yet profound in its implications. Researchers Cheries, Mitroff, Wynn, and Scholl wanted to know if infant perception was guided by a theoretical principle of object persistence called cohesion, which is that an object must maintain a single bounded contour over time. Two groups of 10–12-month-old infants participated. Infants began the test trial of the experiment on the floor, held by their mothers. Each infant in one group watched an experimenter split a half of a large graham cracker into two pieces, placing them with separate motions into one container, and then place a single small graham cracker into another container. The contents of the containers were not visible to the infant. Another group of infants saw the same event except that the larger cracker was presplit into two. Each infant was verbally encouraged to crawl to the container of their choice to obtain his/her crackers. Twenty out of 26 infants in the No-Split condition, a significant majority, chose the container with the larger quantity of crackers while only 12 of 26 infants in the Split condition did so. The researchers concluded that the cohesion principle operates as a constraint on perceptual processing, powerfully affecting the overt behavior of infants less than a year old. In contrast to object representations encoded during uninterrupted perceptual experiences, object representations encoded during a disrupted act of perceptual knowledge acquisition do not seem to persist over time in an intact form. We will use this experiment to frame and introduce enduring questions and controversies about the nature of human perceptual development.

Constructivist and Ecological Views of Perceptual Knowledge Development

Constructivist Views

With utter ease, the human mind apprehends a version of reality – people, crackers, containers, a stable crawling surface,

and encouraging words – by first registering energy in several separate sense modalities. Energy is transformed many times by the neural structures of the brain into objects and events, forming mental representations and sometimes propelling us to act, especially if there is food to act upon. The constructivist position explains perceptual development as learning to make appropriate inferences about sensory impressions by drawing on previously constructed memories gained through similar experiences. This view of how infants accrue knowledge is rooted in the philosophical tradition of seventeenth to nineteenth century British empiricists whose work formed the foundation of modern information processing psychology. One prominent constructivist was Jean Piaget, who argued that infants' increasingly more accurate perception of objects in a spatial frame of reference was achieved by learning associations between visual, auditory, touch, and muscular sensations, constructing knowledge that he termed 'sensorimotor.' Most current information processing accounts of perception and perceptual development are constructivist due to their emphasis on defining levels of processing and the interactions between them. As an example, Les Cohen and Cara Cashion recently proposed that perceptual development in one domain (event causality) progresses from lower (parts) to higher (holistic) levels, and that infants are biased to begin a single act of event processing at the highest developmental level attained, except when information overload occurs.

Ecological Views

Two crucial philosophical arguments made by the early constructivists, the ambiguity argument and the capability argument, were not seen as valid by the originators of the ecological view of perception, James and Eleanor Gibson. The Gibsons' primary assertion is that perception is 'direct,' meaning, does not require inference. Human visual and auditory systems do not deliver single, static representations to the mind that must be disambiguated through further higher-order

inferential analysis. Instead, because humans move while perceiving and because the eyes and ears gather information from two different vantage points, the transformations over time of the optic and acoustic array are highly specific to arrangements of information in scenes and events. Some proponents of the ecological view claim that certain assumptions, or constraints, have evolved to assist humans in their interpretation of potentially ambiguous events. James Gibson showed that the perception of 3D form could result from neural mechanisms that have evolved specifically for the task of computing optical transformation information using geometry, information that changes over time when either the observer or object is in motion. The principle of cohesion identified in the cracker-retrieval experiment is another example of a perceptual processing constraint that is either inborn or matures within the first year and assists us throughout life.

Perceptual Processing Research in Infancy

Neural and Sensory Competencies

The brain

Considering the fact that more than 50% of the cerebral cortex is devoted to sensory and perceptual processing, the importance of perception to human function and evolution cannot be overstated. Prenatal development is the most critical time to ensure optimal sensory functioning. At 18 weeks gestation, virtually all cortical neurons have been formed and have migrated to their genetically preprogrammed locations. Unlike some mammals, human infants are born with well-functioning sensorineural systems. Differentiation and synapse formation, the process of forming tree-like branches to other neurons, is mostly completed during a period of 'blooming' in 2–6-month-old infants, forming approximately double the number of adult neuronal connections. Between the ages of 1 and 10 years unstimulated dendritic connections are 'pruned,' or eliminated; although, new connections are formed throughout life. Early in infancy myelin sheaths rapidly form around neuronal axons, assisting sensory responses and the coordination of activities across brain regions by vastly increasing the speed of neural impulse conduction. Changes in synaptic efficiency are important in understanding the slow rate of maturation of auditory cortex. The relatively slow neural responses through the brainstem in the auditory pathways affect young infants' absolute thresholds to detect sounds in the 4000–8000 Hz range. Two neuronal systems serve visual processing, cortical pathways, and more primitive subcortical pathways. During the first 2 months of life, infant visual behavior is thought to be controlled primarily by the subcortical pathways.

Visual sensory system

Some aspects of newborn visual sensory processing are fairly well-developed in the newborn infant, such as peripheral acuity. The ability to make oculomotor adjustments is also fairly well developed, allowing the infant to use distance information perceptually. Several aspects of the ocular system are extraordinarily undeveloped in the newborn. For example, cone receptors are spaced 4 times further apart in the neonate fovea, allowing them to catch only 2% of the light. In addition, two types of cones do not mature until 2 months of age and

a third type until 4 months. This affects visual perception because photoreceptors in the retina make it possible for us to see color and to discern patterns and changes in surfaces and orientations of objects. At around 20/400 Snellen units, newborn visual acuity is far worse than adults, but improves to adult levels by the age of 8 months. The ability to detect light intensity variations, or contrast sensitivity, is also not impressive in young infants, but is sufficient to detect coarse boundaries between common objects and spatial layouts within close proximity. Finally, the ability to detect direction of movement and velocity of object motion emerges by the infant's third month of life.

Auditory sensory system

The human fetus responds to sounds by 28 weeks of prenatal development. At birth, the inner ear is mature, but sound conduction through the external and middle ear is inefficient. The ability of newborn infants to detect low frequencies is mature at birth, however, for higher frequencies maturity is not reached until the age of 6 months. At this time, infants can discriminate changes in frequency fairly well at higher frequencies, but frequency discrimination at low frequencies is poorer, with the greatest rate of improvement occurring in early childhood. Adult performance levels in many facets of auditory sensory processing are not reached until late childhood. These limitations may be implicitly understood by adult speakers who may speak more slowly and slightly louder to a young child compared to an adult.

Chemical and vestibular senses

Consistent with a proximal-to-distal developmental trend, infants' tactile and vestibular sensory systems develop somewhat in advance of their more remote-sensing visual and auditory systems. The constellation of senses in the somatosensory system, including receptors located in the skin for touch, pain, and temperature, completes development by the twenty-fourth week of gestation. The full-term newborn infant reacts to common invasive procedures, such as a heel stick for blood sampling, with the same expression recognized as painful in adults. Newborns, although they cannot sense saltiness, are able to discriminate sweet, sour, and bitter tastes. The preference for sweet tastes, over the other taste sensations, is evidenced even prior to birth. Rounding out the newborn infant's toolbox of sensory abilities is a well-developed sense of smell.

Visual Perception

Object perception

Neurophysiological research in the 1960s, and subsequent behavioral research, revealed that forms and patterns are perceived using several layers of analysis, beginning with parallel processing of an object's features along many dimensions such as motion, edge orientation, and luminance. While spatial information about the features is preserved at this point in perceptual processing, objects are not recognized until the features are integrated with attention. Newborns are likely equipped for parallel feature analysis and detection, and they have some 'tools' to organize features for object perception, however, some tools take many months to develop as infants gain more experience in the world.

Recent research demonstrates that young infants can use some, but not all, Gestalt principles of perception to organize visual patterns, so that they know which edges and contours form different objects. In one experiment, researchers Paul Quinn, Ramesh Bhatt, and colleagues used what is called the familiarization/novelty-preference procedure to test 3–4-month-old and 6–7-month-old infants' ability to organize a visual pattern with the principle of form similarity. In the first, or familiarization, part of the experiment, infants were presented with stimuli from the top or the bottom group in **Figure 1** for six 15-s periods. Immediately afterward, infants were shown test stimuli, consisting of both novel and familiar stimuli displayed on two screens, and the percentage of time they looked to the novel organization was calculated. Only the older infants looked reliably longer at the novel organization, which indicates that they had used the principle of form similarity to organize the pattern in the familiarization phase. Previous research had found that even newborn infants can use a different Gestalt grouping principle, lightness similarity, to organize visual patterns.

When an object is seen from one angle, and the object is rotated in the third dimension, the image projected to the retina changes. Does a newborn baby perceive the real shape of the object to have changed? Research shows that newborn infants use a perceptual organization tool called shape constancy, allowing them to perceive the object's real shape despite changes in orientation. Size constancy, the ability to perceive that an object is the same size despite changes in distance, is also present in the first days of life. A newborn participant in a size constancy experiment is shown in **Figure 2**.

Researchers also speculate that another important perceptual organizational tool is innate, the perception of unity of object parts when the some of the parts are occluded and other parts are visibly in motion. Although, full attainment of perceptual unity from common motion depends on the rapidly maturing visual sensory abilities of detecting velocity and direction of motion of object parts. This 'edge-insensitive' tool would assist an infant to correctly perceive, for example, that the top and bottom ends of a rake moving behind a narrow tree belong to the same object. In contrast, 'edge-sensitive' perceptual processing emerges much later, after

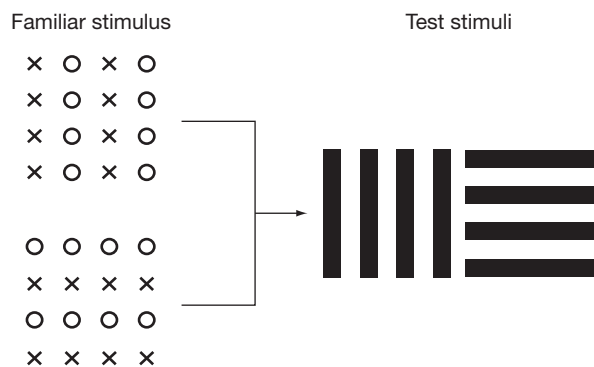

Figure 1 Example stimuli used in testing infants' ability to group according to the similarity principle. Reproduced from Quinn PC, Bhatt RS, Brush D, Grimes A, and Sharpnack H (2002) Development of form similarity as a Gestalt Grouping Principle in infancy. *Psychological Science* 13: 320–328, with permission from Blackwell Publishing.

6 months of development. If the partially occluded objects do not move behind the occluder, the information available to the infant is insufficient for determining the form of an object – if the rake does not move and it is the 5-month-old infant's first time ever seeing this object, she/he might infer that there are two objects behind the tree instead of one object with connected parts.

Space perception

Infants crawling over to their chosen container to reach the crackers were performing complex perceptual and motor activities. Prior to the onset of crawling, infants are processing kinematic, or motion-carried information about objects and paths in a spatial layout based primarily upon information gained through object motion or head movements from a stationery position. Evidence is consistent with the claim that very young infants are capable of interpreting motion cues of objects, however, they may not use as many of these cues during perceptual processing as an adult would. Once they can self-locomote, the nature of spatial perception changes considerably, because perceptual processing must include both object-motion and observer-motion cues in order to be accurate.

When looking while reaching inside the container to retrieve the crackers, a 10-month-old infant uses two types of visual depth perception cues, stereoscopic and pictorial. Stereoscopic perception is the ability to mentally compute the angular difference between two pieces of information registered by two spatially-separated retinas from eyes aimed at the same point on an object. This perceptual milestone is rapidly and fully achieved at the age of 4 months, probably due to maturation, specifically, the development of cell assemblies in layer 4 of visual cortex. Infants' ability to perceive most pictorial cues to depth (familiar size, interposition, texture gradients, linear perspective) arises at the same time, at age 6–7 months. The simultaneous appearance of a group of pictorial depth perception abilities also occurs in macaque monkeys, leading some investigators to conclude that these perceptual abilities have ancient phylogenetic roots. Yet, a structuralist perspective on pictorial depth perception is also implicated in explaining perceptual achievements by learning,

Figure 2 Display of example research paradigm used in assessing infants' ability to process objects according to the size constancy principle. for example, to compute the depth between familiarly-sized people and objects on a television screen.

Face perception

One aspect of infant perceptual processing has inspired more curiosity and controversy than any other – face processing. Early research found that newborn infants visually track a moving face pattern farther than a pattern with scrambled face features, they show greater sucking responses and visual preferences for their mothers' faces over strangers' faces, and surprisingly, will look longer at attractive faces than unattractive faces (as judged by adults) within 6 days of birth. On what basis are brand new babies making facial discriminations? In the 1990s there was wide consensus that the newborn infant's preference to look toward human faces was guided by an innately-given module for processing structural facial information, enabling rather sophisticated face processing during the very first exposures to human caregivers. However, more recent research has been able to clarify the nature of this early mechanism, which seems to be subcortical, and therefore, cannot be construed as an innate cortical processing module. Moreover, as with everything else seen in the first 2 months of life, face perception is also affected by infants' developing visual acuity and contrast sensitivity abilities.

Face processing improves very rapidly in the first months of life, when infants are gaining exposure to particular types of faces within their environment. Several interesting findings have recently emerged related to early visual face processing experience. For example, patients with congenital cataracts whose visual input to the right hemisphere was restricted during the first months had more difficulty with face processing once the cataracts were removed later in life than did patients with input restriction to the left hemisphere, showing hemispheric asymmetry in face processing that begins with infants' earliest experiences. Controversy exists as to the specific localization of face processing in the brain of infants older than 3 months. Proposals are that it is located within the right hemisphere, the fusiform gyrus, or alternatively, within primary visual cortex.

Infants generally see a lot of people in their first few months of life, including themselves. Beginning around 2 months, parents report that they place their infants in front of mirrors, allowing their infants the opportunity to encode a representation of themselves. Indeed, research has shown that even 3-month-old infants can distinguish their own face from the face of another infant. Gender biases in face processing have also been found in 3-month-old infants, with infants preferring to look at female faces when those faces appear alongside male faces – however, the opposite effect is obtained in infants whose primary caregiver is a male. The 'other race effect,' which is the ability to discriminate and recognize faces from one's own race, but not another, has been observed even in young infants. Yet, if infants are raised in one racial environment and adopted into another during early childhood, they find it easier to discriminate faces from their adoptive culture when they are adults. This research finding exemplifies the malleability of the perceptual processing system.

Early experience nudges the perceptual system to begin a path of development that will eventually include the attainment of expert levels of human face processing. At an early step

along this path, 6-month-olds, 9-month-olds, and adults display an equal precocity at discriminating two human faces; however, 6-month-old infants are actually better than adults at discriminating two monkey faces. This remarkable early ability that is apparent only in 6-month-old infants but lost within 3 months, is the very same developmental pattern seen in speech perception research on phoneme discrimination. And yet, if infants view a great number of monkey faces between 6 and 9 months, they retain their ability to discriminate faces from the specific species they viewed. Parallel research findings on face and nonnative language exposure during this early 'sensitive' period leads to the hypothesis these vastly different perceptual systems share common mechanisms that tune us to frequently occurring categories of perceptual stimuli presented within our unique environments.

An adult can accomplish far more with their face processing system than can an infant, however. One necessary, but not sufficient, marker of expertise in face processing is argued to be the ability to encode faces on the basis of second-order relational properties. Faces have a common configuration that includes each eye, the nose, and the mouth, but individual faces vary in terms of the specific spatial relationships between features. Research conducted by Laura Thompson investigated whether or not 7–8-month-old infants attend to these second-order relational properties of female faces. Infants were shown black-and-white photographs such as those appearing in Figure 3. On every trial, a nonmodified face was shown on one computer screen, and a modified face was shown on the other. Modified faces were created using software that spliced

Figure 3 Photographs of females used as stimuli in the experiment. The two photos on the left are nonmodified. The face on the upper right was shortened, and the face on the lower right was lengthened. Reproduced from Thompson LA, Madrid V, Westbrook S, and Johnston V (2001) Infants attend to second-order relational properties of faces. *Psychonomic Bulletin & Review* 8: 769–777, with permission from Psychonomic Society.

out or added very small horizontal segments to the lower regions of the face, resulting in faces that were structurally different from the original. Infants looked reliably longer at the nonmodified faces. The results show that infants form a prototype of a face type (young adult female) in memory by attending to the spatial relationships among facial features, and that they compare new instances of female face to their stored prototype.

Of course, one of the reasons infants find human faces so fascinating to look at is because they convey facial emotional expressions which are instrumental to human communication and language learning. Research reveals that 5–7-month-old infants are able to discriminate the basic human emotional expressions of fear, anger, surprise, and happiness. More impressive is their ability to categorize these expressions, so that when one person expresses a particular emotion, the same expression on a different person's face is seen by the infant as belonging to the same emotional category. One cautionary note must be made, however, before assuming that faces always captivate infants' attention. Recent findings reveal that 5–7-month-old infants, when viewing persons engaged in repetitive activities such as brushing their teeth or hair, preferentially attend to their actions, and not to their faces.

Auditory Perception

Language perception

In order to respond to the verbal encouragement of crawling to one of the two containers of crackers, infants must perceive these auditory sounds as components of language. In addition to processing information commonly associated with all types of sound such as frequency, intensity, and the temporal pace of the frequency and intensity, language also needs to be parsed out from background noise, broken down into a series of varying linguistic components, and eventually processed as meaningful instruction. Whereas some aspects of early language perception might reside in innate tendencies seen in neonates, such as the preference for animal vocalizations over artificial sounds, later tendencies, such as the preference of human vocalizations over rhesus-monkey vocalizations seen at 3-months old, may originate from experience.

One of the most basic and researched components of language perception involves the infants' ability to discriminate between fundamental sounds, phonemes, present in the infant's native language. Although infants are initially sensitive to all phonemes used in all languages, this sensitivity changes as the infant gets older. Researchers including Janet Werker and colleagues, through a series of studies over the past few decades, have mapped out the seemingly counterintuitive development of phoneme sensitivity. While infants 4–6 months of age are able to discriminate between pairs of distinct phonemes in both their native language and between pairs of distinct phonemes not in their native language, the nonnative discrimination ability drops off rapidly from ages 10 to 12 months of age. In comparison, adults have difficulty identifying sounds not common in their native language, and only with significant training can they pick up this ability.

This developmental trend in phoneme detection may seem paradoxical because as the infant nears closer to the age of language production, the sensitivity to some phonemes tends

to drop. However, while this sensitivity to nonnative language sounds decreases, sensitivity to native language sounds continues to increase. At 14 months of age, infants begin to discriminate between similar sounding familiar words, such as *ball* and *doll*, when associated with a picture of each as well as with similar sounding unfamiliar words, such as *bin* and *din* when associated with a picture of an object supposedly representative of the word. The refinement of this ability to separate similar sounds into categorical classes suggests that infant perception of language helps lay the groundwork for subsequent word learning and language production.

Music perception

Music perception parallels language perception in many ways, such as needing to follow a set of identifiable rules to convey auditory information. Often the identifiable distinction between the two is that music does not include the semantic meanings associated with the sound as language does. However, this distinction tends to become blurred when considering motherese, or child-directed speech, which often includes fluctuations in pitch and an expanded range as well as a rhythmic regularity. Sandra Trehub and colleagues recorded mothers' speech to their child on two separate occasions and found that mothers tended to use and repeat very distinct tunes (i.e., particular interval sequences) in their communication that were unique to their individual dyad. Much like infant language perception, Trehub also found that at the age of 6 months, infant's sensitivity to a foreign musical rhythm was greater than 1-year-old infants. Furthermore, the 1-year-old infants became somewhat more sensitive to the foreign rhythm after exposure, while exposure did not affect the adults participants' perception ability.

Multimodal and Amodal Perception

Thus far in the short history of the research on perceptual development, investigators have focused on understanding the development of abilities involving a single sense modality. Yet, most events and the people in them are perceived using more than one sense modality, in other words, humans use multimodal information in everyday perception. A human speaker conveys the intended meaning of an utterance along multiple modalities, making available to infants all kinds of information including auditory speech, the emotional tone of speech, facial expressions of emotion, visible lip movements, gestures, and more – but what can infants do with all of this information? A lot.

To start with, infants exhibit the ability for matching sensory information across modalities, seeming to perceive that the properties specified to separate sensory systems nevertheless belong to the same object or event. For example, at 1 month, infants will choose to gaze at the nubby pacifier on the screen in front of them instead of the smooth one if they previously sucked on the nubby one. They can detect the synchrony of voice and mouth movements (visible speech) by the age of 2 months. At 4 months of age, infants are able to match vowel sounds and visible speech on the basis of the spectral information available in auditory sensory input. By 6 months, infants can match faces and voices on the basis of emotional expression, gender, and age of speaker. Intersensory matches of faces and voices are even

made in early infancy for emotional expressions of other species, including macaque, monkeys, and dogs, which may cause one to speculate, 'What will Mother Nature think of next?'

With regard to multimodal perceptual processing, there truly is a lot more information than meets the eyes and ears. James Gibson argued that the sensory modalities were in fact part of one large perceptual system, whose separate components were working together to pick up information that the sensory modalities had in common. Amodal information is that which overlaps across modalities such as timing, intensity, rate, space. For example, watching and listening while someone beats on a drum, the infant encodes overlapping visual and acoustic information that specifies the rate and rhythm of the drumbeats. In addition to human infant studies, many animal studies have shown that temporal amodal information such as synchrony, rhythm, and tempo is attended to and veridically processed.

The common methodological paradigm for testing infant amodal perceptual processing is the habituation paradigm. Infants sit in front of a computer monitor, and watch and listen to the stimuli presented on the screen. An experimenter watches the baby from directly behind the monitor, measuring time spent looking at the screen before turning away. Infants are presented with the same stimulation on every trial, until their looking time reaches a criterion, usually 50% of the amount of initial looking time. Then, the stimulation is changed so that a new aspect to the multimodal event occurs. After the change, if the infant's looking time increases significantly above the habituated level, they are said to have become 'dishabituated,' and researchers can draw conclusions about the type of information infants were able to perceive as they were becoming habituated to the stimulation. For example, 3-month-old infants can discriminate a change in the tempo of a toy hammer tapping when both video and sound convey the tempo. However, when infants are habituated to the tapping sound without visual cues, or the sight of the hammer tapping without sound, they do not dishabituate when the tempo is changed. As infants get older, they have the capability of encoding amodal properties of events with just one modality of information. With just the sound of the crackers hitting the bottom of the container, the 10–12-month-old infants in the 'No-Split' condition had enough perceptual information to count the crackers.

Perceptual Development Beyond Infancy

Although understandably the majority of research in child perception focuses on identifying abilities in infants under the age of 15 months, findings in children above 15 months of age can also yield important contributions.

Holistic-to-Analytic Shift

Prior to the tidal wave of infancy research, in the 1970s and 1980s, researchers began to address the question, how does perception develop in childhood? Comparisons were made between young and older children and adults, on their responses to the question, 'Which two go together best?' in various perceptual classification tasks. If, for example, a small

grey square, a slightly larger and slightly greyer square, and a large grey square are presented, a majority of 4-year-olds' responses would be that the two smallish, grayish squares belong together; however, a majority of 10-year-olds' responses would be that the small and large squares that were exactly the same color belonged together, and the same thing would happen when exact values on size are presented. The young child's response pattern with these stimuli was notably the same as adult responses with compounds varying on the perceptually integral dimensions of saturation and brightness, implying that the two dimensions form a single perceptual whole. Thus, the original conclusion was drawn that young children's perceptions of adult-separable dimensions are holistic, or 'integral-like,' and that perception shifted to an analytic mode later in childhood. However, in 1994, Laura Thompson reported experiments in which models of different strategies were compared to individual children's response patterns, and, while the holistic-to-analytic shift hypothesis was found to characterize group-averaged data across development, it was not found to be true of individual modes of responding. Consequently, she argued that the holistic-to-analytic shift claim was false.

If a 4-year-old child was encouraged to crawl in the cracker munch experiment, she might just furrow her brow, point to the container with more crackers, and ask you to please bring it over. Underlying the plausibility of this scenario is the notion that perceptual development is fairly complete by 4 years; so, without a fundamental shift in children's way of perceptually categorizing stimuli, is there any development in childhood significant enough to mention? Many researchers would say yes. For instance, throughout childhood, children develop a better ability to discriminate featural differences along dimensions that are perceptually separable. The differential-sensitivity account offered by Greg Cook and Richard Odom posits that each child differs with respect to how stimulus dimensions, such as color, shape, size, are organized in terms of their salience. For one child, color might be very salient but to another child, similarities and differences among objects' colors are initially not noticed, rather, their shapes might be. Increased perceptual experience facilitates detection of relations between less salient dimensions, raising them up in the salience hierarchy. Research by Thompson and others supports the differential-sensitivity account, and extends it by showing that perceptually salient dimensions are processed more accurately and more quickly than less salient dimensions at an early level of stimulus processing.

Recent Findings

In infancy, the relationship between motor development and visual perception develops as the infant becomes increasingly mobile through crawling and walking. The infant needs to accurately perceive the surrounding environment in order to identify which motor skills to put into use. For example, an infant in the beginning stages of learning to walk who sees a desired toy on the other side of the living room may choose to crawl to the toy rather than walk, as crawling, at the time, may still be a quicker and more efficient mode of travel to the toy. Jodie Plumert and colleagues at the University of Iowa have

been assessing perceptual-motor development issues such as this in older children (ages 10 and 12 years) and adults. However, unlike our example of a child moving toward a static object, these researchers evaluated how children and adults would move in response to other moving objects in their surroundings. Namely, participants in their study made decisions as to when to cross intersections on a bicycle in a simulated environment. In this simulated bicycle environment, simulated cars would pass on the road in front of the participants at different rates of speed with different spacing gaps between the vehicles. The children, especially the 10-year-olds, compared to the adults, often ended up with less time to spare. This difference is attributable to their mismatch of how they perceive their abilities relative to the environment.

Questions and Controversies Concerning Perceptual Knowledge Development

What Perceptual and Attentional Processes Acquire and Maintain Perceptual Knowledge?

Modular systems

In 1983, philosopher Jerry Fodor introduced a provocative theory about the nature of the mind. His main premise was that human mental architecture consisted of a three-layer functional system, beginning with a set of sensory transducers. The next layer is a set of computational-input systems, or modules, whose outputs are fed to computationally autonomous central resources for further processing. The domain-specific modules perform their computations only on specific types of input such as phonetic codes, and their operations are not under volitional control. Processing in the modules is extremely fast and ‘informationally encapsulated,’ because processing must be completed within a single module before incorporating the outputs from other modules. The modules have ‘shallow’ outputs to the central system, which are at the level of basic perceptual categories. Further, the modules are associated with fixed neural architecture, and exhibit specific breakdown patterns that are unlikely to influence the operations of the other modules. Finally, the pace and sequencing of computations performed by modules suggests that their ontogenetic development is innately specified. Fodor suggested plausible candidates for modular systems, including a spoken language grammar parser and mechanisms for detecting melodic and rhythmic structure in audition, and in vision, shape analysis, color perception, 3D spatial analysis, visual-motion guidance, and face recognition. The notion of a modular mental architecture is one that has received much empirical support in the field of developmental science. Criticisms of this proposal include the relative lack of specificity of higher-level cognitive activities, and the nativist assumptions, promoting researchers to hypothesize that at least some modular operations are acquired through learning.

Intersensory redundancy hypothesis

In 2000, Lorraine Bahrack and Robert Lickliter proposed a developmental account of attention and perceptual processing in infancy. They argued that the foundation for what is perceived and learned is selective attention. Consequently,

in order to achieve the richest understanding of perceptual development, developmental research should be focused on understanding what guides the development of selective attention. Their account, termed the intersensory redundancy hypothesis, explains how temporally synchronous and spatially coordinated information, presented across separate modalities, provides redundant intersensory information which promotes the detection of amodal information in multimodal events. During early infancy, the amodal stimulus properties that are detected are more salient and selectively attended to, and these properties are processed sooner than are the unimodal stimulus properties. When only unimodal information is available for processing, selective attention is used to encode modality-specific properties, such as the color of the drumstick beating the drum. When there is no competition from intersensory redundancy of amodal properties of events, the unimodal properties are salient to infants, and modality-specific properties are likely to be explored rather than amodal properties. With perceptual development, infants become more facile in the ability to use selective attention in detecting amodal properties in both unimodal and multimodal situations.

Two functionally dissociable perceptual systems

The image of a baby crawling over to a container illustrates a fundamental reality about the development of perception, namely, that it is inextricably linked to the development of action. In 1979, James Gibson wrote, “We must perceive in order to move, but we must also move in order to perceive” (p. 223). But how should we construe the nature of the interdependence between a perceptual system for seeing ‘what’ crackers are inside a container and a perceptual system for telling us ‘how’ to get over to the container? Bennett Bertenthal argues that there are two functionally dissociable perceptual systems, one for perceptual control and the other for object recognition. These systems are very different from each other in terms of their processes, but necessarily interlinked. Object recognition uses processes that connect presently encoded information to previously stored representations, while the action system is directed toward monitoring the present and looking forward into the near future. Object perception involves an allocentric coordinate system while perceptual action involves an egocentric reference system. Object representations are stored in modality-specific form, while the action system uses an amodal format using sensory input translated into muscle action, or body-scaled, information. Lastly, object recognition operates with selective attention so that perceivers know when they have perceived the sought after information, while self-motion and action usually occur without awareness. There is mounting evidence that both systems operate in coordinated fashion from the first moments of life, while they both also undergo considerable refinement through experience.

What Is the Best Way to Describe How Perception Develops?

Core principles, differentiation, enrichment, selective attention

Researchers sharing the core-principles viewpoint of perceptual development, such as those who conducted the cracker-splitting experiment, do not focus on the rapid improvement

of perceptual skill exhibited by humans in their first year. Rather, one might say that the core principles account is focused on the end result of an extraordinary amount of evolutionary adaptive change leading up to the innate endowments of modern-day infants.

If one needed to explain how perception develops in childhood with just a few apt words, perhaps the first words out of the mouth of a researcher sharing the ecological perception viewpoint would be 'differentiation, enrichment,' and the next words, 'selective attention.' For the last edition of the *Encyclopedia of Human Behavior* we wrote: "According to the ecological perceptionists, human perception is guided by a search for order and invariance in a highly fluctuating environment. It is a lifelong nonexistential search for meaning." The first sentence of the quote refers to the process differentiation, and the second sentence, to enrichment. When meaning is attached to stimulus variables through the processes of experiential learning, and this ability to form meaning cannot be explained with a maturational account, enrichment is thought to occur.

Since our sensory systems hand over far more information than our perceptual systems can work with at any given moment, the search is a necessity of life, and infants are born knowing something about how to do it. But, to differentiate well, the search must be conducted quickly, and with precision, as infants become attuned to the relevant perceptual features holding significance for them – and that is what happens with maturation and experience with the development of the brain, the sensory systems, the attention system, and the memory systems. Researchers holding the constructivist view may not resonate to the concept of differentiation and enrichment to the extent that ecological perceptionists do, but they share with them a focus on how more general cognitive functions such as working memory, selective attention, and categorization processes assist young humans in accurately perceiving their world.

Dynamical systems view

The typical characterization of the important questions developmental psychologists must address is a set of dichotomous poles of possibilities, including whether an ability is innately endowed or learned, and whether the path of development is continuous or discontinuous. The dynamical systems approach views this characterization as far too simplistic. New forms of knowledge, including perceptual meanings, can be explained by the processes of self-organization, in the same way that all biological systems are organized. There is a complex system of layers of influence on perceptual learning, from the lowest molecular levels, to the cultural level, all continuously interacting in a process that unfolds over time and never stops changing. Novel meanings are discovered, not because there are explicit instructions in the human genetic code, or because a baby has discovered a regular pattern and associated it with something else in memory, but because new patterns of behavior emerge from older patterns in continuous

small moments of time. The system of behavior will often settle into some preferred way of seeing, or acting, and then, with the right combination of change in other parts of the system, will move out of that preferred mode, and the infant will appear to have learned something. Each person's unique constellation of interacting layers of experience and physiological makeup provides a lifelong stage for perceptual learning and growth to take place.

Personal Relationships in Everyday Life

S Duck, University of Iowa, Iowa City, IA, USA

© 2012 Elsevier Inc. All rights reserved.

Glossary

Attachment The style of approach to relationships that is possibly learned in infancy and which might then affect later adult relationships.

Provisions of relationships The resources that are provided by a relationship in terms of psychological and communicative benefits derived from it.

The Study of Personal Relationships

Personal Relationships, or for some, the ‘science of relationships,’ is an area of study that has grown in the last 20 years from the seeds first planted in the 1950s by Theodore Newcomb’s attempts to predict interpersonal attraction in a group of students living in a college housing facility. It grew from Tony Smith’s clever method of determining the direction of causality in the liking–similarity correlation (using attitude scales ‘filled out by another student’ [who was actually bogus: the forms were filled out by the experimenter]), which finally enabled researchers to discover the causal effects of specific levels of similarity on the dependent variable of attraction. From these and other inventive approaches sprang considerable subsequent attention by psychologists to the experimental manipulation of the degree of liking or attraction felt toward another person by a particular subject, in particular the monumental work by Donn Byrne.

Ellen Berscheid and Elaine Hatfield published, first in 1969 and then again in 1978, two landmark surveys, which are generally recognized as the beginning of the consolidated recognition of the field of study of interpersonal relationships. However, such researchers, mostly social psychologists, treated attraction as essentially an individual attitudinal response to a target person. Despite this one-sided view of the initiation of complex relationships, such research did not overlook cultural factors (e.g., some cultures find slimness attractive while others find plumpness attractive) or the fact that initial attraction did not straightforwardly predict long-term success of relationships. In recent years, work on initial attraction, having served its purpose, has evaporated and been replaced by a multidisciplinary effort to understand the workings of everyday-life personal relationships in the long term, viewing them as complex processes of negotiation and reiteration, routine and novelty, reinvention and continuation.

Personal relationships are long term, socially structured, organized, and relatively enduring interpersonal phenomena that are founded in each person’s liking for the other but are much more than that. Personal relationships involve mutual recognition and mutual influence in ways not necessarily true of feelings of initial attraction. They are also both a reflection of a culture’s influence and a reflection of the fact that the individuals can create a form of relationship that suits them personally. Thus, two partners may marry (cultural form), but conduct that marriage in a way that contains a number of unique elements and practices.

Historically the field of research into personal relationships was greatly influenced by the research in interpersonal attraction and many leaders in the relationships field were also prominent in the older field at first. However, the research has diversified as researchers have become less satisfied with the idea that attraction ‘causes’ relationships or is in any significant way a predictor of relational outcomes. Also increasingly rejected is the idea that any form of relationship can be determined by the activities or preferences of one person (as is implicit in the notion that one person’s attraction to another is the cause of relationships). Finally, the recent emphasis in the personal relationships field on the communicative activity that connects the members of a partnership has caused a move away from an approach that essentially presumed that (success in) relationships could be predicted on the basis of the knowledge of the characteristics of the two partners before they even met. This latter idea is a favorite of the dating agencies, which measure similarities between two people who have not met and then pretend to be able to predict relationship success from there. However, the increasing variety of research has now inevitably replaced this simplistic idea and places far greater emphasis on the interaction that occurs between two people. Some prominent researchers such as John Gottman have been very successful in predicting the outcomes of relationships on the basis of short periods of interaction, particularly during conflict episodes.

The Provisions of Relationships

Nevertheless, all human beings have needs that are satisfied only by relationships and are not simple individual ad hoc creations between two people. Robert Weiss (1998) proposed that there are seven ‘provisions’ of relationships, that is to say, seven different resources that are provided by relationships which people desire. These provisions are as follows:

1. *Belonging and a sense of reliable alliance*: a sense of membership, acceptance, and availability of others to whom one can turn in times of emergency.
2. *Emotional integration and stability*: a sounding board for our opinions and emotional responses against which we can assess the appropriateness of our own reactions to events and experiences in the world, including reactions to, and assessment of, the other people in that world.
3. *Opportunities for communication about ourselves*: a chance to express our own opinions and values and to ventilate the matters that concern us.

4. *Provision of assistance and physical support*: relationships offer us physical support or help with activities that are too laborious or difficult to be performed alone.
5. *Reassurance of worth and value*: evidence that someone cares about and values us for 'who we are.'
6. *Opportunity to help others*: relationships offer people the chance to feel good by doing good to others.
7. *Personality support*: relationships offer validation and support for our ways of doing things and our ways of constructing and understanding experience: individuals tend to select others who have similar outlooks and therefore can support one another.

Recently, researchers have been concerned to discover how a person's approaches to relationships as an adult reflect not only the need for these provisions but also previous experience (usually previous experience in childhood) and the structure of a person's personality.

Mental Models of Relationships: Childhood Experience and Adulthood

Since John Bowlby's classic suggestion that maternal deprivation in infancy causes social delinquency in adolescence, developmental psychologists have shown great interest in the parent-child relationship as a seed-bed for later relational predilections. Mary Ainsworth and her colleagues demonstrated the existence of three styles of attachment of a parent (secure, anxious/avoidant, and ambivalent). A secure style, where the child feels entirely comfortable in relationships, is apparently derived from a parental style where care giving is readily and freely available to the child and the parent is available, attentive, and responsive to the child's needs. An anxious/ambivalent style, where the child is insecure and finds it hard to trust others, is apparently derived from a parental style that is anxious, fussy, out of step with the infant's needs, and so is responsive to the child's needs only unreliably. An avoidant style, where the child tends to be active in avoiding relationships, is apparently derived from a parental style that is unresponsive, rejecting, or inattentive.

Some researchers began to speculate that adult romantic attachments would show a similar pattern and might actually be based on infant experience. Cindy Hazan, Phillip Shaver, and their colleagues showed that the three patterns were indeed present in adults as assessed in a variety of situations and by a variety of methods. Much work has followed. It must be said that virtually none of it conclusively demonstrates continuity between childhood experience and adult preferences, though there is plenty of evidence for parallelism between reports of childhood styles of experience and later adult reports of relational experience. However, our own styles, backgrounds, and preferences influence and modify the form of relationships in which we end up, irrespective of general human needs for certain kinds of provisions from relationships.

Kim Bartholomew was one of several researchers to prefer a 2×2 model of attachment in which there was a differentiation between a person's model of self and the person's model of others developed during the early years of life. Thus, a person

could form an impression of self as either a positive or negative stimulus to other people (valued or not valued) and could also simultaneously form an impression of other people as either reliable or unreliable from their relational behaviors. This creates four possible styles of belief about oneself in relation to others. *Secure* people have a positive impression of self and treat other people as reliable and essentially positive. Such individuals enter relationships without fear or concern, assuming that relationships and other people are both positively desirable and that other people will on the whole tend to like them. *Preoccupied* people have a positive model of others but a negative view of self and therefore tend to be highly dependent on other people's feedback about their own value. *Dismissive* people have a high positive view of self and a low view of others. They are therefore dismissive of what other people say, not needing confirmation of their own positive feelings and dismissing negative comments as being of no value (because they come from an untrusted source). *Fearful* people are those who have a negative view of self and other people and are in the most complex position because they would really like to have positive feelings about themselves but do not recognize other people as a reasonable source of such information. They are therefore in a constant dilemma of high dependence on others and also high avoidance.

Although early experiences and personal attachment styles have been rigorously and systematically researched in the last 25 years, very few researchers believe that this is the whole story about the way in which relationships are developed and maintained. Its long-term deterministic overtones are unacceptable to those scientists who pay attention to the way in which individuals conduct their own lives in their daily communications and who have systematically created an understanding of the ways in which individuals strategize the development and maintenance of their relationships.

Strategies in Developing and Maintaining Relationships

If relationships are not simply caused by the individual characteristics of persons entering them, then they may be affected by the specific behaviors of the participants on particular occasions. Some researchers, especially communication scholars, have asked themselves the broader question of what strategies people use to maintain and develop their relationships. William Douglas has explored the ways in which, at the start of relationships, people make tests of one another's interest, for example, by asking a particularly difficult favor or by allowing the conversation to lapse to see whether the other person is interested enough to pick it up. These tests are direct and calculated ways to establish the other person's interest in continuing a relationship and are strategic actions that are independent of any personal characteristics of the other person.

Leslie Baxter also examined the ways in which people make tests of the commitment of a partner even at later stages of relationships. She found that there were some interesting methods used, most of them to do with the creation of a jealous response in the partner, the extent of which could be used to gauge the partner's interest in the relationship. Another test involved the implicit recognition of the relationship by

others (e.g., if a person were invited to visit the partner's parents and accepted that invitation, then the implication is that the person does not mind that the parents know that the relationship exists).

Kathryn Dindia and Leslie Baxter also looked at the strategies that partners use to maintain their relationships once they have been formed. The frequent strategies covered a very large range of options, including general strategies involving openness and honesty, the sharing of feelings, or optimism and being cheerful with one another, to help them to feel better. Other strategies included such things as ceremonies (e.g., commemorating the origin of the relationship by special dates or reminiscing about it in ways that celebrated the relationship and special occasions within it) or minor pieces of routine behavior (such as a lunchtime phone call to check how the partner's day was progressing). Another strategy was to ensure that a certain period of time was set aside each week for the partners to be alone together and do whatever they liked, uninterrupted. It is therefore clear that relationships are often the result of careful management just as much as they may be affected by chance, but are by no means simply created from the matching of attributes of the people entering them. Although this picture is richer than reported by the first researchers into attraction, it is not complete until it takes full account of the role of outsiders and of the talk that takes place between people in the everyday interactions of relating.

The latest version of such an approach (*Relational Dialectical Theory*, Baxter, 2010) recognizes the way in which individuals are constantly confronted with tensions and contradictions in their relationships, which require that they balance out certain kinds of competitive forces in the comments of their daily lives. For example, it is a cultural prescription that individuals in such relationships are open and honest with one another and yet it is also perfectly acceptable in a culture for individuals to maintain some degree of privacy. A privacy–openness dialectic therefore creates tensions in individuals at moments of intimate disclosure, and somehow the two individuals in the relationship have to manage these tensions. It is also clear that in developing a relationship, individuals necessarily give up some of their independence and autonomy to become members of an interdependent relationship. The negotiation of the autonomy–connectedness dialectic is one that is particularly noticeable in the development of relationships in their early stages, but it can still reemerge in relationships that have some history.

Particularly important in the development of exclusive romantic relationships is the way in which partners negotiate their retraction from the social networks in which they have previously been immersed so that they can spend less time with friends and more with their romantic partner. Their withdrawal from their previous connections with other people outside the dyadic relationship stresses the importance of the role of outsiders in relationship activity and this has recently become a matter of great concern to researchers. Leslie Baxter's work mentioned above has paid close attention to the different forces and stresses to which partners must attend – not only to their own concerns and feelings and their influence on the internal dynamics of particular relationships but also the stressful influence created within the dyad by the knowledge that a relationship must be played out in the context of observation by others.

The Role of Outsiders in Relationship Activity

The influences of outsiders on relationships have also been explored. Many younger people meet or become involved with their dating partners through mutual friends or as the result of being members of the same group of friends, for example. However, the opportunities provided by go-betweens or mutual acquaintances are not the only influence of outsiders. In some teenage gangs, members are implicitly forbidden to date members of other gangs, and most people are keen to have the approval of their parents for possible marriage partners.

As a relationship with a particular partner becomes more intense and involved, the partners withdraw from their own networks of personal friends to spend more time with one another, and the management or juggling of all their relationships as a whole – and the time that they take up – can present difficulties and constraints for the partners. For example, it is a common finding that romantic partners spend only about a third of the time alone with other friends after marriage as they do before marriage. Nevertheless, it remains true that the inception of a close romantic relationship has consequences on other relationships in which the persons are involved, and the management of those issues is likely to have psychological and social consequences. Once again, the issues involved in creating relationships are not reducible to the simple actions of the partners themselves but must be seen in the context of other forces and constraints in life.

Organization of Roles and Time Management

Relationships do not occur in a vacuum as early work on attraction tended to imply. In real life, everyday relationships present partners with various roles and duties to perform, chores to complete, and tasks to undertake. In a relationship such as marriage, there are issues concerning 'who does what' and these have to be managed and negotiated between the partners. Such negotiation and discussions have an impact on the ways in which the relationship itself is experienced by the partners, and affect the development of the relationship.

Leslie Baxter's work mentioned above has paid considerable attention to the complex balancing of different forces and stresses in the development of relationships. For example, she and several colleagues addressed the ways in which teenagers check out the rules for developing relationships and conducting them once established. This is carried out in contexts that make reference to other members of the network, who provided both direct and indirect advice (in the form of gossip and stories about relational successes and failures) that made clear that the individuals in a relationship must adhere to codes of social performance that are accepted in the relevant peer group. In short, they must attend not only to their own concerns and feelings but also to the pressures and influences invoked by those outside their relationship, but who nevertheless have a stake in the way it will be allowed to work.

As part of the influences on the internal dynamics of relationships, it must be recognized that exterior forces such as pressures from work and other demands on one's time are also relevant to the experiences of the individuals within the

relationship itself. Several researchers have explored the 'spillover' effects of work into the experience of a marriage or committed relationship, and recently, the spillover from other sources and directions has also been explored. Not only do poor days at work tend to lead to disruption at home but also vice versa. Likewise, trouble in a major relationship can cause withdrawal from other relationships while the two partners sort out their own troubles.

In part, these issues reflect the significant time that we devote to relationships of one kind or another. The management of time and roles in particular relationships can sometimes become a problem. How much time is the 'right amount' to spend with the family, at work, with a romantic partner, with an aging parent? How is that relational time to be balanced and parceled out between different competing commitments? It is evident from much research that this form of dilemma is experienced in most forms of relationship and that much of it is managed in the daily discourses that make up everyday life.

The Role of Daily Life and Everyday Talk

A late addition to the research on relationships has been the recent focus on the conduct of everyday talk. Given that relationships are not merely emotional creations but are also social organizations and role managers, or products of strategic behavior, it is clear that the partners need to conduct their negotiations somehow and that talk is the natural medium for doing this. Second, it is also the case that people just do spend a lot of everyday talking to one another and that talking to friends and partners is probably one of the biggest slices out of the total talk that people produce in a day. Third, talk is a means by which attitudes and values are expressed and also a way in which instrumental tasks (such as obtaining favors or asking someone out on a date) are accomplished. Talk can also be a very considerable signal of the strength and involvement of a relationship, often being an indicator of the feelings that people have for one another. This happens not only in the obvious ways in which people address explicit emotional messages to one another ('I love you'), but also as a result of some of the other actions that have already been discussed here. For instance, as couples organize the roles and behaviors and duties in their relationship, they also organize the language. Several studies have shown that intimate couples develop private languages or 'personal idioms' that encode the two partners' nicknames for other people, shorthand terms for parts of the body or sexual activities, and generally playful ways of communicating affection, request, or desires. The extent of development of such personal idioms is a useful measure of the intimacy of a relationship.

The functions of language in the conduct of relationships have been classed as instrumental (as above), indexical (or indicative of the emotional tone of a relationship), or essential, by Steve Duck and Kris Pond. The 'essential' role of language is

to embody the relationship and make it happen. In a series of studies, it was shown that relationship partners report that their most frequent daily conversations with partners had no really important content to them, but were, nevertheless, relationally important. The very fact that the conversation happened was important to the life of the relationship. This is part of what is meant by the essential function of talk in relationships.

Such work also analyzes the role of talk as a presenter of ideas and values to others, such that it presents opportunities to test out the values and attitudes that the other person exposes and to test them for validity or for similarity to one's own (as Robert Weiss had suggested above). The focus on talk thus creates the chance for partners to compare some of the items that have been discussed above in the conduct of everyday life. However, it goes further than this and proposes that talk is a rhetorical act and serves not only to present ideas but also to persuade others to accept them. It does not necessarily do this in the obvious sense that partners may seek to influence one another directly, but it also does it by presenting 'rhetorical visions' (i.e., persuasive images or representations of the world) that the other person may simply adopt or accept without being the subject of strong direct influence. In short, by presenting and exposing the speaker's attitudes to the world, or his or her system of meaning, the conversations of everyday life can create opportunities for others to share the representations that are offered there and to find them relationally persuasive. From such everyday conversations, relationships, liking, and many of the other forceful factors described above can be initiated.

Glossary

Ecological momentary assessment Measurement of psychological variables using technology that permits gathering data at random intervals during the course of the day.

Idiographic assessment Interpretation of assessment data based on comparing one person's score on two or more scales.

Nomothetic assessment Interpretation of assessment data based on comparing a person to general patterns in the population.

Objective measurement Measurement of psychological variables based on items that permit a limited set of response alternatives such as multiple-choice items.

Projective measurement Measurement of psychological variables in a format that allows the respondents wide latitude in how they respond to ambiguous stimuli.

Reliability A statistical concept having to do with the degree of consistency across multiple measurements of the same construct.

Utility The degree to which a measurement device is useful in applied or practical settings.

Validity A concept having to do with the degree to which a measurement instrument provides accurate information about the construct that instrument is intended to represent.

The concept of personality is a complex one. It has been used as a superordinate term for concepts that reflect an individual's sense of personal identity, their characteristic interpersonal patterns, their aspirations, and their global tendencies when construing events in the world. Personality overlaps with other important psychological concepts such as attitudes, values, vocational interests, and psychopathology. However, the concept of personality is broader than any of these, reflecting the sum total of a person's distinctive and characteristic style of interacting with and adapting to the social environment. The optimal characterization of personality is elusive since cultures and languages differ on which dimensions of personality seem to be the most important, and even on how to define those dimensions. Psychologists interested in the measurement of personality have been challenged by its broad and amorphous character, and this challenge is reflected in controversies over measurement models applied to the study of personality, the accuracy of personality measures, and continuing efforts to develop a sufficient model of personality. Though measures of personality are often used in the context of theory development and validation in the field of personality psychology, the term 'personality assessment' has special relevance to the applied or practical use of personality measures.

This article reviews major issues in personality assessment. These include a review of measurement models used in personality assessment, a brief history of personality assessment, methods for evaluating personality measures, the relationship between personality assessment and personality theory, and the applied use of personality measures.

Measurement Models in Personality Assessment

Objective Measures

Historically, measures of personality tended to be clustered into two groups referred to as 'objective' and 'projective' instruments. The prototypical objective personality test demonstrates the

following features. First, test stimuli are semantic in nature. Second, the number of acceptable response alternatives to any test stimulus is circumscribed and set by the test developer. Third, this format permits complete standardization in administration and scoring. Fourth, objective measures tap into the respondent's conscious awareness of themselves or their environment.

The prototypical objective personality test comprises a set of multiple-choice items. These tests are generally consistent in the number of response alternatives offered for each item, with two-choice items (e.g., true-false items) and four- or five-choice items representing the most popular alternatives. Among the most popular exemplars of the objective multiple-choice model are the NEO personality inventory (NEO-PI) and the Minnesota multiphasic personality inventory (MMPI), though the latter is sensitive to both personality and psychopathology. Multiple-choice objective personality measures are often referred to as rating scales because the anchors associated with the response options typically define a dimensional rating. For example, five-choice items are often anchored with terms on a scale from 'strongly agree' to 'strongly disagree.'

Another common item format is the use of checklists, where the respondent checks off those items that are self-descriptive or descriptive of others. The checklist format has been particularly popular with test stimuli that are adjectives, so the respondent is asked to check those adjectives that describe him or her. However, some instruments that are called checklists do not use the checklist format: the Symptom Checklist-90 uses a four-choice multiple-choice format, for example. The checklist format has fallen out of favor in recent years because it leaves uncertain whether failure to check an item indicates that the respondent does not consider that adjective to be self-descriptive, or the respondent skipped that adjective.

When the items are self-referential, objective measures are often referred to as self-report measures. The self-report objective measure represents the most commonly used measurement model in personality assessment, presumably because

of its relative efficiency and low cost. Many observer-based systems for measuring personality-relevant behavior in others also use the objective measurement model. For example, the NEO-PI Form S is completed about a person by knowledgeable informants, and various objective measures have been developed for the observation of children in interpersonal situations to detect interpersonal style. In recognition of the complex character of personality, many of the most popular personality measures are actually inventories, meaning they comprise a battery of scales tapping different elements of personality.

It is important to recognize that the term 'objective' in this context has to do with the existence of a clear set of response options. It does not imply the results are objectively accurate, a point the later discussion of response bias will make clearer.

Projective Measures

The prototypical projective measure meets the following conditions. First, test stimuli are ambiguous in some important way. For example, the Rorschach Inkblot Method presents the respondent with a series of inkblots and the question 'What might this be?' The thematic apperception test (TAT) requires the respondent to create a story based on a picture in which people are engaged in unclear behavior. Second, the number of acceptable response alternatives to the stimuli is usually infinite. Though some responses may be considered unacceptable, such as refusing to provide a perception for an inkblot, any response that is cooperative with the instructions would be acceptable. Third, these methods are specifically intended to detect idiosyncratic patterns of responding, such as unusual percepts or justification for percepts on the Rorschach, or unusual story content or story structure on the TAT. Fourth, because of their less structured format, administration and scoring of projective instruments often requires specialized training. Fifth, this additional effort is considered warranted by some psychologists because such instruments are thought to be capable of revealing aspects of personality not generally detectable through more direct methods such as self-report rating scales.

The reference to certain personality instruments as projective has recently fallen into disfavor. In particular, the implication in this term that the value of such instruments stems primarily from the psychodynamic process of projection is inconsistent with much of the evidence concerning their use. As an alternative, some authors have taken to associating these measures with implicit cognitive and emotional processes.

Comparing Objective to Projective

An important distinction for understanding the role that objective and projective measures play in the understanding of personality was described by Cronbach and Gleser. Broadband measures potentially tap into a variety of elements of personality. For example, relatively brief stories on the TAT can be a sign of resistance to the test, cognitive difficulties, anxiety, or a lack of creativity. As a result, broadband measures tend to be of relatively low fidelity; that is, the use of some score as a measure of a specific psychological construct is problematic. An elevated score on a low-fidelity measure can have multiple meanings. In contrast, narrowband measures are sensitive to

a relatively small cluster of personality variables. This tends to be associated with higher fidelity.

As a general though not universal rule, projective measures are perceived by psychologists to be of relatively higher bandwidth but lower fidelity than objective measures. Their higher bandwidth tends to make projective measures popular in certain applied assessment situations, where clinical psychologists, for example, are interested in a relatively broad screening instrument of personal style. On the other hand, their low fidelity makes the interpretation of the results more complicated and raises concerns about validity.

This last concern would seem to be contradicted by the results of several meta-analyses finding little difference in the criterion-related validity of the MMPI and Rorschach. However, it is possible this finding reflects a disproportionate emphasis in the research literature on the Rorschach scales that are the most valid. More compelling is evidence indicating that certain scales derived from projective measures are of relatively good validity. Examples include the measurement of achievement motivation using the TAT and prognosis for psychotherapy using the Rorschach.

Another important line of research finds little association between objective and projective measures that ostensibly measure the same construct. Increasingly, it is recognized that implicit and explicit cognitive processes operate in parallel and measures of one will not necessarily converge with the other. These findings raise doubts about the existence of a homogeneous concept such as anxiety that accounts for both self-perceptions and information processing.

Alternative Measurement Methods

Other measurement methods have emerged in the study of personality. Various attempts to map physiological variables (heart rate, skin conductance, cortisol levels, etc.) to personality variables have met with mixed success, and these methods are often relatively expensive. However, growing sophistication in neuroscience and genetics has sparked optimism for the future of biological approaches to understanding personality.

Since personality is largely manifested through social behavior, the direct observation of behavior would seem to be a particularly promising approach to the study of personality. However, behavioral observation also represents a more expensive method than self-report. Compounding this cost is the contextual element of social behavior. No dimension of personality manifests itself universally, so optimal behavioral observation occurs across multiple settings. Some researchers have relied on self-reported behavioral tendencies, but this approach suffers from the same reliance on self-perception as other self-report instruments.

A relatively recent development has been the application of implicit measures previously used primarily for the study of social attitudes, such as the implicit association test (IAT) or the Stroop color-word test, to measure elements of personality and psychopathology such as self-esteem or anxiety. For example, the IAT is used to evaluate processing speed when the respondent is required to make associations between different pairs of concepts. An application relevant to the study of personality might involve evaluating whether self-reported extroverts respond more quickly than introverts when they are

required to make associations between self-referential words and words having to do with social involvement.

Modern implicit measures demonstrate features of both objective and projective measures. On the one hand, the stimuli are quite clear, only a certain number of response options are available, they are narrowband measures, and the results have a relatively narrowband of reasonable interpretations. On the other hand, they are consistent with projective measures since it is an element of behavior during the testing that represents the variable of interest rather than self-evaluation. It is also assumed that the IAT is capable of detecting aspects of personal style not directly accessible via self-report. The use of implicit measures is complicated by evidence that different implicit measures do not converge with each other. As is the case with projective (broadband implicit) measures, they also do not correlate well with self-report measures.

Ecological momentary assessment (EMA) represents another recent addition to the strategies available for measuring personality-relevant variables. This approach requires the use of portable technology that can be used to gather information at random during the course of the normal day. The data collected can be objective; for example, to gauge general well-being, the respondent may be signaled at random intervals to make a 1–5 rating of level of satisfaction. The data can also be behavioral; for example, the device may record speech at random intervals. With advances in the technology, the options will continue to expand. For example, the use of smartphones that contain global positioning equipment or an accelerometer creates new possibilities that have only recently begun to be explored.

Standardization in Measurement

Regardless of the model of measurement, an important characteristic of any formal personality assessment method is standardization. This term implies equivalence across test users and respondents in terms of the administration of the instrument, its scoring, and its interpretation. Standardization in administration and scoring is often easier to achieve for measures that restrict the set of response options. The MMPI or IAT can be administered successfully after a few minutes of familiarization, and the entire scoring can be completed by computer. Interpretation is often based on comparison of the respondent to a normative or standardization sample. Finding that a respondent's score on a MMPI scale is 1.5 standard deviations above the normative mean is generally treated as evidence of an interpretable deviation from the norm, for example.

The History of Personality Assessment

Francis Galton initiated the modern study of personality in the last quarter of the nineteenth century when he proposed that personality and intelligence are heritable qualities just like physical features, and are capable of scientific study. He pioneered the use of projective techniques by administering a word association task to himself and the use of objective techniques when he asked eminent scholars to describe their temperament using a checklist of terms drawn from Galen.

The development of formal psychological measures began soon thereafter. Early successes in the measurement of intelligence by Binet and Simon around the turn of the century inspired psychologists to generalize the methodology to other domains of psychological functioning. Reflective of the close association between personality and psychopathology, the Woodworth Personal Data Sheet is sometimes described as the first measure of personality. In fact it focused exclusively on emotional adjustment, and was intended to be used to screen American recruits for service in World War I as a method of reducing the rate of shell shock. It was not completed until the war had ended, however.

The first popular measure of personality was the Bernreuter personality inventory (BPI), published in 1931. It consisted of four scales: Neurotic Tendency, Self-Sufficiency, Introversion–Extroversion, and Dominance–Submission. Two additional scales were added later, tapping Self-Consciousness and Solitariness. The BPI was innovative in that it was the first multidimensional inventory of personality attempting to tap a set of key personality dimensions. It quickly became a popular instrument particularly in employment settings.

An important turning point in the measurement of personality was a series of studies conducted by Hartshorne and May in the 1920s demonstrating that many of the children for whom they had strong evidence of cheating on an academic task denied having done so. This finding alerted psychologists to the potential for misrepresentation in self-report. Several important changes in assessment practice resulted from this realization. First, developers of self-report measures began to integrate bias indicators intended to detect invalid responding into the instruments they developed. Patterns of invalid responding are called response sets or response styles, and several have been described in the literature. Perhaps the best-researched is social desirability or positive impression management, which refers to the tendency to self-describe in overly positive terms. Efforts to detect positive impression management usually involve the use of items that suggest an overly positive self-representation, for example, items that indicate denial of lying or swearing or admission of superior functioning. A high score compared to the normative mean is taken as probative evidence of misrepresentation in the positive direction. A second response style that has been discussed more frequently in the literature on psychopathology than personality assessment is malingering or negative impression management, the tendency to self-describe in overly negative terms. Scales intended to detect negative impression management consist of items based on unusually negative self-statements.

Other forms of response bias have been identified that involve inattention to the content of the items. These include random or careless responding, yea-saying (the tendency to respond in the affirmative), and nay-saying (the tendency to respond in the negative). Several strategies have been suggested for detecting inattention to content. One consists of items that are answered infrequently in the keyed direction, for example, answering true to 'I studied watchmaking in Switzerland.' Another approach uses pairs of items that are semantically inconsistent with each other when endorsed according to the key, for example, responding true to 'I feel blue' but false to 'I am sad much of the time.' Though the use of

bias indicators, sometimes called validity scales, remains popular, some researchers have concluded the case for response bias as a factor in responding to personality scales has been exaggerated.

A second consequence of concerns over misrepresentation had to do with the strategy used to develop scales. Early self-report measures were developed using a purely rational-intuitive approach, where the test developer created items that were intuitively related to the construct of interest. The original scales of the MMPI were instead developed primarily using an external approach. This involved developing a large battery of items that was administered to contrasting groups such as normal individuals versus individuals with depression. The depression scale then comprised those items that significantly discriminated between the groups. The result was the inclusion of so-called 'subtle' items, items that were not intuitively related to the criterion. While subtle items were considered desirable for many years, more recent studies have consistently demonstrated items that are conceptually related to the criterion are more valid than empirically derived unintuitive items. Currently a sequential strategy of scale development is preferred in which rationally derived items that are then evaluated on the basis of their external correlations as well as evidence of strong relationships with each other.

Finally, during the 1930s concern over misrepresentation created interest in the use of projective measures on the grounds that their ambiguity would render them more resistant to faking. The dominance of the psychoanalytic model, which emphasized the importance of mental processes outside of conscious awareness, contributed to the belief that instruments encouraging projective activity would provide a deeper level of insight into personality style than would be possible from self-report alone.

Over the next generation, several lines of criticism emerged that ultimately had important influences on the field of personality assessment. One emerged out of the growing behaviorism of the 1960s. Concerns were raised about the extent to which personality measures were capable of predicting ecologically important behavioral outcomes. Supporters of personality assessment responded to this challenge by recognizing the importance of the person-situation interaction to the prediction of behavior, as well as by providing additional evidence that personality measures can predict important life outcomes.

The MMPI also came under attack for lack of compliance with best practices from a statistical perspective. The developers of the MMPI were criticized for allowing item overlap between the scales, which complicated the interpretation of correlations between scales; scales that were extremely heterogeneous in item content; and unbalanced scoring keys. The most extreme example of this last point was a scale on which every item was scored false. Ultimately, these issues were addressed through revision of the MMPI, and inventories developed in recent times have generally avoided these pitfalls.

A more aggressive critique emerged surrounding the use of projective measures. This included concerns about low fidelity; lack of reliability; and unstandardized administration, scoring, and interpretation procedures. As a result of this critique, the popularity of projective measures declined substantially, to the point that some formerly popular techniques have dropped out of assessment practice completely. The Rorschach Inkblot

Method has been relatively resistant to this trend compared to other projective measures because of efforts to establish a more empirical base for the use of the instrument. However, the instrument remains controversial, and many of the scales developed in recent years have yet to be thoroughly validated.

Evaluating Personality Measures

Reliability

The adequacy of a personality assessment instrument can be evaluated on three grounds, referred to as reliability, validity, and utility. The concept of reliability emerges from psychometric theory, and has to do with the degree to which scores on an assessment instrument are stable across observations. By definition, then, the evaluation of reliability requires comparing results across multiple observations of the underlying construct.

The matter of generating multiple observations of the construct has been addressed in three ways in the literature on test reliability. In the case of a multi-item objective measure, the different items can represent the multiple observations. For example, the items of the Beck Depression Inventory can each represent an observation of the common construct depression. This approach to evaluating reliability is called internal reliability, since the measurements are internal to the scale. When interpreting internal reliability it is important to recognize the difference between reliability and item homogeneity. Even if the reliability of a scale is quite high, factor analysis can indicate the scale contains several conceptually distinct subsets of items. Good internal reliability is not a sufficient basis for concluding that the items are all measuring the same construct.

A second approach is referred to test-retest reliability and involves administering the measurement instrument at two or more times. The two administrations of the instrument should occur within a time frame where it is reasonable to assume the underlying construct is unlikely to undergo substantial change. Since personality variables are often expected to be stable for long periods of time, some test-retest reliability studies of personality measures use intervals of several years or more. In contrast, some elements of adjustment and emotional distress can change over relatively brief periods and so test-retest intervals should be much shorter.

The final approach applies to observer-based ratings. Interrater reliability has to do with the degree of consistency across multiple raters. In some studies, the multiple raters know the target in different contexts, which can reduce reliability. For example, research suggests that when the Child Behavior Checklist is completed by a parent and a teacher, the reliability of ratings can be quite poor.

The statistic of choice for both test-retest and interrater reliability is called the intraclass correlation coefficient, of which coefficient alpha is actually a special case. The intraclass correlation theoretically can vary between 0 and 1. Values below 0.60 are generally considered evidence of inadequate reliability. Values above 0.80 are considered particularly good, though some commentators have suggested instruments with reliabilities below 0.90 should not be used for the evaluation of individuals in applied settings. Most popular personality measures demonstrate internal reliability of 0.60–0.90.

Though there is a tendency to refer to ‘the’ reliability of an instrument, it is possible to compute different forms of reliability for the same instrument. The observer version of the NEO-PI allows for the computation of internal reliability across the multiple items of each scale, interrater reliability if two knowledgeable informants complete the instrument, and test–retest reliability if they complete the instrument a second time after some delay. The different forms of reliability will not necessarily agree with each other, since each is influenced by different factors.

Validity

The concept of validity has to do with the degree to which the instrument allows one to make inferences about the construct the instrument is intended to represent, that is, it has to do with the degree to which the behavior of the instrument is consistent with the expected behavior of the construct. A variety of approaches are available for evaluating the validity of a psychological instrument. Face validity has to do with the degree to which items comprising a measure intuitively are reflective of the underlying construct. For example, a measure of depression is face valid if each item reflects an intuitively sensible aspect of depression. Content validity is the degree to which the items comprising the instrument tap the universe of item contents relevant to the construct. For example, the Beck Depression Inventory demonstrates good content validity since each item is intuitively based on a different aspect of the construct depression. Factorial validity has to do with the extent to which factor analysis of the items of a measure produce a structure that is reasonable given the understanding of the underlying construct. Criterion-related validity is perhaps the most commonly studied approach to validity, having to do with the degree to which the instrument correlates with other variables that should be related to the construct of interest. Finding that a depression measure is negatively correlated with a measure of self-esteem and positively related to subsequent suicide attempts is evidence for the criterion-related validity of the measure. The concept of discriminant and convergent validity takes this concept a step further, suggesting that one can hypothesize there are certain variables with which the measure should be relatively well correlated and other variables with which it should be relatively uncorrelated. Finally, the term construct validity has been used to refer to the sum total of validity evidence and the degree to which it justifies concluding that outcomes on the measure can be used to draw valid inferences about the underlying construct.

Utility

The utility of an instrument is the degree to which its use enhances outcomes in applied settings; that is, it has to do with the degree to which the instrument is practically useful. Good reliability and validity are necessary but not sufficient conditions for utility: various other factors affect a measure’s usefulness. The lower the base rate of that which the assessor is trying to detect, the more difficult it is to detect it. Even a highly valid measure has a difficult time detecting a very low probability phenomenon. The utility of an instrument also depends upon its costs. As noted earlier, projective instruments often

require individual administration by a professional with specialized training. Such instruments have a relatively high cost in terms of professional time compared to a self-report measure. Those costs may outweigh any benefits, especially if projective measures tend to be of relatively low fidelity, except perhaps in very high-stakes testing as with public safety candidates. It was noted earlier that projective and objective measures of the same construct often do not correlate well with each other. There is evidence indicating that in some cases this lack of convergence occurs because projective and objective measures tap different aspects of the underlying construct. Under those circumstances, projective measures can enhance the prediction of important outcomes over self-report measures, a phenomenon referred to as incremental validity. This pattern has also recently been found with the IAT as well.

Personality Assessment and Personality Theory

Personality measures are used for two primary purposes. The first is to advance the understanding of personality. Over the last 30 years theorizing about personality has coalesced around what is called the Five Factor Model of personality. This model suggests that five basic dimensions provide an organizational structure for understanding the perception of personality, at least among English speakers. These dimensions are called Neuroticism (alternatively called Emotional Stability, which reverses the keying of the scale), Extraversion, Openness to Experience (though some studies suggest this factor should be labeled Intellect or Culture), Agreeableness, and Conscientiousness. The NEO-PI is the most popular measure of the Five Factor Model though other measures of the model exist.

One important aspect of the Five Factor Model is the hierarchical organization of personality, so that each factor encompasses a set of more specific facets of personality. [Table 1](#) provides the list of facets associated with each of the five factors NEO-PI. The acceptance of a hierarchical structure raises questions about whether the five factors offer the most generally useful level in the hierarchy. Some critics of the Five Factor Model have argued that reducing personality to five factors is overly incorporative, and a more differentiated level such as that represented by the 30 facet scales of the NEO-PI is more useful. Still others argue even five factors are unnecessary and have suggested further reduction to three or even two factors. The optimal level of differentiation between personality constructs probably depends upon one’s goals. Simple and efficient communication about personality may best be served by the five factors, while maximal prediction of behavioral outcomes might be better achieved at a more differentiated level.

Other objections have been raised to the adequacy of the Five Factor Model. Several studies have concluded that even in English, a sixth factor is reliably detectable referred to as Honesty or Humility. Cross-cultural research indicates that when individuals from non-Western cultures are administered items reflecting the five factors, those factors reliably emerge, suggesting the respondents can recognize the five factors. However, when the language used to describe personality language is analyzed other factors tend to emerge, suggesting the primacy of the five factors is culturally derived.

Table 1 NEO personality inventory-revised facets

Model domain	Facets					
Neuroticism	Anxiety	Angry hostility	Depression	Self-consciousness	Impulsiveness	Vulnerability
Extraversion	Warmth	Gregariousness	Assertiveness	Activity	Excitement seeking	Positive emotion
Openness to experience	Fantasy	Esthetics	Feelings	Actions	Ideas	Values
Agreeableness	Trust	Straightforwardness	Altruism	Compliance	Modesty	Tender mindedness
Conscientiousness	Competence	Order	Dutifulness	Achievement striving	Self discipline	Deliberation

A second important topic related to personality assessment is personality development. Among children, research has focused on the concept of temperament. This term refers to early behavioral predispositions that potentially reflect genetic and/or biological influences and that provide the basic building blocks for the development of adult personality. As one might expect, many elements of adult personality such as Neuroticism or Conscientiousness are believed to be presaged by certain tendencies observable even during early childhood. There is also growing evidence that personality continues to evolve in a positive direction as people advance into middle age and beyond: Neuroticism tends to decline while Conscientiousness and Agreeableness increase.

Applied Uses of Personality Assessment

The second use of personality measures is in the context of applied assessment. Personality measures are used extensively for employee selection and development. In the Five Factor Model, Conscientiousness tends to emerge as the best single predictor of job performance. Other models of personality have been proposed specifically for their relevance to understanding occupation behavior. The best-known example was proposed by Holland, who hypothesized the existence of six personality types relevant to the optimal choice of a career path. He labeled these types Realistic, Investigative, Artistic, Social, Enterprising, and Conventional. Each suggests that different types of job activities will be maximally rewarding to the individual. Several measures developed specifically for use in occupational settings rely on Holland's model.

The assessment of normal personality has also been influential in clinical settings. For example, the dimensional perspective on personality has been used to critique the categorical model of personality disorders contained in the current system for the diagnosis of mental disorders. This critique has become very influential in thinking about personality disorders, to the extent that reports indicate the next edition of the diagnostic manual will incorporate dimensional elements. At this point, the specific details have not been released.

When personality tests are used in applied settings for the evaluation of individuals, two approaches to test interpretation are possible. Nomothetic assessment involves comparison of the individual on a scale-by-scale basis to normative information. Reporting an individual is two standard deviations above the mean on a measure of extroversion, and drawing conclusions about the individual from that finding is an example of nomothetic assessment based on interindividual comparisons. Applied personality assessment also frequently

involves gathering data on a number of dimensions of personality, which makes it possible to consider a single individual's standing on multiple dimensions. Idiographic assessment has to do with interpreting the scatter among scores within an individual. Finding a person is much higher on a measure of extroversion than on a measure of openness to experience says something about his or her relative investment in different types of activities. This is an intraindividual comparison. These terms were introduced into the discussion of assessment by Gordon Allport and represent complementary approaches to understanding the implications of a personality assessment.

Final Comments

The study of personality continues to evolve. Some researchers have focused on the interstitial spaces in the Five Factor Model, for example, on the implications of a person being high on Extroversion but low on Conscientiousness. Others are working on developing a cross-culturally valid model of personality. Others are exploring the relationships between traditional measures of personality and more innovative approaches such as EMA. Personality assessment remains a vibrant area of research within psychology, and one that is likely to continue to make contributions to the applied and theoretical understanding of human behavior.

Glossary

Cumulative continuity principle The observation that individual differences become more stable (or less malleable) with age.

Dispositions Stable tendencies to think, feel, and behave in certain ways.

Heterotypic stability Consistency in the same underlying personality disposition across development that may nonetheless demonstrate different behavioral manifestations at different ages.

Homotypic stability Consistency in the same manifestations of personality across development.

Intrinsic maturation hypothesis The perspective that changes in levels of personality traits in adulthood are generated by biological processes residing within the individual.

Life course hypothesis The perspective that adult personality changes result, in part, because of investment in adult social roles.

Maturity principle The observation that personality trait changes in adulthood facilitate the fulfillment of adult roles (e.g., increases in agreeableness and conscientiousness).

Mean-level stability Consistency in average levels for a given trait across developmental periods.

Rank-order stability Consistency in the relative ordering of individuals for a given trait across developmental periods.

Temperament The term usually refers to the dispositional attributes of young children. However, temperament can also generally refer to biologically based individual differences regardless of developmental period.

Personality refers to an individual's stable tendencies to think, feel, and act in particular ways. The field of personality psychology focuses on understanding and assessing these individual differences in thoughts, feelings, and behavior. Accordingly, the subfield of personality development generally seeks to (1) describe patterns of stability and change in personality dispositions across the life span, (2) evaluate the influence of genetic and environmental factors on personality development, and (3) identify the processes that generate both consistency and change in personality dispositions from infancy to old age. Researchers typically address these types of questions using longitudinal designs in which the personality attributes of the same group of participants are assessed repeatedly across an appreciable span of development. Personality is most frequently assessed via self-reports and ratings of the participant by knowledgeable others (peers, parents, teachers); other commonly used assessment methods include observations of behavior in standardized situations; reaction times and other measures of cognitive processing; experience sampling; and a wide range of physiological measures. In this article, we outline three general levels at which personality can be conceptualized, discuss several types of personality stability and change, and then summarize the most recent findings and conclusions emerging from this exciting and interdisciplinary branch of psychology.

Considering Personality at Multiple Levels

What are the building blocks of personality; that is, what are the fundamental ways in which individuals differ from each other? McAdams and Pals have proposed an integrative approach that conceptualizes personality at three levels of

individual variability. The first level reflects those dispositional traits that reflect an individual's general style of adjustment and approach to the social world. Although there are thousands of dispositional traits, personality psychologists generally agree that these traits can be usefully organized into five broad domains: *extraversion* (talkative, enthusiastic vs. quiet, reserved), *agreeableness* (kind, sympathetic vs. critical, quarrelsome), *conscientiousness* (reliable, self-disciplined vs. disorganized, careless), *neuroticism* (anxious, easily upset vs. calm, emotionally stable), and *openness to experience* or simply *openness* (imaginative, novelty seeking vs. uncreative, conventional). These trait domains (commonly referred to as the 'Big Five') are relatively consistent over the life course, generalize across cultures, and emerge in childhood. The Big Five have been linked to a variety of genes, neurotransmitters, brain structures, and neural activation patterns. These domains also predict a wide range of important life outcomes, including academic achievement, crime and delinquency, health and longevity, job performance, personality disorders, and relationship satisfaction.

The other two levels in the framework of McAdams and Pals are characteristic adaptations and life narratives. Characteristic adaptations capture differences in motives and social cognitive processes such as the internal representations of key relationship partners (e.g., parents, romantic partners). These elements of personality are more contextualized than dispositional traits, and thought to be more responsive to situational forces. The third level captures those ongoing personal stories or narratives that individuals use to construct meaning from their lives. This level of individuality captures an individual's 'life story' and is the bedrock of identity.

Most research on personality development has focused on the level of core dispositions. In other words, more is known about the development of the Big Five domains than

characteristic adaptations and life stories. This will probably change in the future as researchers use large-scale longitudinal designs to study constructs at the other two levels of individuality. Nonetheless, this article focuses on dispositional traits because of the dearth of developmental research on the other two levels. However, it is important to keep in mind that there are other ways of characterizing individuals and these other levels of personality also have a developmental dimension.

Defining Different Types of Stability and Change

Just how stable are personality dispositions across the life span? There are no easy ways to answer this question because there are different ways of conceptualizing and measuring stability and change in personality. A broad distinction is often made between homotypic and heterotypic stability (or continuity). Homotypic stability concerns the degree to which people express the same thoughts, feelings, and behaviors across time. This kind of stability focuses on the same manifestations of personality across time.

In contrast, heterotypic stability refers to the consistency of the underlying personality traits that are theorized to have different observable manifestations at different ages.

The investigation of heterotypic stability requires a conceptual understanding of the underlying personality disposition. That is, researchers must draw on a theory to specify how the same underlying personality disposition will appear to outside observers at different ages. The central issue is that many of the more salient behaviors associated with particular personality traits seem to change with development. A shy child might cling to his or her parent in the middle of a crowded room, whereas a shy adult might simply avoid large social gatherings altogether. Likewise, an aggressive toddler might bite classmates and throw temper tantrums, whereas an aggressive teen might use hostile words to insult classmates or use weapons to assault strangers. A theory about the nature of the underlying personality traits (shyness and aggressiveness, respectively) should be able to explain how these different surface manifestations reflect the same underlying personality dispositions.

In contrast to heterotypic stability, the assessment of homotypic stability is less conceptual and more statistical. Homotypic stability concerns the evaluation of different kinds of change using the same measure of personality across time or across age groups. This broad category includes several specific types of stability and change. One type concerns the psychometric properties of the measurement instrument and is investigated under the term *measurement stability*. Two other types of stability and change are typically examined at the level of the sample and refer to particular personality attributes: *mean-level stability* and *rank-order stability* (also referred to as differential stability). Researchers can also investigate stability at the individual level by determining whether a particular individual increased or decreased in his or her absolute or relative trait standing over time.

Investigations of measurement stability evaluate developmental changes in the measures used to assess personality attributes. This kind of stability is important because it helps researchers confirm that they are assessing the same psychological construct at different points in time (e.g., in childhood

and adolescence). If measurement stability is not found, then researchers may wrongly infer that personality change has occurred when all that has happened is that the measure is tapping into a different construct across assessment occasions. Measurement properties can change even if the same items and item responses are used at two separate time points.

A great deal of research in personality development focuses on mean-level stability, which refers to consistency in the average or typical level of a given trait across different developmental periods. One approach is to compare average scores for a personality attribute across different age groups, such as comparing the average level of shyness in samples of children, adolescents, and young adults. Results from these kinds of cross-sectional studies suggest that middle-aged adults (e.g., adults age 40–50) are higher in conscientiousness than teenagers. One problem with this research strategy is that age differences are conflated with birth cohort differences. Although middle-aged adults may actually be more conscientious than teenagers, it is also possible that individuals born in the 1950s are higher in conscientiousness than individuals born in the 1970s due to changes in cultural norms and expectations. The effects of age and birth cohort are inseparably confounded in a cross-sectional study. A better approach is to examine personality changes by following the *same* individuals over time using a longitudinal design. This method allows researchers to test whether average levels of conscientiousness increase for the same group of individuals as they mature from adolescence to adulthood.

Investigations focused on average levels of personality attributes at different ages are sometimes called investigations of 'normative' personality differences because they provide information about the personality characteristics of the so-called 'typical' person at different stages of life. A concern is that average trends may obscure a great deal of individual variability in the way people change. Although conscientiousness may increase on average from adolescence to middle age, it is possible that it increases substantially in some individuals, in some only slightly, and in some it actually decreases. Given this possibility, some researchers prefer to focus on individual trajectories of personality development to determine how well each person in a sample follows the overall mean-level trends for the sample. Techniques for these analyses range from sophisticated growth curve models applied to multiwave data to fairly simple indices of real change, based on difference scores computed across two measurement occasions.

Another popular area of research in personality development concerns the study of rank-order stability. A longitudinal design is required to investigate rank-order stability as it is typically measured using the correlation between the same personality measures administered at two time points but across an interval of sufficient length that will allow for the possibility of real personality change (e.g., more than a few months). These correlations are often called stability coefficients and they reflect the degree to which the relative ordering of individuals on a given trait is consistent over time. If researchers observe a high degree of rank-order stability for aggressiveness, it would mean that relatively aggressive adolescents tend to grow into relatively aggressive adults, regardless of any normative increases or decreases in aggressiveness that may co-occur with age. Rank-order stability is distinct from absolute stability

because individuals may experience an overall decline or increase in absolute levels with age but nonetheless maintain their same position relative to others (e.g., there are large normative increases in height across development, but individuals generally maintain a similar rank ordering). A high degree of rank-order consistency is integral to the concept of a personality disposition.

In summary, there are a number of conceptually and methodologically distinct ways of addressing questions about personality stability and change. This diversity requires the use of precise language to specify the exact type of consistency and change under investigation. Nonetheless, researchers strive to address all types of stability to provide a comprehensive picture of personality development. We now turn to summarizing basic findings about personality development across the life span.

Early Emerging Personality Attributes: Child Temperament

Do emotionally reactive and difficult toddlers become aggressive adults? Do fearful infants become anxious adults? A key research issue in personality development concerns these questions about personality coherence or whether instantiations of individuality in young children are elaborated into adult personality traits. To be sure, individual differences are noticeable in even very young children. Some newborns are extremely fussy and difficult to soothe whereas other newborns are tranquil and easy to comfort. As newborns develop throughout infancy, they exhibit increasingly complex responses to the environment. Emotional reactions, ways of interacting with caregivers, and responses to the broader environment become more differentiated and patterned with age. At some point, these characteristics coalesce into the early emerging individual differences that are commonly referred to as attributes of childhood temperament.

Mary Rothbart and John Bates provided one of the most widely used definitions of temperament: “constitutionally based individual differences in emotional, motor, and attentional reactivity and self-regulation.” An important element of this definition is the emphasis on dimensions of individuality that are thought to be rooted in biology. However, temperament researchers acknowledge that nearly all early emerging individual differences are affected by life experiences as well as by genetically influenced tendencies and other physiological factors. A second important element of this definition is an emphasis on emotional processes as many of the separate dimensions of temperament reflect individual differences in the functioning of affective systems that motivate behavior in either an approach or avoidance fashion.

As with the research on the structure of adult personality traits that seeks to identify a set of basic domains that can be integrated into a hierarchical structure ranging from broader to narrower dispositions, researchers also seek to identify the basic dimensions and organizing structure of childhood temperament. One prominent model for childhood temperament identifies three broad dimensions – positive emotionality, negative emotionality, and constraint versus disinhibition. Positive emotionality captures the tendencies to approach the environment and engage in interactions with others

(i.e., extraversion). Negative emotionality captures the tendencies to become distressed, experience aversive emotions, and feel threatened (i.e., neuroticism). Constraint versus disinhibition captures the ability to exercise control over impulses and direct behavior toward achieving longer term goals (i.e., conscientiousness).

A largely complementary approach classifies temperamental dimensions using childhood analogs of the Big Five dimensions of adult personality – extraversion, agreeableness, conscientiousness, neuroticism, and openness to experience – to organize the dimensions of childhood temperament. Indeed, some researchers actually consider the Big Five to be the dimensions of temperament. These domains are evident in adolescents and even in children as young as 5 years of age. The one caveat is that openness to experience may not have a clear parallel in childhood temperament. The difficulty in linking openness to experience with childhood temperament is perhaps not surprising given that openness seems to have the least consistent link with neurological systems in the brain.

As it stands, there is evidence for a connection between childhood temperament and adult personality. A complication is that longitudinal research focused on the same dispositions from childhood to adulthood is fairly rare. This should change as more and more longitudinal studies are designed to explicitly address this important question.

One of the most recent and impressive examples of personality coherence comes from a study of the Hawaii Personality and Health Cohort. Investigators of this project have followed roughly 2404 individuals from the time they were elementary school children in the early 1960s to the present. A team of investigators video recorded a subset of these individuals when they were middle-aged adults. These recordings were then coded for a diverse range of personality attributes by trained coders. There was an appreciable correlation between the ratings of the individuals made by their elementary school teachers and the observer ratings of those same individuals at midlife. Individuals rated as talkative by teachers in elementary school developed into middle-aged adults who were rated as socially dominant and assertive by observers. Individuals rated as able to cope with new situations and face uncertainty were rated as cheerful and self-confident as middle-aged adults. A key message from this study is that there is a meaningful personality coherence from childhood to middle age.

In a similar vein, researchers studying a cohort of individuals born in New Zealand have found meaningful associations between ratings of 3-year-old children made by clinical interviewers and adult outcomes at age 21. Children who were rated as being irritable and impulsive at age 3 were more likely to be dependent on alcohol and to have been convicted of a violent crime by age 21. The fact that there is a connection between preschool attributes and problems with alcohol and violence during early adulthood is impressive evidence for the coherence of traits related to difficulties with impulse control. This work also points to personality coherence across development even when considering the personality attributes of very young children.

All in all, efforts to integrate childhood temperament with adult personality are progressing as researchers converge on a set of basic dimensions that are relevant for adaptation across the life span. This effort at integration will take some time,

however, because it will be years and even decades before participants in newly initiated studies mature from children into adults. Nonetheless, efforts to unify research on childhood temperament and adult personality represent an exciting area of synergy between developmental psychology and personality psychology that may help to curb the 'jangle fallacy' that permeates psychological science (i.e., if two constructs have different names then they must be different).

Mean-Level and Rank-Order Stability of the Big Five Across the Life Span

What are the patterns of normative personality development? What is the pattern of rank-order stability across the life span? Summarizing research on these topics has been greatly facilitated by a number of meta-analyses that were conducted in the last decade. A meta-analysis is a statistical approach for summarizing research literatures and essentially involves averaging the results from all available studies. This method permits researchers to quantify findings across the entire research literature and is perhaps optimal to narrative reviews, which simply provide qualitative impressions of previous work.

A meta-analysis by Roberts, Walton, and Viechtbauer provided a summary of average levels of the Big Five traits using data from 113 longitudinal samples involving 50 120 participants ranging in age from adolescence through old age. These researchers divided the extraversion domain into two facets: social dominance (traits related to independence and dominance) and social vitality (traits related to positive affect, activity level, and sociability). Average levels of social vitality tended to be fairly flat across the life span, although there was a slight spike upward from adolescence to young adulthood followed by a plateau until the mid-50s when there was a slight decline. Social dominance, on the other hand, showed a more pronounced trend such that there was a consistent absolute increase from adolescence to the early 30s where mean levels remained consistent until the mid-50s, after which the lack of studies precluded further analyses. Agreeableness and conscientiousness showed gradual increases in absolute scores across the life span whereas neuroticism showed gradual decreases. Finally, openness showed a mean-level increase from adolescence to young adulthood and then mean levels remained constant until the mid-50s when it started to show a slight decline in average levels.

One of the more interesting results that emerged from this meta-analysis concerned the adolescent period. Contrary to the popular belief that adolescence involves tumultuous changes in personality, the Roberts et al. meta-analysis demonstrated that the largest mean-level changes in personality occur during the young adult years (i.e., the 20s). This is the phase in the life span when individuals assume the roles of worker, committed romantic partner, and in many cases, parent and caregiver. Furthermore, it is easy to see how increasing levels of agreeableness and conscientiousness and decreasing levels of neuroticism facilitate the successful enactment of the roles of worker, parent, and committed romantic partner. Thus, average levels of traits change in ways that coincide with the time in the life span during which individuals assume mature social roles, a pattern referred to as the maturity principle of adult personality development.

In summary, the available data indicate that average levels of agreeableness and conscientiousness increase with age whereas average levels of extraversion (in the aggregate), neuroticism, and openness decline with age. There are two dominant explanations for these mean-level differences in the Big Five domains across the life span. The *intrinsic maturational position* holds that normative age-related changes in personality are driven by unfolding biological processes related to aging whereas the *life course position* posits that changes stem from investment in particular social roles and the life experiences that accompany these roles. Researchers are currently debating which perspective has the most empirical support. One of the complicating factors is that critical tests of these two explanations are nearly impossible because experimental manipulations of either biological factors or important social roles are neither ethical nor feasible.

At least two different meta-analyses have investigated rank-order stability across the life span. Roberts and DelVecchio examined test-retest correlations from 152 longitudinal studies and found that the rank-order stability of personality increases across the life span, ranging from a low around 0.30 in childhood to a high of 0.70 in late adulthood. This pattern generally held for men and women and for all five of the Big Five traits. A more recent meta-analysis by Ferguson reached similar conclusions, although in his analysis rank-order stability reached a plateau earlier in development than in the Roberts and DelVecchio analysis (perhaps because he corrected the rank-order stability estimates for measurement error).

The finding that the rank-order stability of personality increases from childhood to adulthood is known as the cumulative continuity principle of personality development – that is, personality becomes increasingly stable with age (when viewed through the lens of rank-order stability). This naturally raises questions as to why rank-order stability increases with age. Lower stability is expected when individuals respond to experiences differently or experience personality-altering environments at different times. The transition from childhood to adolescence involves rapid maturational changes, shifting societal demands, exploration of new identities and roles, and initiation of new peer and romantic relationships. These changes may impact individuals in relatively unique ways, thus shifting their relative ordering on a trait and thereby reducing stability coefficients. In contrast, the transition to adulthood is accompanied by fewer maturational changes and social transitions that begin to stabilize. Likewise, a hallmark of adulthood is the increased ability to select environments consistent with individual dispositions. These broad developmental considerations may explain the cumulative continuity principle. Indeed, researchers are now moving beyond simply documenting patterns of mean-level and rank-order stability to testing hypotheses about the underlying mechanisms that produce personality consistency and change.

What Mechanisms Account for Personality Stability and Change?

What specific mechanisms account for the stability of personality over time and, conversely, what account for change? Contemporary research suggests that personality stability and change result from complicated transactions between

persons and situations. Three processes in particular might promote stability in personality by producing a correspondence between personality traits and characteristics of the social environment.

First, personality traits 'draw out' or otherwise evoke corresponding responses from the social environment. This matching between the underlying dimension and the environmental response or reaction may reinforce both the disposition and the individual's social ecology. This process would tend to promote personality continuity. For example, individuals who are aggressive may evoke more hostile responses from classmates and coworkers. These hostile responses may then accentuate the initial tendency toward aggressiveness. In short, it seems as if many individual dispositions generate responses in social environments which end up reinforcing those very dispositions.

Second, personality traits shape how people interpret social situations that can have real consequences for behavior and its effects. The same objective environment, such as a cocktail party, may prove stimulating and exciting to an extraverted individual but terrifying to an introverted person. These different construals of the same objective environment might facilitate self-fulfilling prophecies. The scared introvert might act awkward and stand-offish to fellow party guests, thereby generating unpleasant and strained interpersonal encounters. The upshot is that this process would also tend to reinforce initial personality dispositions.

Third, personality traits can influence the settings that individuals select and create for themselves. One of the consequences of human agency and autonomy is that individuals have the freedom to seek out, modify, and even create environments that are consistent with their individual characteristics. The characteristics of individuals and the characteristics of their social situations are therefore correlated. For example, what people do for a living and how they structure their environments may reflect their personalities. These social contexts may then help to maintain the personality characteristics that were initially responsible for the selection processes in the first place. Individuals who are outgoing and sociable may choose careers that fit well with these tendencies and shun solitary occupations with limited potential for social interaction. Such a career may enhance and sustain these extraverted tendencies.

The upshot of these three mechanisms is that many life experiences serve to deepen and intensify the personality characteristics that were partially responsible for the environmental or social experiences in the first place. This is known as the *corresponsive principle* of personality development. The principle would naturally promote personality consistency across developmental periods.

A different set of mechanisms, however, may explain how personality change occurs. These mechanisms might have particularly important applied value for those wishing to promote certain personality attributes or modify existing ones (e.g., parents, teachers, or therapists). The first mechanism of personality change stems from the observation that individuals are responsive to contextual features of the situation, in other words, behavior changes in response to the salient cues, rewards, and punishments of a given setting. One possibility is that long-term exposure to specific contingencies may produce lasting personality changes. Life events such as marriage, parenthood, or military service may launch individuals into new

environments with clear and salient reward structures that produce enduring changes in personality.

The other processes might involve more complicated social cognitive processes. Observing others might serve as the second process of personality change. The catalyst for this kind of personality change follows from the basic principles of social learning theory. For example, observing that a hardworking coworker is financially rewarded with a year-end bonus might promote imitation of that behavior to achieve a similar reward. Likewise, feedback from others may create personality changes. For example, having a daughter or son who looks to a parent as an important role model might help generate personality changes in the direction of increased maturity for that individual. A countervailing force is perhaps the tendency for individuals to process feedback from others in ways that confirm preexisting self-views. Last, deliberate self-reflection helps generate lasting personality changes. The idea that self-reflection and deliberation can lead to behavioral change is the essence of many psychotherapies. However, an important and perhaps even essential ingredient in these three processes of personality change beyond the responses to situational contingencies might be a strong initial motivation to change. Without this kind of motivation, the individual might not pay attention to particular models, process feedback from others in a way that can promote change, or otherwise invest effort in the process of self-change.

Conclusion

The subfield of personality development is an exciting area of synergy that combines insights from behavioral genetics, clinical psychology, developmental psychology, personality psychology, and social psychology. There has been a dramatic accumulation of new knowledge in this area over the past few decades. Researchers have considerably more insight into how to conceptualize personality at multiple levels and how to describe and statistically model different types of personality stability and change. Key insights from the field of personality development are that personality exhibits a degree of coherence from childhood to adulthood. Nonetheless, there are characteristic changes in personality that seem to accompany aging that reflects increasing psychological maturity and the capacity to fulfill important adult roles. Likewise, individual differences in personality appear to become increasingly stable with age when viewed through the lens of rank-order stability such that childhood personality is probably more malleable than adult personality. Even so, personality changes can occur at all periods of the life span as there is no time in the human life span in which personality attributes are completely fixed. Ultimately, the most important message from the field of personality development is that personality stability and change result from dynamic processes that involve a complicated interplay or transaction between individuals and their environments.

Glossary

Cohort A group of individuals with a common defining characteristic, that is, age group.

Cross-sectional data Refers to data collected by observing many individuals at the same point of time or without regard to differences in time.

Differential stability Refers to the degree to which the relative ordering of individuals on a given variable is maintained over time.

Individual differences in change Implies that some people change whereas others remain stable and also that people differ in degree and direction of change.

Longitudinal data Refers to data collected by tracking the same individuals over time.

Mean-level change Refers to change in the average level of a variable in a population or a sample.

Personality traits Relatively enduring patterns of thoughts, feelings, and behaviors, which are expected to remain stable over time and are consistent across situations.

Structural stability Refers to the stability of the fundamental structure over time, implying similar correlational patterns among a set of variables over time.

Introduction

How do our personalities develop across the adult lifespan into old age? And why do some people change while others remain stable? There have been a number of theories developed by prominent psychologists such as Freud and Erickson to answer these questions. Four, but not mutually exclusive, theoretical perspectives on development might be helpful in visualizing personality development and aging. They are (1) the age-dependent perspective, (2) the life-event perspective, (3) the active-individual perspective, and (4) the lifespan development perspective. The first perspective relies upon the assumption that a person's personality may or may not change as a function of biological aging. The second perspective considers effects of normative life transitions and nonnormative life events on personality development and provides an understanding of how life circumstances can influence people's thoughts, feelings, and behaviors. It assumes that the developing individual is responsive to certain kind of life circumstances and transitions (e.g., retirement) as well as to unexpected events (e.g., death of a child). The third perspective supposes that persons actively regulate their emotions, cognitions, and behaviors, and thus are active agents of their development. In other words, what an individual brings to the context with his or her personality shapes and changes the context itself, which, in turn, may also influence the individual. Finally, the fourth perspective assumes that development is a lifelong process covering all periods of the lifespan. This perspective places emphasis on the potential plasticity of personality as a function of individual and contextual variables and compensatory behavioral changes to biological aging. The main argument is that complex dynamic interactions between individuals and their environment result in personality change (and stability) throughout the lifespan. This perspective provides a broad theoretical background for this article.

The purpose of this article is to give an overview of theoretical and empirical work on personality development and aging from a lifespan development perspective. In the first part,

we introduce personality traits as units of analysis and use the well-known 'Big Five' personality taxonomy to describe the trait domains that can be studied across the lifespan. In the second part, we present the theoretical background of the lifespan development perspective in relation to personality traits. Finally, in the third part, we give an overview of empirical research on personality trait development across the adult lifespan into old age by means of different types of change and stability.

Personality Traits as Units of Analysis

It is common in personality psychology to distinguish between structures and processes of personality. Structures refer to the content and organization of personality, whereas processes reflect the dynamics of personality. In other words, the two aspects refer to the 'having' and 'doing' sides of personality. A structural approach to personality concerns how the parts of personality are organized together into distinct areas of personality and what those areas of personality are. It focuses on how a person is different from other persons. For example, this approach examines how many factors best describe individual differences in thoughts, feelings, and behaviors. A process-related approach to personality concerns how the different parts of personality influence one another and affect individuals' behaviors and reactions to situations. This approach focuses on what goes on inside a person and thus aims to study the psychological functioning. For example, it examines how people regulate their emotions in daily life. Hooker and McAdams have proposed a personality model, called the six foci of personality, that integrates structures and processes within a levels-of-analysis framework and includes traits, personal action constructs such as goals, and life stories as structural components and states, self-regulation, and self-narration as the parallel process constructs. Personality traits, the first level of the model, refer to enduring patterns of thoughts, feelings, and behaviors that are relatively consistent across a

wide variety of situations and over time. They are organized in the conceptual framework of the 'Big Five' or Five-Factor model, that is, neuroticism, extraversion, openness to experience, agreeableness, and conscientiousness. Briefly, neuroticism, or conversely, emotional stability, contrasts even-temperedness with the experience of anxiety, worry, anger, and depression. Extraversion refers to individual differences in the propensity to be sociable, active, assertive, and experience positive affect. Openness to experience refers to individual differences in the proneness to be original, complex, creative, and open to new ideas. Agreeableness refers to traits that reflect individual differences in the propensity to be altruistic, trusting, modest, and warm. Finally, conscientiousness reflects the propensity to be self-controlled, task- and goal-directed, planful, and rule-following. The personality model contrasts traits with states as dynamic processes of personality (e.g., moods, emotions) that are transient and involve short-term change. Personal action constructs reflect motivational constructs such as strivings, goals, motives, and developmental tasks. They are contextualized in time, place, and social role and are less broad than traits. The processes, when related to personal action constructs, can be called self-regulatory processes. Finally, the life story is the individual's narrative understanding of the self. People create life stories that reconstruct the past and anticipate the future to provide their lives with some sense of meaning, unity, and purpose. Self-narration reflects parallel processes related to the life stories.

The personality model emphasizes differential changeability of personality and suggests that some constructs of personality are more responsive or sensitive to change than others. Specifically, regarding the development of structural components of personality, the model assumes that traits change the least and life stories the most, whereas mid-level personality features such as goals are more stable than the latter, but more responsive or sensitive to change than the former. Hence, the time that is needed to accurately capture systematic change in the respective constructs of personality is an important developmental aspect. Time intervals that are too short or too long in relation to the nature of the phenomenon being studied can produce data that, in some cases, are overly sensitive to measurement errors and carry-over effects and, in other cases, are insensitive to variability and change. With respect to personality traits, the expected rate of change may, on average, be quite slow as compared to processes such as states or self-regulation.

In this article, we focus on the development of personality traits rather than other important personality constructs such as goals, motives and life stories, or process constructs, given space constraints, and because most systematic work on personality development and aging refers to this level (for a detailed discussion of the development of other personality constructs, see McAdams and Olson and Mroczek and Little).

A Lifespan Development Perspective

The lifespan development perspective provides a way for understanding development and aging. This view that is based on the theoretical work of Paul Baltes and colleagues seeks to explain the general principles of development at all

ages and seeks to understand why some people exhibit different trajectories of development in different domains of psychological functioning compared to others. Moreover, this view seeks to identify the extent to which these domains can be changed or enhanced at different points during the lifespan. The lifespan perspective recognizes that multiple dimensions of psychological functioning such as personality or cognition can change, that change is multidirectional and multiply caused, and that interdisciplinary approaches are the key for understanding change. Finally, this perspective recognizes that change occurs in social, cultural, and historical contexts. We briefly outline four basic concepts of the lifespan development perspective, which bear relevance for personality development and aging: (1) development as a lifelong process, (2) variability of development, (3) multidirectionality of development, (4) contextualism and development (for an extensive discussion of the lifespan development perspective, see Baltes et al.). These concepts have important implications for personality development and aging as they may offer insights into the structures and processes of personality and thus have the potential to advance the understanding of personality development across the lifespan into old age.

Personality Development as a Lifelong Process

The key assumption of the lifespan development perspective is that development – be it in such diverse domains as cognition, emotion, motivation, or, in this case, personality – is not completed at a specific age or life period (e.g., young adulthood or midlife), but rather extends over the entire lifespan into old age. However, it is assumed that every age period in the lifespan (e.g., infancy, childhood, adolescence, adulthood, and old age) has its own developmental agenda and includes sensitive periods in which the developing individual is especially responsive to certain kind of developmental tasks or life experiences. For example, adolescence is the period of psychological and social transition between childhood and adulthood that includes profound physical changes. Developmental tasks in this period might be that adolescents have to learn to establish intimate relationships and to have other exchanges that support a sense of self-identity and sensitivity for the needs of others. Another example refers to retirement as a period of different changes from the work life to retirement that comprises processes of adaptation to new situations.

Adopting this lifespan development concept for personality traits implies that personality development is a lifelong process. However, in personality research, the question of whether and how much personality changes in adulthood was a controversial issue, resulting in two broad and opposite hypotheses regarding personality trait change. On the one hand, the plaster hypothesis suggests that the adult personality is relatively stable. It assumes that personality is more or less fixed or crystallized at a certain point in young adulthood (e.g., around the age of 30 years) and that personality is thereafter relatively stable. It is argued that stability of personality traits is largely due to biological underpinnings such as genetic influences and environmental stability such as relative, stable parental demands, teacher expectancies, and peer or partner influences. Contrasting this view, the plasticity hypothesis asserts that personality traits remain changeable throughout the lifespan into old age.

Even though there is considerable stability in personality, personality traits are thought to have the capacity to change. Included in this hypothesis is the assumption that personality traits remain open systems that can be influenced by the environment at any age and thus remain susceptible to the pressures of life and the potential socialization effect of life experiences. This does not imply that the social and cultural contexts necessarily influence personality or that the traits must change, rather it assumes that they have the capacity to change at any age and eventually adapt to environments. The main argument is that complex interactions between an individual and its environment produce changes in personality across the lifespan. This idea is consistent with the concept of development as a lifelong process.

Multidirectionality of Personality Development

One central concept conveyed by contemporary work in lifespan development is that lifelong development involves diverse change patterns that differ, for example, in terms of timing (e.g., onset, duration, and termination), direction (e.g., increase, decrease, or stability over time), and order (e.g., change and then stability). With respect to personality development, this implies that developmental trajectories of personality traits can show age trends in every direction and also with different magnitude. In fact, as we show below, previous research has clearly demonstrated that the Big Five personality traits are characterized by multidirectionality in their developmental course across the lifespan; while some traits increase with age, others remain relatively stable or decrease. The concept of multidirectionality of development is strongly related to the concept of multidimensionality. This idea supposes that development may vary between different domains of functioning (e.g., cognition, emotion, motivation, or personality) and may also vary within the respective domains. Pertaining to the 'Big Five' as the conceptual framework for individual differences in personality traits, it implies that each of the traits can develop differentially. As we outlined above, personality can be conceptualized as a multilevel and multifaceted construct that includes both structures and processes within different levels. Taking this idea into account, different developmental trajectories with respect to different structural and process aspects of personality might emerge. Therefore, the concept of multidimensionality emphasizes the importance of comparing developmental trajectories across domains as well as within domains.

Variability of Personality Development

The lifespan development perspective assumes individual differences in development. That is, individuals might differ in their development at every level, not just between persons of different ages or between different persons of the same age but also within an individual over time. Individuals can differ markedly from each other in whether they are stable or changes in their psychological functioning such as cognition, emotion, or personality traits. This idea is embodied in the concept of interindividual differences in intraindividual change, which implies that some people change whereas others remain stable and also that people differ in degree and direction of change. The term 'interindividual differences'

emphasizes the differences among individuals, whereas the term 'intraindividual change' indicates variability within individuals. The lifespan perspective assumes that development across the lifespan is characterized by intraindividual variability. Variability is not a source of error variance, but rather it indicates the potentials for change that individuals have for different levels of psychological functioning. Depending on the life conditions and experiences of a given person, not everyone is characterized by the same developmental trajectories in personality traits. Hence, the capacity to adapt to a changing environment implies a bandwidth of intraindividual variability. To conclude, variability in development speaks to the unique patterns of development particular to individual lives.

Contextualism of Personality Development

Finally, the lifespan development perspective assumes that development is embedded in historical and cultural contexts as well as in more proximal social contexts such as work and family contexts and thus is sensitive to contexts. Put in other words, the contexts are the stages of life in which development of each individual takes place. That is, individuals are integrated in a changing world and in life environments that create opportunities for and limitations to individual developmental pathways. For example, contextual factors such as life circumstances and events in the life cycle – for example, getting married, having children, getting divorce, the empty nest, the death of a spouse, and the development of physical disability and cognitive problems in older age – may influence development. According to Baltes, development is influenced by a dialectical interplay between three sources of contextual influences: (1) age-graded or normative, (2) history-graded, and (3) nonnormative influences. First, age-graded influences include biological (e.g., physical maturity, menopause) and environmental aspects (e.g., social clock, developmental tasks) that have a strong age correlation and shape development in relatively normative ways for all individuals. For example, as individuals move through their life, they are faced with quite similar challenges or developmental tasks and/or demands, such as becoming an adult, finding a place in society, establishing a family, starting a career, and/or being productive in other ways; finally, individuals have to deal with the end of their own life and those of loved ones. Second, history-graded influences denote biological and environmental factors that are associated with historical time and bring about the development of individuals different across cohorts and generations. Examples for this source of influence are wars, changes in technology, or changing social norms. Finally, nonnormative influences are idiosyncratic events that impact only some individuals and do not follow a predictable course. Some individuals experience specific positive life events such as getting an unexpected promotion, whereas others are subject to negative life events such as having a serious car accident or losing the job. Other people, in turn, report multiple life events, whereas others do not exhibit any major change in life circumstances.

With respect to the three sources of contextual influences, it is important to consider that some life circumstances are age-graded and expectable, whereas others are unexpected or off-time. It is assumed that the former might help to bring about change, particularly when clear information is provided

about how to behave adaptively or how to change oneself. The latter, on the contrary, may accentuate individual personality differences. Novel, ambiguous, and uncertain situations might violate expectations, undermine predictability, or generate discomfort and create a strong press to behave in certain ways. Because of the lack of information about how to behave adaptively, precisely at these times, diverse ways in adapting to transitions might be observed. Regarding the developmental period of old age, many challenging developmental tasks in the form of changing life circumstances and negative life experiences (i.e., retirement, illness, widowhood) require adaptation that probably involves personality change. Particularly, changes in health status, changes in social support, and a decrease in autonomy (i.e., the need to have a sense of choice and being the initiator of an action) have been shown to be associated with changes in personality traits.

Social Roles Include Contextual Information

Although we assume that environments may have an influence on development, the issue of conceptualizing and measuring contextual aspects is rather complex. Brent Roberts and colleagues proposed a psychologically meaningful way to investigate contextual influences via the social role concept. They argued that rather than investigating the influence of objective contextual variables on personality development, it may be more meaningful to examine 'subjective' environment in the form of social roles (e.g., worker role, parent role) and to investigate the relation between changes or stability in social roles and personality development. The idea is that roles contain cultural, societal, and individuals' expectations of how to behave in social roles and that an active, psychological commitment or investment to the roles might be associated with personality change. In line with this idea, the work domain might reflect an important social context that might be related to personality change and vice versa. In this context, the transition from work life into retirement is an example of how change in the living context and in a social role (i.e., work role) can have an influence on personality development. First, empirical results in the domain of work suggest that this environmental change, in general, decreases people's pace and activity. Furthermore, people on average get less competitive and argumentative in the new social role of a pensioner. It could be assumed that after adapting to the role of the pensioner, a stable living context has a stabilizing influence on the individual's personality. Likewise, social relationships such as family or romantic relationships might be another way in which social environments and changes in social contexts can influence personality and vice versa. One of the most consistent findings in the aging literature is a decrease in the number of social network partners as people age as well as a decrease of social roles in the late middle and older adulthood. Although older people may have smaller social networks than younger people, they are as satisfied with their relationships as younger persons, feel strong bonds to close friends, and frequently report greater emotional investment in their social relationships because often they have given up their ties to more peripheral relationships. Regarding very old adults, however, more and more individuals of their close social network are passing away. These relationships, in particular, seem to be very difficult to replace with similar close

and intense contacts. Findings indicate that a decrease in social contacts and an increase in loneliness are associated with an increase in neuroticism in very old adults.

To conclude, the concepts of the lifespan development perspective provides the theoretical background for addressing personality development and aging. In the next section, we give an overview of empirical research on personality trait development.

Different Types of Change and Stability

Based, in particular, on the outlined idea of development as a lifelong process, we would expect that our personalities have the capacity to change across the lifespan into old age. Indeed, previous cross-sectional and longitudinal research has shown that both change and stability mark personality trait development across the lifespan, albeit differentially depending on the types of change and stability one considers. In the following sections, we clarify what we mean by change and stability and present empirical evidence for personality trait development organized according to different types of change and stability.

Change and stability are multidimensional constructs, and each conceptualization offers unique perspectives to evaluate personality trait development, both conceptually and empirically (for details, see Roberts et al.). Each type of change and stability offers a particular understanding to personality trait development. Consequently, to draw clear conclusions about personality trait development across the lifespan into old age, it is necessary to define what exactly is meant by the terms 'change' and 'stability.' To that end, we briefly outline three types of change and stability based on samples or populations of individuals and emphasize the establishment of general developmental principles: (1) structural stability, (2) differential stability, and (3) mean-level change. Finally, we describe two additional types of change and stability that are underrepresented in the literature on personality trait development: (4) change in interindividual differences and (5) individual differences in change. The latter type of change addresses the patterns of individual development particular to individual lives and emphasizes the understanding of change and stability within an individual.

Structural Stability of Personality Traits

At the foundation of the different types of change and stability is structural stability, which refers to the stability in the interrelations among a set of variables across different age groups and over time. With respect to personality trait development, this type of stability reflects stability in the structure of personality trait covariances. Consequently, a stable structure would imply that the positioning of traits relative to each other remains stable, suggesting that their meaning remains unaffected by age and aging. This type of stability can address the question of whether the covariation pattern among a set of variables is stable across age groups and time. Change in the structure of personality trait might be indicative of maturation of personality in young adulthood or might reflect aging processes in old adulthood. For example, studies have shown that the personality trait structure matures in adolescence and

becomes more differentiated in late adolescence and young adulthood. Put differently, the results indicated that the correlations among the personality traits decrease during that age period. For example, if the negative correlation between extraversion and neuroticism decreases, it would imply that one could be extraverted without necessarily being emotionally stable. By contrast, a strong correlation would imply that being extraverted is closely connected to low neuroticism. Another theoretically plausible interpretation of structural change in personality might be borrowed from models of cognitive aging. It has been suggested that, as adults grow older, specialized cognitive abilities become less differentiated, that is, they become dedifferentiated and more highly correlated. This dedifferentiation is thought to result from a decrease in the integrity of the physiological systems related to the cognitive abilities, which reduces the specificity of particular skills. Another possible suggestion is that aging effects reflect decline in process-specific functions such as different abilities.

Regarding personality traits, cross-sectional and longitudinal research has demonstrated relative high levels of structural stability in traits over time and across age groups in adulthood. However, it is not clear whether the factor structure remains stable in old age. There is preliminary evidence for structural change in the Big Five traits in old age, suggesting that personality might become less differentiated or, in turn, more dedifferentiated over time in old age. Investigations of structural stability (and also other types of stability and change) often include the testing of measurement invariance or equivalence. This psychometric issue touches the question of whether psychological constructs are comparable across different age groups and/or across measurement occasions for the same individuals. Frequently, in lifespan developmental studies, it is implicitly assumed that the measurement process of constructs is similar across age or time. However, there may be age differences or age-related changes in the conceptual frame of reference in interpreting or reacting to a given item of a questionnaire or stimulus materials in experimental studies, thus altering the way the latent construct underlying the item or stimulus is measured. Therefore, it is important to systematically establish that the same attribute (e.g., neuroticism) is being measured in the same way across different groups (e.g., age groups) or on different measurement occasions. Measurement invariance or equivalence is considered a prerequisite for making meaningful inferences about change and stability of personality traits.

Differential Stability of Personality Traits

This type of stability, also called rank-order stability, refers to the degree to which the relative ordering of individuals on a given variable is maintained over time. It explicitly requires longitudinal research and is typically assessed through test-retest correlations or stability coefficients of measurement occasions separated by a specified time interval. This type of stability can address the question of whether people retain their standing on a trait dimension relative to others over time. A high test-retest correlation would implicate either that individuals are stable in a given trait over time or are changing, but in more or less the same way. This situation can occur when a normative developmental event such as

retirement impacts all individuals in the same way (e.g., if retirement causes everyone to decrease or increase in a personality trait by the same amount). By contrast, a low test-retest correlation indicates that individuals are changing over time and there are individual differences in the direction of change, implying that some individuals are increasing in a personality trait whereas others are decreasing. This can occur when nonnormative events impact personality traits (e.g., if some individuals get divorced and decline or incline in a particular personality trait whereas others do not experience this life event and maintain the same personality trait level). In addition, a low test-retest correlation can also occur when the factors that influence the personality trait are normative, but individuals have unique reactions to these events (e.g., if retirement causes some individuals to increase in a personality trait but causes others to decrease in the same trait). Finally, from a methodological point of view, a low test-retest correlation could also simply reflect measurement error or less reliable measurements.

Longitudinal studies have been conducted to investigate differential stability of the Big Five personality traits. In order to test whether trait stability maximizes and stabilizes at a specific period in the lifespan, Roberts and DelVecchio conducted an extensive meta-analysis and included 152 longitudinal studies. Estimates of mean population test-retest correlation coefficients showed that the overall trait stability increased from 0.31 in childhood to 0.54 during the college years, to 0.64 at age 30, and then reached a plateau around 0.74 between ages 50 and 70. Their findings suggest that there is a tendency for increasing relative stability of personality traits from childhood to old adulthood, a pattern that has been termed the 'cumulative stability principle.' Moreover, differential stability did not vary markedly across the Big Five traits, nor across assessment method (e.g., self-reports, observer ratings, and projective tests), or gender. A slightly different pattern of trait stability is found for very old adults (i.e., 80–100 years). Results from previous studies indicate a decrease in differential stability in personality traits such as emotional stability (or inversely, neuroticism), imagination, sensitivity, and dominance in very old age. Hence, personality seems to become more plastic and prone to change again in very old age. To conclude, although a relatively high differential stability coefficient around 0.70 is found in late middle and older adulthood, it is not perfect (1.0) and leaves room for individual change. As mentioned above, individual change can be due to unexpected life events or off-time lifespan transitions. The decrease in trait stability in very old adults might point to an increase in vulnerability as social and psychological resources diminish with age. For example, cognitive impairments, which are quite prevalent in very old individuals, can also decrease the stability of certain personality traits.

Mean-Level Change of Personality Traits

This type of change, also called absolute change, refers to the extent to which the average level of a variable changes systematically across different age groups and over time. With respect to personality trait development, it reflects (1) cross-sectional age differences and (2) longitudinal age-related change in the average levels of personality traits. This type can address

the question of whether average scores of individuals show systematic age differences or age-related change over time. Mean-level change is often equated with 'normative change' in personality. Normative change occurs when most people change in the same way during a specific period within the lifespan (e.g., adolescence). Change in the mean levels might be thought to result from maturational and/or contextual processes (e.g., cultural and historical influences) shared by a population. These shared processes could be biological in origin, such as the general period when adolescence begins or when menopause occurs in women. The timing of these biological phenomena is partially driven by genetic factors and tends to happen within a specific period of the lifespan for most people in the particular population of interest. Likewise, it is also possible that normative change in personality traits arises due to similar life tasks and an engagement and investment in age-graded life tasks and social roles (see above).

Previous research on mean-level change in personality traits found a mixture of different patterns of how people change with age. Roberts, Walton, and Viechtbauer conducted an extensive meta-analysis and included 92 samples from longitudinal studies. Their results indicated that on average individuals became more socially dominant (a facet of extraversion), especially in young adulthood. They became more conscientious and emotionally stable and less neurotic through midlife. Although much of the change on agreeableness was positive, the findings indicated that the increase was only statistically significant in old age. Other studies reported a positive association between agreeableness and age in adulthood. Finally, people demonstrated gains in social vitality (another facet of extraversion) and openness to experience in adolescence and the equivalent decreases in old age for both of these trait domains. It seems that, on average, as people age, they appear to get better at dealing with the ups and downs of life. In particular, they tend to become more responsive, more caring, and more pleasant in social interactions and also more forgiving. Many of these longitudinal personality trait development patterns are similar to those found in cross-sectional studies despite the potential cohort confound. Mixed results are found regarding mean-level changes in very old adults. While some studies did not find any change at all, other investigations showed increases in agreeableness and decreases in extraversion. An increase in agreeableness in very old age might reflect differential survival because low levels of agreeableness are related to coronary heart diseases, whereas a decrease in extraversion might reflect an adaptation to lower general energy level in old age. Further research on mean-level changes in very old adults is needed.

Change in Interindividual Differences in Personality Traits

Irrespective of the level of differential stability and mean-level change in personality traits across age and time, the amount of interindividual differences (divergence) in personality traits might increase, decrease, or remain stable across age groups or over time. Empirically, this type of change can be examined by comparing personality trait factor variances cross-sectionally and, preferably, longitudinally. An increase or decrease of personality trait variances would indicate – even under conditions of perfect differential stability and no mean-level change – that the amount of change is different for different persons. Thus,

the examination of age differences and age-related changes in variances in personality traits across the lifespan into old age is of particular importance to our understanding of the self. Simply focusing on the age variable neglects the fact that aging is differential, that is, people show different age trajectories. Regarding a broad array of person variables, it is assumed that variability increases with age. Indeed, with respect to cognitive functions and processes, there is empirical evidence for increasing variability with age regarding variables such as reaction time, memory, or fluid intelligence. This phenomenon is called 'aged heterogeneity.'

Pertaining to personality development, there are numerous reasons why increasing differences among individuals might arise. For example, homogeneous developmental trajectories might reflect a more biologically driven developmental process, whereas increasing variances might denote changes triggered by external influences that are socially driven. Hence, the amount of interindividual differences should be relatively stable if personality traits are more genetically based. By contrast, increasing differences among individuals might arise as a consequence of the combined effects of individuals' unique experiences over more years that would produce increasing differences among them. The genetic influence or the timing of genetic activity on interindividual differences vary widely according to age and thus cause individuals to diverge. Also, older people, somewhat freer from societal constraints, would be more likely to choose their own courses of action. In addition, significant changes in physiological and functional status in later adulthood may also produce change of divergence with age. Although this type of change and stability offers additional information about personality trait development, very few studies focused on this type and the results were mixed. Regarding long-term change in old age, there is preliminary evidence for increases in interindividual differences in some personality traits such as openness to experience, suggesting that older participants became more heterogeneous with respect to being open. Increased heterogeneity might result from events or life circumstances that impact only some individuals. Not every older adult is hit by cognitive or physical problems that constrain his or her daily life.

Interindividual Differences in Personality Trait Change

Although the four discussed types of change and stability, particularly differential stability and mean-level change, conceal important information on individual differences in personality traits, the fact that some individuals may be stable, and others changing, is hidden by the aggregate nature of the accompanying statistical techniques for estimation, that is, correlations and repeated-measures means. If individuals change differentially, this does not necessarily lead to mean changes, but it must lead to either change in the rank order of individuals or change in variance. Lifespan development researchers have advocated the idea of individual differences in intraindividual change, which implies that some people change whereas others remain stable and also that people differ in degree and direction of change. These are changes that deviate from the population mean-level patterns of change. This type complements the other types of change and stability by addressing unique patterns of development particular to individuals.

Specifically, it emphasizes change and stability within the individual and implies that individuals change differentially, that is, the degree and direction or pattern of change (e.g., linear, quadratic) may vary across people. Although the investigation of individual differences in personality trait development may offer an understanding of each individual's unique pattern of development, the phenomenon of individual differences in change of personality variables has until recently been largely overlooked. One reason for this is that for many years, there was a lack of adequate statistical models to estimate change accurately. However, a variety of methods are now available that allow to model change over time, particularly the assessment and prediction of intraindividual change. With respect to personality trait development, there is now growing evidence for the existence of systematic interindividual differences personality trait change in young, middle, and old adulthood. There is preliminary evidence showing that individual differences in rate of change seem to be more influenced by nonnormative events than by normative events.

Taking a perspective of interindividual differences in individual change may result in an important developmental question whether changes in different personality traits are related over time across individuals, and if so, to what degree. While differential stability addresses the rank order of change in a single personality factor, the aspect of correlated change covers the amount of correspondence in rank orders of change across several personality factors such as the Big Five personality traits. Investigating correlated change can address the question of whether there is an overall commonality in change in personality traits. Empirically, correlated change may be addressed by correlating intraindividual longitudinal change scores in different personality factors. The issue of correlated change is underrepresented in the personality development literature, whereas it is more prominent in other fields of research, particularly in research on cognitive aging. It is an open question, however, whether changes in the Big Five personality traits are related or not across individuals. It might be that the same underlying causes of change such as social roles, life events, and social environments (for a comprehensive review of potential mechanisms of change and stability, see Caspi and Roberts; Roberts et al.) operate simultaneously on multiple personality constructs such as the Big Five personality traits.

To conclude, previous findings on personality trait development across the adult lifespan into old age imply that although there is evidence for average personality trait changes, there are reliable differences in change between individuals.

Summary

Personality development is an important issue in personality and developmental science. Four take home messages stand out. First, personality is a multidimensional construct with different units of analysis. In this article, we focused on personality traits as structural components of personality. However, personality traits represent only one part of the big picture of individual differences. Therefore, it is important for future research to concurrently consider the multidimensional nature of personality. The levels-of-analysis framework could be a point of departure for such research efforts because it integrates

both structural and process units of analysis and also emphasizes that some units of personality are more responsive or sensitive to change than others. Second, the lifespan development perspective provides a helpful theoretical background for visualizing personality development and aging. Moreover, such a perspective offers broad theoretical explanations for personality development. In this article, we emphasized four important concepts with respect to personality trait development. The key hypothesis is that personality trait development is a lifelong process and that complex dynamic interactions between biological underpinnings and social, cultural, and historical contexts account for change and stability. Third, change and stability are multidimensional constructs. Therefore, a complete understanding of personality development requires attention to several conceptually and statistically distinct types of change and stability. In this article, we summarized empirical research on trait development based on five types. Fourth, there is now considerable empirical evidence for both change and stability of personality traits across the lifespan into old age. At the same time, research has clearly demonstrated individual differences in personality development. To conclude, recent theoretical advances and empirical findings suggest that the future is bright for the scientific study of personality development and aging.

Glossary

Kappa score An estimate of reliability, for instance, a kappa of 0.50 between two diagnostic systems means that a diagnosis in one system accounts for half of the variance in diagnosis under another system, after accounting for chance agreement.

Paranoid pseudocommunity The conspiracy network of persons an individual with paranoid personality disorder perceives as against him/her.

Personality disorder Chronic disruptive adjustment patterns, found as a formal diagnosis on Axis II of the DSM system.

Personality type Patterns of behavior that operate as a predisposition to a personality disorder.

Personality disorders (PDs) are static, cognitive, emotional, and behavioral patterns that result in significant impairment for the individual. Notably, elements of the patterns may be active (e.g., parasuicidal behavior) or passive (e.g., failure to recognize emotional context). PDs are generated at an early age, likely as coping mechanisms to manage particular life challenges. These patterns may even emerge as effective coping mechanisms, becoming maladaptive only later in life as interpersonal relationships become more complicated and intricate. The more distorted or disturbed that environment is, the more distorted a coping pattern will emerge. At least as much as any other psychiatric diagnoses, PDs represent violations of social norms and are therefore largely culturally defined.

PDs are therefore not as clearly bizarre as psychosis, nor do they include the clear anxiety symptoms of mood and anxiety disorders (traditionally known as the 'neuroses'). However, PDs are severely maladaptive, because (1) the cognitive, emotional, and behavioral patterns dominate the person's interpersonal presentation and are thoroughly integrated in the personality, (2) having formed in adolescence or earlier, these patterns are maximally chronic, and (3) persons with PDs commonly avoid treatment and may be difficult to treat if for some reason they enter treatment. In fact, their presence in therapy is usually stimulated by some social or legal coercion.

The same patterns may be present to a lesser (or less rigidly applied) degree, such that they do not result in diagnosable levels of dysfunction. In fact, the pattern may simply persevere within socially accepted boundaries. Within this perspective, such a personality type (a behavior pattern seen as within the normal range of adjustment) may be a way-station on the developmental road toward a full-blown PD diagnosis.

Personality Disorder Diagnosis: DSM and ICD Classifications

While we default to discussing the diagnostic methodology of the Diagnostic and Statistical Manual of Mental Disorders (DSM-IV-TR) below, we clarify differences with the International Classification of Diseases (ICD-10) where relevant.

ICD-10 and DSM-IV identify 8 and 10 separate PDs, respectively. The ICD-10 system excludes narcissistic PD, and classifies schizotypal PD elsewhere under 'schizophrenia, schizotypal and delusional disorders.' Notably, this latter difference may leave schizotypal PD a billable disorder in any system that excludes compensation for treatment of PDs in general. Comparison studies show that the ICD and DSM systems are quite reliable with each other regarding the presence or absence of a PD (kappa scores in the mid-high 90s, meaning that a diagnosis in one system accounts for almost all of the variance in diagnosis under the other system after accounting for chance agreement). Individual PD-specific differences in the two diagnostic systems, including those with poorer inter-system reliability, are addressed in the sections below on the individual PDs.

The DSM-IV-TR PDs have traditionally been grouped into three clusters. Cluster A includes those PDs denoted by peculiar or eccentric behavior, such as the paranoid, schizoid, and schizotypal PDs, as. Cluster B focuses on dramatic and emotionally labile behavior: it includes the histrionic, narcissistic, antisocial, and borderline PDs. Cluster C, which emphasizes chronic fearfulness and/or avoidance behaviors, includes the avoidant, dependent, obsessive-compulsive, and passive-aggressive PDs. Following is a discussion of each individual PD, organized by DSM clusters.

Paranoid Personality Disorder

Paranoid PD (PPD) can be thought of as anchoring the least disturbed and fragmented end of a continuum of paranoid disorders. Paranoid schizophrenia lies at the opposite end with the greatest degree of fragmentation and departure from reality. However, since there is neither a thought disorder nor even a well-formed delusional system in PPD, it is not listed under the DSM paranoid disorders and is not a psychotic condition.

Behavioral, Interpersonal, and Cognitive Patterns

Individuals with PPD manifest hyperalertness toward the environment and have a chronic mistrust of most people. They see

themselves as morally correct, yet vulnerable and envied, and see others as far less than perfect. As a result, their information base is continuously distorted and their affect is constricted. Consequently, they find it difficult to adapt adequately to new situations or relationships, which is paradoxical because of their hyperalertness to their environment. Paradoxically again, they will frequently be correct in assuming that other people are against them. Due largely to their mistrust of others and ability to elicit distrust from others, individuals with PPD have trouble developing intimacy and are continually seeking various ways to be self-sufficient. They avoid the emotional complexities of working out a meaningful relationship and tend to be litigious. For example, they may write negative letters to public figures or bring lawsuits on minimal grounds.

The concept of the paranoid pseudocommunity holds that a person with PPD is unable to communicate freely with other persons and has a pattern of finding fault with others as a result of inadequate social development. The culmination of this personality pattern is the individual's misconception of himself as the center of a community of persons who are in a conspiracy against him. Because the situation does not exist as the person with PPD perceives it, he/she is said to be living in a pseudocommunity.

Diagnostic Considerations

The DSM-IV-TR requires evidence of chronic, pervasive, and unreasonable mistrust of others, such that the motives of others are perceived as malevolent, beginning by early adulthood as indicated by at least four of the following behaviors: (1) unreasonably expects exploitation or deception, (2) is preoccupied with unsupported concerns about loyalty or truthfulness of friends or associates, (3) is reluctant to confide in others due to fear that what is said will be used maliciously against him/her, (4) perceives communications as demeaning or threatening without supporting evidence, (5) persistently holds grudges and is unforgiving, (6) perceives unwarranted character attacks and is quick to anger or counterattack, and (7) has recurrent unwarranted suspicions of partners' infidelity. Finally, the occurrence must not be exclusively during the course of schizophrenia or a psychotic mood delusional disorder.

Therapeutic Considerations

In order to relate to, or even treat the individual with PPD, it is essential to gain their trust through empathy, but not through participation in the disorder patterns. It is especially necessary to empathize with and articulate the consequences of such an individual's behavior, such as the sense of being isolated and not understood or the interpersonal rejection that appears unfair to the person with PPD. Underlying beliefs with which individuals with PPD often struggle with are (a) I am unique and others are jealous; (b) others will exploit my mistakes; (c) it always pays to be wary, accusatory, and adversarial (some individuals with PPD do make good trial lawyers); (d) people who are trusting or content are fools, that is, I cannot be that way; and (e) negative events are generated purposefully by others.

Schizoid Personality Disorder

The essential feature of schizoid PD is impairment in the ability to form adequate social relationships. As a result, people with schizoid PD are shy and socially withdrawn or, as novelist Joan Didion states in *The White Album* (p. 121), "only marginally engaged in the dailiness of life." They have difficulty expressing hostility and have withdrawn from most social contacts. But, unlike agoraphobia, the behavior is ego-syntonic (i.e., the individual is at least minimally comfortable with the behavior).

Behavioral, Interpersonal, and Cognitive Patterns

The daily life of a person with schizoid PD is characterized by distancing behaviors and alienation. The individual with schizoid PD reacts to disturbing experiences and conflicts by apparent detachment from the environment rather than by manifesting normal coping responses. Like the person with an avoidant PD (discussed later in this article), a person with schizoid PD has inadequate interpersonal relations. But unlike a person with an avoidant PD, an individual with schizoid PD does not care, so therapy is quite difficult. Temperamentally, people with schizoid PD gravitate toward jobs that require solitude, such as work as a nighttime security guard. As they age or become vocationally dysfunctional, they are likely to move into a 'skid row,' particularly if they are males. Despite an excessive engagement in fantasy and peculiar communication styles, these individuals do not show the loss of contact with reality characteristic of a psychotic disorder.

An example of an individual with schizoid PD is Walter Mitty, the hero of James Thurber's novel and the movie *The Secret Life of Walter Mitty*. Mitty is essentially detached from his environment and is much more absorbed in his elaborate, heroic fantasies. Given the situation of an idle moment or a disturbing experience, he plunges into his imaginings, rather than utilizing normal coping mechanisms. Most schizoid persons are considered to be cold and withdrawn because they do not seem to respond to their environment. Walter Mitty, however, seems more warm and likeable, although no more reachable, than other schizoid personalities.

Diagnostic Considerations

In the DSM-IV-TR, schizoid PD is marked by social-relationship detachment, introverted behavior, and constriction of expression or emotion in social settings. While people with schizoid PD have few, if any, friends, they show no communication disturbance (i.e., they have the social skills to maintain relationships). Thus in order to fulfill a basic requirement of functional impairment, the individual with schizoid PD must cause vocational or social disruption by the individual meeting at least four of the following: (1) no desire or enjoyment of close relationships, including with family; (2) almost always seeking solitary activities; (3) having little or no interest in sexual experiences with a partner; (4) taking pleasure in few or no activities; (5) lacking close friends, confidants, other than first-degree relatives; (6) appearing indifferent to praise or criticism; and (7) being emotionally detached, cold, or flat. Schizoid PD demonstrates one of the poorest reliabilities

between the DSM and ICD (kappa scores estimate as low as 0.32, meaning that a diagnosis in one system accounts for just under one-third of the variance in diagnosis under the other system, after accounting for chance agreement).

Therapeutic Considerations

To develop a therapeutic relationship with an individual with schizoid PD, the therapist must work cautiously to develop trust and not distress the patient with initial confrontations. Initially, the therapist can support the patient's need for interpersonal distance and focus more on practical matters. As trust builds, greater emphasis can be placed on relationships and the need for insight.

Individuals with schizoid PD experience numerous cognitive thought distortions, such as (a) any disruption of my emotional routine (however minimal the emotions are) is scary and messy – in that sense they are analogous to an individual with obsessive-compulsive disorder's fear of disruption of external routines; (b) I can survive alone (maybe not optimally, but at least predictably), and need space to do that; and (c) it is necessary to be free and independent.

Schizotypal Personality Disorder

Schizotypal PD is a PD characterized by the need for social isolation, marked behavioral peculiarities, and unconventional thinking and beliefs. These individuals may seem dysfunctionally detached, have few ties or responsibilities, may seem cognitively confused, self-absorbed and ruminative, and have either an anxious wariness and hypersensitivity or emotional flattening or lack of affect.

Behavioral, Interpersonal, and Cognitive Patterns

There are many similarities between schizotypal and schizoid personalities. Most notable of the similarities is the inability to initiate or maintain relationships. The difference between the two is that those labeled as schizotypal avoid social interaction because of a deep-seated fear of people. Individuals with schizoid PD simply feel no desire to form relationships because they see no purpose in social interaction. Individuals with schizotypal PD are much more likely than people with schizoid PD, to show dysphoria and anxiety. Additionally, people with schizotypal PD exhibit odd thinking patterns and are more likely to develop eccentric belief systems and become involved in fringe religious groups. The individual with schizotypal PD is also more likely to be emotionally labile, overtly suspicious, and hostile of others than is a person with schizoid PD. Many individuals with schizotypal PD also appear to meet the criteria for the Borderline PD. Any therapist's attention must be directed not only toward the interpersonal withdrawal processes, but also to the emergent disturbances in affect and thinking that are common.

Diagnostic Considerations

Schizotypal PD is marked by static interpersonal deficits, cognitive or perceptual disturbances and unusual behavior. According to the DSM-IV-TR, in order to diagnose an

individual with schizotypal PD at least five of the following symptoms must be present: (1) ideas of reference; (2) evidence of magical thinking or odd beliefs that are not subculturally determined; (3) unusual perceptual experiences, including bodily illusions; (4) odd thinking and speech; (5) suspicions or paranoid ideation; (6) inappropriate or constricted affect; (7) odd, eccentric, or peculiar behavior or appearance; (8) lack of close friends or confidantes other than first-degree relatives; and (9) excessive, nonhabituating social anxiety that tends to be associated more with paranoid fears than with negative judgments about self.

A family history of schizophrenia is not unusual. If symptoms of schizophrenia begin to emerge, the schizophrenic diagnosis takes precedence and the schizotypal diagnosis is considered 'premorbid.'

Histrionic Personality Disorder

Individuals with histrionic PD (HPD) seek attention and are often overreactive, with the response being expressed more dramatically and intensely than is appropriate. This category has traditionally been labeled the 'hysterical personality.' However, 'hysterical' wrongly suggests a disorder that parallels the causes and symptoms of what has been traditionally labeled 'hysterical neurosis.'

Behavioral, Interpersonal, and Cognitive Patterns

Individuals with HPD may elicit new relationships with relative ease, as they appear to be empathic and socially able. However, they turn out to be temperamentally and emotionally insensitive and have little depth of insight into their own responsibilities in a relationship. Even though they may be flirtatious and sexually seductive, there is little mature response or true sensuality. If one accepts the apparent sexual overture in the behavior, the histrionic individual may act as if insulted or even attacked. Individuals with HPD quickly avoid blame for any difficulties of interpersonal relationship and, in that sense, show a degree of the projection that is characteristic of paranoid disorders.

Diagnostic Considerations

People with HPD show attention-seeking and excessively emotional behaviors, apparent by early adulthood. According to the DSM-IV-TR, in order to diagnose an individual with HPD at least five of the following symptoms must be present, as evidenced by at least five of the following: (1) discomfort when not the center of attention; (2) interactions often marked by inappropriate sexually seductive or provocative behavior; (3) rapidly shifting and shallow emotional expression; (4) consistent use of physical appearance to draw attention to self; (5) impressionistic, nondetail speech style; (6) self-dramatization, theatricality and exaggerated emotional expression; (7) suggestibility; and (8) perception of relationships as more intimate than is actually the case.

Treatment Considerations

Individuals with HPD are more responsive to dramatic forms of communication and will, at least initially, be more

responsive to a short-term dramatic therapy approach; a therapy approach lacking drama and exaggeration may be viewed as invalid by some with HPD simply because of the lack of intensity.

To establish rapport, the therapist may need to exaggerate their own emotions, show support, while allowing the individual with HPD to be the center of attention. Once the patient is engaged in therapy, a shift can be made to focus on disturbed interpersonal relationships and avoidance of responsibility. Eventually, group therapy is recommended.

Individuals with HPD experience numerous cognitive thought distortions, such as (a) being responsible or attending to details means the loss of 'zest for life'; (b) rejection is disastrous; (c) people will not love me for what I do but what I pretend to be, or what I present to entertain/entice them; and (d) being 'special' means never having to say 'I am sorry' (or at least I do not have to feel it or mean it).

Narcissistic Personality Disorder

The term narcissistic PD (NPD) has its roots in the mythical Greek character, Narcissus. As divine punishment for being cruel to those who loved him, the gods cursed the beautiful narcissus to fall in love with his own reflection. He wastes away and dies, unable to focus on anything but himself. So, too, do persons with NPD exhibit a pathological focus on themselves to the exclusion of others. In individualistic (e.g., North American) societies, such a personality pattern frequently yields substantial social gain in the form of career success, notoriety, or even political power. As a character in Peter de Vries's novel, *Consenting Adults*, describes, 'I have this crush on myself – but the feeling is not returned.'

Behavioral, Interpersonal, and Cognitive Patterns

Individuals with NPD manifest an unrealistic sense of self-importance, resulting in substantial problems in interpersonal relationships. Individuals with NPD share this characteristic with those diagnosed as antisocial PD, except that they are not so aggressive or hostile and their value systems are more asocial and hedonic than individuals with antisocial PD. In 1984, Otto Kernberg introduced the subdiagnosis of malignant narcissist. It was first applied to people like Adolf Hitler and Joseph Stalin, and recently it has been suggested as fitting Saddam Hussein.

Diagnostic Considerations

An individual with NPD shows a static pattern of grandiosity, need for admiration, and lack of empathy, apparent by early adulthood. According to the DSM-IV-TR, in order to diagnose an individual with NPD, at least five of the following symptoms must be present: (1) grandiose self-importance; (2) preoccupation with fantasies of unlimited success, power, brilliance, beauty, or ideal love; (3) belief in one's specialness or uniqueness and consequent belief in only associating with or being understood by certain others; (4) a need for excessive admiration; (5) a sense of entitlement; (6) interpersonally

exploitive behavior; (7) lack of empathy; (8) envy of others or belief that others are envious of him/her; and (9) arrogant and haughty behavior or attitude. Individuals with NPD have poorly integrated personalities and may experience brief psychotic episodes.

Treatment Considerations

Treatment of an individual with NPD may be even more difficult than a person with antisocial PD to engage in therapy. The likelihood that they would choose to enter therapy is low and their participation in therapy is often due to the coercion of a loved one. The person with NPD may have been threatened by a loss of a dependency role, as in a marital situation. Psychodynamic techniques and modeling techniques may be well suited to confront the pathology of narcissism. The therapist can work to channel the psychopathology into 'productive narcissism' by role playing, utilizing a multiple marital-group setting, or in imagination.

Individuals with NPD experience numerous cognitive thought distortions, such as (a) I am special, unique, elite; (b) I like to challenge or compete with others, but because of both 'a' and the fact it is psychologically necessary for me to prevail, I may play by other rules (usually known only to me); (c) any defects I have come from my bad parents and/or background; (d) recognition, admiration, and respect are necessary and others exist to provide it, and indeed, promote it; and (e) sharing, serving others, or selfless behaviors are signs of weakness and signal disintegration of myself.

Antisocial Personality Disorder

Antisocial PD (ASPD) essentially connotes someone who shows chronic disregard for social rules and laws. This is an interesting diagnosis that deserves special consideration in light of its evolution as a concept. The first reference to the classic notation 'psychopathic' (meaning a disease originating in the mind) occurred in 1891, and was an attempt to characterize extreme social deviance as congenital. Hervey Cleckley, a pioneer in this area, described psychopathy as having a 'mask of sanity,' or the absence of the usual indicators of insanity. These are persons who discard meaningful relationships, goals, and success for reasons that others cannot understand. More recently, the term 'Sociopathic personality pattern' was adopted by the American Psychiatric Association for DSM-I (to emphasize that this pattern is largely a result of social conditioning). While ASPD started with a broader definition, subsequent DSM editions yielded the behavioral diagnostic description below.

Since the emergence of ASPD in the DSM, knowledge about the personality origins of criminal behavior has actually made an interesting return toward earlier thinking on the topic. Research, originated by Robert Hare, has reshaped conceptualizations of ASPD. This work has essentially demonstrated, over the course of nearly three decades, that the earlier conceptualizations of psychopathy can be measured reliably, and have greater predictive validity than do the more behavioral conceptualizations of ASPD in the DSM.

Behavioral, Interpersonal, and Cognitive Patterns

Individuals with ASPD exhibit chronic violations of moral and legal rules. People with ASPD show an inability to delay gratification, difficulty with authority, and narcissism in interpersonal relationships. Those with ASPD often show: (1) a very low level of anxiety and little avoidance learning; (2) significant resistance to standard social-control procedures; and (3) high degree of stimulation-seeking behaviors.

Diagnostic Considerations

According to the DSM-IV-TR, in order to diagnose an individual with ASPD, at least three of the following symptoms present by the age of 18, with a pervasive pattern of disregard or violation of others and evidence of conduct disorder with onset before the age of 15: (1) failure to conform to socio-legal norms as denoted by repeated acts that are grounds for arrest; (2) irritability and aggressiveness, as seen in repeated fights or assaults; (3) consistent irresponsibility in work or financial obligations; (4) impulsivity or failure to plan ahead; (5) deceitfulness, as indicated in lying or conning; (6) reckless disregard for one's own or others' safety; or (7) lack of remorse.

Antisocial (DSM) and dissocial (ICD) disorders show poorer reliability with each other than most DSM/ICD pairs (kappa score estimates as low as 0.50). One criticism of the DSM approach is that the required connection to conduct disorder allows nearly infinite combinations of symptoms for any individual fitting the ASPD diagnosis. The resulting increased heterogeneity of the diagnostic group may make inter-system diagnostic reliability more difficult.

Treatment Considerations

Individuals with ASPD are not likely to enter treatment and are most prevalent in institutional and family therapy settings. In treatment, attention should be paid to the stimulation-seeking nature of these clients. An individual with ASPD needs to develop prosocial activities to fulfill their stimulation-seeking nature or they may revert to more deviant patterns.

Borderline Personality Disorder

At first glance, borderline PD (BPD) may seem to overlap with the schizotypal PD, as both imply an easy transition into a schizophrenic adjustment. However, individuals with BPD are neither as consistently withdrawn socially or as bizarre in symptomology as are individuals with schizotypal PD. BPD diagnosis covaries most commonly in inpatients with a diagnosis of HPD. BPD is one of the most consistently diagnosed personality disorders and constitutes ~1–2% of the general population. The combination of symptoms classified in the DSM under BPD, harkening back to the traditional psychodynamic conceptualization of the disorder, is known in the ICD system as 'emotionally unstable PD,' focusing on the key diagnostic criteria for the disorder. In the ICD system, EUPD can have 'Impulsive' or 'Borderline' subtype.

Behavioral, Interpersonal, and Cognitive Patterns

Persons in the BPD category do show significant emotional instability, are impulsive and unpredictable in behavior, and are irritable and anxious. They also often show 'soft' neurological signs, and avoid being alone or experiencing the psychological emptiness or boredom to which they are prone. There is some evidence that as these individuals improve, they show more predictable behavior patterns, yet this is combined with increasingly evident narcissism.

Those with BPD are intense and labile emotionally and cognitively, and are draining to a significant other (and therapists). They fear facing their own intense negative emotions over time, and so find it hard to grieve the many relationship losses they generate. They maintain a facade of competence and independence, yet desperately want various types of help, and then react negatively when it is not forthcoming.

Individuals with BPD seem to decrease symptomology in their thirties, although much of the underlying psychopathology is still there. On occasion, someone with BPD may exhibit 'pseudologia phantastica,' in which he/she engages in pathological lying. This lying may be the individuals attempt to enhance self-esteem. Some individuals with BPD may or may not be aware of their lying.

Diagnostic Considerations

According to the DSM-IV-TR, in order to diagnose an individual with BPD, at least five of the following symptoms must be present: (1) frantic efforts (excluding those behaviors in #5) to avoid actual or imagined abandonment; (2) an unstable and intense interpersonal relationship pattern, with extremes of idealization and devaluation; (3) persistent and markedly disturbed or unstable identity or sense of self; (4) two impulsive self-damaging behaviors (excluding #5); (5) recurrent suicidal behaviors, gestures, or threats or self-mutilation; (6) affective instability due to marked mood reactivity, usually a few hours, not more than 3 days; (7) chronic feelings of emptiness; (8) inappropriate, intense anger or lack of anger control; and (9) transient, stress-related paranoid ideation or severe dissociation.

Treatment Considerations

BPD is often treated with a psychological technique called dialectical behavioral therapy (DBT). This form of treatment, developed by Marsha M. Linehan, a psychological researcher at the University of Washington, United States, is the first empirically validated method to treat BPD. DBT combines psychological theories from Western (cognitive behavioral techniques for emotional regulation) and Eastern (Buddhism-based reality techniques, such as mindfulness, distress tolerance, and acceptance) traditions. The technique is effective for BPD, other mood disorders, and behaviors associated with self-injury.

DBT draws heavily on interpersonal intervention. Thus the DBT therapist must attend vigilantly to how the therapist and client reciprocally influence each other. For example, a client with BPD may become verbally aggressive every time the therapist tries to address a presenting problem. As a result,

the unassuming therapist may discontinue discussion of this topic. In this example, the client punishes the therapist's therapeutic behavior, and the therapist reinforces the client's aggressive behavior. A DBT therapist uses the tension created by not responding in the typical manner to encourage the client to create more effective and flexible coping behaviors.

Treatment of BPD with the DBT protocol is divided into two components, individual and group-based sessions. Individual therapy focuses on weekly events recorded on diary cards. Self-injurious and suicidal behaviors take precedence, followed by behaviors that interfere with therapy. Eventually, behaviors that interfere with quality of life are considered and new skills are discussed. The second component includes weekly group meetings that focus on the development of mindfulness skills, interpersonal effectiveness skills, emotion regulation skills, and distress tolerance skills. Most people with BPD gradually improve, but changes are usually slow and about 50% still meet criteria at follow-ups 4–7 years later.

Many therapists feel frustrated, incompetent, or hopeless in the treatment of individuals with BPD because of the treatment-resistant nature of the disorder and behaviors that interfere with therapy. These patients may be difficult to keep in therapy, frequently fail to respond to therapeutic efforts, become very angry at the therapist, and make considerable demands on the emotional resources of the therapist, particularly when suicidal behaviors are prominent.

The following beliefs are common: (a) I am afraid I will be alone forever, as no one who really gets to know me will want to love me; (b) If I ignore my own needs, I can entrap some people into relationships, but, since I cannot control my feelings, and I need the relationships, I will be very unhappy; (c) though I need people, they will eventually hurt or reject me, so I must protect myself; (d) I deserve any bad things that happen to me; and (e) my misery (and/or 'badness') is how people recognize me as a unique self.

Avoidant Personality Disorder

These individuals are shy and inhibited interpersonally, yet at the same time desire to have interpersonal relationships, which distinguishes them from those with the schizotypal or schizoid PD. They also do not show the degree of irritability and emotional instability seen in the BPD. This is a common secondary diagnosis in inpatient populations.

Behavioral, Interpersonal, and Cognitive Patterns

Avoidant PD (AVPD) is close to the anxiety disorders, since there is a degree of anxiety and stress, and low self-esteem is common. However, behaviors that produce the distress are relatively ego-syntonic. Their depression and anxiety are more related to the perceived rejection and criticism of others. This common disorder is seen more often in men. Any disorder in childhood that focuses on shyness predisposes one to the AVPD.

Other cognitions common to a person with AVPD include (a) if people really got to know me, they would see how inadequate (or odd) I really am, and they would reject me; (b) I am unable to cope with unpleasant people or situations;

(c) not thinking about a problem or unpleasant situation or not trying to cope with it may allow it to go away; (d) you will never leave me because I will make sure I leave you first; and (e) nothing ventured, nothing failed.

Diagnostic Considerations

According to the DSM-IV-TR, in order to diagnose an individual with AVPD, the individual must experience a combination of social inhibitions, feelings of inadequacy, and hypersensitivity to negative evaluation apparent from early adulthood, and exhibited by at least four of the following symptoms: (1) avoidance of occupations with significant social contact because of hypersensitivity to negative evaluation; (2) avoidance of interpersonal involvement unless sure of being liked; (3) restraint in intimate relationships because of fear of shame or ridicule; (4) preoccupation with social criticism or rejection; (5) inhibitions in new interpersonal situations as a result of feelings of inadequacy; (6) belief that one is socially inept, personally unappealing, or inferior; and (7) unusual reluctance, because of potential embarrassment, to engage in personal risks or new activities.

Treatment Considerations

To develop a therapeutic relationship with an individual with AVPD, the therapist should minimize negative feedback, offer frequent reassurance, and model a more 'laid-back,' relaxed interpersonal style. Social skills training, programmatic relaxation training, and assertiveness training is helpful in the treatment of an individual with AVPD. Someone with AVPD is often more concerned with the risk in relationships and may benefit from existential and confrontative therapy approaches.

Dependent Personality Disorder

In one way, individuals with dependent PD (DPD) can be seen as successful individuals with AVPD. They have achieved a style that elicits the desired relationships, though at the cost of any consistent expression of their own personality. They show elements of agoraphobia, not crystallized, and they lack any real self-confidence.

Behavioral, Interpersonal, and Cognitive Patterns

People with DPD have a pervasive need to cling to stronger personalities who are allowed to make a wide range of decisions for them. They are naive and show little initiative. There is some suspiciousness of possible rejection, but not to the degree found in the AVPD. If the individual is not in a dependent relationship, anxiety and upset are common. Even if enmeshed in a dependent relationship, there is still residual anxiety over the possibility of being abandoned.

Underlying cognitive systems that are often included are (a) I am perpetually at risk of being alone in a cold and dangerous world; (b) I am not able to cope with and/or enjoy life without a supportive other; (c) a loss of self is a fair price to pay in order to obtain a relationship with a supportive other, even if they periodically abuse me in some fashion;

and (d) I need constant access to this other, with as much intimacy as I can elicit, so I will be as subservient and inoffensive as I need to be.

Diagnostic Considerations

According to the DSM-IV-TR, in order to diagnose an individual with DPD, at least five of the following symptoms must be present: (1) inability to make everyday decisions alone; (2) allowing others to assume responsibility for major life areas; (3) difficulties in expressing disagreements with others, from a fear of loss of support or approval; (4) difficulties in self-initiation, from self-image problems rather than deficits in motivation or energy; (5) excessive efforts to gain support or nurturance from others, to the point of doing things he/she finds unpleasant; (6) feeling of discomfort when alone, related to fears of being unable to care for him-/herself; (7) quick replacement of relationships to get care and support; and (8) unrealistic preoccupation with fears of having to care for oneself.

Treatment Considerations

Many individuals with DPD believe that dominance and abuse are forms of love, even with adequate early nurturance. Thus, to facilitate the therapeutic relationship the therapist may need to take on a more dominant, protective, and nurturing role than he/she normally would. Eventually, assertiveness training and methods help clients gain insight into their dependent behavior, via feedback from a group, from catharsis, or from other consciousness-raising techniques.

Obsessive–Compulsive Personality Disorder

This disorder is occasionally confused with the obsessive–compulsive disorder (which is an anxiety disorder), but there are significant differences between the two syndromes. First, the individual with obsessive–compulsive PD (OCPD) seldom becomes obsessed about issues. Second, for the person with OCPD, the term compulsive refers to a lifestyle in which compulsive features are pervasive and chronic, but it does not refer to a specific behavior such as persistent hand-washing. Third, the person with an OCPD is not upset, anxious, or distressed about his/her lifestyle, whereas anxiety is generic and often obvious at times in the functioning of the person with obsessive–compulsive disorder.

Behavioral, Interpersonal, and Cognitive Patterns

According to Sigmund Freud, the essential characteristics of a person with OCPD are that they are ‘exceptionally orderly, parsimonious and obstinate.’ They are preoccupied with rules and duties, are unable to express warmth and caring except in limited situations, are highly oriented toward a lifestyle marked by productivity and efficiency, are temperamentally and emotionally insensitive, and are generally distant from other individuals. They are inclined to be excessively moralistic, litigious, and hyperalert to criticism and perceived slights from others. They can be described as workaholics without warmth.

The extent to which the ritualistic and conforming behavior is generalized throughout the person’s life and, more importantly, the degree to which it is functional must be taken into consideration before a diagnosis is made. For example, a pilot develops rituals for determining that his plane is safe before takeoff. If a part of the ritual is omitted by a copilot, the pilot may experience considerable distress and may actually risk alienation by insisting on the performance of the ritual. The pilot’s insistence on carrying out a ritualistic check of the instruments makes him appear obsessive, but it also keeps him alive.

It is true that a degree of compulsivity is effective, particularly in our society. It becomes a problem when it overwhelms the rest of the personality. Paradoxically, individuals with OCPD are often indecisive in their thinking and poor planners of their time, a result of their narrow focus and concern with precision, even when precision may be irrelevant.

Typical underlying beliefs such as (a) to err or worse, to fail, is anxiety-provoking, will allow others to criticize me, and makes me feel less than a whole person; (b) to lose control is anxiety-provoking; (c) my obsessiveness and/or compulsivity are powerful enough to avoid errors, failure, or finding myself with nothing to do, yet; (d) regarding meaningful decisions, rather than ‘Better to have tried and failed than to never have tried at all,’ my motto is ‘Better to have not tried at all, than to have and failed’; (e) details are important, that is, if you can see trees, no need to look for the forest; (f) I am responsible for myself and others; and (g) I hate others when they do not follow ‘the rules,’ (i.e., my rules) and especially if they get by with it.

Diagnostic Considerations

To diagnose an individual with OCPD, he/she must exhibit excessive attention to orderliness, perfectionism, and control, and a lack of flexibility, openness, and efficiency, apparent by early adulthood. According to the DSM-IV-TR, in order to diagnose an individual with OCPD, at least four of the following symptoms must be present: (1) preoccupation with details, to the exclusion of an overall perspective (they see the trees rather than the forest, and not even all of the trees); (2) perfectionism that interferes with tasks; (3) excessive devotion to vocation and productivity; (4) overconscientiousness, scrupulousness, or inflexibility in matters of morality or values (and not accounted for by subcultural or religious factors); (5) hoarding worthless objects that are without sentimental value; (6) reluctance to delegate or cooperate as a result of control issues; (7) financial miserliness toward self and others, to save for impending catastrophes; and (8) rigidity and stubbornness.

Treatment Considerations

Individuals with OCPD have often experienced backgrounds with adequate caregiving and nurturance combined with (1) ‘performance’ as a condition of love–attention; (2) judgments of failure and/or invidious comparisons with siblings or peers; (3) rules presented as impersonal abstracts; and (4) demands for persistence even where success (at least as defined by parents) is unlikely, and then punishment for ‘mistakes.’ Therefore, to initially develop a therapeutic relationship,

the therapist needs to provide consistent though not 'overly emotional' support, accept the patient's hierarchical view of the world, and provide a diagnosis by logic and schemata (patients prefer to follow the DSM-IV-TR diagnosis, as it provides a sense of mastery and some evident goals).

The therapist may have difficulty developing rapport, as individuals with OCPD lack emotionality and a sense of humor. Often, the therapist will have to prove they are competent before the patient will allow rapport to build. The use of covert sensitization technique can be utilized to eliminate compulsive patterns. Another technique is the use of paradoxical intention, where the patient strives to do the thing he/she fears or dislikes. The goal is to reduce the behavior, ironically by increasing the behavior first. Thus, a person who fears rejection may be instructed to keep asking for dates until he/she finds out that it is not so anxiety-provoking to be rejected. Eventually the patient is instructed to vary the circumstances and quantity of the behaviors avoided. Over time, the individual with OCPD develops a greater sense of control over his/her behaviors and may then choose to give them up. Group therapy is recommended to continue with the reinforcement of the new behaviors. At times, the group may be upset by the patient's judgmental behaviors and condescension.

Looking Forward

The DSM-V revision has been slated for release some time in 2013 with the 11th ICD revision coming 2 years later in 2015. However, criticisms about the DSM development process threaten to delay that release (many would argue, appropriately so). In general, these criticisms allege that the goal to effect a diagnostic paradigm shift via the DSM-V is not sufficiently grounded in empirical evidence. The most significant element of the proposed changes is toward a continuous

(rather than categorical) conceptualization of disorders. Interestingly, PDs have long been conceptualized as extremes on the continua of personality traits that cross into diagnostic status when they substantially interfere with functioning. Thus it is unclear the degree to which any such formal change in DSM-V will affect PD diagnoses.

Glossary

Affect Perceived emotion or mood.

Anxiety sensitivity Dimension that describes individual differences in the fear of anxiety-related sensations and their consequences.

Aspect An intermediate trait level between domains and facets.

Big Five A model of personality traits consisting of neuroticism, extraversion, agreeableness, conscientiousness, and openness to experience.

Big Three A model of personality traits consisting of negative emotionality, positive emotionality, and disinhibition versus constraint.

Clinical trait Personality trait that is believed to increase risk for one or more psychological disorders.

Domain Broad dimension of personality (i.e., a 'Big' trait).

Facet A narrow, specific trait that is subsumed within a broader trait.

Factor analysis A statistical method that identifies unobserved dimensions ('factors') that account for correlations among observed variables.

Hierarchical structure Organization wherein broader entities may be divided into more specific entities, which themselves may be further divided.

Level of abstraction A particular section within a hierarchical structure.

Taxonomy System of classification.

Trait Dimension along which individuals vary with regard to behavioral, emotional, and cognitive tendencies that show consistency across time and situations.

Personality traits describe individual differences in behaviors, emotions, and thoughts that tend to be relatively consistent over time and across situations. Dating back to ancient civilizations, humans have attempted to categorize interindividual differences along various dimensions and to understand how these traits relate to one another. For example, the ancient Greeks described four 'humors' or temperaments that define consistent patterns of human behavior: sanguine (cheerful, courageous), choleric (easily angered), melancholic (depressed, irritable), and phlegmatic (calm, unemotional). Throughout the past century, personality researchers developed multiple models of basic personality traits, resulting in many different trait taxonomies and individual traits that overlap with one another to varying degrees. Thus, it became important to understand how these traits covary with one another; in other words, researchers needed to know to what extent different traits represented overlapping characteristics that co-occur within the same individual. This pattern of trait covariance – referred to as 'personality structure' – is essential to the interpretation and synthesis of the large body of literature on personality traits.

Elucidating the structure of personality is important for several reasons. First, it is only by identifying basic personality traits and understanding their associations with one another that we can study how personality characteristics relate to behaviors and outcomes of interest, such as job performance, psychological disorders, and social functioning. Furthermore, particularly because personality traits are strongly heritable, understanding personality structure may shed light on the causes and development of individual differences in behavior, attitudes, emotions, and psychopathology. Thus, an accurate and comprehensive model of personality structure is needed in order to clarify the causes and consequences of individual differences.

Major Models of Personality and Trait Affect

Big Five/Five-Factor Model

The 'Big Five' or 'Five-Factor Model' is a well-replicated, hierarchical taxonomy of normal personality traits. The groundwork for the Big Five dates back to 1936, when Allport and Odbert extracted all of the words in the English dictionary that were relevant to personality. Their approach was rooted in the lexical hypothesis (originally proposed by Sir Francis Galton), which states that most socially meaningful variation among people has been encoded in language. Allport and Odbert made a list of ~18 000 words relevant to personality; roughly 4500 of these terms specifically described personality traits. Starting with Raymond B. Cattell in the 1940s, numerous psychologists conducted factor analyses on this list over the next several decades. Factor analysis is a statistical method that identifies unobserved dimensions ('factors') that account for the pattern of correlations among observed variables. As such, it was an ideal tool for examining whether this large pool of personality terms could be reduced to a relatively small number of basic, underlying traits.

These analyses eventually converged on the Big Five as broad traits that capture much of the interindividual variance, yielding five broad domains: neuroticism (frequency and intensity of negative emotions, maladaptive cognitions and coping strategies, stress reactivity), extraversion (sociability, assertiveness, energy, experience-seeking, positive emotions), agreeableness (empathy, humility, cooperativeness, trust), conscientiousness (persistence, neatness, organization, caution, planfulness), and openness/intellect (creativity, open-mindedness, intellectualism). The Five-Factor Model – most commonly assessed with Costa and McCrae's Revised NEO Personality Inventory (NEO PI-R) – was developed later based on analyses of personality questionnaires, and converged on traits very

similar to those noted above. However, openness in the Five-Factor Model is broader than intellect from the Big Five tradition, in that the former tends to emphasize characteristics such as curiosity, esthetic interests, novelty-seeking, and originality, in addition to those associated with intellect (e.g., being insightful and sophisticated).

The Big Five has been widely validated and replicated, across cultures and languages. Working from the lexical hypothesis, factors similar to the Big Five have been uncovered in a wide range of languages, including Dutch, German, Italian, Chinese, Czech, Hebrew, and Russian. However, Western languages and cultures show more similarity to the English Big Five than do non-Western languages, illustrating that personality models are affected by culture and language. Replicability tends to be strongest for agreeableness, conscientiousness, and extraversion across languages and cultures. In contrast, intellect/openness tends to vary the most from culture to culture, with a range of different emphases and subtexts, from intellect to unconventionality. In further support of the validity of the Big Five, these five traits are evident not only when individuals rate themselves but also when they are asked to rate other people, whether they may be strangers or long-term romantic partners. These ratings tend to have good agreement with the target's ratings of their own personality, although the level of agreement varies by trait (it is strongest and most consistent for extraversion) and as a function of the level of acquaintance between judge and target. Overall, the Big Five is a very robust model of personality, showing substantial consistency across methodologies, cultures, and languages.

The Big Three

The Big Three is another prominent trait taxonomy, consisting of three primary traits: neuroticism or negative emotionality, extraversion or positive emotionality, and disinhibition versus constraint. Negative and positive emotionality refer to individual differences in the tendency to experience negative and positive emotions, respectively. Disinhibition versus constraint describes individual differences in undercontrolled versus overcontrolled behavior: Whereas disinhibited individuals tend to be impulsive and reckless, constrained individuals are risk-avoidant and planful. Whereas the Big Five was developed largely in 'normal' samples (i.e., nonclinical samples), the Big Three was developed in the context of – and is often applied to – 'abnormal personality,' that is, traits in individuals with significant psychopathology. The Big Three has its roots in the work of Hans Eysenck (largely conducted from the 1940s to the 1970s); note that in Eysenck's original model, the trait that maps onto disinhibition versus constraint is labeled 'psychoticism.' Subsequent to Eysenck's work, other personality researchers (e.g., Tellegen, Watson & Clark, Gough) have converged on similar models of the Big Three. This more recent work has helped to clarify our understanding of all three trait domains, particularly disinhibition versus constraint.

Connections to Trait Affect

As suggested above, two of the Big Five and Big Three traits exhibit close links to trait affect. Extensive evidence has established that neuroticism measures are strongly correlated with

individual differences in negative emotionality, whereas extraversion is strongly associated with positive emotionality. To emphasize the close association between these constructs, we refer to them jointly as neuroticism/negative emotionality (N/NE) and extraversion/positive emotionality (E/PE) in this article. N/NE and E/PE are closely connected to more general biobehavioral systems that evolved to address very different evolutionary tasks. Specifically, N/NE is a component of the withdrawal-oriented behavioral inhibition system, which serves to protect organisms by inhibiting behavior that might lead to pain, punishment, or some other undesirable outcome. In contrast, E/PE is a component of the approach-oriented behavioral activation system, which directs organisms toward situations and experiences that potentially may yield pleasure and reward. It has become clear that N/NE and E/PE represent basic dimensions of temperament that (a) are strongly stable over time, (b) are at least partly attributable to innate biological factors, and (c) have emotional products as core, defining features.

Development of a Consensual Hierarchical Structure

Throughout much of the twentieth century, trait psychologists produced countless studies of personality structure that appeared to yield confusing and contradictory results. Finally, starting in the 1980s, considerable progress began to be made toward the articulation of a consensual, comprehensive taxonomy of traits. The first major development was the explicit recognition that personality traits are ordered hierarchically at different levels of abstraction or breadth, a point for which supportive evidence has continued to accrue. For example, the broad higher order trait of conscientiousness can be decomposed into several distinct yet empirically correlated facets, such as deliberation, dependability, and industriousness. As a higher order trait, conscientiousness may be thought of as representing the shared variance among these facets, accounting for the correlations between them. The development of hierarchical models permitted the integration of general factor models – such as the prominent Big Three and Big Five schemes – with multidimensional, primary trait models that were the focus of most older personality inventories.

The second key development was the recognition that the Big Three and Big Five models – which originally had appeared to be somewhat incompatible in their nature and scope – actually define very similar trait structures. The accumulating data established that two common higher order traits – N/NE and E/PE – are included in both models. Moreover, correlational and factor analytic evidence revealed that the third Big Three dimension (disinhibition versus constraint) essentially combines the Big Five dimensions of conscientiousness and agreeableness. The final Big Five factor (i.e., openness, intellect, or culture) is virtually unrelated to the Big Three. Each level of the hierarchical structure of personality will be further described throughout the remainder of the article, but [Figure 1](#) provides a summary of the contents and interrelationships of different levels of personality structure.

The hierarchical structure of personality allows for a large degree of both flexibility and precision in research contexts, in

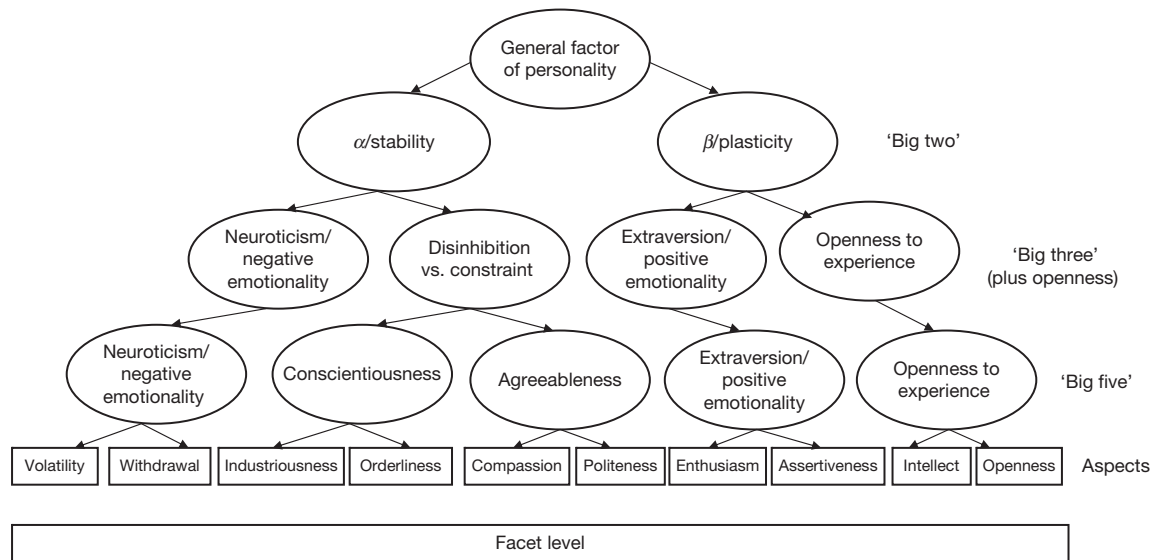

Figure 1 Hierarchical model of personality, showing each level of abstraction. Note that facets are not listed because there is not currently a complete consensual structure at this level.

that one can select the level of abstraction that is likely to be maximally informative and interesting. For example, if one is interested in a general phenomenon such as diurnal variation in relation to personality, it may be best to focus on one of the broad, upper levels of the hierarchy. In contrast, if one wants to study traits that might differentiate closely related constructs (such as depression and anxiety), it may be most informative to select more specific traits from the lower levels of the hierarchy. In addition, by simultaneously including multiple levels of abstraction in the same study, one may determine which level is primarily responsible for the association with a given construct and, therefore, describe more precisely how that construct relates to personality traits.

Personality Superfactors

The Big Two

The traits in the above models of personality were hypothesized to be independent of one another. However, it has been known for some time that there are weak to moderate correlations among the traits in the Big Five, as well as (to a lesser extent) among the traits in the Big Three. Numerous explanations have been put forth for these correlations, including that they are method artifacts of particular instruments or individual raters, or that they reflect social biases to evaluate some traits positively and others negatively. However, subsequent research has found that although these biases may inflate the magnitude of coefficients somewhat, the intercorrelations among the Big Five and among the Big Three remain substantial and consistent even after controlling for them.

Digman was among the first to systematically study these intercorrelations, conducting a meta-analysis examining the associations among the Big Five. He found that two higher order dimensions emerged from these associations, which he called α and β . Alpha consists of low N/NE, high agreeableness,

and high conscientiousness, whereas β is defined by high E/PE and high openness to experience. Other studies have identified a similar structure across a variety of measures and methods, incorporating the Big Three traits (wherein α corresponds to low N/NE and low disinhibition, and β essentially represents E/PE) and using informant data. Furthermore, when two factors are extracted from lexical studies, these factors are quite similar to α and β (called social propriety and dynamism, respectively). DeYoung has referred to α as 'stability' to reflect the fact that high levels of this factor are likely to facilitate socialization and getting along with others; he called β 'plasticity' to denote that high levels of the trait are likely to contribute to personal growth and exploration.

General Factor of Personality

Even at the level of the Big Two, stability and plasticity are significantly correlated, leading to recent interest in 'the Big One,' that is, a general factor of personality that is situated at the apex of the personality hierarchy. This trait may be comparable to Spearman's g in the domain of intellectual ability and consists of high levels of both stability and plasticity; as such, it can be interpreted as adaptiveness or social desirability (i.e., the extent to which someone is functioning well versus poorly). A recent meta-analysis of 212 studies supported a model in which the Big Five domains load onto stability and plasticity, which then load onto the general factor of personality. For the most part, these results did not depend on the type of sample or measure used. This general factor of personality also seems to be relevant to some important behavioral criteria, such as job performance as rated by supervisors. However, research on the general factor of personality is quite new, and it is currently unclear whether we should interpret the general factor of personality as a meaningful construct, or if it is best viewed as an artifact of social desirability biases or problematic statistical procedures.

Lower Order Traits

Aspects of the Big Five

Traditionally, each of the traits in the Big Five or the Big Three has been divided into numerous lower order traits called facets. However, DeYoung and colleagues have argued for an intermediate level between domains and facets that they referred to as 'aspects' of the Big Five. They argued that this intermediate level is interesting because behavior genetic studies have indicated that the genetic variance tends to cluster into two subfactors per domain, rather than into numerous individual facets. It is important to note that this study included several measures of facet-level Big Five traits, and thus was not limited by the idiosyncrasies of a specific measure.

Factor analysis revealed two aspects within each of the Big Five domains that then were correlated with factor scores reflecting shared genetic variance among Big Five facets; the results of these analyses suggested that these aspects reflect distinct biological substrates. In the N/NE domain, the first component was marked primarily by anxiety and sadness (referred to as withdrawal), and a second component was defined primarily by anger and hostility, and also included impulse control problems and emotional lability (volatility). E/PE consisted of assertiveness, which was marked by dominance and an ability to lead others, as well as enthusiasm, which was related to positive emotionality, gregariousness, and friendliness. Conscientiousness was broken down into industriousness (efficient, disciplined, achievement-striving) and orderliness (organized, perfectionistic). Agreeableness consisted of compassion (empathy, altruism, tender-mindedness) and politeness (cooperation, compliance), whereas openness contained intellect and openness, two components that were described previously. Although this structure was tested in multiple samples and corresponds well to previous genetic analyses, it should be replicated in additional studies.

Facet-Level Traits

There is currently little consensus regarding the contents of the facets – that is, the most specific traits in the personality hierarchy – that fall within each of the Big Five domains. This is partly due to the fact that few lower order measures of personality traits exist, and most research includes only one of these facet-level inventories. This limits our understanding of how the structural schemes modeled by these different measures might relate to one another. A comprehensive model of the facets within each domain – cutting across different measures – is needed to allow researchers to create a shared, consensual trait taxonomy. Determination of a lower order taxonomy is further complicated by the fact that some facets seem to be a blend of two or more domains, rather than falling neatly into a particular higher order domain. We review here three Big Five domains – N/NE, E/PE, and conscientiousness – in which research has been conducted to synthesize different facet-level conceptualizations into a larger, inclusive model.

N/NE facets

A comprehensive review of the faceted personality models – including models in the tradition of the Big Three, Big Five,

trait affect, and others – reveals many different conceptualizations of the contents subsumed within the N/NE domain. However, several trends may be identified across most or all of the N/NE models. First, nearly every model has a facet related to individual differences in anxiety/fear. Although anxiety and fear are distinguished from one another in many theoretical models, they are often combined when assessing personality traits. Second, numerous models contain both a depression/sadness facet and a stress reactivity or vulnerability facet. Note that in some models, a single facet combines aspects of fear/anxiety, depression/sadness, and/or stress reactivity, as the first two constructs have a close empirical relation, and the third assesses the perceived or experienced likelihood that negative affects such as anxiety and depression will be triggered under stressful circumstances. Finally, despite its substantial secondary loading in the Big Five agreeableness domain, a hostility/anger/aggression facet is present in nearly all N/NE models. Thus, these four components – anxiety, sadness, angry hostility, and stress vulnerability – appear to represent central N/NE facets.

Two other N/NE facets appear in two or more models of the domain. First, mistrust/suspiciousness/cynicism has traditionally been located in the Big Five agreeableness domain, rather than neuroticism; however, it appears to be a blend of low agreeableness and low N/NE, and so sometimes is included in models of the latter. Second, numerous models contain content relevant to dependency, approval-seeking, and the need for emotional support.

Thus, in synthesizing the N/NE models as exemplified by major personality inventories, six specific facets can be identified: anxiety, sadness, angry hostility, stress vulnerability, mistrust, and dependency. In addition, there is evidence that stress vulnerability may be best conceived as a broad nonspecific component of N/NE that describes the elicitation of negative affect, rather than being an independent facet within this domain. When this model – consisting of anxiety, sadness, angry hostility, mistrust, and dependency as facets, with stress vulnerability marking the shared variance among them – was tested in independent samples of college students and psychiatric patients, it was found to fit the data well in both groups.

E/PE facets

Based on an extensive review of data and contemporary models of E/PE, Watson and Clark created an integrative model of E/PE that synthesizes the major elements included in current conceptualizations of the construct. This integrative model has four central facets: affiliation (consisting of warmth and gregariousness), positive affectivity or emotionality (consisting of joy and enthusiasm), energy (consisting of liveliness and activity), and ascendance (consisting of exhibitionism and dominance).

In this model, two other facets are also considered to be part of E/PE, but have a less primary role: venturesomeness (excitement-seeking and desire for change) and ambition (achievement and endurance). Venturesomeness bears some resemblance to impulsivity, which was a central feature in some prominent early models of extraversion. However, impulsivity has since been found to be a separate construct and is generally not considered to be a facet of E/PE, although some debate remains regarding this issue. The status of ambition as a facet of extraversion has also been questioned, as it is

often instead included in the conscientiousness domain. However, there is evidence that ambition/achievement overlaps with E/PE as well, particularly with the positive emotionality component of E/PE.

An empirical test of a model similar to the one described above was conducted in independent samples of college students and psychiatric patients; however, ambition was excluded. This study identified a replicable structure for E/PE, consisting of four facets: sociability, positive emotionality, ascendance, and fun-seeking. Three of the E/PE facets correspond closely to the above model: both contain ascendance facets, sociability is equivalent to affiliation, and fun-seeking is very similar to venturesomeness. The only notable difference is that the positive affect and energy facets in the earlier model formed a single facet (i.e., positive emotionality) in these analyses. Although positive affect and energy are theoretically separable, they may not be empirically distinct when considered in the context of other closely related facets of E/PE.

There currently is some debate over the nature of E/PE and whether sociability/interpersonal components or positive emotional components provide the 'glue' that holds together the individual facets of the trait. There is evidence to support the centrality of both sociability and positive emotionality to E/PE. In terms of sociability, increased social activity has been found to increase state positive emotionality in between- and within-subject analyses, and both trait positive emotionality and extraversion are moderately associated with average hours of social activity. On the other hand, studies have also found support for the centrality of positive emotionality, in that elevated levels of state positive affectivity are associated with increased social behavior, as well as an increase in other nonsocial pleasurable activities. Furthermore, the E/PE facets of ascendance, ambition, and affiliation are all more strongly related to positive emotionality than to one another, suggesting that positive emotionality is largely responsible for holding together the various facets of E/PE. Finally, several studies have pitted these two hypotheses regarding the core of E/PE against one another. They concluded that positive emotionality is the central organizing feature of E/PE, and that enjoyment of social activities is simply one manifestation of high positive emotionality. Although it is likely that the influence of positive emotionality and sociability is bidirectional, the evidence to date indicates that positive emotionality is stronger and more central to higher order E/PE.

Conscientiousness facets

A structural analysis of several faceted measures of the conscientiousness domain yielded six facets: industriousness (hard-working, ambitious, resourceful), order (effectively plans and organizes tasks), self-control (cautious, delays gratification, patient), responsibility (cooperative, dependable, of service to others), traditionalism (compliant with rules, norms, and traditions), and virtue (acts according to accepted rules of good or moral behavior). Industriousness, order, and self-control are most strongly associated with one another, and self-control is most closely associated with higher order conscientiousness. It appears that industriousness and orderliness are most specific to conscientiousness, with the other facets showing more prominent secondary loadings with other domains. In addition, research has shown that these conscientiousness facets are

differentially associated with various relevant behaviors, such as drug use, work dedication, preventative health behaviors, and traffic risk behaviors.

Clinical Traits in the Personality Hierarchy

Clinical traits are dispositional constructs that were developed within the psychopathology, rather than the personality, literature. These lower order traits are hypothesized to be particularly relevant to one or more psychological disorders, often as vulnerability factors that predispose individuals to develop these disorders. Because clinical traits are dimensional and vary continuously across individuals, they can be studied in both normal and clinical populations. We focus here on several clinical traits that have been widely studied and are relevant to numerous psychological disorders: self-criticism, perfectionism, and anxiety sensitivity.

As illustrated previously, the hierarchical position of Big Five facets is relatively straightforward, in that each is intended to relate strongly to one of the higher order Big Five domains and only weakly to the others. However, the location of clinical traits in the hierarchy is more complicated. Broadly speaking, these three clinical traits are facets of N/NE, as they clearly show the strongest relation with this general trait. However, they also have more moderate correlations with other higher order traits. In addition, some data are available regarding how these clinical traits relate to specific facets within the Big Five and Big Three models, allowing us to characterize these traits more precisely within the hierarchy of normal personality.

Self-Criticism

Self-criticism is defined as the tendency to engage in negative self-evaluation that results in feelings of worthlessness, failure, and guilt when expectations are not met; it was originally seen as particularly relevant to the development of depression. Correlations between self-criticism and N/NE are strong ($r_s = \sim 0.50-0.65$), with a particularly strong association with the depression facet. Self-criticism also has a weaker but moderate negative correlation with extraversion of ~ -0.30 to 0.40 , and is most strongly related to the positive emotionality component of E/PE. In addition, there is some evidence for a moderate negative correlation with conscientiousness and agreeableness.

Perfectionism

Generally speaking, perfectionism is characterized by the setting of excessively high standards of performance. In addition, many definitions of perfectionism include a tendency toward negative emotional responses that follow the failure to meet one's standards; this tendency shows a close empirical association with self-criticism. There is now a consensus that perfectionism broadly consists of two primary components: (1) maladaptive perfectionism/evaluative concerns/self-critical perfectionism, and (2) adaptive perfectionism/personal standards/achievement-striving.

The strongest correlate of maladaptive perfectionism is N/NE, with correlations ranging from roughly 0.30 to 0.60 ,

depending on the measure. Specific N/NE facets from the NEO PI-R that relate to maladaptive perfectionism are anxiety, angry hostility, depression, vulnerability, and self-consciousness, although the depression facet was the only significant predictor of maladaptive perfectionism scores in a multiple regression. There is also some evidence for an inverse relation with E/PE (particularly positive emotionality), agreeableness, and conscientiousness. In contrast, adaptive perfectionism is most strongly correlated with conscientiousness and has moderate correlations with all six of its facets; industriousness has a particularly strong relation with adaptive perfectionism. In addition, adaptive perfectionism is positively related to the assertiveness and activity facets of E/PE. When the conscientiousness facets are regressed onto adaptive perfectionism, industriousness and dutifulness are both significant predictors. Thus, maladaptive and adaptive perfectionism clearly have different locations in the personality hierarchy. Maladaptive perfectionism looks very similar to self-criticism, characterized primarily by high N/NE (particularly, sadness/depression) and low E/PE. Adaptive perfectionism is primarily related to high conscientiousness (particularly, industriousness) and high levels of the energy and assertiveness components of E/PE.

Anxiety Sensitivity

Anxiety sensitivity describes individual differences in the fear of anxiety symptoms, due to a belief that these symptoms are likely to have harmful consequences. Anxiety sensitivity was originally seen as a vulnerability factor for the development of panic disorder. It is conceptually distinct from anxiety itself and instead involves one's response to anxiety symptoms, or the 'fear of fear.' Based on studies of several different measures of anxiety sensitivity, this trait is moderately correlated with N/NE ($r_s = 0.30-0.50$) and is most specifically related to the anxiety and self-consciousness facets of the NEO PI-R. E/PE has a weaker correlation with anxiety sensitivity, and the sociability components of E/PE appear to be primarily responsible for this association. It is interesting to note that the trait of absorption (a component of openness to experience), which reflects a tendency to become engrossed in imagined or actual sensory experiences, may also be weakly related to anxiety sensitivity.

Conclusion

Personality researchers have made significant progress in elucidating the contents of – and associations among – the domain level and higher order traits in personality structure, particularly with regard to the Big Five and Big Three. Furthermore, by articulating the hierarchical nature of these models, we now have a powerful and efficient taxonomy that can be utilized at varying levels of specificity. However, further clarification is needed at both the highest and lowest levels of the personality hierarchy. At the highest levels, it will be helpful to explore further the utility and meaning of the Big Two and the general factor of personality. At the lowest levels, there

currently is no consensus regarding the facet-level contents of the hierarchy, with numerous hypothesized models containing different sets of specific component traits. Relatedly, it remains unclear exactly where prominent clinical traits fit into the hierarchy. With further research, we will move closer to the ultimate goal of articulating a comprehensive, consensual model of the structure of personality.

Glossary

Attitude A global evaluation of a person, object, or issue indicating the extent to which it is liked or disliked.

Attitude accessibility How readily an attitude comes to mind in the presence of the attitude object.

Attitude certainty A belief held about an attitude that reflects the conviction with which the attitude is held, or an assessment of the correctness of the attitude.

Attitude strength The extent to which an attitude is persistent and resistant, and impacts thinking and behavior.

Central route Persuasion through effortful thought and extensive elaboration that involves generating cognitive responses.

Peripheral route Persuasion through less effortful mechanisms including mental shortcuts, simple associations, and impact of contextual cues.

Persuasion The process by which attitudes are changed.

Resistance The extent to which attitudes remain firm when confronted with an attempt to persuade.

Persuasion is the process by which attitudes are changed. Persuasion processes can change three aspects of an attitude: valence – whether the attitude is positive or negative, extremity – where the attitude falls within a given valence, and strength – whether the attitude is consequential or not. Persuasion processes can be broadly divided into those that require extensive thoughtful consideration of information relevant to the attitude object, and those that require comparatively little thought relevant to the attitude object. Situational and personal variables determine whether more thoughtful or less thoughtful processes are likely to occur. Variables that determine the extent of elaboration are important to understand, because thoughtful processes result in stronger, more consequential attitudes, whereas less thoughtful processes result in weaker attitudes. Understanding the variables that determine the type of processing that is likely to occur makes it possible to predict the likely consequences of any persuasion attempt. As attitudes are generally the best predictors of behavior, understanding the processes through which attitudes are changed is critical to understanding changes in behavior.

Persuasion Attempts

A persuasion attempt refers to any effort to produce attitude change. It is common to experience numerous persuasion attempts each day, from a car commercial portraying a drive on a gorgeous day with great friends or a famous actress advertising cell phones, to political candidates expressing positions on policy or a lawyer making closing arguments in a criminal trial. In each case, the goal is to persuade the audience to change their attitudes in order to produce changes in behavior (e.g., purchases, voting).

To help to identify all of the aspects of a persuasion attempt that might produce attitude change, it is helpful to look at three elements: the source, the message, and the audience. Persuasive attempts contain a variety of attributes intended to enhance attitude change, which could include an attractive source, a message containing convincing arguments, or efforts to make

the topic seem personally relevant to the audience. Persuasive communications contain a variety of attributes intended to enhance persuasion, which could include an attractive source, a message containing convincing arguments, or efforts to make the topic seem personally relevant to the audience. Although it is useful to look at source, message, and audience variables to identify elements that potentially impact persuasion, the type of processing that the recipient of a message engages in is the most critical determinant of what impact a persuasion variable has on attitude change. After describing high and low thought persuasion processes, we explain how any given variable (e.g., source credibility or a person's emotions) can produce attitude change under both high and low thinking conditions.

Two Routes to Persuasion

There is general agreement among those who study persuasion that it is critical to distinguish between attitude change that involves extensive thought, as you might expect from a conscientious jury member during a trial, and attitude change that involves little thought or cognitive effort, such as someone flipping aimlessly through ads in a magazine. The elaboration likelihood model (ELM), proposed by Petty and Cacioppo, places persuasion along a continuum from processes that require extensive thought (central route to persuasion) all the way to those that require hardly any thought at all (peripheral route to persuasion). Overall, the extent to which an individual is motivated and able to process issue relevant information determines whether the central or peripheral route to persuasion is taken. Understanding which route to persuasion is taken is important, because this determines whether the resulting attitude is likely to be a strong attitude that is stable, resistant, and consequential for behavior or a weak attitude that is not.

Peripheral Route

Under circumstances when an individual does not have either the motivation or the ability to thoughtfully consider information that is relevant to the attitude object, it is likely that

attitudes will reflect the influence of peripheral route processes. Low motivation to process information could occur because the attitude object is not relevant to that person, or the person is one who generally does not enjoy thinking (i.e., the person is low in 'need for cognition'). Low ability to process could occur because of outside distractions or because the individual does not have the knowledge to understand the persuasive message.

When either motivation or ability to process information is low, a variety of peripheral route processes are more likely to be responsible for persuasion. When the peripheral route is taken, attitude change reflects elements of the persuasive communication that do not require extensive thoughtful processing, like attractiveness and credibility cues, classical conditioning, mere exposure, and various heuristics (e.g., more arguments are better). For example, someone who is uninterested in cars and who is just flipping through a magazine could form associations between a car in an ad and the beautiful scenery or an attractive endorser, or he or she might notice the large number of features the car has without reading them, and each of these could lead to attitude change about the car on the basis of the peripheral route. Although the peripheral route can produce attitude change, the resulting attitudes are relatively weak, because they are not based on the extensive elaboration of issue relevant information and so are not integrated into existing memories. These weak attitudes are less likely to persist over time, resist future persuasion attempts, or predict behavior.

Central Route

Under circumstances when individuals are highly motivated and able to process information relevant to the attitude object, it is likely that attitudes will reflect the influence of central route processes. High motivation to process information could occur because the attitude object is personally relevant or the person enjoys thinking in general. High ability to process occurs when there are few distractions and the person has the knowledge to understand the information presented. Central route processes require extensive thought and elaboration on information relevant to the attitude object. For example, someone who has the time and is interested in buying the kind of car presented in an ad would carefully consider the attributes of the car that are enumerated in the ad, including the safety record, fuel mileage, and resale value and relate this information to their existing needs. High elaboration processing is typified by careful consideration of the presented information in which it is compared and integrated with existing information in memory.

Persuasion under high elaboration conditions is determined by the thoughts that are generated. If the thoughts are in the direction of the persuasion attempt (positive toward the car), then attitude change will move in that direction; however, if the thoughts are predominantly against the direction of the advertisement, then the attitude will change in a direction opposite to the intended direction, referred to as a boomerang effect. This can occur when an individual successfully counter-argues the presented arguments by using the information available in memory to undermine the persuasion attempt. Because elaborative thought reflects the integration of new information

with existing memories, the resulting attitudes tend to be strong ones that persist over time, resist persuasion attempts, and predict behavior.

Under high elaboration conditions, attitude change reflects object-relevant thoughts that are generated, including whether they are positive or negative and the number of thoughts. In addition, when thinking is high, people also consider the validity of their thoughts. The self-validation hypothesis holds that the confidence with which thoughts are held is critical because it determines the extent to which thoughts influence attitudes. When thoughts are held with confidence, they are more likely to impact attitudes, whereas when people have doubts in their thoughts, they are less likely to impact attitudes. A variety of circumstances can undermine thought confidence, including feedback indicating that the quality of thoughts is not good, body cues undermining thoughts such as sitting in a slumped posture or shaking one's head, or experiencing negative feelings for reasons unrelated to the persuasive message. Everyday experiences such as feeling sick, sleepy, or light-headed could also lead someone to doubt the thoughts he or she has at the moment, making these thoughts less likely to influence attitudes. On the other hand, when someone is feeling particularly mentally sharp and awake and the thoughts come to mind easily, the thoughts he or she generates are more likely to impact his or her attitudes because they are held with high confidence. In this way, confidence in thoughts, as opposed to doubt, leads to a closer relationship between the valence of thoughts generated and attitudes.

Researchers have developed techniques to assess whether message recipients are engaging in high as opposed to low elaboration processing. One commonly used approach is to develop two messages designed to persuade in the same direction on the same issue, where one message provides strong cogent arguments and the other message provides weak and specious arguments. The extent to which strong arguments lead to greater attitude change than weak arguments indicates the extent to which recipients of the message carefully considered the content of the message. On the other hand, if participants do not carefully consider the content of the message, then attitudes will be influenced less by the quality of the arguments presented. Manipulating argument quality allows researchers to assess the extent to which a variable, such as motivation or ability to process the message, can impact whether the central or peripheral route to persuasion is taken. Studies have shown that when a topic is personally relevant to the recipient, when the recipient is someone who likes to think, when there is little distraction in the environment, and when the recipient has the knowledge needed to process the message, the impact of argument quality on attitudes is greater than when each of these elements is not present. A second method of assessing the extent of elaborative processing is the relationship between the valence of the issue-relevant thoughts and the attitude. A closer relationship between the valence of thoughts and attitudes indicates attitudes that reflect high elaboration processing, whereas a weaker relationship indicates that attitudes reflect something other than thoughts, indicating low elaboration processing. Thus, using manipulations of argument quality and measurements of thoughts provide assessments of the extent of elaboration that is taking place.

Multiple Roles: The Case of Incidental Emotion

To this point, several ways that variables impact persuasion have been described: serving as cues under low elaboration conditions, serving as arguments or affecting the valence of thoughts or confidence in thoughts under high elaboration conditions, and by influencing whether the central or peripheral route to persuasion is taken (i.e., whether people are placed under high or low elaboration conditions in the first place). Under the ELM, the same persuasion variable has the potential to impact persuasion in each of these ways depending on whether elaboration likelihood is constrained to be high, constrained to be low, or is not constrained. This potential for a single variable to play multiple roles is illustrated in the case of incidental emotions. Incidental emotions are emotions produced outside of the persuasive communication itself (e.g., emotion that comes from a television program in which an advertisement is embedded). Whether in the laboratory or in real life, incidental emotions can result from experiences that evoke an emotional response, including reading about or writing down events that evoke either positive (e.g., happiness) or negative (e.g., sadness) emotions, or simple events such as winning a monetary prize. The research presented next indicates that emotion that is elicited outside of the persuasive communication can serve multiple roles in persuasion.

Low elaboration

When either the motivation or the ability to process issue-relevant information is lacking, incidental emotion serves as a peripheral cue, consistent with the peripheral route to persuasion. Therefore, incidental affect influences the resulting attitudes in the direction consistent with its valence, and so positive feelings produce more positive attitudes whereas negative feelings produce more negative attitudes.

Two processes have been identified that can produce this simple cue effect of emotion under low elaboration conditions, classical conditioning, and misattribution. With classical conditioning, a simple association is formed between an object and the stimuli that evoked positive or negative responses. A variety of research has shown that pairing an attitude object with positive or negative stimuli, such as receiving a free lunch as opposed to smelling a noxious odor, has a direct impact on the attitudes expressed towards unrelated objects. These conditioning effects occur even when the stimulus is presented so quickly that it falls outside of the awareness of the observer and little or no time is allowed for reflection, illustrating that no effortful thought is required for this process, consistent with low elaboration processes.

Emotion can also impact attitudes under low elaboration conditions when the emotional response is misattributed to the attitude object. For example, rather than evaluating the merits of a persuasive message, the recipients might misattribute their current emotional state to their response to a persuasive message. Therefore, with positive emotions, the attitude moves in the direction advocated by the message to a greater extent than with negative emotions. Incidental emotions can also be directly attributed to the attitude object in the absence of a persuasive message. In this case, an individual simply asks himself or herself how he or she feels about the attitude object, and if he or she is feeling good as opposed to bad, for example

because of the weather, then this can lead to the expression of a more positive as opposed to a more negative attitude.

According to the ELM, these direct cue effects of emotion are expected particularly under low elaboration conditions, whereas other processes are expected to operate under high elaboration conditions. In a study directly testing this view, some participants were told that they could choose an attitude object (a pen) to take home, leading to high personal involvement with the product, whereas others were told that they would choose another unrelated product, leading to low personal involvement when learning about the pen. They were then exposed to a television program that produced a positive or neutral mood, and this was followed by a set of commercials including one about the pen. In both high and low involvement conditions, positive mood led to more positive attitudes towards the pen, but through different processes. Under high involvement, the positive mood led to more positive thoughts about the pen than the neutral mood and this explained how mood influenced attitudes, whereas under low involvement, attitudes did not reflect the positivity of the thoughts. The absence of effects of thoughts suggests that mood had an impact on attitudes through low elaboration processes such as conditioning or misattribution which operate in the absence of thoughtful processing.

High elaboration

Under high elaboration conditions, attitudes are a function of cognitive responses to a persuasion attempt. In the study reviewed above, when the attitude object (a pen) was highly personally relevant, mood biased attitudes because mood influenced whether thoughts were more positive or less positive. As thoughts did not play a role under low personal relevance, this shows that high elaboration conditions are necessary for thoughts to explain the biasing effect of mood on attitudes.

Evaluating persuasive arguments sometimes requires forming judgments of the likelihood of an event occurring. When events are associated with specific emotions, individuals already experiencing those emotions judge the likelihood of those events occurring to be higher. For example, feeling angry makes angering events seem more likely to occur, while feeling sad makes saddening events seem more likely to occur. As these likelihood judgments influence the assessment of the persuasive arguments presented, these changes in likelihood judgments impact attitudes. Taken together, evidence shows that incidental emotions can have an impact on evaluations through cognitive responses, in the form of thoughts in response to a message or likelihood judgments, which is consistent with high elaboration processing. Thus, when elaboration likelihood is constrained to be high, persuasion variables that have an impact on attitudes, such as incidental emotion, do so by influencing cognitive responses.

In addition to affecting the valence of the thoughts when thinking is high, emotions can also serve in other roles. For example, if the emotion is salient after a persuasive message has already been processed, then emotions can affect the confidence people have in the thoughts they have generated. More specifically, if people are made to feel happy after generating thoughts, they become more confident in these thoughts than if they are made to feel sad after thinking. This means that if the thoughts generated were largely favorable to the message,

then placing people in a happy state after processing will enhance persuasion because people will be more confident in and rely more on their positive thoughts. However, if the thoughts generated were largely unfavorable, then placing people in a happy state after processing will reduce persuasion because people will have greater confidence in their negative thoughts and rely on them more. The opposite occurs if people are placed in any emotion associated with doubt following the message such as sadness.

Unconstrained elaboration likelihood

The discussion to this point has focused on circumstances where elaboration likelihood is constrained to be either high or low because of variables related to the motivation and ability to thoughtfully process information. When this is not the case, persuasion variables can have their impact by influencing the extent of elaboration, determining whether high or low elaboration processes are likely to influence attitudes. The impact of traditional motivation and ability variables like personal relevance and distraction has already been discussed; however, other variables including incidental emotions can also impact extent of elaboration so long as elaboration is not already constrained to be either high or low by other variables (e.g., distraction). Two accounts for the impact of incidental emotion on extent of elaboration are discussed below.

According to the feelings-as-information account, moods and emotions provide information about the status of the current environment and through this can impact the motivation to engage in effortful processing. In particular, negative affect indicates that the environment is problematic, and this is associated with a higher level of effortful processing in order to address the issues in the environment. On the other hand, positive affect indicates that the environment is safe, and so is associated with less effortful processing. Indeed, a number of studies appear to show that experiencing positive mood makes engaging in effortful processing of a persuasive message less likely. However, a close review of the methods used by researchers showed that the persuasive communications used in this research are often counterattitudinal topics, such as nuclear waste and tuition increases, which are likely to elicit negative moods and emotions. This suggests that those experiencing positive affect were avoiding effortful processing of these messages as a way to maintain their good mood, rather than because they used a simple mood-as-information cue. According to this hedonic contingency viewpoint, those who are feeling happy are particularly sensitive to the hedonic consequences of a persuasive message, and so will choose to avoid extensive processing of persuasive messages that are likely to lead to negative feelings, but they will extensively process persuasive messages that appear likely to produce positive feelings. As those experiencing negative feelings are less concerned about maintaining their current state, their level of effortful processing is unrelated to whether the message is positive or negative. Evidence shows that when presented with proattitudinal messages, those in a positive mood engage in high elaboration processing, as illustrated by a strong effect of argument quality on attitudes. Thus, evidence suggests that incidental affect can also influence whether high or low elaboration processing takes place.

Attitude Strength

Strong attitudes are those that remain stable over time, resist future persuasion attempts, and are predictive of behavior. Weak attitudes are less consequential in these ways. Attitudes that result from the central route tend to be stronger than those resulting from the peripheral route. A variety of indicators have been developed to assess whether an attitude is likely to be strong or weak, including the extremity, accessibility, importance, and certainty with which the attitude is held. In general, attitudes that are more extreme, those that are more likely to come to mind spontaneously, those that are more important, and those held with more certainty are more consequential than attitudes lacking these attributes.

Strength indicators can be divided into those that directly reflect structural aspects of the attitude, such as attitude accessibility, and metacognitive indicators of strength that reflect beliefs about the attitude, such as the certainty with which the attitude is held. Metacognitive indicators reflect secondary thought, meaning that they are thoughts that reflect on other thoughts, in this case the attitude itself. On the other hand, structural components indicate a component of the attitude itself, so attitude accessibility is proposed as a direct assessment of the link between the representation of the object in memory and its evaluation. Both structural and metacognitive strength indicators are associated with strength consequences. Attitude accessibility is the most widely studied structural strength indicator, and attitude certainty is the most widely studied metacognitive indicator.

Attitude Accessibility

The accessibility of an attitude is an indication of how readily the attitude comes to mind in the presence of the attitude object. Accessibility can be assessed simply by measuring how quickly an individual is able to respond when asked to express his or her attitude. Research shows that the more quickly an attitude comes to mind, the more likely it is to remain stable over time, resist future persuasion, and predict behavior. More accessible attitudes have been shown to better predict a variety of behaviors from voting in elections to preferences for games, and purchasing decisions. On the other hand, an attitude that does not come to mind at all in a given instance is unlikely to predict behavior.

A number of variables have been shown to influence the accessibility of an attitude, including expressing the attitude multiple times and having direct behavioral experience with the attitude object. For example, if a person is asked multiple times for his or her view on a new movie or a political candidate, or if he or she had direct experience watching the movie or meeting the candidate versus just hearing about it indirectly, the attitude will come to mind more quickly and easily. Of most relevance to persuasion is the finding that more extensive thought about the attitude object enhances attitude accessibility because more thought leads to greater integration of the new evaluation formed with existing memories, consistent with the high elaboration processes described in the ELM. There are two common accounts for the processes responsible for the consequences of attitude accessibility. The first account

is that more accessible attitudes are simply more likely to come to mind directly making the attitude more consequential. However, a second account holds that individuals form impressions of how easy or difficult it is to bring an attitude to mind, and these metacognitive judgments of accessibility are responsible for the consequences of accessibility. Thus, there remain interesting questions regarding what structural properties accessibility reflects as well as the mechanism for the consequences of accessibility. Regardless of the outcome of these alternatives, accessibility remains the most broadly supported structural indicator of attitude strength capable of producing each of the strength consequences.

Attitude Certainty

Attitude certainty is a belief held about an attitude that reflects the conviction with which the attitude is held, or an assessment of the correctness of the attitude. Certainty is measured using questionnaire items that assess the extent to which the individual feels certain, confident, and sure about the attitude. Greater certainty is associated with attitudes that exhibit greater persistence, resistance, and prediction of behavior. As a metacognitive indicator of strength, attitude certainty consists of thoughts about the attitude.

According to the ELM, greater extent of elaboration is associated with stronger attitudes. Consistent with this, results show that antecedents of elaboration like distraction and whether or not someone likes to think influence attitude certainty. One process through which this occurs is that antecedents of elaboration produce an increased amount of thought and individuals form a perception of this amount of thought. If the perception is that a lot of thought has gone into an attitude, then it is held with greater certainty than if the perception is that little thought has gone into the attitude. The experience of resisting a persuasive attempt also has consequences for attitude certainty, but in this case the impact depends on an assessment of the resistance situation. If an individual believes that strong arguments were easily resisted, then higher attitude certainty results. However, if an individual believes that it was difficult to resist weak arguments, then lower certainty will result. In sum, attitude certainty reflects metacognitive perceptions people form about their responses to persuasion attempts including the amount of thought and the perceived ability to resist persuasion. Both accessibility and certainty provide indicators of which attitudes are likely to exhibit attitude strength.

Resistance

Resistance is the extent to which an attitude remains firm when confronted with an attempt to persuade. That is, if attitude change is motion, then resistance is the friction that goes against attitude change. Resistance is achieved through a number of different processes, and can be triggered through environmental cues such as forewarning of persuasion, and enhanced practice in counterargument such as inoculation. In addition to these two topics, metacognitive perceptions that individuals form regarding how successful they were at counterarguing persuasion are also relevant to resistance, as reviewed earlier.

Forewarning

The phrase, 'And now a word from our sponsors,' is an example of a forewarning, because it warns the audience of an upcoming persuasion attempt. Forewarning has different impacts on persuasion processes prior to and after the actual message is received. Prior to the message, the impact of forewarning depends on whether processing is likely to be more or less thoughtful, consistent with the ELM. Being forewarned under high personal relevance leads individuals to bolster their attitudes prior to receiving the persuasive message, resulting in increased resistance. However, being forewarned under low personal relevance leads individuals to acquiesce or give in to the message, even before it is received, in order to maintain a more positive view of the self as someone who is not overly malleable. One way advertisers avoid forewarning effects is by placing product tie-ins directly into programming.

Inoculation

Attitudes can be particularly susceptible to persuasion attempts when they lack an extensive cognitive foundation in memory. This can make it difficult to resist counterattitudinal persuasive messages. This lack of cognitive foundation is common in the case of cultural truisms, which are widely accepted but generally go unexamined during day to day life. Truisms include the value of 'freedom of speech,' and, 'brushing your teeth every day.' The notion of inoculation is that just as immunizations make people more resistant to disease, showing people arguments attacking their attitudes and training them to counterargue them increase resistance to future attempts to change these attitudes. The inoculation approach of training individuals to counterargue the persuasive message, is more effective at increasing resistance than providing individuals with additional support to bolster their existing attitude. Thus, inoculation provides an effective way to increase the resistance of attitudes, because it increases the ability and motivation to counterargue persuasive messages that are counterattitudinal.

Dissonance: Persuasion from Behavior

Leon Festinger was the first to describe cognitive dissonance, which provides a striking example of how our own behaviors can lead to attitude change. According to cognitive dissonance theory, any two thoughts that are related to each other can either be consonant or dissonant. Dissonant cognitions occur when one thought does not follow from or fit with the other (e.g., I am an environmentalist; I drive an SUV) Holding two dissonant cognitions in the mind simultaneously leads to an aversive state of arousal that individuals are motivated to reduce. Dissonant cognitions often arise when an individual thinks about a past behavior and realizes that it was inconsistent with an attitude that he or she holds, such as holding a positive attitude towards safe sex, but failing to use a condom. Under these circumstances, as it is more difficult to change the behavior than to change the attitude, the most common way to resolve the inconsistency is to change the attitude to be in line with the behavior. While changing the attitude typically requires cognitive effort, the negative affective state

associated with dissonance is a powerful motivator to engage in biased elaborative processing. The result of dissonance processes is that individuals persuade themselves to change their attitudes to be in line with their behaviors. In this way, the dissonance resulting from a failure to use condoms could most readily be resolved by changing the attitude to be more negative towards condoms.

A number of experimental paradigms have been used to illustrate dissonance in the laboratory, and these provide explanations for some surprising phenomena in persuasion. Dissonance explains what happens to people who agonize over a difficult decision, whether it is a simple purchase or a major life decision, and then after the decision express more positive views of the chosen option, and more negative views of the nonchosen option. This is referred to as the 'spreading of alternatives,' and it occurs because the negative attributes of the chosen option and the positive attributes of the option not chosen are dissonant with the behavior of the choice that was made. Another example of dissonance occurs when people who are humiliated during an initiation to join a group like a fraternity or the armed forces, end up liking these groups more than if there was no hazing. As going through humiliation to join a group is dissonant with any negative aspects of the group, the attitude toward the group is changed to be more positive. This is referred to as 'effort justification' because the attitude change results from having to justify to the self the willingness to go through so much to join the group. These are just two examples of the paradoxical consequences of dissonance for persuasion (see the dissonance entry for more in-depth discussion).

Application: Problem of Sustainable Behavior Change in Health Communication

With roughly half of all causes of mortality in the United States being due to factors directly influenced by behavior, including smoking, drug use, and sedentary lifestyle, the importance of developing effective health communications is clear. While it is common in a health campaign to focus only on increasing the factual knowledge of the audience, evidence shows that simply increasing knowledge does not result in behavior change. For example, knowing a lot about safe sex and condoms is not a good predictor of sustained increases in condom use. As attitudes are generally the best predictors of behavior, rather than knowledge, theories of persuasion like the ELM provide clear proscriptions on how to improve the effectiveness of health promotion campaigns so that they produce prohealth attitudes that are strong in that they resist future persuasion and predict behavior. Resistance is also critical as other sources of persuasion like old drinking buddies or a potential sexual partner can quickly overwhelm weaker attitudes.

According to the ELM, taking the central route to persuasion is the key to establishing strong attitudes to produce sustained behavior change. In particular, procedures that increase the formation of highly elaborated, accessible, and confidently held attitudes will be the most likely to result in actual and sustained behavior change. Messages that are tailored to the particular concerns of the recipients of the

messages, such as whether they are using condoms to reduce the transmission of STDs or to prevent pregnancy, are effective at increasing the personal relevance of the messages, and as a consequence make it more likely that recipients will take the central route to persuasion. In general, anything that increases the personal relevance of the communication will have this effect. In addition, it is important that messages are presented in a way that allows for thoughtful processing. As medical information is often technical, pretests should be conducted to assess whether a given population can understand the message before it is more widely distributed. Presenting the message in a medium that is self-paced, like a written flier, allows the audience to set a comfortable pace that allows for thoughtful processing, whereas audio and video media have a set presentation speed, and so do not allow for self-paced consideration. In addition, circumstances where there are few distractions and the information is presented at the correct knowledge level for the audience are likely to increase their ability to process the message extensively. Once the circumstances are established for high elaboration processing, attitudes will be influenced by whether the arguments are strong or weak. Therefore, it becomes critical under these circumstances to establish ahead of time that the arguments to be presented are seen as cogent and strong within the intended population. In this way, the basic understanding of persuasion processes and the distinction between the central and peripheral routes to persuasion and their distinct consequences can assist in the development of more effective health promotion campaigns in the future.

Glossary

Classical conditioning The learning of an association between an unconditioned stimulus (e.g., sting) and a previously neutral conditioned stimulus (e.g., bee).

Conditioning The process by which a conditioned stimulus (e.g., bee) is paired with an unconditioned stimulus (e.g., sting) until the conditioned stimulus evokes a conditioned response, such as fear, even in the absence of the unconditioned stimulus.

Exposure therapy Repeated and systematic exposure to a feared stimulus.

Extinction learning A reduction in fear as a result of new learning that occurs during repeated exposure to the feared

stimulus that supersedes the original conditioning information.

Habituation A decrement in response (e.g., psychophysiological response or subjective fear) as a result of repeated exposure to the feared stimulus.

Operant conditioning The forming of an association between a behavior (e.g., escape) and a consequence (e.g., reduced anxiety).

Phobia An intense and persistent fear that is cued by the presence or anticipation of a specific object or situation.

Vasovagal response A physiological response that characterizes blood-injection-injury phobias consisting of a brief acceleration in heart rate followed by a deceleration, bradycardia, drop in blood pressure, and possibly fainting.

Overview of Specific Phobias

Diagnostic Definition of Specific Phobias

A phobia is defined as an intense and persistent fear that is cued by the presence or anticipation of a specific object or situation. Exposure to the specific object or situation consistently provokes an immediate anxiety response. The phobic object or situation might be endured with great distress, but is more typically associated with a strong avoidance tendency despite the knowledge that the fear is excessive or irrational. To be considered a phobia, the avoidance, anxious anticipation, or distress associated with the feared object or situation must be marked enough to cause significant interference in daily routine, occupational or academic functioning, social activities, or relationships.

Specific Phobia Subtypes

The diagnostic manual published by the American Psychiatric Association identifies five subtypes of specific phobias which are distinguished by the focus of the fear or avoidance. Animal subtype refers to fear that is cued by animals or insects (e.g., spiders, snakes, dogs, mice). Natural environment subtype refers to fear that is cued by objects in the natural environment (e.g., storms, heights, water). Blood-injection-injury subtype refers to fear that is cued by seeing blood or an injury, or by receiving an injection or an invasive medical procedure. Situational subtype refers to fear that is cued by a specific situation such as flying, driving, enclosed places, or elevators. Other subtype is a residual category reserved for fears that are not captured by the aforementioned subtypes, and includes phobias of vomiting, choking, loud noises, and costumed characters. Much heterogeneity exists between the subtypes of specific phobias. As described

below, the subtypes differ with respect to age of onset, type of onset (traumatic vs. nontraumatic), familial pattern, and physiological response to the feared stimulus.

Clinical Picture

Fear upon exposure to a phobic object or situation is the most characteristic emotional response in specific phobias. Fear is characterized by an organism's defensive response to imminent threat and is typically defined by three response systems: physiological, verbal-cognitive, and overt behavior. For most phobias, exposure to the feared object or situation produces heart rate acceleration and in some cases might result in situationally bound panic attacks with prominent physical symptoms. The blood-injection-injury subtype is unique in that it is characterized by a dyphasic vasovagal response consisting of a brief acceleration in heart rate followed by a deceleration, bradycardia, drop in blood pressure, and possibly fainting. The cognitive symptoms of fear typically involve subjective appraisals of danger and attentional biases toward feared stimuli. The behavioral symptoms of fear involve either freezing or fleeing from the feared stimuli.

Although fear is the most characteristic emotional response in specific phobias, recent research suggests that disgust is also a common emotional response associated with certain phobias, particularly blood-injection-injury and spider phobias. Disgust is characterized by revulsion toward stimulus identified as disgusting or revolting in nature or as potential sources of contamination. Similar to fear, disgust is defined by three response systems. While both fear and disgust are associated with avoidance behavior, they differ with respect to cognitive appraisals and physiological symptoms. Fear is associated with heart rate acceleration and cognitive appraisals of a stimulus as potentially threatening or dangerous, whereas disgust is

associated with heart rate deceleration and cognitive appraisals of a stimulus as being revolting or a contamination threat. There is some evidence that fear reduces more quickly than disgust when an individual with a specific phobia is exposed to the feared stimulus for a prolonged period.

Phenomenology of Specific Phobias

Prevalence

Phobias are very common in the general population but do not always result in sufficient distress or impairment to warrant a diagnosis of specific phobia. Prevalence rates for specific phobias vary depending on the subtype being assessed and the threshold used to determine distress or impairment in epidemiological studies. The lifetime prevalence estimates for specific phobias range from 6% to 23%, making them the most common anxiety disorder and among the most common psychiatric disorders in the community. Phobias of heights, spiders, mice, and insects are most common among individuals in the community, whereas claustrophobia (fear of enclosed places), blood-injection-injury phobias, and small animal phobias are most common among treatment-seeking individuals.

Gender

The ratio of women to men with specific phobias is ~2:1; however, the sex ratio varies across phobia subtypes. Approximately 75–90% of individuals with the animal, natural environment, and situational subtypes are female, and ~55 – 70% of individuals with the blood-injection-injury subtype are female.

Age of Onset

Specific phobias can develop at any point in the lifespan, but symptoms typically first develop in childhood or early adolescence. The age of onset varies across subtypes. For example, phobias of animals and objects in the natural environment tend to develop in early childhood and blood-injection-injury phobias also tend to develop relatively early. Age of onset for the situational subtype has a bimodal distribution, with a first peak in childhood and a second peak in the mid-twenties.

Course

Many fears that develop during childhood (e.g., strangers, darkness, animals, imaginary creatures) are transitory experiences that remit spontaneously. Developmental milestones and life experiences appear to influence the content and course of phobias. For example, the most common childhood fears tend to relate to physical harm and injury, and the fear of heights tends to develop as a child becomes increasingly mobile. The child's cognitive capacities for recognizing potential dangers are also likely to influence the development of phobias. Developing a specific phobia in adolescence increases the likelihood of persistence of symptoms or the development of additional specific phobias. Phobias that persist into adulthood rarely remit spontaneously.

Theoretical Perspectives on Specific Phobias

Psychodynamic Model

According to psychodynamic theories, phobias develop as a result of repressing unresolved unconscious conflicts. For example, Freud proposed that some individuals develop phobias due to an unresolved Oedipal conflict characterized by unacceptable sexual impulses toward the opposite sex parent and aggressive impulses toward the same sex parent. If an individual is unable to repress these impulses, the anxiety associated with the unresolved Oedipal conflict is displaced upon an object or situation that is less relevant and threatening.

Behavioral Models

Mowrer's Two Factor Model

The most influential early theory of fear acquisition was Mowrer's Two Factor Model, which developed out of Pavlov's theory of classical conditioning and Watson's theory of instrumental conditioning. The Two Factor Model proposes that fears are acquired by classical conditioning and maintained through instrumental conditioning. Classical conditioning is the process by which a conditioned stimulus (e.g., a bee) is paired with the unconditioned stimulus (e.g., pain) until the conditioned stimulus evokes a conditioned response, such as fear, even in the absence of an unconditioned stimulus.

For example, an insect phobia might develop after being stung by a bee. The sting stimulates the pain receptors and represents the conditioned stimulus. The pain evoked represents the unconditioned stimulus. Through associative learning, pain of the sting becomes paired with stimuli associated with the unconditioned stimulus (e.g., conditioned stimuli such as bees and parks). As a result, the conditioned stimuli provoke a conditioned fear response, the strength of which depends on several factors including the intensity of the unconditioned stimulus (e.g., sting) and the number of pairings of the unconditioned stimulus (e.g., sting) and conditioned stimulus (e.g., bees). In addition, stimuli resembling the conditioned stimuli (e.g., wasps, hornets) can become fear evoking through the process of stimulus generalization and second-order conditioning. According to Mowrer's Two Factor Model, extinction naturally occurs when the conditioned stimulus (e.g., bee) is presented over successive trials without the unconditioned response (e.g., sting), until eventually the conditioned stimulus (e.g., bee) stops eliciting the conditioned response (e.g., fear). In phobias, however, this process is reduced or prevented by actions that allow an escape or avoidance of the conditioned stimulus. Avoidance and escape behavior is reinforced because it reduces fear in the short term, but it ultimately impedes fear reduction in the long term.

Although the Two Factor Model has received a great deal of empirical support, it has also been criticized on a number of grounds. First, empirical data suggest that a significant percentage of individuals with specific phobias report having always been afraid of the phobic object (e.g., animals, water), in the absence of conditioning. Second, the Two Factor Model assumes that all neutral stimuli can become phobic objects, but it is found that some objects are more likely to become conditioned stimuli than others. For example, harmless spiders are more likely than knives and electrical outlets to become

conditioned stimuli that elicit escape and avoidance behavior. Thus, it has been argued that some stimuli are 'biologically prepared for conditioning,' a limitation of conditioning not accounted for by the Two Factor Model. Third, contrary to the model, not all individuals who have traumatic experiences with phobic stimuli develop phobias, perhaps because they had many previous nonaversive encounters with phobic stimuli. Thus, subsequent theories have been developed to expand the model to account for phobias that do not appear to be acquired through direct classical conditioning.

Rachman's pathways

Rachman proposed that phobias develop via three pathways. First, as proposed by the Two Factor Model, a previously neutral object or situation might become associated with a conditioned fear response due to a traumatic event through classical conditioning (direct conditioning). Second, a phobia might develop as a result of observing another individual model fear behavior (modeling) or witnessing another individual experience a traumatic event (vicarious learning). For example, an individual might develop a water phobia after witnessing a near drowning or a child might develop a bat phobia in response to witnessing his or her mother scream and run away each time a bat is encountered. Thus, the model's anxious response acts as the observer's unconditioned stimulus and evokes a fearful or anxious unconditioned response in the observer. The pairing or contiguous presence of this unconditioned stimulus (e.g., model's fear response) with a conditioned stimulus (e.g., bat) leads to an association between the two, and the conditioned stimulus (e.g., bat) subsequently evokes a conditioned fear response when it is encountered on its own. Third, Rachman proposed that a phobia might develop as a result of being warned about the dangerousness of an object or situation and being instructed to avoid it (parents – instructional transmission) or as a result of being given information about the dangerousness of an object or situation (media – informational transmission). For example, a child might develop a snake phobia after his or her parents repeatedly warn about the dangerousness of snakes or an individual might develop a flying phobia after watching media coverage of a fatal plane crash. Rachman's pathways account for the acquisition of a greater number of phobias than the original Two Factor Model; however, epidemiological studies suggest that ~50% of individuals with specific phobias have no memory for conditioning events associated with the development of their phobias, and that modeling, vicarious learning, and instructional transmission are rarely implicated in the development of phobias. Given that many phobias develop in childhood and are typically investigated retrospectively many years later, one potential explanation for this finding is that conditioning events are simply forgotten. However, current epidemiological research suggests that many phobias cannot be accounted for by conditioning events. As described in the nonassociative model below, a fourth nonassociative pathway is thought to account for certain innate phobias.

Cognitive – Behavioral Models

Cognitive theories of phobia acquisition and maintenance elaborated upon the behavioral models by considering the role of cognitive mechanisms such as expectations and

memory representations of the conditioned and unconditioned stimuli. According to cognitive theories, fear and avoidance behavior are determined by the expectation that a behavior will lead to an aversive consequence, and is maintained by confirmation of the expectation (e.g., watching media coverage of plane crash or experiencing turbulence while flying). Moreover, the avoidance behavior prevents disconfirmation of the irrational expectations.

According to cognitive theories, individuals with specific phobias exhibit cognitive biases that serve to maintain phobias. For example, they overestimate the probability of threat and consequences of harm, scan the environment for potential threats, and interpret ambiguous situations as those that are likely to lead to worst-case scenarios. Recently, the cognitive perspective has been enlarged because of findings suggesting that negative cognitions about phobic objects can occur at an automatic level that is implicit and beyond self-report.

Looming Vulnerability Model

According to the Looming Vulnerability Model, individuals with anxiety disorders, including specific phobias, have mental representations of dynamically intensifying danger and rapidly escalating risk. Thus, individuals with specific phobias not only overestimate threat, but they also appraise the threat as moving through time and space. Threat is perceived as rapidly rising in risk, progressively worsening, or actively accelerating. For example, individuals with spider phobia spontaneously imagine spiders as jumping or crawling toward them in the absence of actual movement.

Network Model

According to the Network Model, cognitive representations of feared stimuli (e.g., bees, hornets, parks), response information (e.g., subjective fear, escape behavior), and meaning information (e.g., danger) are all linked in fear structures or networks in long-term memory. These fear structures evoke fear and motivate avoidance or escape behavior when they become activated by incoming information that matches information stored in the fear network. By avoiding or escaping the feared stimulus, corrective information regarding the actual safety of the stimulus cannot be incorporated into the fear network.

Biological Model

Biological Preparedness Theory

Certain fears appear to be inborn. Seligman proposed that certain classes of objects, such as animals and reptiles, are more likely to become phobic objects than others, such as electrical outlets and knives, despite being objectively less threatening. Seligman's Biological Preparedness Theory proposes that humans and other organisms are biologically prepared to acquire phobias of objects with evolutionary significance. That is, organisms are hard-wired to fear certain objects that, at some point in evolution, could potentially threaten the survival of the species, and these particular fears should be more resistant to extinction (i.e., more difficult to unlearn the fear association). In support of the biological preparedness theory, research has demonstrated that Rhesus monkeys are more likely to acquire phobias of reptiles than phobias of flowers after observing another Rhesus monkey

behaving fearfully toward the object. However, evidence from human studies has been less conclusive. Further, although it was initially proposed that biologically prepared phobias would be more resistant to extinction, they are generally no more difficult to treat than other phobias.

Nonassociative Model

The Nonassociative Model acknowledges that evolutionary-neutral phobias are acquired through learning or conditioning processes, but asserts that most evolutionary-relevant phobias (e.g., heights, water, spiders, strangers, separation) are innate and arise without any direct or indirect associative learning. According to this model, natural selection has favored individuals who displayed fear when first encountering a dangerous object or situation, and most members of a species will fear certain evolutionary-relevant stimuli given normal maturational processes and background experiences. Whereas conditioning models assert that phobias are learned, nonassociative models conceptualize phobias as innate fears which have not yet been unlearned. It is assumed that innate fears persist due to poor habituation or insufficient opportunities during critical developmental periods for safe exposure experiences (i.e., non-threatening interactions with the feared object or situation). Individuals are thought to recover from phobias by learning to stop responding fearfully to predisposed or prepared stimuli.

The nonassociative model has been challenged on the basis that it predicts more fear than is actually observed in the general population and does not adequately explain why some individuals habituate poorly to predisposed fear stimuli. Further, while the inability to recall a conditioning event is interpreted as supporting the nonassociative model, this finding could also be accounted for by childhood amnesia (i.e., the inability of adults to recall events that occurred prior to age 4). Finally, it would be assumed from nonassociative models that innate evolutionary-relevant phobias have a strong genetic component, but behavioral genetics studies report only moderate heritability and a large impact of specific environmental factors.

Rather than conceptualizing phobias dichotomously as resulting from associative or nonassociative processes, more recent integrative models propose that phobias are best conceptualized on a continuum with respect to the extent of association or learning required to evoke fear, ranging from purely innate phobias requiring no associative processes to purely learned phobias resulting from aversive conditioning events.

Genetics Model

The transmission of specific phobias appears to have a familial component. Individuals with specific phobias are significantly more likely to have a relative with specific phobias compared to individuals without specific phobias, and genetics studies report higher concordance rates among monozygotic twins than dizygotic twins. Both an overall 'phobic predisposition' (e.g., neuroticism, behavioral inhibition, anxiety sensitivity) and stimulus-specific genetic contributions have been implicated. Collapsing across the different subtypes of phobias, the average heritability of phobias, or the percent of variation in a phobia that is due to additive and nonadditive genetic factors, has been estimated at 40%. The heritability estimate for each

subtype of specific phobias has been reported as follows: 58% for animal phobias, 43% for blood-injection-injury phobias, 37% for natural environment phobias, and 23% for situational phobias. It is generally assumed that the genetic predisposition interacts with conditioning experiences to increase the risk of developing specific phobias.

Treatment of Specific Phobias

Psychodynamic Therapy

Psychodynamic therapy aims to explore past traumatic events in order to increase an individual's awareness of the symbolic nature of the phobia (e.g., to become aware that the phobia is connected to sexual or aggressive impulses). The goal is to both expose and reduce unconscious psychological conflicts and to gain greater conscious control over the conflicts. Psychodynamic therapy is not considered an effective treatment for specific phobias.

Cognitive – Behavioral Therapy

Specific phobias are among the most treatable of psychiatric disorders, and cognitive – behavioral therapy (CBT) is considered the most effective treatment. A recent meta-analysis reported that the average participant receiving cognitive and behavioral interventions showed more improvement than 85% of nontreated individuals. Although behavioral and cognitive interventions arose from distinct theoretical traditions, the interventions are typically combined in practice. A fundamental component of CBT is repeated and systematic exposure to feared stimuli. An exposure hierarchy is created consisting of feared situations that are ranked from least distressing to most distressing (see [Table 1](#)). The individual begins by confronting an object or situation ranked low on the exposure hierarchy in a gradual and predictable manner that maximizes the patient's perception of control. The individual is encouraged to remain in the situation until anxiety reduces by at least 50% rather than escaping from the situation when anxiety becomes too intense.

Exposure therapy can be conducted in a number of ways. In vivo exposure involves coming into direct contact with the feared stimulus. An individual with a spider phobia might begin exposure therapy by observing photos of a spider and

Table 1 Sample hierarchy of feared situations for spider phobia

<i>Feared situation</i>	<i>Distress (0–100)</i>
Most distressing: allow large spider to crawl on arm	100
2nd most distressing: touch large spider with finger	90
3rd most distressing: allow small spider to crawl on arm	80
4th most distressing: touch small spider with finger	70
5th most distressing: walk within 1 ft of large spider	60
6th most distressing: stand in room with large spider, walk within 5 ft of spider	50
7th most distressing: walk within 1 ft of small spider	40
8th most distressing: stand in room with small spider, walk within 5 ft of spider	30
9th most distressing: view photo of real spider, then touch it	20
10th most distressing: view cartoon photo of spider, then touch it	10

then move through the exposure hierarchy by touching photos of a spider, being in the same room as a spider, moving progressively closer to a spider, touching a small spider, and then eventually touching a large spider. In vivo exposure has demonstrated robust effect sizes across a variety of types of specific phobias and is considered the most effective form of exposure therapy. In vivo exposure is often conducted in conjunction with participant modeling, a technique grounded in social learning theory in which the patient observes the therapist confronting the feared stimulus effectively before attempting the exposure on his or her own. In some cases, imaginal or virtual reality exposure might be used if it is not practical to perform in vivo exposure (e.g., fear of hurricanes) or if the phobia is sufficiently severe such that in vivo exposure would be too distressing in the early stages of treatment. For example, an individual with a spider phobia might imagine a spider in graphic detail and later imagine touching the spider and allowing it to crawl up his or her arm. Systematic desensitization is an approach that combines imaginal exposure with relaxation training. The rationale behind this treatment is that repeated exposure to feared stimuli in conjunction with the use of an anxiety-incompatible response (i.e., relaxation) should eliminate the conditioned fear response. Although it has been found to be an effective treatment for specific phobias, the addition of relaxation training does not appear to improve outcome beyond the effect of exposure therapy alone. Regardless of the exposure method used in therapy, homework between sessions, consisting of exposure exercises conducted either alone or with a helper, is considered a core component of CBT.

Due to the physiologically different processes operating in blood-injection-injury phobias, traditional in vivo exposure therapy requires modification to reduce the vasovagal response and potential for fainting. Patients are first taught to recognize early signs of drop in blood pressure and then practice tensing and then releasing the tension in the body. Muscle tension is then used in combination with in vivo exposure exercises. This applied muscle tension technique has been found to be an effective treatment for blood-injection-injury phobias.

Individuals taking part in imaginal or in vivo exposure therapy typically move up the exposure hierarchy at a gradual pace over a number of treatment sessions. However, research has demonstrated that a massed approach to treatment with prolonged exposure within one session can also be effective. In one session treatment (OST), patients are exposed to their entire hierarchy, starting with the least distressing situation and moving up to the most distressing situation, within a single 3 h session. In flooding therapy, patients immediately confront a feared situation ranked at the top of the exposure hierarchy. Both of these treatment approaches are quite cost and time effective; however, flooding therapy requires a very motivated patient who is willing to remain in a situation that provokes intense anxiety.

Habituation is one potential mechanism by which exposure therapy reduces conditioned fear responses. Habituation refers to a decrement in response (e.g., psychophysiological response or subjective fear) as a result of repeated exposure to the feared stimuli (see [Figure 1](#)). Habituation theory assumes that prolonged exposure will result in fear reduction; however, habituation has been questioned as a mechanism of change in exposure therapy because some patients do not experience

Figure 1 Habituation/extinction learning curve.

fear reduction with prolonged exposure. Further, some patients experience reductions in physiological responding during exposure without a corresponding reduction in subjective fear, a finding that cannot be reconciled with habituation theory. The mechanism currently thought to best account for fear reduction is extinction learning. Patients learn not only to unlearn a previously learned association (e.g., spiders are dangerous) during exposure therapy, but more importantly, they learn to attribute novel significance to the conditioned stimulus (e.g., spiders are relatively safe). During this process, separate mental representations (e.g., spiders are dangerous and spiders are safe) exist simultaneously and compete with one another. Which representation is selected depends on the match or mismatch between the context in which extinction learning occurred and the context in which the fear cue is subsequently encountered. One implication of extinction learning is that the extinction of learned fear during exposure therapy does not easily generalize to new situations unless the new situation contains salient stimuli that were present during extinction learning trials, thus, many exposure exercises should be conducted across a variety of contexts. The extinction learning theory is also compatible with the emotional processing theory, which proposes that fear reduction during exposure therapy requires the learning and integration of new information that is incompatible with the existing representations of threat that are coded in memory.

The cognitive component of CBT aims to elicit and challenge negative automatic thoughts regarding the perception of threat and the inability to cope effectively with threat and to replace these automatic thoughts with more realistic and adaptive thoughts (see [Table 2](#)). Exposure exercises are also viewed as an important component of cognitive therapy; however, the rationale for exposure differs in cognitive therapy. Rather than habituating to the feared stimuli or extinguishing learned fear, exposure exercises are framed as behavioral experiments or hypothesis testing. Individuals with specific phobias learn that their feared consequences do not occur and their anxiety does not persist at catastrophic levels. The mechanism thought to account for fear reduction in cognitive therapy is expectancy violation. During behavioral experiments, erroneous beliefs regarding the probability and severity of feared consequences are disconfirmed and corrective information regarding the threat is incorporated.

Pharmacological

Relatively few studies have examined the efficacy of pharmacotherapy for specific phobias, either alone or as an adjunct to

Table 2 Sample thought record for dog phobia

<i>Situation</i>	<i>Emotion</i>	<i>Automatic thoughts</i>	<i>Evidence</i>	<i>Countering statement</i>
Encounter a dog on the street.	Fear (90%)	The dog will bite me and I will get rabies.	<p><i>For:</i> Some dogs bite. Some dogs have rabies.</p> <p><i>Against:</i> It is rare to get bitten by a dog. I am not provoking the dog. The dog is on a leash. Most domestic dogs get rabies shots.</p>	Although it is not impossible to get rabies from a dog bite, it is extremely unlikely especially if it is a domestic dog and I am not provoking it. There are effective treatments to prevent rabies if a dog bites me.

psychological treatments. Benzodiazepines might temporarily be helpful in acute situations, such as when taken before a flight or medical procedure, but anxiety returns without medication. Although benzodiazepines might decrease anticipatory anxiety associated with a phobic situation, reduce phobic arousal, and increase motivation for undertaking uncomfortable treatment, the reduction of symptoms might actually be counterproductive if the medication prevents activation of the fear network during exposure exercises. Pharmacotherapy is not currently considered an effective treatment for specific phobias, particularly in the long term.

One recent development with potential promise has been the augmentation of exposure therapy with d-cycloserine, a partial agonist of glutamatergic *N*-methyl-D-aspartate (NMDA). The medial prefrontal cortex and amygdala, and the connections between them, have been implicated as the primary neural system underlying fear extinction. The medial prefrontal cortex plays an essential role in regulating the amygdala-mediated expression of conditioned fear during the process of extinction by inhibiting the retrieval of previously learned fear associations. Activation of NMDA receptors within the amygdala appears to be essential for extinction learning, and NMDA receptor agonists have been shown to enhance the extinction of fear memories and thus facilitate the process of extinction learning. d-cycloserine is administered acutely and intermittently prior to exposure exercises, and the augmenting effects appear to occur between sessions during the postextinction consolidation periods rather than within exposure sessions.

Summary

Specific phobias are prevalent anxiety disorders characterized by an intense and persistent fear or disgust response that is cued by the presence or anticipation of a specific object or situation. A variety of theoretical models have been developed to account for the onset and maintenance of specific phobias, including those emphasizing classical and operant conditioning, cognition, biological preparedness, and genetics. Specific phobias are among the most treatable of all psychiatric

disorders and CBT is currently considered the most effective treatment approach.

Glossary

Allophone A variant of a phoneme; different sounds within a group that convey the same meaning.

Articulation Speech production; the postures and movements of the speech organs in speech production.

Coarticulation The overlapping of articulatory gestures in the production of adjacent speech sounds.

Feature A distinguishing attribute of a linguistic unit.

Formant A vocal tract resonance; in the spectrogram, they are observed as bands of concentrated acoustic energy. Relationships between formants characterize vowels.

Fundamental frequency The lowest frequency of a periodic wave; in speech, fundamental frequency corresponds to the rate of vocal fold vibration.

Phonation Voicing that occurs when the vocal folds (vocal cords) open and close, causing the airstream from the lungs to vibrate.

Phone A speech sound or segment.

Phoneme A minimal contrastive unit of speech; the smallest unit of speech that conveys meaning.

Prosody Phonetic aspects of speech that apply across segments, such as stress and intonation.

Source-filter theory A theory of speech production that quantifies the relationship between articulation and the acoustic output of the vocal tract.

Spectrogram A visible record of speech that provides information regarding frequency, intensity, and time.

Phonetics is the study of speech sounds. It involves description of the possible sounds of the languages of the world, investigation of how the human vocal tract produces those sounds, and the attempt to understand how such sounds are perceived. Historically, phonetics was taken to be the study of speech sounds without regard to their linguistic function. Contemporary phonetics is concerned with the aspects of sound that are necessary to convey meaning from the speaker to the listener, with explanations for the patterns of speech sounds used within and across languages, as well as with the changes that occur in those patterns over time. Although the latter concerns used to be considered exclusively the domain of phonology (the study of how sounds are organized into systems used in languages), it is apparent that speech production and perception influence and are influenced by linguistic function. Advances in technology coupled with the interplay of theory, experiment, and modeling have made it possible to explore these influences in new ways.

Why Study Phonetics?

Henry Sweet was a nineteenth century phonetician on whom George Bernard Shaw's Professor Henry Higgins of *Pygmalion* was based. He considered phonetics to be the foundation of all study of language, applied or theoretical. At the applied or practical level, phonetics is useful for teaching pronunciation to nonnative speakers of a language or to the deaf. Actors, politicians, broadcast journalists, and others may wish to acquire or eliminate an accent or affect a dialect. Teachers of reading can benefit from a thorough knowledge of phonetics to better understand the relationship between written and spoken language. Speech pathologists who diagnose and treat speech disorders must be able to describe disordered speech accurately, to understand how that speech is being produced,

and to determine appropriate courses of correction. Engineers who design speech transmission devices, speech recognition systems, or speech synthesizers must have knowledge of phonetics. Linguists use phonetics to describe and catalog the sounds of the languages they study, patterns of sound change in the historical development of a language, and the sequence of events in language acquisition.

On a theoretical level, phonetics relates the physical aspects of how speech sounds are produced and perceived with their function in language. Phonetic theory should account for the sounds observed in human languages and the relative frequency with which they occur. It should make sense of the data acquired by linguists who phonetically describe the observed sequence of events in language acquisition and the types of sound changes that occur in languages. In addition, it should be able to account for the effects of physical damage to or deformities in the speech organs, as well as neurophysiological deficits.

A Brief Historical Perspective

Phonetics had its beginnings in the work of the Sanskrit grammarian, Panini, in the fourth century BC. Sir William Jones brought the Sanskrit work to light in the West in 1786. In the Indian writings, phonation and articulation were understood to be distinct processes, and the larynx was known to be the site of phonation. Places of articulation were used to classify speech sounds.

In the second half of the eighteenth century, phonetic science focused on how the different sounds in speech could be produced by the vocal apparatus. C. G. Kratzenstein developed one of the earliest speech synthesizers in order to obtain a prize offered by the Imperial Academy of Sciences of St. Petersburg for explaining the physiological differences between the five

vowels of the Russian language. Wolfgang von Kempelen also produced an early speech synthesizer, or 'talking machine,' built primarily of wood and leather with the vocal cords represented by a reed and the airstream supplied by a bellows. C. J. Ferrein sought a physiological explanation for how the vocal cords produced phonation.

In the mid-nineteenth century, the relationship between physiology and phonetics was still at the forefront of phonetic science, culminating in Johannes Müller's source-filter theory of speech production which still guides much of phonetic research. Also influential was A. M. Bell's *Visible Speech*, a system of speech classification designed for use in teaching the deaf to speak. In addition, Bell established the notion of cardinal vowels, vowels that serve as reference points for the articulatory description of the vowel inventory of a language. Henry Sweet elaborated on Bell's visible speech, producing a speech classification system which ultimately served as the basis for the International Phonetic Alphabet (IPA).

In the early twentieth century, Jean Pierre Rousselot produced a body of experimental work designed to obtain measurements of articulatory positions and to create permanent records of speech sounds. Jan Baudouin de Courtenay pointed out the distinction between a *phone*, or speech sound, and a *phoneme*, or a group of speech sounds which have no significant differences in meaning in the language under study. During this time period, phonetics began to be treated as a science separate and distinct from phonology, or in Baudouin's terms, psychophonetics. Phonologist Ferdinand de Saussure contributed to the view with his notions of *parole* versus *langue*. He believed that although speech ('parole') was the substance of language ('langue'), it was essentially unrelated to linguistic function just as the substance of which chess pieces were made was unrelated to the game of chess. In a different vein, the work of R. H. Stetson in the early 1900s introduced the notion of motor phonetics with studies of speech as a set of 'audible movements' rather than sounds produced by movements. He defined the syllable as being delimited by a chest pulse, contrary to the prevailing view of his colleagues that syllables were bounded by points of minimum sound. His work anticipated the contemporary interest in the relationship between speech production and speech perception.

Since the 1950s, improvements in the technologies used to quantify the production and perception of speech have allowed empirical tests of traditional phonetic theory. Results from the studies converge on the notion that phonetics and phonology overlap, that is, the perception and production of speech are intimately linked with each other as they are with linguistic function.

Preliminaries to the Study of Phonetics

One aspect of a phonetician's job is to understand what happens when human beings speak, which includes understanding how the speech sounds are produced and what the acoustic characteristics of the speech sounds are. Articulatory phonetics is the particular branch of phonetics concerned with the description of speech sounds in terms of postures and movements of the speech organs. Acoustic phonetics is concerned with how articulatory positions and movements shape speech

sounds and how speech sounds may be classified on the basis of acoustic characteristics. To study phonetics, it is necessary to have some knowledge of (1) the anatomy and physiology of the speech organs, (2) basic acoustics, and (3) the instrumentation and methods used to describe and analyze speech. The next three sections are devoted to these topics.

Anatomy and Physiology

The speech production apparatus is typically divided into three physiological components: the respiratory system, which furnishes the airstream that powers speech, the larynx, or voice box, which is the source of sound energy, and the supralaryngeal vocal tract, which consists of air-filled cavities that act as an acoustic filter (see [Figure 1](#)).

The respiratory system consists of the lungs and respiratory musculature. The muscles involved include the internal and external intercostals, the diaphragm, and abdominal muscles. The external and most of the internal intercostals muscles are involved in inhalation, while some internal intercostals and the abdominal muscles can act during exhalation to maintain steady air flow from the lungs. In quiet respiration, exhalation lasts about as long as inhalation. During speech, the duration of exhalation is markedly increased and is determined by the length of utterance. The steady air flow generated by the lungs during exhalation essentially powers speech.

The second physiological component, the larynx, is a cartilaginous group of structures which contains the vocal cords (more accurately called the vocal folds) and the glottis. The vocal folds are, literally, folds of ligament attached to the arytenoid cartilages on each side of the larynx. During normal breathing, the arytenoids are quite far apart, but for speech, they move closer together to narrow the glottis (the opening between the vocal folds). When the vocal folds are in complete contact, the glottis disappears. Phonation or voicing occurs when the vocal folds move together and subglottal air pressure builds up sufficiently to push them apart. Air rushes through and the vocal folds again come together as a result of their elasticity and the suction (Bernoulli force) generated by the airflow through the narrow glottis. Thus, the larynx acts as a valve to change the steady air flow from the lungs into a series of quasiperiodic pulses of air.

The third component is the supralaryngeal vocal tract (henceforth, the vocal tract). It encompasses the structures above the larynx, including the nasal cavity, oral cavity, and pharynx, and it acts as a variable acoustic filter on the source of acoustic energy to produce the characteristic resonances of speech sounds. The oral cavity serves as a resonating chamber with highly variable size and shape. The nasal cavity is partially filled and divided into several smaller cavities by membranes; thus, it is a relatively poor resonator. The pharynx, or throat, is a resonating cavity behind the oral cavity and above the larynx.

Anatomical structures of the vocal tract which are important for classifying speech sounds with respect to articulatory position are shown in [Figure 1](#) (left side). The *lips* are used to close, constrict, or change the length of the oral cavity. The *teeth* are a point of constriction for some speech sounds. The *tongue* is a mass of muscles. Its base is attached to the hyoid bone which, in turn, is connected by a membrane to the top of the larynx. Although phoneticians generally divide the tongue into several

Figure 1 Major anatomical components of the speech production system with the top and side view of the larynx.

functional regions, including the tip (or apex), blade, dorsum, and root, the boundaries between regions are not anatomically distinct. The flexibility of the tongue allows significant manipulation of the shape and size of the oral cavity. The *hard palate* is the hard, bony part of the roof of the mouth. An important landmark on the hard palate is the *alveolar ridge*, the rough-textured ridge directly behind the upper front teeth. The *velum*, or *soft palate*, is at the back of the roof of the mouth; it can be raised to close the nasal cavities off from the rest of the vocal tract, or lowered to open the velic port and introduce nasal resonance.

Basic Acoustics

Sound results when a vibrating source first compresses nearby air molecules creating a region of increased air pressure. Then as the source moves back past its resting position, it pulls the disturbed air molecules back along with it resulting in an area of low air pressure or rarefaction. In other words, the local air molecules vibrate with the source. Each vibrating air molecule disturbs the molecules near it to produce the alternating high- and low-pressure areas which set up the wave motion of sound. Note that the molecules themselves only oscillate and disturb the next molecules; they do not themselves travel along the sound wave.

To illustrate the important characteristics of wave motion, sine waves are shown in [Figure 2\(a\)–2\(c\)](#), which graph the air pressure of sound waves at a point some distance from the sound source measured repeatedly over time. The physical

characteristics of each wave include its amplitude and wavelength. Amplitude corresponds to the air pressure or strength of disturbance, and wavelength is the space occupied by a single cycle of the wave. The temporal dimensions of sound waves include the period, frequency, and propagation velocity. The period of a wave is the duration of time it takes to complete one cycle. For the wave in [Figure 2\(a\)](#), the period is 0.01 s. Frequency refers to the number of cycles per unit time, usually cycles per second, or hertz (Hz). Thus, the frequency, which is the inverse of the period, is $1/0.01$ or 100 Hz. The speed of propagation of a wave varies directly with the density of the medium through which it travels; thus, a wave travels faster through solids than gases. Propagation speed of a sound wave is about 1100 feet (or 35 000 cm) per second through air at sea level, and is independent of the frequency. Waves may be periodic (each cycle of the wave having the same period) or aperiodic (each cycle of the wave having a different period). An aperiodic wave may be characterized by the range of frequencies of its components, a fact which is important for acoustic classification of fricatives.

The three sine waves in [Figure 2\(a\)–2\(c\)](#) may combine to form the complex periodic wave in [Figure 2\(d\)](#), and complex periodic waves can be fully described as the sum of a number of sine waves, or Fourier components, of different amplitudes, frequencies, and phases. The frequency of the lowest frequency component of a complex wave corresponds to the fundamental frequency (f_0) of the complex wave. Notice that the period of one cycle is the same for the lowest frequency component wave in [Figure 2\(a\)](#) and the complex wave in [Figure 2\(d\)](#).

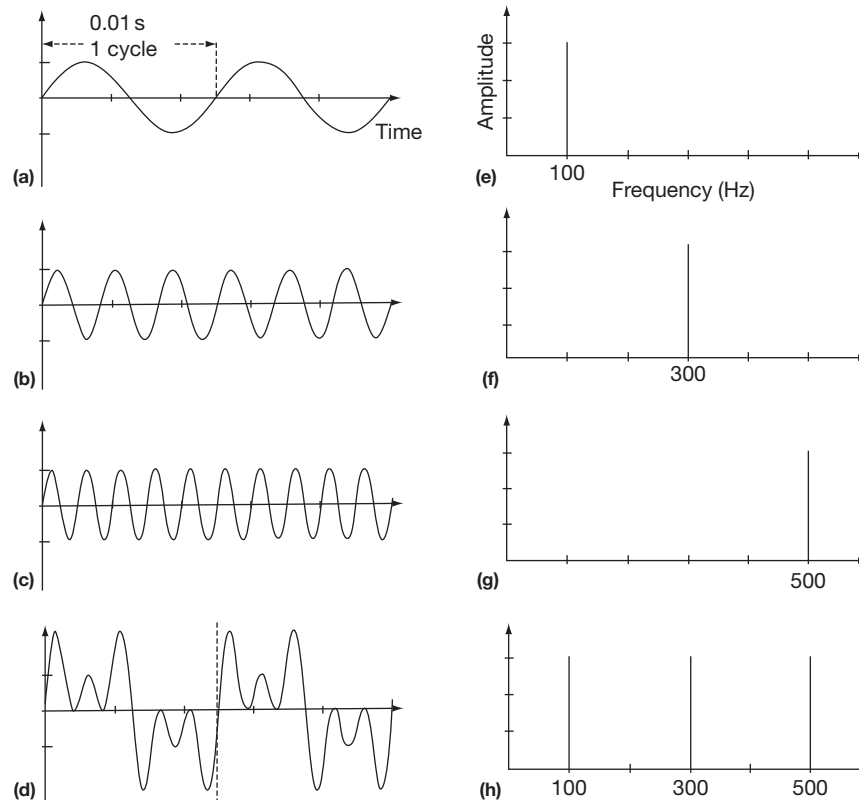

Figure 2 (a) Sine wave with a frequency of 100 Hz. (b) Sine wave with a frequency of 300 Hz. (c) Sine wave with a frequency of 500 Hz. (d) The sum of the three components in (a–c). (e–h) Corresponding amplitude spectra.

The frequency of each higher frequency component of the complex wave is an integer multiple of f_0 . These components are referred to as the second, third, etc., harmonics (f_0 is the first harmonic). Figures 2(b) and 2(c) represent the second and third harmonics of the complex wave. In speech, f_0 corresponds to the rate of opening and closing of the vocal folds, and harmonics arise due to the elastic nature of the vocal folds. The amplitude spectra specify the frequencies and amplitudes of each of the component sine waves (Figure 2(e)–2(h)).

The sound source provided by the vibrating vocal folds is shaped by the vocal tract into resonant speech sounds. The laryngeal source of quasiperiodic pulses of air provides a set of spectral components (fundamental frequency and harmonics) that, on its own, produces a weak buzzing sound. When the laryngeal source passes through the vocal tract, resonance properties of the vocal tract act as an acoustic filter that amplifies some frequencies of the source and suppresses others. Resonance refers to the propensity of an object undergoing forced vibration to oscillate with greatest amplitude in response to applied frequencies near its own natural frequency. Strike a tuning fork and it will vibrate at its natural, or resonant, frequency. Place the vibrating tuning fork near another tuning fork which has the same resonant frequency, and the second fork will begin to vibrate. The irregularly shaped, air-filled cavities of the vocal tract also act as resonators amplifying their natural frequencies. The resonant frequencies of the vocal tract are called formants.

The preceding description essentially summarizes the source-filter theory of speech production first postulated by

Johannes Müller in 1848. Source-filter theory, which continues to be developed, accounts for much current data and allows for the quantification of the relationship between articulation and the acoustic output of the vocal tract. In the source-filter theory, there is a clear separation of the glottal source of sound energy and the filtering of the sound by the vocal tract configuration which amplifies sound energy at certain frequencies and attenuates others. The resonant frequencies are the formants associated with voiced speech sounds which determine, to a great extent, perception. A major strength of the source-filter theory is that it provides a means of quantifying the relationship between articulatory postures and acoustics.

Instrumentation and Methods

Descriptive methods: phonetic transcription

Phonetic transcription is a tool for describing the sounds of speech. One level of phonetic transcription, broad transcription, is concerned primarily with the functional distinctions between sounds. A phone is a speech sound, and a phoneme is a group of speech sounds which have no significant differences in meaning in a particular language. For example, the *p* in *pat* and *spat* are two different phones, but not different phonemes, in American English. Only the first is accompanied by unvoiced airflow (aspiration) on release of the lip constriction. The *p* in *pat* and the *b* in *bat* are different phonemes; they are two different sounds which convey different meanings. When transcription is for the purpose of noting phonemes, or how sounds convey meaning, a simple set of symbols placed

between slashes (/ /) is used. For example, the *p* in *pat* and the *p* in *spat* are both indicated as /p/ in a broad transcription. The small differences in pronunciation of the *p* are ignored. Another level of phonetic transcription, narrow transcription, specifies articulatory details of the production of speech sounds. Narrow transcription has different symbols that are placed in square brackets ([]) for each allophone, or variant, of a phoneme. A narrow transcription of the *p* in *pat* is [p^h], indicating that the *p* is produced with aspiration. A narrow transcription of the *p* in *spat* is [p]. Narrow transcription is particularly useful when transcribing an unknown language or disordered speech.

The most commonly used set of symbols for phonetic transcription is the IPA. The first version of the IPA was published in 1888 and was based on the premise that there should be one symbol for each speech sound possible without regard to language. From time to time, revisions are made to the alphabet by adding or removing symbols and renaming symbols or categories. Many of the symbols are taken from the Roman alphabet, with other letters and diacritics (marks added to a symbol to modify its value) used as necessary. For example, the raised *h* in [p^h] is a diacritic which signifies aspiration, and the colon in [a:] indicates a longer duration. With the development of Unicode, the IPA symbols are readily available for use in word-processed documents and computer displays.

Analytic instruments and methods

The sound spectrograph, first introduced in the 1940s, is an instrument that provides a visual record of sound called a

spectrogram. Spectrograms, including their computerized digital versions, display time from left to right on the horizontal axis, frequency on the vertical axis, and amplitude on a gray scale with greater amplitude producing darker marks or on a color scale. In the spectrogram of a production of *stop now* in the bottom of [Figure 3](#), the formants associated with the vowels can be seen as dark bars. They remain steady while formant frequency is constant, and bend up or down as the configuration of the vocal tract changes over time, indicating the dynamic nature of speech. Fundamental frequency can be observed in the vertical striations which occur during voiced sounds. Blank spaces in the spectrogram indicate the absence of sound energy, as during vocal tract obstruction for the unvoiced stop consonants /t/ and /p/. Frication, as for the /s/, is indicated by relatively intense energy spread over a broad range of frequencies. The nasal sound /n/ is indicated by a dominant low frequency formant with several higher frequency, very low amplitude formants.

Digitized speech waveforms (top of [Figure 3](#)) display the amplitude variations in the acoustic signal over time, and permit fast, accurate measurement of duration and amplitude of speech. The flexibility of computerized digital speech signals allows the speech scientist to choose any segment of an utterance for further analysis. Speech processing software permits editing of the waveform or spectral components for experimental purposes. For example, silent gap duration associated with a stop consonant can be increased or decreased, and the resulting waveform played to listeners. Effects of such manipulations provide a window into the nature of speech perception.

Figure 3 Top: the speech waveform of a digitized production of *stop now*. Bottom: a spectrogram of the same production. See text for details.

The development of speech synthesizers has made it possible to control almost any speech feature of interest, and thus to test hypotheses regarding the importance of the feature for perception. Two basic types of speech synthesizers use either an articulatory or acoustic level of control. Articulatory synthesizers are based on acoustic models of the speech signal. Acoustic synthesizers produce speech based on the manipulation of acoustic parameters over time. The earliest speech synthesizers, such as those of Wolfgang von Kempelen and C. G. Kratzenstein in the 1800s, were mechanical models of the vocal tract. The Vocoder, an acoustic synthesizer developed by Homer Dudley in the 1930s, first analyzes input speech, then reconstructs the acoustic signal. A later development, the use of operator-specified control signals instead of input speech, made the Vocoder more suitable for use in experimental phonetics. A significant improvement in speech synthesis occurred with the development of the Pattern Playback at Haskins Laboratory in the 1950s. The Pattern Playback is an acoustic synthesizer that uses hand-painted patterns, usually formant tracks, on transparent acetate that are scanned with a beam of light and converted to an acoustic signal. Manipulation of the number, duration, and frequencies of the formants provided much new data regarding the acoustic information for speech perception. With digital computers, both acoustic and articulatory syntheses have become more rapid and flexible. Of the two basic types of synthesis, acoustic synthesis is less complicated and efficiently produces relatively high-quality speech. Articulatory synthesis is particularly useful for testing hypotheses about articulation directly. With the development of noninvasive, safe imaging techniques, such as magnetic resonance imaging (MRI), ultrasound, and alternating magnetic field devices, detailed information about vocal tract configuration during speech production has become available, and articulatory synthesis has been enhanced.

Articulatory and Acoustic Classification Schemes

In this section, classification schemes for the two major classes of speech sounds, consonants, and vowels, are described. Although both articulatory and acoustic classification schemes have been devised relatively independently, here they are intertwined in order to highlight the intimate relationship between articulation and the acoustic characteristics of speech sounds. Although most of the examples are from English, the principles apply across languages.

Consonants

Consonants are produced with a degree of obstruction of the vocal tract. They are typically described according to the place of articulation (the place of the major vocal tract constriction), the manner of articulation, and the presence or absence of voicing. **Table 1** lists and describes significant places of articulation and provides selected examples of phonemes produced in those places.

The manner of articulation refers to the way in which the airstream is obstructed. The categories of the manner of articulation include stops, nasals, fricatives, affricates, and approximants (glides and liquids), as well as flaps, taps, and trills.

Table 1 Some places of articulation

Place	Description	Examples	As in
Bilabial	Made with two lips	p, b, m	Pat, bat, mat
Labiodental	Lower lip to upper front teeth	f, v	Fat, vat
Dental	Tongue tip to upper front teeth	θ, ð	Thin, then
Alveolar	Tongue tip to alveolar ridge	t, d, n, s, z	Tip, dip, nip, sip, zip
Retroflex	Tongue tip to back of alveolar ridge	r	Rat
Palatoalveolar	Tongue tip to postalveolar palate	ʃ, ʒ	She, pleasure
Palatal	Tongue dorsum to hard palate	j	Yes
Velar	Tongue dorsum to soft palate	k, g, ŋ	Kate, gate, sing

Stop consonants are produced by stopping the airstream through the vocal tract. Plosives are a type of stop consonant. A plosive occurs when the velum is raised to block the passage of air through the nasal cavity and a complete closure is formed at some point in the oral cavity. Air pressure builds up behind the closure and is released explosively when the articulators are opened. Examples are /p, t, k, b, d, g/, the initial sounds in *pad*, *tad*, *cad*, *bad*, *dad*, and *gad*.

Acoustic characteristics of stop consonants include a silent period of about 50–100 ms duration, a transient burst of energy of no more than 40 ms duration upon release of the vocal tract occlusion, and formant transitions. Stop consonants may also be categorized according to their voicing characteristics. The time interval between the release of the stop and the onset of vocal fold vibration is called voice onset time (VOT).

Nasals occur when there is a closure at some point in the oral cavity and the velum is lowered to open the velic port to permit passage of air through the nasal cavities. The nasal stops in English are /m, n, ŋ/, as in the initial sounds of *map* and *nap* and the final sound in *sing*. When the velic port is open, the vocal tract is a relatively long tube from the larynx to the opening at the nose with a side branch in the oral cavity. As longer tubes are associated with lower frequencies, nasal consonants typically have a dominant low-frequency resonance of about 300 Hz called a nasal murmur.

Fricatives result from narrowing the vocal tract at some point by the close approximation of articulators. As the airstream moves through the narrow constriction, turbulence occurs producing the 'noisy' quality associated with aperiodic waves. Fricatives may be voiced or voiceless. Voiceless English fricatives include /s, ʃ, f, θ/, the initial sounds in *so*, *show*, *fin*, and *thin*. The corresponding voiced fricatives are /z, ʒ, v, ð/ as in *zoo*, *pleasure*, *view*, and *the*.

Affricates are combinations of a stop consonant and a fricative having the same place of articulation as the stop. The initial sounds in *chair* and *jump* are examples of English affricates that result when /t/ and /ʃ/ are combined and /d/ and /ʒ/ are combined, respectively. Approximants are sounds made when articulators are moved into approximation, but not so close as to produce the turbulence associated with a fricative. They are divided into glides, or semivowels, and liquids. There

are only two English glides, /w/ and /j/ as in *wet* and *yet*. The liquids in English include /l/ as in *led* and /r/ as in *red*. Liquids have well-defined formant structures like those of glides and vowels. As is true for stops, the articulatory movements associated with liquids are quite rapid, resulting in relatively short acoustic transitions.

A flap, or tap, can be heard in the medial sounds of *latter* or *ladder*. It is made with a very rapid movement of the tongue tip to and away from the alveolar ridge. The primary acoustic feature is its brief duration compared to distinctive production of /d/ or /t/. A trill is produced aerodynamically; air passes through a constriction formed by a relaxed articulator. The resulting Bernoulli forces cause an oscillation of the articulator toward and away from the point of constriction. This series of brief occlusions imposes periodic modulation on the acoustic signal. In Spanish, there is a phonemic contrast between the flapped [r], as in *pero* which means *but*, and the trilled [r] as in *perro* which means *dog*.

The sounds that have been described so far have all been produced with a *pulmonic egressive* airstream mechanism. *Pulmonic* refers to the lungs, and *egressive* means that the air flows outward. There are a number of speech sounds in a variety of languages that are produced in other ways, with an inward air flow (*ingressive*), by moving the closed glottis up or down (the *glottalic* airstream mechanism), or by raising or lowering the velum to move the column of air in the oral cavity (the *velaric* airstream mechanism). For example, one class of such sounds, ingressive velaric clicks, is common in North American Indian and South African languages. The *tsk-tsk-tsk* sound of disappointment or admonition is a series of such clicks.

Vowels

Vowels are characterized by a relatively open vocal tract and vibrating vocal folds. In general, none of the articulators come in close contact, and the airstream is relatively unobstructed. Acoustic classification schemes for vowels are based on formant patterns which are shaped by the relative positions of the articulators along several dimensions: the front-to-back position of the highest point of the tongue, the relative height of the tongue body, and the degree of lip rounding. Lips can be rounded, neutral, or spread. In /u/ as in *food*, the lips are rounded, in /i/ as in *feed*, the lips are spread, and in /ə/ as in the initial vowel sound in *about*, the lips are in a neutral configuration. Lip rounding is often associated with back vowels, while spreading is associated with front vowels. Thus, distinctions between vowels are not typically made on rounding alone. There are exceptions to this rule, and some languages do make use of front rounded or back spread vowels. For example, the /y/ as in *tu* in French is a front, rounded vowel, and can be demonstrated by trying to pronounce /i/ as in *feed* while rounding the lips.

Four vowels, /i, u, ɑ, æ/, represent the extremes of the articulatory positions and form the vowel quadrilateral. When the vowel /i/ as in *feed* is produced, the tongue is in the extreme high, front position with the lips spread. When /u/ as in *food* is produced, the tongue is in the extreme high, back position, and the lips are rounded. The /ɑ/ sound as in *father* is made from the extreme low, back position with the lips in a neutral configuration. The /æ/ as in *bad* is a low, mid front (the tongue

cannot move as far forward in a low position as when it is in a high position) vowel with lips spread. There is a set of eight reference vowels defined along the periphery of the quadrilateral called the cardinal vowels. The front cardinal vowels (/i, e, ε, a/) are equidistant from one another, as are the back cardinal vowels (/u, o, ɑ, ɔ/). The schwa (/ə/) is a mid, central vowel produced with the tongue in a relatively neutral or resting position; it is represented near the center of the vowel quadrilateral. (Figure 4 illustrates a relative articulatory position of the vowels of the vowel quadrilateral, the cardinal vowels, and the schwa in a vowel space.) The first three formants are sufficient to identify a given vowel (see Figures 5 and 6 for schematic representations of the formant patterns and articulatory postures, respectively, associated with the vowels /i, I, ε, æ, ɑ, ɔ, u, u/ as in *heed, hid, head, had, hod, hawed, hood, and who'd*). The specific formant values and articulatory positions of vowels in the space are for canonical vowels. Much variability occurs when the vowels are actually produced, even in isolation.

Certain pairs of vowels share most of the same articulatory features, but differ primarily in tongue root position or in tenseness of tongue muscles. These are the tense – lax pairs,

Figure 4 The relative articulatory positions and acoustic relationships of the vowels of the vowel quadrilateral (/i æ ɑ u/), the cardinal vowels (/i e ε a ɑ ɔ o u/), and the schwa (/ə/) in a vowel space. Front-back and high-low refer to the tongue position.

Figure 5 Schematic representations of the formant patterns (F1, F2, and F3) for indicated vowels.

Figure 6 Schematic representations of the articulatory patterns for the vowels in [Figure 5](#).

and include /i/ as in *beet* versus /I/ as in *bit*, /u/ as in *food* versus /ʊ/ as in *good*, and /e/ as in *bait* versus /ɛ/ as in *bet*.

Examples of a rhotacized, or r- colored, vowel are found in *bird*, *herd*, *purr*, or *pearl*. This single-vowel sound is called the *schwar*, and it can be produced in several ways. The front of the tongue can be retracted, the back of the tongue can be bunched, or the tongue root can be retracted into the pharynx.

Nasalized vowels occur when the velic port is open, as is often the case when a vowel precedes a nasal consonant, for example, in the word *bond*. As with consonants, nasalization of vowels results in a low-frequency nasal formant. In English, there is no vowel distinction based on nasalization; however, such distinctions are made in other languages. For example, in French, *mon* (meaning *my*) pronounced [mɔ̃] contrasts with *mot* (meaning *word*) pronounced [mo].

Diphthongs are like vowels in that they are produced with a relatively open vocal tract and have well-defined formant structures. In general, they cannot be adequately characterized by a single vocal tract shape or single formant pattern. The diphthong /aɪ/ as in *eye*, for example, begins with the formant structure for /a/ and ends with the formant structure for /i/.

Prosody and Suprasegmentals

The phonetic aspects of speech that apply across segments, such as stress, pitch, and timing, are referred to as suprasegmentals or prosodies. Vowels and consonants are the segments of speech that combine to form syllables. Although people intuitively know what a syllable is, there is no entirely adequate objective definition of the term. Syllables are usually defined as a pulse of air, bounded by either the production of a consonant as in the syllables *pop*, *op*, or *pa* or a self-imposed reduction of air flow as in the string of syllables *ah-ah-ah*. However, while this allows for general agreement on the number of syllables in such words as *phone* (one), *phoneme* (two), *phonetic* (three), and *phonological* (five), it does not account for the

disagreement for words such as *pool* or *fear*, which may be considered to have either one or two syllables.

Stress can be defined as giving emphasis to one or more syllables in a word or phrase and it is most commonly associated with, but not equivalent to, variations in loudness. In general, stressed vowels will be louder, longer in duration, higher in pitch, less subject to modification by context, and contain a more distinct vowel than unstressed syllables. In unstressed or weakly stressed syllables, the vowel tends to be reduced toward the schwa. In English, stress can play a grammatical role, indicating whether a word is being used as a noun or a verb. Consider *to construct* versus *a construct*. In the case of the verb, primary stress is on the second syllable, while for the noun, primary stress is on the first syllable. Stress can also serve a contrastive function as in the sentence *I have a DOG, not a cat*.

Variations in pitch are used to convey both linguistic and nonlinguistic information. Absolute values of pitch are used to convey nonlinguistic information regarding the speaker's gender, age, and emotional state. It is the relative changes in pitch that convey linguistic information at the phrase or sentence level (intonation) or the word level (tone). Although English and most other Indo-European languages are not tone languages, a majority of the world's languages are. In tone languages, differences in pitch can signify different words. For example, in Chinese, the word *ma* spoken with rising pitch means *hemp*, and spoken with falling pitch means *to scold*. In some tone languages, differences in the pattern of pitch changes within a word can convey syntactic information, such as tense or possession. Most languages, including English, use an intonation pattern of falling pitch to signal the end of a grammatical unit. A variation in that pattern signifies a change in meaning. For example, in the declarative sentence, *She ate squid*, pitch falls, signifying the end of the sentence. However, when pitch rises at the end of the same sentence, it signifies a question: *She ate squid?*

Timing variations may also convey linguistically relevant information. For example, the vowel in *cab* is longer than the

vowel in *cap*. In general, vowels are longer when they precede a voiced consonant as opposed to a voiceless consonant. In addition, there are many languages in which variations in duration of vowels or consonants result in semantic differences. In Italian, *papa* means *father* and *pappa* means *porridge*. The two words are distinguished on the basis of the longer double consonant or geminate. In English, such distinctions based on geminates occur across, but not within, word boundaries, as in the phrase *cite Ed* versus *cite Ted*. Timing variations in the pattern of relationships among syllable durations determine the rhythm of a language. For example, English is a stress-timed language, which means that the duration between stressed syllables tends to be (loosely) the same. Compare ‘The boy ate the peanut’ and ‘The elephant ate the peanut.’ *Elephant* has more segments than *boy*, yet the time from stressed syllable to stressed syllable is about the same in each sentence. In syllable-timed languages such as French, the duration of syllables rather than stress groups remains relatively constant.

In general, it is the relative values of stress, pitch, and timing that contribute to the semantic or syntactic information conveyed by the speaker to the listener. Inappropriate application of the suprasegmentals by nonnative speakers of a language, the deaf, or those with speech disorders results in perceptual errors and speech that does not sound natural.

Features and Feature Detection

One theory of speech perception, feature detection theory, was based on the distinctive feature theory proposed by Roman Jakobson, Gunnar Fant, and Morris Halle in 1963 that is still recognizable in the phonetic descriptions of sound in the section ‘Articulatory and Acoustic Classification Schemes.’ Jakobson, Fant, and Halle recognized that speakers of any language use only a subset of all possible speech sounds. For example, the first sound in *think*, /θ/, is a common speech sound in English, but it is not used in French. Clicks are common in some American Indian and South African languages, but not in English. Yet, despite many such differences in the inventories of speech sounds used in the various languages of the world, there are regularities within and among languages. Jakobson, Fant, and Halle proposed that all speech sounds in all languages could be described by the presence or absence of 12 features. Noam Chomsky and Morris Halle, in their 1968 book *The Sound Pattern of English*, extended the list to more than 30 distinctive features (see Table 2 for some of the Chomsky–Halle features and their descriptions).

The notion that each abstract linguistic unit could be described as a unique ‘bundle’ of distinctive features led to the hypothesis that neurons in the auditory nervous system were selectively responsive to each feature, as instantiated in the acoustic signal. Feature detection theory was appealing because it provided a physiological mechanism devoted to speech, which could account for the fact that speech is rapidly processed (human beings produce and perceive about 20 phonemes per second) and that infants seem innately predisposed to perceive phonetic categories. Although feature detection theory was generally abandoned because it failed to account for the finite number of features or the relative importance of acoustic and phonetic features, distinctive features continue to be useful for describing speech sounds.

Table 2 Some Chomsky–Halle features for classifying segments

Features indicating	Feature name	Description
Place of articulation	Anterior	Obstruction in front of palatoalveolar region
	Coronal	Blade of tongue raised from neutral
	Distributed	Constriction extending in the direction of air flow
	High	Tongue body above the neutral position
Manner of articulation	Rounded	Narrowing of lip orifice
	Tense	Deliberate, maximally distinct gesture
	Nasal	Lowered velum, open nasal passage
	Lateral	Lowered mid section of the tongue at one or both sides
Phonation	Strident	Acoustically noisy sounds
	Continuant	Accompanied by little or no turbulence
	Voiced	Vocal cords in position for spontaneous voicing
Major sound	Consonantal	Radical obstruction in the midsagittal region of the vocal tract
Classifications	Vocalic	Produced in the oral cavity, constriction not greater than for high vowels, and vocal cords in position for spontaneous voicing
	Sonorant	Spontaneous voicing possible

Coarticulation

The articulatory and acoustic classification schemes that have been described may lead to the misconception that conversational speech is a collection of distinct segments strung together like beads. However, speech is a dynamic process. It is not made up of static postures corresponding to phonemes with movements simply connecting one phoneme posture to the next. Speech sounds, as they are produced, are modified by the phonetic context in which they occur. For example, ‘I want to go home’ is usually produced more like ‘I wanna g’home,’ and ‘I have to go home’ is usually produced more like ‘I hafta g’home.’ In the modification, or coarticulation, of *want to*, the stop consonants are completely assimilated, and the /u/ in *to* is reduced to the schwa vowel. In the case of *have to*, the voiced labiodental becomes voiceless, the stop consonant is only partially assimilated, and the /u/ in *to* is reduced to the schwa. The coarticulations involve the overlapping of articulatory gestures due to the requirements for rapid production and processing of speech and exhibit the tendency of speakers to expend the least amount of articulatory effort necessary to convey the message. Factors such as stress, rate of speaking, and formality of the situation in which speech occurs affect the degree of coarticulation, but even in the most precise productions, the sounds are coarticulated.

Experimental Phonetics

Thus far, the articulatory basis of speech sound production and the acoustic consequences of articulation have been examined. However, speech communication also includes the listener’s

perception of the speaker's message. It seems obvious that what the listener perceives is the acoustic signal produced by the vocal tract, but this, ultimately, turns out to be a superficial explanation. Experimental phonetics is the application of experimental methods and investigative techniques to test hypotheses about speech perception and production. It is concerned with such issues as determining the features that signal contrasts between sounds, defining the units of speech perception, discovering how context affects speech perception, understanding the neural representation of the speech code, and establishing the relation between speech perception and speech production.

Glossary

Circadian rhythm A roughly 24-h physiological cycle that determines our sleep and arousal patterns.

Ego depletion The idea that self-control or will power is an exhaustible resource that can be used up.

Frontal lobe The front portion of each hemisphere of the brain. Responsible for higher intellectual functioning, including planning.

Implementation intention A simple plan that states links a situational cue (e.g., time, event, thought) to a desired behavior.

Planning fallacy The tendency to underestimate task-completion times.

Procrastination The act of putting off actions or tasks to a later time.

Subgoal A lesser goal that forms part of a greater goal.

Working memory Short-term mental storage of information created by consciously thinking about something. Working memory is needed for complex tasks such as comprehension, reasoning, comparing, and planning.

Introduction

Understanding the complex nature of human behavior requires consideration of how we mentally represent past experiences, respond to present events, and prepare for future events. This article focuses on the last of these: planning and goal-setting. To be able to carry out, effectively, behaviors necessary to achieve future goals requires planning. Planning has a variety of definitions, but at its core it is a mental activity that prepares us for future action. We make travel plans, plan a meal, plan our next move in a chess match, or plan how we will engage the attractive person sitting across the room at a party. Plans can be quite simple (e.g., mailing a letter) or relatively complex (e.g., writing an article on planning).

Elements of Planning

Planning requires several steps. We must first develop a mental representation of our goal as well as the context in which we wish to achieve it. Then we must imagine different possible actions that might help us reach this goal, comparing them to determine which will be the most effective. Comparing mental representations, of course, requires that we are able to store them, at least temporarily, in our working memory.

Planning is useful because it allows us to explore different possibilities, without committing to them, changing our minds as we mentally simulate different possible solutions to a problem or goal. Although planning can consume cognitive resources, the alternative – action without planning – certainly has potential costs of its own.

Planning also encourages creative solutions, as you think about the world in ways that might not be possible physically. For example, you might work backwards, starting from your goal (e.g., say a location on a map) in order to determine the most effective path to it.

Early Research on Planning

Early work on planning was based on the relatively simple idea that we formulate plans to resolve discrepancies between an undesirable present state and an imagined ideal state (i.e., a goal). Resolving this discrepancy required one to act on the environment in such a way that the ideal state could be achieved.

This early model assumed that individuals would operate in a kind of feedback loop where they continued to engage in behaviors aimed at accomplishing their goal, repetitively comparing their present state to their desired ideal until it was achieved. Thus, this model purported that, when planning a solution to a problem, rather than choosing our actions blindly, we select actions most likely to lead us to the final goal, and evaluate the impact of those means. However, a major limitation of this model was that it could not account for adapting to the situation by alternating between different goal-related behaviors or even changing the goal entirely. In short, it was a little too simple. Moreover, this model emphasized efforts to return to a state of equilibrium, thus avoiding change. Of course, we now know that people will create discrepancies even when they are not lacking anything – that is, besides merely satisfying deficiencies, people can identify goals that seek development and growth.

More recent work on planning has focused primarily on examining how factors such as the difficulty (easy or hard), time frame (long or short term), and the degree of detail (general or specific) particular to a given plan can impact goal achievement. Studies that investigated these factors found evidence that regardless of whether goals were short or long term in nature (although breaking down large goals into more manageable subgoals is beneficial – more on this idea will be discussed below), the degree of difficulty and specificity was especially important, with more specific and more challenging goals tending to lead to greater achievement. Specificity appears to be important because it provides guidelines that enable individuals to determine how well they are adhering to their

plan: in other words, how people know if their best is good enough without an objective set of criteria to base it on. Difficulty is also important in that it defines a higher level of achievement as necessary for goal attainment, thus motivating greater effort expended toward accomplishing a goal.

The role of developing a plan with specific, objective performance goals versus planning on simply doing well (and on having fun) became a central focus in research on academic goal-setting. In one study that examined outcomes associated with performance-oriented goals (i.e., to get good grades) and mastery-oriented goals (i.e., to simply enjoy learning the material), students with mastery goals reported greater interest in the course material but tended to have lower grades; the opposite was true for students who had set performance goals. Thus, these findings suggest that the nature of the goal one sets influences the type of outcome: if your goal is to do well relative to an objective standard, you tend to perform better; if the aim is to simply 'get the most out of it that you can,' you will not perform as well, although you are more likely to enjoy yourself. However, a follow-up study revealed that the students who had set mastery-oriented goals were more likely to enroll in related courses the following semester as compared to students who had set performance-oriented goals (although the same pattern in grades was also found). These results suggest that how we plan out a specific goal not only affects the relevant outcome but may also impact subsequent plans we make.

Measures of Planning Ability

Tower of Hanoi

The most commonly used tool to study planning, especially by cognitive psychologists and neuropsychologists, has been the Tower of Hanoi, a puzzle created by the mathematician Édouard Lucas in 1883. In the classic version of this game, there are three rods, and between four and nine disks of increasingly smaller diameter. The goal is to move the stack of disks from the first rod to the third while following these two rules:

1. You may only move one disk at a time
2. You may not place a larger disk onto a smaller disk

The puzzle can be played with any number of disks, and though it seems impossible to many novices, it is always solvable with a minimum of $2n - 1$ required moves, where n is the number of disks. Researchers usually use a five-disk version, which would require 31 moves, although the typical novice takes about 64 moves to complete the task. Clearly, an individual cannot plan and maintain that many moves in memory. Research on how individuals solve the Tower of Hanoi problem showed that people break their plans down into separate subgoals, usually by first trying to get the largest disk into its final location. Once the largest disk has been placed, a new subgoal of placing the next largest disk is planned. [Figure 1](#) shows the eight moves required of a very simple version of the game with only three disks.

It appears that most people try out different subgoal strategies to determine which is the most effective. People with higher intelligence and greater working memory capacity (which are related to each other) tend to perform better on the task. Performing a secondary task will consume cognitive resources and reduce performance. However, with practice

people can improve solving the puzzle in fewer moves. Rather than merely memorizing all of the moves, practice appears to improve people's ability to choose effective subgoals.

Tower of London

A variation on the Tower of Hanoi is the Tower of London developed to detect deficits in planning that typically accompany brain damage. In particular, damage to the left anterior frontal lobe has been shown to be associated with individuals needing to make a greater number of moves to solve the puzzle. Those with damage to other areas of the frontal lobe (e.g., right anterior, left, or right posterior) do not exhibit this impairment. The ability to withhold responses and direct attention and memory processes to ongoing and future tasks appears to be controlled by neurons in the prefrontal cortex. These neurons, particularly those concentrated in the principal sulcus, enable individuals to coordinate attention and memory in order to develop plans and then act on them. Conversely, damage to the prefrontal cortex is associated with poor impulse control.

Social Cognitive Aspects of Planning

Research on planning used to be the exclusive domain of cognitive psychologists and those studying artificial intelligence. In the past two decades, however, it has become increasingly less common to find studies on planning in cognitive journals (or textbooks!). This is primarily because cognitive psychologists have turned their sights to various aspects of memory and expertise.

The research on planning continues, however, but is now studied primarily by social psychologists who have changed the focus of the research. Planning as studied by social psychologists tends to focus more on the plans needed to meet personal goals that people have for themselves (or that have been imposed upon them by others). Unlike the Tower of Hanoi, which can be completed in a matter of minutes, personal goals, especially self-improvement goals, tend to take much longer.

Examples of personal goals studied by social psychologists range from the mundane to the complex, and include everything from shopping for groceries, to writing a term paper, to losing weight, to getting married. As such, the research questions have changed somewhat. Social psychologists do not disparage cognitive accounts, and often embrace them. But social psychologists also acknowledge the role of desires, fears, and various other social motives. Indeed, a complete examination of how we plan for such far-reaching goals really must include motivation. Consider, for example, two people who are both planning to complete their income taxes by hand: one person expects to have to pay additional taxes beyond what was withheld by the government, and the other person expects to get a refund from the IRS. Of these two individuals, who is more likely to actually finish sooner? Who will plan to finish sooner? We'll get to this answer in a little while.

How to Set Effective Goals

An important part of planning is setting realistically achievable goals. Good goals motivate hard work and lead to improved performance. The concept of effective goal setting

Figure 1 A simple version of the Tower of Hanoi puzzle. The puzzle is always solvable with $2n - 1$ moves, where n is the number of disks. With only 3 disks, 8 moves are required.

is so important in Industrial/Organizational (I/O) psychology that entire management systems have been based on it. As noted previously, we find that specific and difficult goals tend to lead to better task performance than vague or easy goals. The researchers Locke and Latham, who have spent over four decades studying this area, offer four principles of successful goal setting – to which we have added a fifth.

1. Set challenging, but attainable goals. So long as they are within your ability, a difficult goal is more likely to produce higher levels of effort and increase performance than an easy goal. Commitment to very difficult goals does not last long.
2. Set specific rather than vague goals. Specific (and difficult) goals tend to produce higher performance than merely urging people to 'try hard' or 'do your best.' There should be little or no ambiguity about what has to be achieved.
3. Set measurable goals. For goals to be effective, people need feedback about their progress. It is difficult to modify your plan of action if you do not know how you are progressing.
4. Set your own goals; do not let others set them for you. Commitment is higher for goals that you set yourself.
5. Break long-term goals into smaller subgoals. Following from the previous principles, if you have a long-term goal (i.e., get a college degree) you must break it down into smaller subgoals that are specific, challenging, attainable, and measurable.

In the sections that follow, we will outline various difficulties people have in following these rules of goal setting, and also difficulties people have in following the plans they have made for themselves. Finally, we address some biased thoughts people have when planning their future (and past).

Self-Improvement Plans: The New Year Resolution Fallacy

Americans are obsessed with self-improvement. Each New Year, we make a resolution to improve some aspect of ourselves, and each year most of us fail to keep our resolutions, often within the first month! Paradoxically, many of us will make the same resolution next year! Why? As it turns out, resolutions that make us feel good about our future potential self (i.e., thinner, better read, or otherwise improved) are less effective at actually helping us to reach that potential. This is because resolutions that make us feel good about ourselves are poorly structured – they merely restate the goal (e.g., lose weight), but do not elaborate on the steps required to achieve the goal – and also tend to lack concreteness or specific details about the behaviors required at each step. Indeed, people who make poor self-improvement plans tend to feel more energized and actually predict that they have a greater likelihood of success than do those who make good plans. It seems that poor planning can be rewarding, albeit in a short-sighted way.

Delay Discounting

The tendency to focus on the immediate good feelings produced by (poor) self-improvement planning rather than be rooted in a concept called delay discounting. This is the tendency to prefer a smaller, more immediate reward to larger reward obtained in the more distant future. Consider the following two choices:

- Choice A: Receive \$1000 today
Choice B: Receive \$4000 in 10 years

Most people will choose A over B, because the 10-year wait in choice B lessens the appeal of the \$4000. Delay-induced discounting can help to explain seemingly irrational behaviors such as gambling, taking drugs, or failing to save money for retirement in favor of purchasing a big-screen TV. As one might predict, however, individual differences in the tendency to discount long-term gains are (negatively) related to both intelligence and working memory. Further, preliminary evidence suggests that a reduction of brain activity in the anterior prefrontal cortex may exacerbate delay discounting.

Construal Level and Procrastination

Research also shows that events that are distant in time are mentally represented in a more abstract fashion than immediate events which are represented in a more concrete fashion. When an event is distant, abstract thinking dominates, and this tends to focus on whether to engage in the event at all or not ("Should I start working on my chapter for the Encyclopedia of Behavior?"). As an event – in this case, a deadline – grows closer in time, it becomes more important to plan a specific course of action ("I'd better create an outline and start writing"). Interestingly, the opposite is also true. If you are induced to think about an event in less concrete terms (i.e., more abstractly), then you are also likely to perceive the event as more distant, and thus less likely to initiate action. Thus, the level at which you construe an event (abstract vs. concrete) can explain the extent to which you will procrastinate.

Construal level theory is most likely to apply to tasks that are relatively easy and not extremely important to you. For more difficult and important tasks, the case can be made for maintaining at least some high-level representation of the situation. This is because abstraction has been found to improve self-control, presumably by allowing people to focus on the reasons why they are engaged in the difficult behavior in the first place. So, although concrete representations make events seem more immediate, and thus require plans and action, abstract representations can help us stay focused by increasing the perceived importance of the task.

Chronic procrastinators may not benefit from such advice. Indeed, research has shown that they tend to represent tasks more concretely than do people who do not procrastinate. Focusing on task details too much may overwhelm people, ironically causing them to avoid the situation altogether. Clearly, more research is needed in this area.

Self-Control and Ego Depletion

One important predictor of success in life is the ability to delay gratification. A series of fascinating studies has found that children who are able to wait longer to eat a marshmallow tend to do better in school – even as young adults – than do children who cannot wait and eat the marshmallow immediately. Like marshmallows, temptations abound that can derail our goal pursuits. Pursuing one's goals often means forgoing activities that are rewarding in the short term. Unfortunately, overriding temptations requires controlled effort that takes cognitive resources. Put differently, it takes less effort to do

something than it does not to do something. When you are on a diet, it can be much more difficult to turn down dessert than it is to eat it.

A host of other things can deplete the cognitive resources needed to engage in self-control. For example, being depressed, tired, or in a bad mood can reduce self-control. Additionally, resisting one temptation will make it harder to resist a second temptation. Consistent with this notion, it is also true that being in good physical condition, well-rested, or in a good mood can enhance our self-control.

How does this relate to planning? It suggests that we should take into account those situations and times in which we are most at risk for temptations that will derail us from our goals. When planning, we should keep in mind the extent to which our self-control resources might be depleted.

Circadian Rhythms

A related consideration here is one's circadian rhythm. We each have a 24-h biological cycle that determines our sleep-wake pattern. Although environmental factors (e.g., light, noise, temperature) can play a role, your circadian rhythm tends to be stable over your lifetime. Cognitive arousal is usually highest in the first third of the day, lowest in mid-afternoon, and after a sub-peak, drops off quickly right before sleep. There are individual differences, however. Some people prefer to work in the morning, whereas others prefer the evening because they feel more awake. Unfortunately, the increased arousal in night owls also tends to cause greater anxiety and worry about performance, which inevitably leads to procrastination – the tendency to delay a task.

Consider this example: Adrienne has a goal to exercise more. Her goal commitment is high; she considers exercise very important. She is also somewhat of an evening person and thus cannot get up early enough to exercise before work. Thus, daily she plans in her head to run on the treadmill after work. Unfortunately, she also has a demanding job that regularly requires her to stay in the office past 6 p.m. By the time Adrienne arrives home, she is so tired (and hungry) that she is much more likely to have a glass of wine, collapse on the couch, and watch TV, than to run on a treadmill. Clearly she is planning her exercise regimen at the wrong time of day. Her fatigue and hunger will both compromise her self-control. She either needs to change her plans to leave work sooner, or plan to exercise in the morning. After all, running does not require thinking, so if she can find a way to get herself out of bed; this may be a workable solution for her. The next section provides a technique that might help her to do just that.

Implementation Intentions

Peter Gollwitzer has developed a model of volitional planning that relies heavily on what are called implementation intentions. These are specific and (deceptively) simple action plans for how a goal will be attained. Implementation intentions are always stated in an 'if-then' format. Let's call your goal 'Z,' the effective response 'Y,' and the situation cue 'X.' An implementation intention to reach a goal would be stated like this:

When I encounter situation X, I will initiate behavior Y, in order to reach goal Z.

Specific examples of implementation intentions usually imply, but do not explicitly state, the goal. Instead, they focus on the situational cue and the required behavior:

1. After I start the coffee machine, I will take my vitamins.
2. If I feel tempted to eat a piece of chocolate, I will ignore that thought and eat an apple.
3. After I go swimming tomorrow, I will perform a breast self-examination.
4. When I arrive at the office, I will not turn on my computer until I have finished the paperwork on my desk.
5. When I turn on my computer, I will do a literature search before reading my email.
6. If it is Monday, then I will do my math homework.

Following our earlier guidelines for setting an effective goal, the situational cue and behavioral response of an implementation intention should be as specific as possible.

Poor: If it is the weekend, then I will exercise more.

Better: If it is 9 a.m. on Saturday, then I will run 3 miles on the treadmill.

Note the difference between an implementation intention and a simple statement of one's goal, for example, I will floss my teeth more. An implementation intention requires that an explicit connection be made between a situational cue (when the 11 p.m. news comes on) and a behavior (I will walk to the bathroom and floss my teeth). This helps to automate the process so that we need not depend on our memory to remember to do the task. Once the connection is made, the situation automatically cues the behavior. Implementation intentions have a moderate to large effect compared to simple goal intentions (i.e., I will perform a breast self-exam) that do not reference a situational cue (when I take a shower after swimming).

The benefits of implementation intentions are largest when people are confronted with aversive tasks (eat more vegetables) or difficult or complex ones (write a term paper). These sorts of goals tend to suffer from the following problems:

1. Failing to get started
2. Getting distracted
3. Overextending oneself
4. Failing to call a halt to fruitless goal-striving.

Implementation intentions are important because they facilitate both the initiation of desired behaviors as well as maintaining persistence in the face of potential distractions, setbacks, or challenges. But, they can also help us to drop subgoals if it appears that they are not working. For example, consider the amount of time one could spend (waste) researching a topic using a search engine like Google. A useful implementation intention here might be: if I do not find an answer after the fifth page, I will stop searching and move on to the next subgoal. Of course, Implementation intentions are most effective when you have a strong goal commitment. Indeed, you are unlikely to engage in such intentions if you are not committed to your goal.

Implementation intentions are most useful to people who have poor self-regulatory skills (e.g., schizophrenia, drug

addicts in withdrawal, children with attention deficit hyperactivity disorder (ADHD), and people with damage to their frontal lobe), but they are also useful for people who are preoccupied with distracting thoughts and anyone who has recently engaged in an ego-depleting task. As mentioned earlier, self-control suffers if we engage in multiple resource (ego) depleting tasks in a relatively short period. Working hard at one task makes us less likely to find the strength to work hard at a second task. Similarly, resisting one temptation makes a second temptation more difficult to resist, unless we remind ourselves to work harder. Research has found that making an implementation intention while engaged in an ego-depleting task can help us to persist longer and perform better at a difficult second task.

It is somewhat ironic that although the focus of social psychologists has been on long-range personal goals, the most effective solution to goal-striving seems to be to make very simple short-term plans!

Perfectionism

Because implementation intentions help us to stay on task and to worry less, one should find that perfectionists benefit from their use. There are, however, two types of perfectionists. First is the self-oriented perfectionist, who sets his or her own (overly high) standards. These people do benefit from implementation intentions. However, a second form of perfectionism exists, the socially prescribed perfectionist, who has a strong need to meet expectations and standards prescribed by significant others. For these people, implementation intentions can backfire. Rather than inspiring action, forming such intentions instead causes worry and self-criticism that actually interferes with goal progress.

Another limitation to implementation intentions would come in the form of a 'ceiling effect' in which performance is already so high that intention formation does little further good. Such results have been found when predicting class attendance with people scoring high and low on conscientiousness. Those who scored high did not benefit from implementation intentions.

Planning Fallacy

When planning a future task, individuals often underestimate how much time it will take for them to complete it. This optimistic 'planning fallacy' has been shown to occur for predictions about a wide range of tasks, including writing term papers, programing software, doing one's taxes, and Christmas shopping. The interesting thing about the planning fallacy (and the reason it's called a 'fallacy') is the fact that people seem to know that they do it! When told that other people underestimate how long it will take to accomplish a task, most people laugh, because they can think of times in which they have done this. And yet, this knowledge does not seem to help them make better predictions for the future. Why is this?

One reason has to do with a sort of cognitive neglect. When planning a task, people focus too much on the events

that are required to complete the task but neglect to consider any potential distractions that will slow them down. It seems that previous distractions are categorized as flukes, and thus unlikely to happen again. Although any particular distraction may not occur again, it is almost inevitable that some unknown distraction will rear its head before the task is completed.

A second reason for the planning fallacy is wishful thinking – simply wanting to finish. This is especially true when anticipating a desired outcome. As before, consider two people planning to do their taxes, one who expects to receive a tax return, and the other who expects to have to pay additional taxes. Although both people will estimate that they will finish sooner than they actually do, the person expecting the tax refund will show a stronger effect. Consistent with the cognitive neglect mechanism, those expecting the refund gave less credence to their past experiences when making their prediction.

One effective way to reduce the planning fallacy is to use implementation intentions discussed earlier. Note that this reduces the bias not by making people's plans more accurate, but by helping them to finish earlier than they normally would.

It is important to note that not everyone shows the planning fallacy. First, there is evidence to suggest that the bias is less likely to occur when predictions are made privately. Thus, we make optimistic predictions in order to appear more productive and successful to others.

Finally, the planning fallacy is sensitive to individual differences, for example, the extent to which people demonstrate hippie- or yuppie-oriented traits. People with yuppie traits are goal oriented, hard working, and organized, whereas people with hippie traits tend to have a live for the moment philosophy with few concerns for the future or regrets about the past. As you might expect, yuppie traits are associated with completing a task sooner and consequently showing less of an optimistic bias. In contrast, hippie traits are related to both earlier predicted times and later completion times, resulting in greater optimistic bias. People with hippie traits appear to have strong social concerns. This makes them more likely to promise others that they will finish things early, but also more likely to get distracted by opportunities for recreation (e.g., social functions).

Related Areas

Readers interested in the social aspects of planning might also be interested in two additional areas of study: affective forecasting and hindsight bias.

Affective Forecasting

Affective forecasting is the prediction of one's future emotional state. Research has shown that people exhibit an 'impact bias' in which they overestimate their emotional reactions – both negative and positive – to things like sporting events, election outcomes, and romantic events. The reason for this bias is threefold: First, people underestimate their own ability to cope with negative events. Second, people tend to focus too

much on the target event and neglect other events and activities that will occupy their attention and thus reduce the strength of their emotions, whether positive or negative. Finally, when confronted with emotional events we usually spend some time trying to make sense of them, spending time thinking about both their causes and meaning. Rather than strengthening their emotional feelings, as might be expected, sense-making has been shown to reduce it.

Hindsight Bias

Sense-making also produces another bias, called hindsight bias. Hindsight bias is the tendency to believe that one could have predicted an event with greater accuracy than is really the case. Although the bias is not large, it is somewhat akin to the belief that you 'knew it all along.' Many researchers argue that hindsight bias prevents us from learning from the past because our mistakes are less surprising than they should be. The implication for planning, of course, is that people will continue to make the same mistakes in the future. One way to counteract the hindsight bias is to make an explicit prediction for an event before the event occurs. This allows you to compare your (unbiased) prediction with reality and, with any luck, learn from the past so that you can plan for a more successful future.

Glossary

Locomotor play Nonfunctional gross motor movement.

Object play Not functional use of objects.

Ontogeny Development within a species.

Play Behaviors that are means, not ends, oriented and not immediately functional.

Pretend play Playful interactions where make-believe, or fantasy, is invoked.

Social play Peer play interactions where roles are reversed and reciprocal.

Introduction

This article outlines a definition of play, then describes the ontogeny of locomotor, object, social, and pretend play, and also examines possible functions of each. It argues that some forms of play serve a function, especially during childhood, and may, in fact, be at the vanguard of phylogenetic change.

What Is Play?

Virtually all students of play acknowledge the difficulty of trying to define it. It may be that we really do not need a 'formal' definition of play because most people 'recognize it when they see it.' In fact, there are many cases in which children and adults alike have difficulty recognizing play. For example, there have been empirical studies into the ways in which children and youth categorize behaviors as play or nonplay and there is disagreement, suggesting that some level of definitional consensus is necessary.

Burghardt suggests that there are core criteria, all of which must be present, for a behavior to be categorized as play: The behavior must be voluntary, observed in a 'relaxed field,' the behavior is not functional in the observed context, the behaviors are repeated but the behavioral elements are exaggerated, segmented, and nonsequential in relation to the functional behavior. A relaxed field is one where the individual is safe, healthy, and well fed. Further, the child should choose to, voluntarily, engage in some social, locomotor, fantasy, or object-directed activity that is not directly or immediately functional. The nature and sequence of these behaviors would not resemble those in a functional context. For example, the child would use an exaggerated 'play face' to announce playful intent as he or she approaches a peer, and in the course of wrestling, the players would switch roles. These criteria can be realized in the four domains of play: locomotor (e.g., rolling down a hill), object (e.g., piling blocks in different configurations), social (e.g., play fighting), and pretend (e.g., enacting domestic roles). Further, each of these domains, with the obvious exception of social play, can be either social or solitary.

Locomotor Play

Locomotor play, like all other forms of play, follows an inverted-U developmental course: it begins in early infancy, peaks during childhood, then declines during adolescence and more rapidly in adulthood. The trends in locomotor play in humans appear to show in two successive peaks, reflecting two types of locomotor play, probably with different functions: rhythmic stereotypies and exercise play.

There is only limited evidence documenting infants' locomotor play, the exception being Thelen's longitudinal study of rhythmical stereotypies during the first year of life. Rhythmical stereotypic behaviors are gross motor movements with no ascribed goal or purpose to those movements; examples include body rocking and foot kicking. Stereotypic behaviors tend to peak during the midpoint of the first year of life; at 6 months, some infants spend as much as 40% of a 1 h observational period in stereotypic behavior. After this point, the behaviors gradually disappear from normal children's behavioral repertoires. Across the first year of life, infants spend 5.2% of their time in stereotypic behaviors, with no observed gender differences.

Exercise play means gross locomotor movements in the context of play, such as functionless swinging, marked by positive affect; it can be solitary or social, with parents or peers. Relatively low rates of American parent-infant physical play have been reported, with rates peaking at around 4 years of age. Exercise play with peers increases from the toddler to preschool period and then declines during the primary school years. Specifically, for 2-year-olds, Rosenthal reports that it accounts for about 7% of behavior observed in day-care settings. For children 2–4 years of age, Field reports exercise play accounting for 10% of all day-care behavior. In one observational study in a British nursery school, McGrew found that approximately 20% of 4-year-olds' activity was physically vigorous, such as run, flee, and wrestle. For children aged 6–10 years, exercise play declines, accounting for only 13% of all outdoor behavior observed during school recess periods.

Males engage in exercise play at higher rates than females do. Thus males, because they compete with each other for mates, are bigger, more aggressive, and more active than females. These differences in physical activity form an important basis for the

existence of segregated sex peer groups, as noted earlier, which begin in preschool and wane in early adolescence.

Both rhythmic stereotypies and exercise play have physical training benefits. It could be postulated that infants' rhythmic stereotypies are primarily functional for the immediate benefits of improving control of specific motor patterns. The correspondence between the ages at which these movements occur and cerebral development suggests that, initially, rhythmic stereotypies may be manifestations of immature sensorimotor integration. Play may modify or eliminate irrelevant synapse formations; with maturation, these patterns are used in more goal-directed ways. Such a hypothesis is consistent with the lack of sex differences in these behaviors, because there is no reason to suppose that control of motor patterns at this very basic level of generality is more important for boys than for girls.

With the onset of locomotion, another developmental course may begin, as evidenced by the correspondence between exercise play and muscle differentiation, strength, and endurance. Byers and Walker, in a review of the animal play and motor training literatures, suggest that exercise play may improve skill and economy of movement due to the effects of exercise on muscle fiber differentiation and cerebellar synaptogenesis. Exercise play during the juvenile period may have a lasting effect on subsequent economy and skill of movement.

In children, the age course of exercise play corresponds to the growth of arm and leg muscles and bones during the preschool period. Consistent with this claim, an experimental, longitudinal study of children documented the relation between one form of exercise play, jumping, and bone mineral content. Exercise play during the school years and beyond might continue to benefit muscle and bone remodeling and strength and endurance training; physiological effects.

Object Play

There is little descriptive information about the different ways in which children use objects, including in playing with them, in the child development literature. Where researchers have addressed children's object play they have typically conflated object play with a variety of other uses for objects, often under the label 'constructive play.' Much of the study of children's interactions with objects during childhood has been influenced by Smilansky's questionable adaptation of Piaget's theory of play. According to Piaget, however, construction is not considered to be play per se because it is more concerned with the end product of activity, while play is more concerned with the activity or means than with the end.

What is sometimes considered object and construction 'play' includes not only play and construction, but also exploration and tool use. Play with objects, following the definition of play used in this article probably has a pretend play component in many cases. Using objects in pretense initially entails children simulating someone else's use of those objects. Exploration of objects and using objects as tools are different still. Exploration is exhibited when individuals first encounter objects. Through exploration, children find out that objects are flat or rounded, long or short, used for drinking or for covering

one's head. These attributes and the ways in which they observe others utilizing them, in turn, are related to children's play with those objects.

Regarding tool use, age trends too are evidenced with skills increasing from infancy through early childhood. Studies of tool use in childhood also show increases in facility with age but they are drawn almost solely from performance on experimental tasks. Developmental descriptions of children's use of objects in children's everyday worlds, encompassing exploration, play, construction, and tool use are sorely lacking. One clear exception to this trend is the comparative work of Tomasello and colleagues who have compared tool use of chimpanzees and young children. According to Tomasello, tool use, like exploration and play with objects, is influenced by the social context. Indeed, it may be learned and developed in a social context, probably with children interacting with a significant adult.

Naturalistic, time budget descriptions of children's tool use are important because they are an important step in making functional inferences about different forms of object use. To this end, Pellegrini and Gustafson's observation on a sample of preschoolers across a year using objects in construction, exploration, play, and tool use clarifies this picture. They found that total tool use, object play, construction, and exploration accounted for 24%, 26%, 10%, and 2%, respectively, of all observed behavior.

A difference favoring females for construction was found, consistent with the extant literature. Girls' uses of objects for construction often took the form of art activities, all relatively sedentary activities. Boys used objects in play and marginally more as tools. Boys' play with objects was often embedded in the context of fantasy play, where objects were used to enact superhero themes, consistent with the classic findings of Saltz, Dixon, and Johnson. Also consistent with the ethnographic literature, they found that boys, more than girls, tended to use objects as tools, primarily as weapons. Bock's study of Botswana pastoralists indicated that boys engaged in more object play than girls did. Additionally, boys' object play followed an inverted-U curve accounting for 11% of the observations at 0–3 years, 17% at 4–6, and 3% at 7–9 years. For girls, an inverted-U curve was also observed for object play, but the peak was at a later age: 4% at 0–3 years, 8% at 4–6 years, 11% at 7–9 years, 15% at 10–12 years, and zero at 13–15 years. The trajectory for play pounding for girls paralleled object play: 5%, 16%, 17%, 22%, and zero, respectively.

Functions of children's object play have typically been examined in terms of children's ability to use objects in creative and flexible ways, such as associative fluency and lure retrieval tasks, or the ability to use and create tools to retrieve a toy, results which do not replicate under double blind conditions. Another limitation in all of these experimental studies was the limited time of the play treatment. In all cases, children were allowed to interact with the objects for about 10 min, a seemingly limited dosage of a treatment. To counter this problem, year-long observations of children's exploration, play, construction, and tool use were used to predict children's associative fluency and performance on lure retrieval tasks.

The predictive relations between observed object uses and performance on the associative fluency task and on the lure

retrieval tasks, where children's spatial intelligence was statistically controlled, revealed that neither observed play nor exploration predicted problem solving. That exploration was not predictive may be due to the fact that it is more typical of infants and toddlers than preschoolers, and low levels of exploration were observed. Further, the lack of relations between play with objects and performance on any of the problem-solving tasks in the current results raises a question on the often trumpeted value of play for both convergent and divergent problem-solving tasks with objects, an argument similar to that made by Smith.

Construction and tool use did, however, differentially predict performance on another aspect of using objects flexibly. Construction was a significant predictor of associative fluency and performance on the connected tool retrieval task, possibly because it is an 'ends' oriented behavior and it enables children to coordinate means toward some end product. This set of skills may have been sufficient to solve the simpler, connected, retrieval task and the associative fluency task but less effective with the more complex, unconnected, retrieval task. For the latter task, a more diverse and specific set of skills, reflected in the total tool category, was necessary.

Social Play

Social play takes the form of interaction between children and adults and between peers. The earliest forms of social play occur between children and adults, typically parents. For example, a mother playing peek-a-boo with her infant is one of the earliest, and pan-cultural, forms of social play.

A problem associated with the study of social play is that many writers do not differentiate social interactions which are 'play' as defined in this article, from more general, nonplay, social interactions. For example, in one foundational study, Parten explicitly refers to her categories of social interaction among peers as reflecting children's *social participation*, yet she also sometimes substitutes the word *play* to describe some of these behaviors. For example: 'The child *plays* (emphasis mine) in a group that is organized for the purpose of making some material product, or striving to attain some competitive goal, or of dramatic situations of adult or group life, or of playing formal games.' This section limits the discussion to interactions which are clearly play, peer play in the form of rough-and-tumble play (R&T) during childhood and into adolescence. Social pretend play is discussed in the next section.

R&T was first used in the social and behavioral sciences by Harlow in his discussion of the social play of rhesus monkeys, where it resembled 'play fighting.' Following Harlow, Blurton Jones defined children's R&T structurally in terms of 'play face,' physically vigorous behaviors, exaggerated movements, and soft, open-handed hits or kicks, a pattern clearly different from aggression. R&T is also characterized by reciprocal role taking and self-handicapping, such that players alternate between dominant and subordinate roles; for example, alternating between being on top and on bottom and between being the aggressor and being the victim.

R&T also follows the play-typical developmental, inverted-U, curve, accounting for about 4% of all behavior during the preschool period, peaking during the primary school years at around 10%, and declining again in early

adolescence to around 4%. These data, like the time and caloric costs documented in the animal literature, suggest that the time costs associated with R&T are modest.

There are also robust sex differences in the R&T of many animals, including humans. For example, in a group of 13-year-old American middle school, males' R&T play was close to double that of females.

Traditional accounts for the functions of R&T posit that it affords safe opportunity to practice for fighting and hunting skills that will be useful in later life. There is, however, no direct evidence supporting this hypothesis. A number of researchers posit that a motivating factor in social play is its unpredictability: Will I win or will I lose? Even with this uncertainty, there is a modicum of safety in play, and children are willing to take chances in this context. Children who engage in social play, from this argument, should be less fearful of uncertainty in the play context and behaviorally more flexible in responding to novel events, relative to less playful contexts. The only direct evidence to test this hypothesis showed a positive and significant relation between varied social play (indexed in terms of the variety of subcategories of R&T observed) and novel responses to social problems.

R&T may also relate to social affiliation/cohesion benefits for boys during childhood. Most basically, R&T typically occurs in sexually segregated male groups that are typified by high activity and rough behavior. That most boys enjoy R&T and most girls do not may be reason enough for them to bind as a group, though the relative frequency of physically vigorous behavior that is not R&T is also very important.

R&T may be related to another dimension of social affiliation, social dominance, where dominance is defined as winning and holding resources at the relationship and group levels. At the dyadic relationship level, individual A is dominant to B if in a contest for resources, he or she accesses those resources. These dyadic relationships, in turn, can be used to order individuals within a group hierarchically; for example, $A > B > C$. Exploiting its playful tenor to take advantage can be used to defeat an opponent and access resources. Even without cheating, children say they can determine their own as well as peers' strength from these encounters. So, children may use R&T in an indirect way to display their physical prowess, without using aggression, or blatantly cheating.

This picture changes in adolescence where R&T and aggression co-occur. Neill's pioneering factor-analytic study of 12–13-year-old boys' playground behavior found that R&T and aggression often co-occurred. Results from a study of adolescents by Pellegrini support this finding. In a longitudinal study of adolescent boys, Pellegrini found that asymmetrical choices for R&T were observed during the first year of middle school (12 years), but not the second (13 years), and R&T was significantly and positively related to peer-rated dominance in both years. Thus, in adolescence, in contrast to childhood, youngsters' use of R&T corresponds to using aggression as a way in which to control resources.

Pretend Play

Pretend play is arguably the most thoroughly studied aspect of human play behavior. Pretend has been used as *the* defining

attribute of children's play and considered a paradigm example of children's play. This was reinforced empirically in an interview study conducted by Smith and Vollstedt where pretend was *the* most important defining attribute of play.

For Piaget, symbolic play is an extension of the representational process where children recognize that one thing stands for another and through repeated engagement of pretend play children practice having one thing representing another and separating the symbol from its referent. This ability, in turn, is important for children's more general representational competence. Engaging in pretense, however, may not actually have children 'representing' in the strict sense that they are representing others' mental states when they play. Instead, Harris posits that young children 'simulate' the actions of others in their pretend play and this early form of pretense does not involve young children's representing the mental states of their co-players. Through repeated social interactions in pretend play with peers, children, by 3 years of age, come to recognize that this assumption is not correct, recognizing that they and their peers sometimes do not share the same view of a scenario that is being enacted. At this point, children put their own beliefs and desires about the scenario aside and try to imagine the beliefs and desires of their peers. With this accomplished, children will go back to their original simulation and try to understand it from the points of view of their peers. By 4 or 5 years of age, children understand that they have different beliefs from others. Correspondingly, understanding others' points of views depends on the accuracy of children's simulations, not on the accuracy of their representation of others' beliefs and desires.

A close adult-child relationship, such as the mother-child relationship, is central to the beginnings of social pretend play. Mothers seem to deliberately teach their infants to differentiate pretend from nonpretend behavior, teach them to extend their play themes, and under certain conditions, reinforce children's pretend enactments. Evidence suggests that mothers actually guide children's play to higher levels. Tomasello also stresses the importance of mother-infant interaction in the development of very young children's understanding of the mental states of others. From Tomasello's position that infants check to see if mothers are responding to their efforts to direct attention suggests that they, the infants, are beginning to view others as intentional agents.

Also important for the development of the symbolization processing in both pretend play and language is the realization by children that their imitations of adults can be used to solve social problems. Thus, they recognize that adults are using gestures and vocalizations to get something done (i.e., recognizing adults' intentions) and they use those same strategies to attain a goal. They come to realize that adults' use symbols, language, and gestures, to direct their attention. Correspondingly, by the second year of life, children recognize when adults use objects in pretense indicative of also recognizing adults' intentionality. Continued experiences with adults and peers extend children's ability to understand that others have different views of situations and symbols than they do.

At around 1½–2 years of age, pretense becomes more peer-oriented and peaks in the preschool years, around 5 years of age. The transition to pretend play with peers is a hallmark of preschool children's social cognitive and linguistic

development. Because social pretend play involves the communication and coordination of abstract meaning between people, there is a possibility for ambiguity and the breakdown of interaction. To avoid such breakdowns, children must use decontextualized oral language, where meaning is conveyed primarily through linguistic means, rather than with shared knowledge assumptions or gestures. It is also through these sorts of cooperative peer interactions that preschoolers come to recognize that their views of pretend play bouts and those of their peers differ.

It is worthwhile here to discuss two possible immediate benefits of pretend play: for early literacy skills and theory of mind. Others have been proffered elsewhere. In terms of the benefits of pretense during childhood, Lee Galda and I examined different forms of social pretense in preschool children and their subsequent relations to measures of emergent reading and writing. We argued that social pretense predicts early literacy because they both share the design features of being representational, realized in decontextualized language, and having narrative structure. In our longitudinal work, the level of representation in children's pretense (object transformations, such as feeding a doll, or ideational transformations, such as defining a role as Daddy) predicted children's early writing performance, while use of metalinguistic terms in pretense predicted their subsequent reading, with verbal IQ controlled. These results support the hypothesis that the ambiguity inherent in negotiating meaning in social pretense affords opportunities to verbally explicate meaning and become adept at manipulating different symbolic systems.

There is also evidence for a link between pretend play and theory of mind. Smith reviewed nine correlational studies examining this relation and suggests three possible models to explain the data. He notes that, with verbal ability or intelligence statistically controlled, and of the 46 correlation coefficients reported, 14 were statistically significant. The correlations that were the highest (e.g., 0.49) were between joint pretense and joint proposals in play and theory of mind. He suggests a facilitative but not an essential causal link between pretend and theory of mind. In short, there are a number of ways in which to develop theory of mind and pretend may be one of them.

Conclusion

That play is observed primarily during the juvenile period suggests that the extended juvenile period is crucial to the role of play in developmental plasticity and to assembling the complex set of skills necessary for survival and reproduction. From this position, children use the resources afforded by them (safety and provisioning by a parent) to experiment with a variety of strategies that are effective in that niche. When faced with a relatively novel or uncertain, but safe, environment, play affords opportunities for behavioral and cognitive innovation and subsequent practice of newly developed behaviors and strategies.

With this said, we must also ask why children should play to learn or develop innovative behaviors and strategies when they might more efficiently learn them through direct adult tuition or, less directly, through observational learning. Part of the answer to this is that actual adult tuition has been rare in

human history, until recent times. More fundamentally, however, adult tuition and observation of adults will only transmit existing practices. The possible benefit of play, relative to adult-directed strategies, is that behaviors generated in the context of play can be more innovative and most suitable to the varied niches inhabited by humans. For example, juveniles can take the behaviors they have observed and then, in play, recombine elements of these behaviors into novel routines. In support of the innovative potential of peer play, levels of children's symbolic functional play are more varied and complex when adults are absent, relative to when they are present. The degree to which children's play is more innovative in solitary situations or with peers needs more study, however.

More generally, play is a relatively low cost and low risk way to learn new behaviors during periods of immaturity and thus likely to impact subsequent evolutionary processes. The safety inherent in a protected and prolonged juvenile period supports the sort of innovations in play that could lead to solutions to abrupt environmental changes and thus be copied by peers as well as adults. Exploration and play in one's niche may enable individuals to forecast what their developmental niche will be, a strategy that may be especially important in novel environments. Successful innovations would, in turn, be naturally selected. From this position, play occurs primarily during the juvenile period when resources are abundant, but the benefits may be reaped then or later in development, possibly impacting phylogeny.

Glossary

Antiwoman Aggressive behavior, demeaning attitudes, or negative beliefs, directed toward or against women.

Experimental research on pornography effects Research which systematically manipulates exposure to pornography and assesses its causal relationship with consequences of interest (e.g., antiwoman attitudes or behavior).

Naturalistic research on pornography effects Research which seeks to assess the association of exposure to

pornography and phenomena of interest (e.g., antiwoman attitudes or behavior) in a naturally occurring 'real world' settings.

Operationalization Definition of a phenomenon, such as pornography, in concrete and objective terms so that it may be described and studied systematically.

Pornography Sexually explicit material; a variety of functional and content-based definitions appear in this article.

The subject of pornography has long provoked public consternation and scientific scrutiny. More than a century ago, Dr. Ivan Bloch, originator of the term 'sexology,' pronounced that "there is no sexual aberration, no perverse act, however frightful, that is not photographically represented today." Social science has evinced interest in pornography since at least the 1960s, and at the close of the first decade of the new millennium, we find that social scientists have kept up their conceptual and empirical contributions to the study of sexually explicit media. While the characterization of pornography and its impact on behavior are still evolving, it is appropriate to provide an overview of the state of scientific knowledge at present. The current discussion reviews attempts to define pornography, considers the content and history of sexually explicit materials, and reviews evidence concerning the use of sexually explicit material and its effects on feelings, thoughts, and behavior.

Defining Pornography

The term *pornography* is believed to have been derived from the Greek words *porno* and *graphos*, which when combined, translate roughly into 'writings about prostitutes.' Indeed, at one time, the first definition listed in the Oxford English Dictionary referred to pornography as 'a description of prostitutes or of prostitution, as a matter of public hygiene.' In contemporary Western society however, *pornography* has come to denote the general category of sexually explicit materials. We note, however, that in law and legal discussion, the term 'obscenity' is often employed to describe sexually explicit materials that merit state censorship. The daunting challenge is that while a clear definition of the term *pornography* is necessary for conceptualizing and operationalizing these materials for the purposes of scientific study, no consensus has been arrived at by social scientists or in legal or lay opinion concerning the precise definition of such materials.

Functional Approach to the Definition of Pornography

Functional definitions of pornography emphasize the perceived purpose or function of sexually explicit materials.

Using this approach, any material is deemed pornographic if it appears to have been created, selected, or consumed to serve a specified sex-related purpose. Examples of such purposes are varied, and range from materials that appear to be intended to provoke sexual arousal, to materials that employ sex to dehumanize or oppress a class of people, typically women. Most functional definitions of pornography do not classify a material as pornographic if it has not been created to arouse sexual desire, if it is not used to demean individuals or to maintain a sexually driven power imbalance in society, or if it is not typically used as masturbatory aid.

A functional approach to the definition of pornography can be found in the American legal characterization of obscenity. In American law, a work may be considered obscene if "(a) . . . the average person, applying contemporary community standards, would find that the work, taken as a whole, appeals to the prurient interest." (*Miller v California*, 1973). This definition of obscenity is a functional one because it emphasizes the role that such material is perceived as playing in satisfying an unwholesome interest in sexual matters. Beyond the area of jurisprudence, functional definitions also exist in the scientific literature, with some researchers defining pornography as 'media material used to increase sexual arousal.' Functional definitions of pornography often rely on inferences made by external observers regarding the perceived intent or impact of sexually explicit materials. This approach can be problematic because wide variations exist with respect to individual perceptions and reactions to such materials. Functional definitions can also focus upon the objectively measured consequences of exposure to pornography, including sexual arousal and emotional responses.

Content-Based Approach to the Definition of Pornography

Content-based approaches to the definition of pornography have been widely employed to differentiate between pornographic and nonpornographic sexually explicit materials. According to such definitions, a material is considered pornographic if its content portrays a prespecified characteristic or a number of such characteristics. Common examples of content characteristics that some qualify as pornographic include the

explicit depiction of breasts or genitalia, or the manipulation of such body parts, as commonly occurs during sexual behavior. An example of a content approach to the definition of obscenity can be found in the Criminal Code of Canada, according to which, "Any publication the dominant characteristic of which is ... sex and any one or more of the following subjects, namely crime, horror, cruelty and violence, shall be deemed to be obscene" (Criminal Code of Canada, Section 163(8)).

Content focused definitions of pornography appear with regularity in the scientific literature because such definitions are amenable to operationalization and empirical validation, and because it appears scientifically plausible that the content of sexually explicit materials may determine their effects. The use of content-based definitions of pornography also affords the possibility of identifying conceptually and practically important categories of sexually explicit materials based upon their manifest content and the related effects, theorized or actual. In this connection, social scientists commonly distinguish between 'violent pornography' and 'erotica'; the former is defined on the basis of sexual content that portrays and endorses sexual violence, while the latter is defined on the basis of sexual content that portrays and endorses consensual sexual activity. Social scientists have also considered a category of degrading pornography, said to include degrading or debasing content that dehumanizes at least one participant, who is typically female. When the nature of the sexually explicit material under discussion has been categorized by researchers as violent pornography, degrading pornography, or as undifferentiated 'sexually explicit material,' we refer to it as such in this review.

It is theorized that exposure to violent or degrading pornography may encourage the adoption of antisocial attitudes, dehumanizing beliefs, and aggressive behavioral tendencies. In contrast, it is hypothesized that exposure to erotic portrayals of nonviolent and nondegrading sexual content, featuring performers who appear to be participating through positive choice, may foster the adoption of nonviolent, nondegrading, and consensual sexual attitudes and behaviors. Theorists also differ with respect to the likelihood that an individual will adopt attitudes and behaviors that are modeled in violent or degrading pornographic or erotic materials, with some consensus emerging that the likelihood of adoption of modeled attitudes and behaviors will be a function of the individual viewer's existing dispositions in relation to such attitudes and behaviors. However, whether it is the consensual, degrading or violent content of sexual media, or the predispositions of those who choose to consume, or some synergy of the two, that is of primary significance, is an important and unresolved question.

History and Content of Sexually Explicit Media

Historical Perspective

Sexual representations have appeared throughout history and have been found on nearly every continent. Among the oldest sexual representations are rock carvings of women which emphasize the breasts, buttocks, hips, and vulva. The *Willendorf Venus* is an example of this idealized female figure. Carved from limestone and found near the village of Willendorf in

lower Austria, it is thought to be at least 18 000 years old. Sexually explicit etchings and paintings of men, women, and animals, some of which date back to 13 000 BCE, have also been found in caves in France and Spain. From ancient Greece and Rome, we have many examples of medallions, statues, and ceramics that depict nude men and women, as well as heterosexual and homosexual behaviors. Some of the best examples of erotic Roman frescoes and mosaics were discovered in the ruins of Pompeii, which was buried in volcanic ash in AD 79. Sexual representations can also be found in cultures outside of Europe. Examples include Taoist sex manuals that were once common in China (200 BC), the *Kama Sutra* of Vātsyāyana, written for wealthy young men in India (AD 400), and the South American sexual pottery of the Moche (AD 150–800), which featured sexual acts, but rarely depicted penile–vaginal intercourse.

The modern history of the distribution and proliferation of sexually explicit materials is closely associated to the development of technological innovations. It is said, for example, that Poggio Bracciolini's *Facetiae* (1474), a collection of sexually explicit satirical short stories, was printed a mere 19 years after the Gutenberg Bible. Over the next several hundred years, low production costs of printing technology allowed pornographic engravings and novels to flourish as forms of both political satire and sexual entertainment. The invention of photography (~1825) and development of moving pictures in the later 1800s offered new technologies that were quickly adopted to become primary modes of production of sexually explicit materials. Examples of nudity and sexual activity can be found among some of the first photographs ever taken and among some of the first films ever developed for the cinema. Sexually explicit cinema appears to have peaked in the late 1970s when the invention of the videotape player allowed individuals to view such material in the comfort of their own homes. More recently and arguably exponentially more impactful, the Internet emerged in the mid-1990s as a new and highly accessible mode of distribution of sexually explicit text and imagery. Given the range of Internet distribution, it appears that the sheer amount of accessible sexually explicit material worldwide has never been greater. Although reliable figures are difficult to come by, a recent study estimated that over \$97 billion in revenue was generated in 2006 by all forms of commercial sexually explicit media worldwide.

Content of Sexually Explicit Materials

Many attempts have been made to characterize the content of sexually explicit media. Such efforts have reviewed sexual comics, novels, magazines, pay-to-listen audio recordings, videotapes, photographs, and digital Internet content. Although numerous methodological differences prevent comparisons across media, time periods, or studies, several commonalities do emerge from this literature.

Sexually explicit materials typically present two performers engaged in various sexual behaviors. Although presentations of individual women appear with some frequency, pornographic media depicting three or more actors are less common. Female performers are most often attractive, young, and Caucasian, with blond hair and thin bodies, though some studies have found that as many as 10% of models are from a visible ethnic

minority. Less consistency is noted in the features of male performers. Pictorial depictions of minors are virtually absent from the findings of published studies, though textual depictions of minors are reported on occasion.

The five most commonly depicted sexual behaviors include coitus, fellatio, cunnilingus, anal penetration, and orgasm/ejaculation. Convergent evidence across studies suggests that fellatio is more commonly presented than cunnilingus. For most media sampled, anal sex occurs less frequently, but is still represented. The only study to directly compare the frequency of male and female orgasm found that depictions of male orgasm are more frequent. Homosexual representations are also reasonably common, and depict female–female more often than male–male sexual behaviors. The former often appear to be designed for consumption by heterosexual males and the latter for consumption by males with an interest in same-sex sexual activity.

Another feature commonly explored in content analyses concerns power imbalance between the performers. These are often defined as depictions of dominance and submission, or depictions of sexual coercion. While most analyses of pictures and videos find that the vast majority of scenes contain no evidence of a male–female power imbalance, such imbalances have been noted in over 40% of online stories and in more than one-third of erotic novels. Although it is uncertain why such a large discrepancy exists, it is possible that sexual stories have more frequent depictions of power imbalances because real human performers are not required to act out uncomfortable, embarrassing, or humiliating scenes.

Similarly, depictions of the purposeful infliction of pain appear to be uncommon in traditional sexually explicit media, occurring in <6.5% of all scenes in X-rated films, in <2% of all pages in *Hustler*, and in even fewer pages of *Playboy*. Further, the vast majority of such acts in magazines and films appear to be presented as consensual. It is worth noting that recent studies of sexually explicit materials on the Internet suggest that higher rates of violence and lower rates of consent may exist in some contemporary sexual media.

Summary and Critique

Humans have long been interested in producing and consuming explicit sexual representations. Although historic examples reviewed in this paper depict much of the same behavior that is found in contemporary sexually explicit materials, it would be naïve to assume that all such representations were considered sexually explicit or pornographic in their respective times and cultures or to attempt to infer the original intent of these artifacts in relation to our own experiences with sexual media. However, it would be equally presumptuous to assume that no commonalities exist between historic sexual representations and contemporary sexually explicit materials.

For those concerned about the content of contemporary sexually explicit media it may be noted that depictions of pleasurable sexual experiences occurring between consenting adults are most common. While evidence of the existence of violent, nonconsensual, or pedophilic material is beyond question, the frequency of such depictions is low.

It should be kept in mind that the results of existing studies offer a ‘best guess’ as to the type of content that exists and is

consumed in the real world. Although research reports produce exact statistics, encouraging the temptation to compare frequencies between studies and to use these figures to estimate the prevalence of content features in the universe of sexually explicit media at large, such efforts may be misguided. Published research on the content of sexually explicit media does not employ random or probability sampling, and many studies employ different levels of content coding and analysis. Moreover, despite apparent nominal similarities in content categories, operational definitions across studies can be surprisingly different. Given these limitations, it is difficult to be certain about the prevalence of the content features that have been discussed.

Consumption of Sexually Explicit Material

Gender Differences in Consumption of Sexually Explicit Materials

Several studies conducted in North America, Europe, and Asia confirm that men and women have differing degrees of experience with sexually explicit materials, with men generally reporting greater exposure than women. It is unclear whether gender differences in self-regulated exposure to sexually explicit materials are a function of the content of such material, or of the gender-related social and reputational costs of consumption of such material, the gender differences in inherent interest, or other factors.

A recent convenience sample of American university students across several campuses reported that among young adults, 87% of men and 31% of women had been exposed to sexually explicit material within the last 12 months. Among users of such material, the modal frequency of use was once or twice a week for men and once a month or less for women. The American figures reported here represent middle-of-the-road estimates, with some studies reporting that as many as 90% men and 73% of women use sexually explicit materials, while others reporting that as few as 10% of men and 1% of women use such materials. What remains constant is the gender difference in self-reported exposure.

Use of Sexually Explicit Materials and Contextual, Social and Personality Factors

A number of studies indicate that the use of sexually explicit materials is related to contextual, social, geographic, and personality factors. While only a few studies have assessed the social context of exposure, it appears that most users of sexually explicit material consume it alone, with approximately half of all users also reporting some consumption with a partner.

One study concerning social and demographic factors associated with the use of sexually explicit material in the United States found that per capita subscriptions to sexually explicit Internet websites were positively related to average household income, the number of household residents between the ages of 18 and 24, the degree of household education, and residence in an urban (versus rural) locale. The same study found that sexually explicit Internet website subscriptions were negatively related to the number of household residents over 65 years of age. Also, contrary to many expectations, increased

rates of subscriptions to Internet websites were found in areas that have higher rates of marriage and lower rates of divorce. Finally, this study also found that per capita subscriptions to sexually explicit websites were highest in states with conservative positions on religious, gender and sexual issues.

Attempts have also been made to identify personality variables that play a role in men's choice of different types of sexually explicit videos. For example, men's preference for violent pornography was found to be associated with dispositions that are characterized as being antisocial and low in the need to appear in a socially desirable light, as aggressive and dominant, as interested in sexual variation, and as relatively lower in intelligence. Men's preference for consensual erotic material, however, was found to be associated only with dispositions that were characterized as having an interest in sexual variation.

Summary and Critique

Research clearly indicates that men and women have different degrees of experience with sexually explicit material. While men typically report more experience than women, a specific explanation for this difference is not clear. It is also interesting to note the variability in the prevalence of exposure figures reported in existing studies. Two explanations are offered. First, a number of studies differed in their assessment of sexually explicit material use, with some inquiring if participants had ever been exposed to sexual media, while others asked about current use. Second, the lowest prevalence of sexually explicit material exposure was reported in a sample from a country with intense media censorship, indicating that cultural and legal differences in the regulation of access to sexually explicit material play an important role in the prevalence of exposure to such media. A few studies have identified contextual, social and personality factors that relate to sexually explicit media use. Although interesting and relevant, the associations reviewed here should be considered tentative until they are confirmed by additional research.

Effects of Sexually Explicit Material on Feelings, Beliefs, and Evaluations

One approach to research concerning the effects of sexually explicit materials is to consider such stimuli as persuasive messages that consist of implicit and explicit portrayals and endorsements of beliefs, sociopolitical values, and sexual behaviors and themes. It has been theorized that such messages, contained within sexually explicit stimuli, may influence what people feel, what people think, and what judgments they make. Some assert that sexually explicit material of all types – consensual erotica as well as violent pornography – is primarily a communication about the separation of pleasure from social relationships and responsibility (attachment, commitment, etc.). Others go further, contending that such media primarily portray messages that endorse the sexual subordination of one party (typically women or, less typically, minorities) by another (typically white males), while still others disagree, viewing consensual erotica as a communication of sex-positive scripts, values, and messages.

Sexually Explicit Media and Feelings

According to numerous studies, exposure to sexually explicit media can trigger strong sexual arousal and emotional reactions. Among many men and women, exposure to sexually explicit materials leads to, both subjectively reported and physiologically substantiated, increases in sexual arousal. Early work in this area established that men and women experience similar degrees of sexual arousal responses when they were instructed to engage in sexual fantasy or were exposed to sexually explicit stories, pictures and videos. Further work found that married men and women reported the highest degree of sexual arousal response to depictions of casual sex compared to depictions of romantic sex or a prostitute–client relationship. More recent efforts suggest that men's sexual arousal is driven more by actor characteristics, especially gender, than by the behaviors depicted. In contrast, women appear to be less sensitive to the characteristics of the actors, with their sexual arousal more contingent on the types of behaviors that are depicted. Recent evidence also suggests that men may be more sexually aroused by sexually explicit material than women, though the difference is small.

Research has also consistently shown that exposure to sexually explicit materials can provoke both positive and negative emotional reactions, and that highly negative affective reactions do not always preclude positive affective reactions and sexual arousal responses within the same individual. When specific affective reactions are studied, both men and women have been found to react to sexually explicit materials with feelings of boredom, excitement, shock, irritation, and agitation, and that women may react with equally positive but more negative emotions than men. Evidence also suggests that emotional responses to sexually explicit stimuli may be stable characteristics of individuals, and that the content of specific erotic stimuli – including themes of degradation and violence – may contribute to the experience of negative emotional reactions.

A number of studies suggest that experimental long-term exposure to sexually explicit material can modify emotional reactions to such material. For example, it has been found that repeated exposure to sexual stimuli can lead to reductions in sexual arousal responses to similar materials. It has also been shown that such reductions can be reversed with the introduction of new sexual content. Similarly, a number of studies also suggest that sexual anxiety can be reduced by repeated exposure to sexually explicit stimuli, and indeed, this technique has been used by some therapists to treat sexual anxiety disorders.

It is worth noting that the evidence of the habituation of emotional responses to sexually explicit stimuli has been used to suggest that repeated exposure to such material creates a general emotional desensitization, which contributes to sexual callousness and to problems in male–female sexual relations. While this is possible, at this time there exists little evidence that the habituation of sexual arousal and sexual anxiety can be generalized to the wider spectrum of human emotions or that the habituation of such emotional reactions can be generalized to nonsexual situations. What is more, there is little or no nonexperimental evidence to suggest that

those who choose to consume sexually explicit materials in real world situations do, or do not, experience emotional desensitization of this sort.

Sexually Explicit Media and Beliefs

Working from the perspective that various types of sexually explicit materials may teach consumers to divorce sexual pleasure from the context of monogamous relationships, experimental research – involving systematic exposure of young adults, using both university student and nonstudent samples, to sexually explicit stimuli – has shown that exposure to sexually explicit media can influence beliefs regarding a number of sexual topics. Specifically, such experiments have found that repeated exposure to nonviolent and nondegrading sexually explicit materials may increase participants' estimates of the number of people who engage in infidelity and in infrequently practiced sexual behaviors. Massive exposure to similar materials has also been found to increase participants' endorsement of the belief that inhibiting sexual desire can be unhealthy.

Similarly, experimental efforts to show that sexually explicit material encourages beliefs that aid in the oppression of women have found that exposure to violent pornography increases men's acceptance of myths about rape that ascribe responsibility of sexual assault to a female victim. A meta-analysis of 16 experimental studies of the relation of exposure to violent pornography and antiwoman beliefs has confirmed that there is a small association between such exposure and rape myth acceptance in experimental settings. This meta-analysis also revealed that the association was larger when effects of violent pornography were compared to the effects of nonviolent erotica, though the effects for nonviolent erotica were still present.

While experimental studies appear to demonstrate a link between exposure to sexually explicit materials and rape myth acceptance, critics have suggested a number of reasons for a cautious interpretation of these findings. First, it is noted that a number of naturalistic studies have found no association or even an inverse association between men's exposure to sexually explicit materials and their attitudes towards women. For example, nationally representative survey research, as well as research conducted with actual consumers of X-rated videos, has shown that consumers of sexually explicit media may have more positive views of women's rights than nonconsumers of such material. This has been corroborated by a meta-analysis of observational studies of the relation between exposure to sexually explicit materials and rape myth acceptance, which found no evidence of an association between exposure and rape myth acceptance among real world consumers of sexually explicit materials. Second, the close association in time between experimental exposure to sexually explicit stimuli and measurement of rape myth acceptance in these experimental studies has led some critics to suggest that participants' perceptions of what the researchers may have desired to find may have influenced participant responses. If the participants are aware of a study's objectives, they may modify their responses to help corroborate the expectations of the experimenter. In support of this criticism, studies that have been controlled for this possibility by temporally separating

exposure to violent pornography from the assessment of rape myth acceptance have found no association between exposure to violent pornography and rape myth acceptance.

Sexually Explicit Material and Evaluations

Experimental research has demonstrated close associations between individuals' positive or negative emotional responses to sexually explicit stimuli, their positive or negative evaluations of such material, and their weak or strong inclination to restrict access to such materials. It has been observed that individuals may evaluate sexually explicit materials as either pornographic or nonpornographic in order to justify their negative or positive emotional responses to sexual representations.

Experimental research concerning long-term exposure to sexually explicit stimuli has found that such exposure can increase relative acceptance of a range of nonmonogamous sexual behaviors, including premarital sex, extramarital sex, extra-cohabitational sex, and sexual nonexclusivity. Prolonged exposure has also been found to increase relative acceptance of both male and female promiscuity and sex without emotional involvement. Consistent with these findings, exposure to sexually explicit material was also found to result in a devaluation of marriage as an essential social institution, and to a desire for fewer children. Experimental long-term exposure to sexually explicit material has been found to result in changes in sexual satisfaction, with participants viewing massive amounts of such material reporting lower sexual satisfaction, and lesser satisfaction with their sexual partners' level of affection, physical appearance, sexual curiosity, and sexual performance. Finally, results from some long-term exposure studies suggest that exposure to sexually explicit media can have an impact on how people negotiate gender politics. Experimental massive exposure to sexually explicit stimuli has been found to increase acceptance of male dominance and female submission, lead to less support of the women's liberation movement, and result in lower recommended sentences of incarceration in response to a hypothetical rape scenario.

Although these studies generally indicate the antisocial effects of exposure to sexually explicit materials, we must consider the fact that experimental exposure research imposes exposure to sexually explicit stimuli in a fashion not chosen by those exposed to it, and it is unclear whether the findings of experimental massive exposure studies are informative about real world situations, which involve self-regulated exposure to such material. Note also that observational studies in real world settings have not found a relationship between the use of sexual media and antiwoman political attitudes. Finally, as critics have noted, erotica-induced sexual dissatisfaction could be considered an antisocial impact, or instead, could be viewed as a 'good thing,' in which alternative standards of sexual curiosity and performance, as demonstrated by sexually explicit material, may result in healthy strivings for improvement rather than ignorance-bred satisfaction with the status quo.

Summary and Critique

A number of experimental studies indicate that exposure to sexually explicit material can influence feelings, thoughts, and evaluations. The intent of many studies presented in this

section has been to show that exposure to the assumed central messages of sexually explicit material contributes to the breakdown of social order vis-a-vis the family unit or to the male oppression of women. In general, experimental evidence, within the limits of such an approach, appears to be more supportive of the first proposition than the second.

It is essential to note that virtually all the studies discussed in this section were carried out in an experimental setting in which participants were exposed to specific amounts of sexually explicit materials depicting particular content, irrespective of participants' existing inclination to view or to avoid such media. Consequently, the extent to which sexual media content may influence consumers' thoughts, feelings and judgments in real world settings remains unclear. Contrary to expectations, available evidence from naturalistic research suggests that the use of sexually explicit material is not related to antiwoman attitudes. As noted, one study found frequent consumers of X-rated videos to be more politically supportive of women's rights than others, one found that those who frequented erotic movie theatres showed the same prowoman disposition, and another study found more positive attitudes among men who attended a pornographic cinema than men who were enrolled in an undergraduate university course. When it comes to the relationship between sexually explicit media exposure and the outcome at focus, the results of experimental studies discussed in this section are clearly at odds with the findings of naturalistic studies.

Effects of Sexually Explicit Material: Behavior

Evidence for Small, Nonnovel Increases in Sexual Behavior

It is well established that exposure to sexually explicit stimuli leads to sexual arousal in many, if not most, individuals, and sexually aroused individuals may experience an increased motivation to find sexual release. In line with this expectation, experimental studies have consistently found that exposure to sexually explicit materials induces small, short-term increases in nonnovel sexual behaviors. In student samples, increases are typically found among autoerotic behaviors such as masturbation and sexual fantasy. Studies involving participants with readily available sexual partners often find short-term increases in partnered activities including, but not limited to, coitus. Increases in sexual behavior tend to be short-term, dissipating within 24 h of exposure. Experimental studies that have specifically evaluated adoption or performance of novel or low-frequency sexual behaviors, including sadomasochism, group sex, extramarital sex, or the introduction of novel foreplay behaviors or positions of intercourse, have found little evidence that exposure to sexually explicit materials induces changes in such behaviors. Finally, some experimental studies have also found evidence of habituation of sexual responses over time. When participants are repeatedly exposed to similar erotic materials over time, the impact of such material on sexual behavior becomes attenuated.

Limited Evidence of Increases in Novel Sexual Behaviors

Although exposure to sexually explicit material has generally been found to lead to short-term increases in the practice of

nonnovel sexual behaviors, there is also evidence that some individuals report increases in novel sexual behaviors following exposure. One study, for instance, found that 11% men and 4% of women reported using a new or seldom used foreplay technique within 24 h of viewing sexually explicit stimuli. Other studies suggest that exposure to sexual stimuli featuring clitoral self-stimulation in the context of autoerotic or partnered sexual behavior can result in increased clitoral self-stimulation and increased orgasm in some women.

A number of conceptualizations seek to explain why exposure to sexually explicit stimuli may induce changes in new or infrequently practiced behaviors. One view asserts that explicit depictions of sexual behavior may serve to normalize the performance of the depicted sexual acts, disinhibiting willingness to report them or their actual practice *per se*. This view is consistent with the evidence that exposure to sexually explicit stimuli can result in attitude changes regarding the acceptability of a range of sexual behaviors. Similarly, as previously noted, exposure-induced reductions in general sexual anxiety may also remove barriers to the practice of earlier anxiety provoking behaviors. This possibility is supported by a study which found that the anxiety reducing effects of exposure to sexual stimuli are accompanied by an increased motivation to participate in a larger variety of sexual behaviors. It should also be noted that exposure to sexual media may provide the opportunity to learn about previously unknown behaviors by observing and imitating the behaviors of an explicit sexual model. Although this explanation is consistent with the reported motivation to view sexually explicit materials among some individuals (i.e., to learn new techniques), to our knowledge, no study has convincingly demonstrated the significant acquisition of previously unknown sexual behavior through exposure to such material alone.

Sexually Explicit Materials and Aggression

The possible link between men's exposure to sexually explicit materials and their enactment of antiwoman aggression has generated intense research interest. Although concern about a pornography – aggression link probably extends as far back as the 1780s, when the Marquis de Sade penned his violent erotic novels, concern about violent pornography and antiwoman aggression was heightened by feminist discourse in the 1970s and the 1980s. The following section begins by presenting evidence that experimental exposure to violent pornography results in increased aggressive response in laboratory settings. Following this, evidence showing that efforts to generalize experimental findings beyond the constrained laboratory conditions that produced them have generally failed to substantiate a link between sexually explicit media exposure and antiwoman aggression in real-world settings is reviewed.

Experimental research concerning violent pornography and aggression have often adopted the research paradigm employed frequently by scientists who study nonsexual causes of aggression. In this experimental approach, male participants are angered by a female confederate of the experimenter, who is posing as a fellow participant, through acts of verbal aggression and/or painful electrical shocks. Male participants are then shown either violent pornographic stimuli, nonviolent erotic stimuli, or nonsexual material. In a final phase of the

experiment, male participants are told that they will be evaluating the performance of the female confederate, who is still posing as another research participant, on a learning task. The male participants are then instructed to punish the female confederate when she makes predetermined mistakes in her learning task. Male participants are free to choose the intensity of the punishment they decide on for the female, which is allegedly delivered by electric shock, and they are given no alternative but to submit her to electrical shock. In the final phase of such experiments, the male participant and the female confederate are physically separated, communication occurs through an intercom, and the punishment is apparently, but never actually, delivered to the confederate.

Initial experiments using this design found that participants who were shown a sexually explicit film delivered stronger electrical shocks (or, in other versions of these procedures, stronger blasts of noise) to the confederate than participants who saw a neutral nonsexual film. Additional work has found that this effect is attenuated when participants are shown less explicit sexual stimuli like nudes or semi-nudes, but augmented when participants are shown violent pornography in which the victim is depicted as ostensibly enjoying being sexually assaulted. These results have been confirmed by at least one meta-analysis, which has found that experimental exposure to violent pornography and nonviolent sexually explicit stimuli in laboratory settings generally results in increased aggression toward the female confederate in this paradigm, while exposure to simple nudity decreases such aggression.

Although experimental studies in these laboratory conditions indicate that violent pornography and even nonviolent sexually explicit materials can enhance male–female aggression, a number of theoretical and empirical challenges suggest that the results from such experiments may not apply meaningfully to real world settings and are in fact uninformative concerning any relation between sexually explicit materials and aggression in natural settings. First, it has been asserted that the experimental setting in which an angered male is required to aggress against his female tormentor and has no nonaggressive response alternative is essentially guaranteeing that the male will aggress. In this connection, it has been questioned whether angered men would aggress at all if they had a nonaggressive response option open to them. Demonstrating that this may indeed be the case, a study which allowed angered male participants to choose whether or not to aggress against a female confederate who had angered them found that, even after viewing violent rape theme pornography in which the victim appeared to enjoy being assaulted, almost all male participants chose not to aggress at all against the female confederate. Second, we note that the same experimental studies of long-term exposure to sexually explicit stimuli that found a negative attitudinal impact, reported lessened antiwoman aggression after long-term exposure to sexually explicit materials, as a function of lessened overall arousal. We note as well that studies that have used sexual stimuli consisting of simple nudes who are not engaged in overt sexual behavior, and elicited positive emotional responses from men, have also been found to decrease aggression against a female, presumably as a function of positive affect and its incompatibility with hostile aggression. Finally, there is at least one example of an experimental study that involved significant exposure to

violent pornography and which showed, in a later aggression opportunity separated in time from the exposure to violent pornography no effect of exposure on aggression or indeed on rape myth acceptance.

Further evidence suggestive of caution with regard to extrapolation of experimental laboratory results is provided by a considerable number of observational studies that have failed to find any evidence of a link between sexually explicit media consumption and antiwoman aggression in the real world. Specifically, studies examining the prevalence of sexually explicit materials of diverse kinds in Denmark, Sweden, Germany, Japan, and the United States have not found any increase in reports of sexual assault that could be attributed to the legalization of sexually explicit material or its widespread availability. More recently, crime statistics from the United States indicate a decrease in the number of sexual assaults since the introduction and expansion of Internet pornography, which has massively increased the accessibility of all forms of sexually explicit materials, including violent pornography, in that country. Moreover, a number of studies of sex offender populations have revealed that convicted sex offenders may report less experience with diverse sexually explicit materials than nonsexual offenders and nonoffenders. While there are at least isolated exceptions to observational studies of the lack of association between prevalence of sexually explicit materials, use of sexually explicit materials, and sexual crime, given the preponderance of these real world findings, it seems likely that the link between pornography exposure and aggression found in experimental research may be an artifact of constrained laboratory conditions, which do not reflect the circumstances of pornography consumption in natural settings.

General Summary and Critique

The preceding analysis has provided a survey of current knowledge regarding the nature of sexually explicit materials and the effects of exposure to such material. In this review, definitions of sexually explicit material have been shown to be heterogeneous, focusing alternatively on the perceived intent or the perceived content of such material. The cultural and historical ubiquity of sexually explicit material has been illustrated, and research concerning the content of contemporary sexually explicit material has been reviewed and critiqued, and difficulties associated with these assessments have been noted. Patterns of use of sexually explicit material were considered, and men emerged as the gender that most frequently accesses sexually explicit materials. We have also reviewed evidence that exposure to sexually explicit materials can influence the way people feel, think, evaluate, and behave.

Experimental studies in the laboratory setting have generally found evidence that sexually explicit materials can influence feelings, thoughts, evaluations, and sexual and aggressive behavior. Although many take this as evidence that sexually explicit material can induce antisocial changes along a number of dimensions, evidence for any of these effects among real world consumers of sexually explicit material is sparse. For this reason, although we are inclined to believe that self-regulated exposure to sexually explicit material that occurs outside of experimental settings may impact sexual behaviors and

attitudes in both positive and negative ways, we must conclude by admitting that clear evidence for such effects is still lacking. Although it is unsatisfying to leave this summary without firm conclusions, given the publication of two recent reviews, one explicitly concluding that pornography use is a risk factor for sexual aggression at least among certain predisposed individuals, and the other claiming that such an association remains unestablished, we feel that such an approach is appropriate as many of these questions appear to be undecided among social scientists today.

Glossary

Broaden-and-build theory of positive emotions The notion that positive emotions broaden momentary cognitive capacity and flexibility, which in turn builds lasting psychological, physical, and social resources.

Character strength A personality characteristic that represents what one does well. These include universally accepted, morally valued, characteristics that are stable across time and situations. Examples include kindness, gratitude, social intelligence, the capacity to love and be loved, or perspective.

Eudaimonic A view of well-being that focuses on increasing virtue and promoting strength of character as opposed to pleasant emotions.

Hedonic A view of well-being that focuses on increasing positive emotions and subjective appraisals of well-being.

Positive intervention A cognitive or behavioral strategy or collection of strategies that aims to increase well-being through promoting the factors that support it.

Subjective well-being A widely accepted definition of well-being that focuses on subjective appraisals. It includes a combination of an affective component, high positive affect and low negative affect, and a cognitive component, appraising one's life as well.

Synopsis Positive psychology is a burgeoning research area that attempts to better understand and promote the factors that relate to human flourishing. Research in positive psychology includes three main areas of focus: positive emotions, positive character traits, and positive institutions. Research on the nature of well-being has furthered our understanding of what it means to live a good life. Applied uses look to further promote human well-being by adopting this knowledge into empirically testable intervention methods. As positive psychology grows it aims to move these interventions to more settings to further support positive institutions and increase worldwide well-being.

Introduction

Ten years ago, Martin Seligman established the field of positive psychology to foster research on 'positive' aspects of living and create a psychology of human strengths and flourishing. Seligman noted that since World War II, psychological research has focused almost exclusively on pathology, neglecting factors associated with well-being. Positive psychology's founding has helped research on these topics flourish. The measurement of once nebulous constructs, such as happiness, has advanced to the point that we now have well-validated and widely used measures. The purpose of this article is to introduce the organizing principles of positive psychology, review important topics and theories, and outline directions for future growth.

What Is Positive Psychology?

Positive psychology is the study of optimal functioning. It examines the psychological resources and characteristics that allow people to function adaptively in the face of the many demands of life. An orienting principle of this approach is that removing the factors that lead to pathology, deficits, or failure is not sufficient to build mental health or promote flourishing. Instead, this requires an understanding of the factors that make life worth living such as happiness, success, and virtue. Positive psychology adopts a strengths perspective, examining what each individual does well. This approach, however, does not replace preexisting paradigms; instead it offers a complement to help promote understanding of the determinants and consequences of living well.

The central tenets of positive psychology include the following: (1) positive and negative aspects of functioning do not lie on a bipolar continuum but instead represent unique dimensions (i.e., happiness is not the opposite of unhappiness), (2) hypothetically moving from a +2 to a +5 requires different techniques than moving someone from a -5 to a -2, (3) working on strengths is more beneficial than working on weaknesses, and (4) psychology needs to understand what allows people to flourish just as it aims to understand the characteristics and factors that predispose individuals to languish. Positive psychology research following from these tenets can be organized in three broad areas.

The Pillars of Positive Psychology

As defined by Seligman and Csikszentmihalyi, the three pillars of positive psychology are the study of positive emotions, positive character traits, and positive institutions. It is useful to consider research in each of these pillars as furthering the objectives of positive psychology.

Positive Emotions

Emotions are physiological and cognitive responses to our environment that motivate and organize behavior to function adaptively. To understand the benefits of positive emotions, it is useful to understand their role in guiding behaviors. Positive emotions are defined as emotions that are positive in valence and resemble positive states (such as satiety, safety, and comfort). These include activated and energizing emotions

such as joy and happiness, as well as more deactivated and calming emotions such as serenity or peace. Positive emotions are a crucial component to well-being and an important area of positive psychological research.

The Role of Positive Emotions

Positive affect may be one of the most important contributors to a person's overall well-being. Increasing positive affect is useful not only because people enjoy pleasant states, but also because they lead to greater success, better job performance, improved social relationships, and better physical health. These benefits result from cognitive and motivational effects of positive emotions. Fredrickson posits in her broaden-and-build theory of positive emotions that these emotions 'broaden' people's momentary thought-action repertoires, which in turn motivate behavior that 'builds' lasting physical and psychological resources.

Positive emotions signal safety in the environment, which presents opportunities to increase long-term survival by building resources. For example, emotions such as amusement lead to a desire to experiment intellectually with new ideas and play physically with others. Interest leads to a desire to explore and integrate new information, and contentment leads to savoring of a situation. These activities can build lasting physical, social, and psychological resources. Furthermore, as opposed to specific tendencies (like fear leading to withdrawal or anger leading to retaliation) from negative emotions, response tendencies from positive emotions are more varied and flexible.

Substantial research literature supports both the 'broaden' and 'build' aspects of this theory. Positive emotions are related to broadened thinking, enhanced flexibility of thought, creativity, and problem-solving. Individuals induced with positive emotions evidence more self-other overlap and show less of their own race bias in responding. Positive emotions also build lasting resources. In times of psychological distress, positive emotions promote psychological resilience. In fact, the experience of positive emotions after significant stressors predicts reduced depressive symptoms and increased posttraumatic growth. Recent intervention research further supports the broaden-and-build theory by demonstrating that an experimental intervention that increases positive emotions also leads to long-term increases in psychological resources such as agency thinking, optimism, savoring, autonomy, and personal growth.

Positive Character Traits

Another aspect of positive psychology focuses on understanding the characteristics that define human excellence. What factors allow some to succeed and flourish? How do we define what a person does well? To facilitate research on these aspects, Seligman and Peterson created a classification of human strengths. A strength is a universally accepted, morally valued, personality characteristic that is stable across time and situations. These strengths elevate those who bear witness to them and are the focus of moral and civic education. Seligman and Peterson identified 24 strengths organized under 6 core virtues, including courage, justice, humanity, temperance, wisdom, and transcendence.

Using character strengths is a strategy to build happiness. Engaging in new activities related to one's signature strengths for a period of 1 week has been shown to create lasting boosts in well-being for as long as 6 months. Using strengths is an important route to happiness because it not only builds momentary pleasure but helps promote engagement and meaning in one's life. Because strengths represent forms of authentic self-expression, working on a strength is intrinsically rewarding and enjoyable and using strengths in the service of others promotes meaning and purpose in one's life. Positive psychology further posits that building and working with an individual's strengths may be more beneficial than working on weaknesses. Using and building character strengths is not as emotionally or mentally taxing as addressing a weakness. Rather, it is fun and leads to further use of that strength.

Positive psychology has expanded the language and knowledge of strengths. Future research can help to better understand how strengths contribute to well-being and how strengths can be promoted and taught through interventions and education.

Positive Institutions

The final focus of positive psychology is to identify positive institutions such as work, school, and government settings and policies that enhance individuals by promoting positive emotions and positive character traits. These institutions provide goals and values that guide individuals to make choices and develop the best aspects of themselves. Institutions that enhance and cultivate character strengths play an important role in promoting optimal functioning of individuals. Another consideration of what makes a positive institution is to consider not just promoting individual wellness but enhancing community wellness. Assessing this requires translation of concepts developed at an individual level to conceptualize wellness at a systems level.

Current attempts in positive psychology to address and focus on positive institutions include applying positive psychology principles to schools in an attempt to create positive models of education. Creating satisfying work environments relies on supporting basic psychological needs such as autonomy and competence. Research on topics such as flow and engagement also highlight aspects of jobs and schools that could be developed to create more intrinsically rewarding experiences. For example, these settings can focus on providing tasks that match the level of demand to individual skills to avoid both boredom and burnout. As positive psychology expands into more applied areas, recommendations for creating and supporting positive institutions will continue to develop.

Well-Being Across Time and Culture

Positive psychology's advancement has drawn on the empirical and theoretical contributions of mainly Western researchers. Definitions of well-being, however, may vary by culture and the specific factors that promote well-being are likely closely tied to what it means to be well or happy within that culture. It is therefore important to consider historical and cross-cultural considerations of the definition of well-being to better

understand how positive psychology can contribute to a more universal view of human flourishing.

A review of the history of happiness in Western societies highlights that the notion of happiness as conceptualized by many modern Americans to cultivate positive feelings and experiences is in stark contradiction with previous views of the nature of happiness. A brief review of these eras reveals that the Homeric era focused on good fortune, the classical view emphasized cultivating virtue, medieval Christian perspectives asserted living in accordance with God's will and plan brings lasting well-being, and enlightenment thought began to enlarge the role of pleasure in conceptions of well-being. Modern views, therefore, have largely departed from classical and medieval notions that contend that virtue or character are more important than feeling good. Instead, as captured by theories which use a subjective definition of happiness, the modern view focuses on emotions and thoughts.

As definitions of what constitutes a 'good life' varies by time and culture, the goals and activities that individuals engage in to promote their own happiness reflect the attitudes and values of their internalization of these values. For example, equating a 'good life' with the frequent experience of positive emotions may be a construction of modern Western culture. In Western cultures 'happiness' is viewed as an important goal. Research supports that in these cultures, happy individuals are even rated as more likely to go to heaven. Indeed, the importance of goal fulfillment in determining satisfaction might help explain the variability across nations in the relationship between income and satisfaction. In some countries or cultures, prevailing values emphasize modest aspirations or non-material strivings (i.e., family, religion). These values mold individual expectations and help explain high levels of individual well-being even in the absence of material wealth. Research in groups such as the Maasai, the Amish, and slum dwellers in Calcutta has revealed higher than expected levels of well-being given their lack of material wealth.

In these cultures and for many individuals, psychological well-being is tied to the various goals set individually and culturally. For one, well-being might stem from achieving status and wealth whereas for another, it might come from connecting with others or devoting one's life to a higher calling. In general, a negative relationship exists between materialism and well-being. This relationship, however, is moderated by those who actually do have the income to pursue material possessions showing less negative impact on their well-being. These findings illustrate the importance of recognizing that even though trends in a certain time or place might suggest certain pathways toward well-being, it is critical to know the values of the individual to better understand the specific aspects that might contribute to one's own well-being.

Another consideration is how to define and therefore measure well-being. Although a majority of psychologists do adopt a subjective well-being perspective and focus on the mental states of individuals to determine well-being, a growing minority define well-being using prescriptive approaches that nominate needs and characteristics necessary to achieve the good life. These 'needing' or eudaimonic approaches highlight aspects besides pleasure which contribute to the good life, such as engagement and meaning, psychological needs such as autonomy, relatedness, and competence, and other

psychological attributes such as self-acceptance and environmental mastery. Current psychological literature supports the theory that achieving these indicators of eudaimonic well-being leads to experiences of happiness and pleasure. Furthermore, strengths of character, such as love, hope, and gratitude, are found to be strongly correlated with hedonic conceptions of well-being such as life satisfaction. These strengths of character connect us to others and are representative of virtues included in medieval Christian as well as classical views of well-being. Historical representations of well-being, therefore, continue to be connected to recent research approaches used within positive psychology.

While creating a field that aims to study human flourishing, it is also necessary to encapsulate the complexities of cultural variations in notions of well-being. Cross-cultural research consistently finds that individuals in Eastern cultures report lower levels of subjective well-being than individuals from Western cultures. These findings, however, do not mean that individuals in Eastern cultures experience less well-being or are functioning less optimally than individuals in Western cultures. Instead, it demonstrates the importance of understanding how emotions and character strengths might contribute differentially to notions of well-being across cultures.

As previously mentioned, cultural norms shape the goals that drive individuals and contribute to well-being. Individuals from Eastern cultures, for example, strive to fit in and meet obligations whereas individuals from Western cultures self-enhance, emphasizing their own accomplishments and successes. Another foundational goal in Eastern cultures is achieving a sense of cognitive and affective balance. Eastern cultures, therefore, will not strive to overly promote positive affect but instead aim at balancing positive and negative emotions. Individuals from Eastern cultures, therefore, are much more reliant than their Western counterparts on negative aspects of experiences when forming judgments of satisfaction. This focus on balance, however, is also supported by research on positive emotions that suggests a critical ratio of 3:1 positive to negative emotions is an important determinant of flourishing rather than unbridled promotion of positive emotions.

Balance in life is also important to Buddhist conceptions of well-being. Many aspects of positive psychology may seem in opposition to Buddhist ideals, which hold that pleasurable stimuli either internal or external are transient and therefore do not lead to true, sustainable well-being. Chasing positive emotions, fostering relationships, and striving toward goals may seem counterproductive to an individual who believes he or she should desire nothing. Craving, which is concerned with obtaining some desirable object, moves the source of well-being from one's mind to external objects. Research bears out that due to adaptation, life circumstances and material goods lead to only transient boosts in positive emotions and satisfaction. According to Buddhism, expectations for happiness that lead to striving for material wealth, recognition, power, or approval actually lead to negative emotions such as anxiety or frustration. A Buddhist concept of well-being, therefore, emphasizes achieving mental balance through cultivating internal well-being that is not dependent on transient positive states, fame, or fortune. Instead, a possible synthesis of Buddhist principles suggests well-being flows from achieving balance of mental skills in the conative, attentional,

cognitive, and affective domains. Motivational concepts from self-determination theory suggest many similar concepts may be important to achieving eudaimonic well-being. These include pursuing intrinsic goals, cultivating mindfulness and awareness, behaving in ways that are consistent with psychological needs, and acting in autonomous ways. The focuses on intrinsic goals and volitional activity maps on to conative balance, mindfulness is akin to attentional balance, and achieving psychological needs helps promote cognitive balance.

Eudaimonic notions of well-being might provide an important point of synthesis, therefore, of positive psychological concepts into Eastern definitions of well-being. Even in Western cultures, pursuing engaging and meaning in one's life leads to higher levels of subjective well-being than pursuing pleasure. This is in line with Buddhist notions that suggest that the search and quest for pleasure is likely to paradoxically hinder its acquisition.

Not surprisingly, eudaimonic conceptions of well-being require characteristics to be ubiquitous; that is, they have to be valued across time and culture to be nominated as a character strength. Indeed, the core virtues of courage, justice, humanity, temperance, wisdom, and transcendence are included in philosophical and religious traditions from around the world, including Confucianism, Taoism, Buddhism, Hinduism, Athenian philosophy, Judaism, Christianity, and Islam. This analysis suggests the importance of human strengths in the worldwide definition of flourishing.

What Is the Good Life?

Pathways to the Good Life

Positive psychology research aims to create an understanding of the factors, characteristics, and settings that create lives full of flourishing and success. This requires, however, a definition of what might constitute the 'good life.' Theorists disagree over how to conceptualize the 'good life.' Some focus on increasing pleasant feelings and evaluations of one's life. These theorists, deemed hedonists, adopt a subjective approach to the good life relying on self-reports. Not all agree, however, that well-being is a sum of pleasant feelings and positive evaluations about one's life. These researchers argue that instead, well-being comes from achieving a sense of mastery over the environment, creating meaningful lasting relationships, and living in accordance with one's true nature. These conceptions, known as eudaimonic approaches, align more closely with the notion that well-being flows from living well or realizing one's potential.

Eudaimonic views of well-being are similar to 'needing' accounts of well-being, which focus on the content of one's life as an important determinant of well-being. These theories identify the objective circumstances required for a good life. 'Needing' approaches have been referred to elsewhere as 'objective list' theories of well-being. In these approaches, well-being is achieved through satisfaction of needs which are listed a priori. Theorists propose different elements on these objective lists. For example, Maslow's hierarchy of needs argues for the fulfillment of basic needs before people can meet their full potential. The capabilities approach similarly argues for essential needs including food, shelter, health, security, and freedom

as a condition for individuals to have the ability to create their own well-being. Objective lists highlight the importance of certain things that are truly valuable to well-being, irrespective of the value that individuals assign to it. These may include things such as education, relationships, career success, democracy, beauty, and material comforts.

The objective lists approach has two advantages. First, like Maslow's hierarchy of needs, they highlight the need for addressing primary needs before indulging in higher pursuits. The second advantage is that these lists provide objective indicators of well-being. Thus, one cannot be considered 'happy' unless he or she is objectively well-off in some sense. Seligman and Royzman provide an example of orphan children living on the streets who might be subjectively 'happy' by engaging in activities that provide momentary pleasure with little concern for the future. The appeal of an objective list approach is that even if these individuals report being happy, they would fall short of being considered 'well,' on the basis of a lack of objective criteria.

Despite these appeals, objective lists have limitations as well. First, there is no general consensus as to which items should be included on objective lists. Although some needs may be universal, other needs are likely to differ across cultures or across individuals who have different values. Second, objective list accounts of well-being are often linked to objective outcomes to determine well-being. Therefore measuring well-being requires the assessment of outcomes such as literacy rates or crime rates. Again, the relative importance of these outcomes may differ by individual values, which introduces a subjective element into this assessment. Lastly, objective lists ignore any subjective evaluation of well-being, which is too strict a criterion for developing a theory of well-being.

In order to address the limitations of both subjective and objective approaches to well-being, some have developed 'hybrid' theories that combine the 'liking' and 'needing' approaches. Seligman's authentic happiness theory is such an example and includes hedonic and eudaimonic elements by positing three distinct pathways (pleasure, engagement, and meaning) that contribute to an individual's well-being. An important component of the authentic happiness theory is that each pathway neither supports nor opposes any other pathway; therefore, each pathway should be cultivated to achieve lasting happiness. Empirical work has demonstrated that these pathways are indeed distinct and that the presence of all three pathways is associated with the highest levels of life satisfaction. This supports Seligman's notion that a 'full life' consists of experiencing positive emotions, pursuing engagement, and obtaining meaning. A brief overview of each of these pathways and how they may contribute to well-being follows.

Pleasure

Pleasure or hedonic accounts of well-being are often adopted by psychologists because they focus on the subjective mental state of the individual. These accounts view well-being as characterized by the presence of pleasure and the absence of pain. Pleasure, however, does not merely include the experience of pleasant affect or the fulfillment of drives. Instead, pleasure encompasses subjective evaluations about one's life, and one's conditions as well. This approach has the considerable

advantage of being face valid. An individual is considered happy if he reports himself as such and each individual is considered the expert on his or her own happiness.

Given the subjective nature of this pathway, these ratings are made most often from self-report measures. Some of the most common assessments of subjective well-being include the Satisfaction with Life Scale and the Positive and Negative Affect Schedule (PANAS). These measures demonstrate considerable reliability and validity. The Satisfaction with Life Scale, for example, is one of the most widely used measures of well-being. This brief five-item measure represents a cognitive judgment of how satisfied one is with one's life. A substantial body of cross-culture research has supported its use in a variety of cultures and populations. Additional measures of well-being tap more affectively based assessments. Measures such as the PANAS and other self-report measures of positive emotions provide evaluations of an individual's affective experience. Frequency of positive emotions is strongly related to more reflective components such as happiness and life satisfaction. Concepts such as happiness blend affective as well as cognitive measures as many individuals interpret happiness as an evaluation of their emotional state.

Engagement

An alternative route to well-being is through engaging in activities that are engrossing and absorbing, a state that Csikszentmihalyi has called 'flow.' Flow is most often experienced during activities that require appropriate demands, given one's level of skill. A flow state is subjectively experienced as being absorbed in the task, a loss of self-awareness, distorted perception of time, and a strong intrinsic reward from the activity.

Given that flow experiences do not lead to pleasure in the moment, how might they contribute to well-being? Reflecting upon a flow experience is often positive. Many hobbies and leisure activities such as sports, games, or horseback riding are pursued because we lose ourselves in these activities. Flow can also reframe important yet mundane tasks into more interesting activities. For example, making a game out of one's math homework by seeing how many problems one could solve in 30 min serves to make the task feel less bothersome and more intrinsically interesting. Indeed, people typically report experiencing more flow at work and school than during leisure time. Individuals who frequently experience flow achieve better outcomes due to increased persistence. Flow states, therefore, may lead to long-term well-being through promoting positive resources – such as nurturing talents, cultivating interest, and honing skills. These resources may lead to an upward spiral of both increased subjective as well as objective well-being. Following from these findings, we would expect that individuals who endorse frequently entering flow in their lives are more productive and achieve higher levels of success, although more research is needed to support this claim.

Meaning

The final pathway suggested by Seligman is to pursue happiness through meaning. Theorists have long proposed that finding meaning in one's life is important to achieve psychological

well-being. Human beings show a tendency to try to understand seemingly ambiguous events by constructing explanations and these explanations can have a powerful impact on how we react and respond to the situation. Although theories differ on the role that causal explanations play, they agree that these explanations influence psychological processes and behaviors. Meaning in life allows one to transcend oneself, either connecting to others or to a higher power. Although the searching for meaning is linked to lower levels of well-being, those who report that their life has significant meaning or purpose report higher levels of well-being. Finding meaning in life may link to well-being through promoting positive social relationships or a sense of one's actions as efficacious and fitting into a larger picture.

The creation of meaning following negative events is one manner in which people cope positively with loss, trauma, and stress. Indeed, Wilson and Gilbert have suggested that finding meaning after events is part of the psychological immune system, which helps us find causes for why things went wrong. Meaning-making has been a proposed mechanism for the process of recovery following traumatic events and an active ingredient in interventions such as writing and other forms of posttraumatic growth. More globally, meaning in an abstract sense allows discovery of one's purpose in life, which can provide individuals with goals that guide action and promote well-being. Pursuing a meaningful or virtuous life may also provide individuals with a feeling of knowing one's true self or being authentic. Authenticity and self-knowledge have been tied to both a sense of meaning in one's life as well as increased well-being.

People search for meaning in a variety of different ways such as religion, work, or volunteering. One way in which individuals may develop a sense of meaning is through pursuing actions that are concordant with one's sense of self – or rather drawing on one's strengths. Various studies have demonstrated that using one's strengths leads to increases in subjective well-being. Working on strengths as opposed to working on deficits may represent an empowering approach to benefiting individuals and thus support autonomy and meaning. Meaning, therefore, can link to long-term well-being through providing important goals, fostering social connections, and providing opportunities to exercise individual strengths.

Positive Relationships

The ability to form strong, lasting relationships is a hallmark of our humanness. In youth, people work to maintain their friendships and these interactions provide opportunities to build physical and cognitive resources. As people age, the task of coupling becomes important to one's evolving sense of self. Relationships contribute to our well-being in a variety of ways. They provide a shoulder to cry on in times of need and companions with whom to celebrate life's successes. Not surprisingly, relationships are one of the most consistent and robust predictors of individual well-being and a major component of the good life. Being happy, full of virtue, or objectively well-off is irrelevant if one lives a life of solitude and loneliness. In fact, good relationships appear to be a necessary, though not sufficient, condition for high well-being. Learning about the characteristics that promote successful relationships and examining

the benefits that flow from these connections is an important area within positive psychology.

Most people aim to couple and all invest considerable effort to build strong and healthy relationships. Relatedness is a fundamental psychological need and fulfilling this need leads to increased well-being. The self-help literature has long catered to people's interest to be more effective 'people persons.' Research psychologists used empirical studies to translate practical wisdom into supported recommendations. In close relationships, the largest predictor of relationship satisfaction is not how couples deal with bad news, but how people react to good news that their partners share. In response to positive news, individuals can respond in either active or passive manner (i.e., engaging in the news or blowing it off) and a constructive or destructive manner (i.e., building on the news or belittling the news). Responding active-constructively to good news serves to enhance the positive experience by reliving the event with the storyteller. This allows the storyteller to further savor the event and in turn strengthens the relationship.

Building better relationships is important because regardless of one's current level of relationship satisfaction, one can always find ways to improve the quality of relationships in one's life. Individuals report that achieving more intimate relationships is a more important goal than developing a large number of friendships. Studies show that most of our intimate interactions take place with the same set of six people. A study of very happy individuals – that is, individuals who score in the top 10% of a sample on measures of happiness – demonstrated that these individuals reported good quality social relationships, spending the least amount of time alone and the most amount of time interacting with friends and family. The number of friends, however, that puts an individual in this category is unclear. Both the quantity and quality of social networks have been linked to better health, coping, and happiness. Thus, further research is needed to unpack this question.

Another reason for increasing relational skills is the growing dearth of interpersonal interaction. In America, social networks have been decreasing with fewer individuals joining clubs and other civic organizations. Over the last 20 years, the average number of confidants or people with whom one can discuss 'important matters' has dropped by one-third from three to two. The decrease of social capital – the social networks one has in society and the associated norms of reciprocity and trustworthiness – may very well be an important issue, although it begs the question of whether this drop is a meaningful one. Typically, studies find a positive relationship between the number of individuals in one's social network and well-being. It is unclear from this overall analysis, however, if the benefits of having more friends demonstrate diminishing returns; that is, if more friends are more beneficial only up to a point. One can imagine that a larger social network might diminish the quality of each of those social interactions as individuals can only devote so much time and energy to each relationship. The meta-analysis found that the quality of social contacts was a better predictor of well-being than merely the quantity of social contacts, suggesting that larger and larger networks are not necessarily more beneficial if quality is sacrificed.

Positive psychology can play a role in reversing this trend by both demonstrating the importance of relationships as well as

developing interventions aimed to improve interpersonal skills. Although positive relationships are beginning to appear as a key area for research in the field, it should be growing over the coming years.

Applied Positive Psychology and Positive Interventions

Currently the field of positive psychology is working to move from the laboratory to the real world. Efforts to translate research include both program creation as well as training opportunities to increase the knowledge base of those who want to apply positive psychology in a variety of settings. Positive psychology programs aim to increase well-being through 'positive interventions,' foster positive character traits, promote resilience, and help individuals achieve optimal functioning.

Defining a 'Positive' Intervention

A major thrust of positive psychologists is to develop empirically supported techniques to increase well-being. These techniques, deemed positive interventions, are cognitive or behavioral strategies, or a collection of cognitive and behavioral strategies that promote well-being by building happiness, satisfaction with life, or positive affect, through processes that lead to well-being such as engagement, meaning, and pleasure. The term positive generally refers to adding something as opposed to subtracting something, or fixing something that is broken. This definition helps clarify the difference between a 'negative' intervention and a 'positive' intervention. The general practice of psychology is to repair deficits, moving people from a minus five up to a minus one or even a neutral point. Positive psychology differs by helping move people from a plus one to a plus five.

Consider a baseball analogy. If a pitcher wants to improve his game, he might accomplish this by fixing the mechanics of his poorly breaking curveball, or he could learn how to throw a proper knuckleball, or he could enhance his already effective change-up. A 'negative' intervention would be noticing that his curveball often does not break and learning to use a better release for getting more spin on the ball. A 'positive' intervention would either develop something new, such as adding a new pitch to the repertoire (i.e., learning how to throw a knuckleball), or it could further enhance a current strength (i.e., increasing the speed differential between the slow pitch and the fastball to develop a more deceptive change-up). All of these interventions would have the net effect of improving overall pitching; however, the focus of each approach is different. Differentiating positive psychology exercises from other interventions and approaches is not to say that other approaches are useless. Different approaches, however, may be targeting a different pathway or offer different benefits. Additionally, positive interventions are sometimes easier, more cost effective, or more fun to do.

Positive Interventions in Practice

Fordyce completed one of the first empirically tested programs of positive interventions. Fordyce developed his program, called the 14 fundamentals, by observing the behaviors of

happy people and incorporated these strategies into his recommendations. These recommendations include: socialize, strengthen close relationships, be outgoing, be a better friend, develop a healthy personality, lower expectations, be optimistic, make happiness a goal, be active, create meaning, get organized and make plans, develop a present orientation, reduce negative feelings, and stop worrying. Teaching these strategies in a classroom setting led to boosts in well-being compared to various control groups who received no such instruction. Further research has extended this line of research by studying these and other strategies in isolation to create specific recommendations of techniques that can promote well-being.

These include varied techniques such as promoting optimism, hope, gratitude, kindness, and meditation. Overall, these interventions are effective at increasing well-being. A recent meta-analysis of positive interventions found that on average, these techniques lead to small-to-moderate boosts in happiness, affect, and life satisfaction. The greater the number of interventions included in a single program, the more effective it is, suggesting that programs like Fordyce's, which include many different strategies, are often wise ways to promote well-being.

Positive interventions have even begun to infiltrate the clinical realm. Positive psychotherapy incorporates positive psychology principles such as building pleasure, engagement, and meaning as a road to recovery from depression. Sessions teach new skills such as expressing gratitude, responding active-constructively, and identifying and cultivating signature strengths through the use of positive psychology exercises. In a randomized controlled trial, positive psychotherapy was more effective at increasing well-being and reducing depressive symptoms than either medication or treatment as usual. Also, fewer participants dropped out of the positive psychotherapy condition, suggesting that clients may enjoy discussing and building strengths, pleasure, and meaning rather than discussing the negative aspects of their lives. This research suggests that positive psychology may be able to contribute to gross human well-being through promotion of mental well-being in individuals with and without mental disorders.

Applied positive psychology is growing in other venues as well. The number of educational programs awarding degrees in positive psychology is steadily increasing. The University of Pennsylvania is offering its sixth year of the Masters of Applied Positive Psychology Program, with each class providing a new crop of experts eager to apply theory and research for education, law, business, and education. New conferences, professional organizations, peer-reviewed journals, and research centers appear each year. The inaugural World Congress for the International Positive Psychology Association in 2009 welcomed over 1500 people from 52 countries. Positive psychology initiatives also look to recast education, prevention, and training.

Future Directions

As positive psychology advances into its second decade, an important indicator of its usefulness to psychology will be its staying power. Is positive psychology merely a fad or does it

have more to offer? Although there is still much to learn about how to promote healthy, happy, productive lives, researchers have greatly clarified the measurement of individual constructs and advanced integrated theories over the past 10 years.

An important goal of positive psychology is to use its knowledge of well-being to actually enhance human lives. The future of positive psychology therefore rests on its ability not just to enhance an understanding of well-being but actually to increase the total amount of well-being in the world. New research examines how to bring positive psychology to the masses, to instill its principles throughout nations, schools, and therapy offices.

Another future direction of positive psychology is to expand its definition of well-being and refine measurement for more facets of well-being. This includes incorporation of national indicators of well-being to better characterize national levels of happiness as well as using eudaimonic conceptions of well-being to ensure that positive psychology does not just make people feel happier but actually makes people more complete, functional, and virtuous human beings. A limitation of current positive psychological research is an overreliance on subjective measures of well-being because they are simple and easy to collect. This has led to an imbalance of research and theory overemphasizing hedonic compared to eudaimonic perspectives. Just analyzing subjective measures, such as positive affect, runs the risk of over emphasizing positive feelings to the absence of other important features of flourishing, such as promoting engagement, meaning, and virtue in life. This view might suggest to some that the goal of positive psychology is to aim to maximize positive emotions and put off pursuit of relationships, success, or political change. Indeed, although the general trend suggests that happiness leads to success, the happiest individuals tend to be less successful and less motivated to pursue change compared to those who have more moderate (although still above average) levels of happiness. Therefore, refining operational definitions of eudaimonic aspects of well-being may help advance the field by expanding the knowledge of factors that lead to a more balanced perspective or, as Seligman notes, the 'full life.' All of these new directions aim to advance the initial goals of positive psychology to move people not just to a point of neutrality by eliminating the factors that create disorder and sadness, but to help promote happy and flourishing human beings.
